13. PALMA *frondibus pinnatis, foliis lanceolatis plicatis geminatis sparsis*. Palm-tree with winged leaves, whose lobes are spear-shaped, plaited, and come out by pairs from one point, standing thinly along the midrib.

14. PALMA *foliis simplicibus integerrimis flaccidis*. Palm-tree with single, entire, flaccid leaves; commonly called Dragon-tree.

The first sort here mentioned is the common Date-tree, which grows plentifully in *Africa*, and some of the eastern countries, from whence the fruit is brought to *England*. This rises to a great height in the warm countries; the stalks are generally full of rugged knots, which are the vestiges of the decayed leaves, for the trunks of these trees are not solid like other trees, but the center is filled with pith, round which is a tough bark full of strong fibres while young, but as the trees grow old, so this bark hardens and becomes ligneous; to this bark the leaves are closely joined, which in the center rise erect, being closely folded or plaited together; but after they are advanced above the vagina which surrounds them, they expand very wide on every side the stem, and, as the older leaves decay, the stalk advances in height. The leaves of these trees, when grown to a size for bearing fruit, are six or eight feet long; these have narrow long leaves (or pinnæ) set on alternately their whole length. The small leaves or lobes are toward the base three feet long, and little more than one inch broad; they are closely folded together when they first appear, and are wrapped round by brown fibres or threads, which fall off as the leaves advance, making way for them to expand; these never open flat, but are hollow like the keel of a boat, with a sharp ridge on their back-side; they are very stiff, and, when young, of a bright green, ending with a sharp black spine. These trees have male flowers on different plants from those which produce the fruit, and there is a necessity for some of the male trees to grow near the female, to render them fruitful; or, at least, to impregnate the ovary of the seed, without which the stones, which are taken out of the fruit, will not grow. Most of the old authors, who have mentioned these trees, affirm, that unless the female or fruit-bearing Palm-trees have the assistance of the male, they are barren; therefore in such places, where there are no male trees near the female, the inhabitants cut off the bunches of male flowers when they are just opened, and carry them to the female trees, placing them on the branches near the female flowers to impregnate them; which, they all agree, has the desired effect, rendering the trees fruitful, which would otherwise have been barren. *Pere Labat*, in his account of *America*, mentions a single tree of this kind, growing near a convent in the island of *Martinico*, which produced a great quantity of fruit, which came to maturity enough for eating; but, as there was no other tree of this kind in the island, they were desirous to propagate it, and accordingly planted great numbers of the stones for several years, but not one of them grew; therefore after having made several trials without success, they were obliged to send to *Africa*, where

where these plants grew in plenty, for some of the fruit; the stones of which they planted, and raised many of the plants. He then conjectures, that the single tree before-mentioned, might be probably so far impregnated by some neighbouring Palm-trees of other species, as to render it capable of ripening the fruit, but not sufficient to make the seeds prolific, as is the case when animals of different kinds copulate.

The flowers of both sexes come out in very long bunches from the trunk between the leaves, and are covered with a spathe, (or sheath) which opens and withers; those of the male have six short stamina, with narrow four-cornered summits filled with farina. The female flowers have no stamina, but have a roundish germen, which afterward becomes an oval berry, with a thick pulp inclosing a hard oblong stone, with a deep furrow running longitudinally. The bunches of fruit are sometimes very large.

This species of Palm is by Dr. *Linnaeus* titled *Phoenix*, which is the *Greek* name of it, and he makes it a distinct genus. There are some varieties, if not different species of this tree, in the warm countries, but as we cannot expect to see the trees in perfection in our country, it is not likely we shall come to any certainty how they differ from each other.

These plants may be easily produced from the seeds taken out of the fruit, (provided they are fresh) which should be sown in pots filled with light rich earth, and plunged into a moderate hot-bed of tanners bark, which should be kept in a moderate temperature of heat, and the earth frequently refreshed with water.

When the plants are come up, they should be each planted into a separate small pot filled with the same light earth, and plunged into a hot-bed again, observing to refresh them with water, as also to let them have air in proportion to the warmth of the season, and the bed in which they are placed. During the summer time they should remain in the same hot-bed, but in the beginning of *August* you should let them have a great share of air to harden them against the approach of winter; for if they are too much forced, they will be so tender as not to be preserved through the winter without much difficulty, especially if you have not the conveniency of a bark-stove to keep them in.

The beginning of *October* you must remove the plants into the stove, placing them where they may have a moderate share of heat (these being somewhat tenderer, while young, than after they have acquired some strength); though indeed they may be sometimes preserved alive in a cooler situation, yet their progress would be so much retarded, as not to recover their vigour the succeeding summer. Nor is it worth the trouble of raising these plants from seeds, where a person has not the conveniency of a stove to forward their growth, for where this is wanting, they will not grow to any tolerable size in twenty years.

Whenever these plants are removed, (which should be done once a year) you must be very careful not to cut or injure their large roots, which is very hurtful to them; but you should clear off all the small fibres which are inclinable to mouldiness, for if these are left on, they will in time decay, and hinder the fresh fibres from coming out, which will greatly retard the growth of the plants.

The soil in which these plants should be placed, must be composed in the following manner, *viz.* half of light fresh earth taken from a pasture ground, the other half sea sand, and rotten dung or tanners bark in equal proportion; these should be carefully mixed, and laid in a heap three or four months at least before it is used, but should be often turned over, to prevent the growth of weeds, and to sweeten the earth.

You should also observe to allow them pots proportion-

able to the sizes of the plants, but you must never let them be too large, which is of worse consequence than if they are too small. During the summer season they should be frequently refreshed with water; but you must be careful not to give it in too great quantities, but in winter they will require very little.

These plants are very slow growers, even in their native countries, notwithstanding they arrive to a great magnitude; for it has been often observed by several of the old inhabitants of those countries, that the plants of some of these kinds have not advanced two feet in height in ten years; so that when they are brought into these countries, it cannot be expected they should advance very fast, especially where there is not due care taken to preserve them warm in winter; but however slow of growth these plants are in their native countries, yet they may be with us greatly forwarded, by placing the pots into a hot-bed of tanners bark, which should be renewed as often as is necessary, and the plants always preserved therein both winter and summer; observing to shift them into larger pots as they advance in growth, as also to supply them with water properly. There are plants now in the *Chelsea* garden, whose leaves are seven feet long, which were raised from seeds more than twenty years ago, and their stems are not two feet high; one of which has produced some small bunches of male flowers.

The second sort here mentioned, is the Cocoa nut, whose fruit are frequently brought to *England*, some of which are of a large size. The branches of this tree are winged like those of the former, but the small leaves or lobes are three times as broad; they open flat, their borders fold backward, and are of a lighter green than those of the first sort. The whole leaf (or branch) is often twelve or fourteen feet long; the male flowers grow in different parts of the same tree with the fruit, proceeding from the trunk between the leaves; they are disposed in long bunches, as are also the females; the nuts growing in very large clusters, which are covered with a thick fibrous coat adhering closely to them. The nuts are large, oval, and have three holes in the shell at the top; the kernel is firm, white within, and the shell contains a quantity of pale juice, which is called the milk.

The Cocoa nut is cultivated in most of the inhabited parts of the *East* and *West-Indies*, but is supposed a native of the *Maldives*, and the desert islands of the *East-Indies*; from whence it is supposed it hath been transported to all the warm parts of *America*, for it is not found in any of the inland parts, nor any where far distant from settlements. It is one of the most useful trees to the inhabitants of *America*, who have many of the common necessaries of life from it. The bark of the nut is made into cordage, the shell of the nut into drinking bowls, the kernel of the nut affords them a wholesome food, and the milk contained in the shell, a cooling liquor. The leaves of the trees are used for thatching their houses, and are also wrought into baskets, and most other things which are made of osiers in *Europe*.

This tree is propagated by planting of the nuts, which in six weeks or two months after planting will come up, provided they are fresh, and thoroughly ripe, which is what few of them are, which are brought to *England*; for they always gather them before they are ripe, that they may keep during their passage; so that the best way to bring nuts into *England* for planting, would be to take such of them as are fully ripe, and put them up in dry sand in a tub, where the vermin may not come to them; and these will often sprout in their passage, which will be an advantage, because then they may be immediately planted into pots of earth, and plunged into the bark-bed.

The third sort is commonly called Macaw-tree by the inhabitants of the *British* islands in *America*. This rises to the height of thirty or forty feet. The stem is generally larger toward

toward the top than at bottom; the branches (or rather the leaves) are winged; the small leaves or lobes are long and broad; the stalk and leaves are strongly armed with black spines of various sizes in every part; the male and female flowers are on the same tree, coming out in the same manner as the Cocoa nut. The fruit is about the size of a middling Apple, and is inclosed in a hard shell.

The Macaw-tree is very common in the *Caribbee Islands*, where the negroes pierce the tender fruit, from whence flows out a pleasant liquor, of which they are very fond; and the body of the tree affords a solid timber, with which they make javelins, arrows, &c. and is by some supposed to be a sort of ebony. This tree grows very slow, and requires to be kept warm in winter.

The fourth sort grows naturally at *La Vera Cruz*. This hath winged leaves or branches like the other sorts. The small leaves or lobes are as narrow as those of the first sort, but are not quite so stiff; they spread open, are flat, and their edges fold backward; their ends are blunt, and have no spines; the midrib is armed with long black spines, which frequently come out by pairs from the same point. The flowers come out from between the leaves, and the fruit grows on the same plant as the male flowers, which are about the same size and shape as those of the former sort; but, as the lobes of the leaves are much narrower, and have no spines on their surface, there can be no doubt of its being a distinct species.

The fifth sort is commonly called Cabbage-tree in the *West-Indies*. This rises to a very great height in the countries where it grows naturally. *Ligon*, in his history of *Barbadoes*, says, there were then some of the trees growing there, which were more than two hundred feet high; and that he was informed they were a hundred years growing to maturity, so as to produce seeds. The stalks of these trees are seldom larger than a man's thigh; they are smoother than those of most other sorts, for the leaves naturally fall off entire from them, and only leave the vestige or marks where they have grown. These leaves (or branches) are twelve or fourteen feet long; the small leaves or lobes are about a foot long, and half an inch broad, with several longitudinal plaits or furrows ending in soft acute points; these are not so stiff as those of the first sort, and are placed alternately. The flowers come out in long loose bunches below the leaves; these branch out into many loose strings, and are near four feet long, upon which the flowers are thinly placed. The female flowers are succeeded by fruit about the size of a Hazel nut, having a yellowish skin, fitting close to the strings of the principal foot-stalk.

As the inner leaves of this encompass the future buds more remarkably than most of the other species, so it is distinguished by this appellation of Cabbage-tree; for the center shoots, before they are exposed to the air, are white and very tender, like most other plants which are blanched; and this is the part which is cut out and eaten by the inhabitants, and is frequently pickled and sent to *England* by the title of Cabbage; but whenever these shoots are cut out, the plants decay, and never after thrive; so that it destroys the plants, which is the reason that few of the trees are now to be found in any of the islands near settlements, and those are left for ornament.

The sixth sort is commonly called Prickley Pole in *Jamaica*, where it naturally grows. These trees are commonly found in thicket, where a great number of them are close together. Their stalks are slender, seldom more than five or six inches diameter, but rise to the height of forty feet, and are closely armed with long thorns. The leaves are placed circularly on the top, (as in most of the other species). These are winged, but the lobes are shorter and greener

than those of the other sorts, and are closely armed with thorns. The flowers come out in the same manner as those of the Cocoa nut, upon long branching foot-stalks; they are larger than the largest gray Peas, flattened at the top, and are covered with a red skin. The inhabitants of *Jamaica* make rammers and rods for scowering of guns, of the stems of these trees, which are very tough and pliable; but there is no use made of any other part, so far as I can learn.

The seventh sort is called in the *West-Indies* the Oily Palm, and by some Negroes Oil, for the fruit of this tree was first carried from *Africa* to *America* by the negroes. It grows in great plenty on the coast of *Guinea*, and also in the *Cape de Verd Islands*, but was not in any of our *American* colonies till it was carried there; but now the trees are in plenty in most of the islands, where the negroes are careful to propagate them.

The leaves of this tree are winged; the small leaves or lobes are long, narrow, and not so stiff as most of the other sorts; the foot-stalks of the leaves are broad at their base, where they embrace the stem, diminishing gradually upward, and are armed with strong, blunt, yellowish thorns, which are largest at their base. The flowers come out at the top of the stem between the leaves; some bunches have only male flowers, others have female; the latter are succeeded by oval berries, bigger than those of the largest *Spanish Olives*, but of the same shape; these grow in very large bunches, and when ripe are of a yellowish colour.

From the fruit the inhabitants draw an oil, in the same way as the oil is drawn from Olives; from the body of the tree they extract a liquor, which, when fermented, has a vinous quality, and will inebriate. The leaves of the tree are wrought into mats by the negroes, on which they lie.

The eighth sort is called Palmetto-tree, or Thatch, by the inhabitants of *Jamaica*, where this tree grows upon all the Honey-comb rocks in great plenty. It rises with a slender stalk ten or twelve feet high, which is naked and smooth, and at top garnished with many fan-shaped leaves placed circularly; these have foot-stalks two or three feet long, which are armed with a few strong, green, crooked spines; the pinnæ, or lobes, do all meet in one center, where they join the foot-stalk, and are joined together a third part of their length from their base; they are at first closely folded into plaits, but afterward spread out like a fan; their ends being pliant do often hang downward, and between these pinnæ hang down long threads. The flowers and fruit come out from between the leaves; the fruit is of the shape and size of the small *Lucca Olives*. The leaves of this tree are used for thatch all over the *West-Indies*.

The ninth sort grows naturally in *Japan*, and also upon rocky dry mountains at *Malabar*. This in time rises with a strait trunk about forty feet high, which has many circles round it the whole length, which are occasioned by the vestige of the leaves, which are placed circularly round the stem; so as these separate entirely and fall off, the circles remain where their base embraced the stalk. The stalks are terminated by an obtuse cone, just below which the leaves are placed; those on the large trees are eight or nine feet long, but those of the small plants are much less; the largest I have seen were not more than two feet long. The base of the foot-stalk, which partly embraces the trunk, is broad and three-cornered, and is armed on each side with short spines to the place where the lobes, or small leaves, begin. These pinnæ or lobes are long, narrow, and entire, of a lucid green on their upper side, standing by pairs along the midrib very close together. The flowers and fruit are produced in large bunches at the foot-stalks of the leaves; the fruit is oval, about the size of a large Plum, and nearly of the same shape; the skin or covering changes first yellow, and

and afterward red when ripe; of a sweet taste, under which is a hard brown shell, inclosing a white nut, which is in taste like the Chestnut.

From the pith of the trunk of this tree is made the sago; this is first pulverized, then it is made into a paste, and afterward granulated.

The tenth sort grows naturally at *St. Helena*, from whence the plants were brought to *England*. The leaves of this on the plants now in *England* are ten feet long, the midrib or foot-stalk is broad, and flat on the under side, but rises with a sharp ridge on the upper; the small leaves or lobes are ranged alternately on the sides, which are also broad; these are from two feet and a half to nine or ten inches long, the longest being at bottom, decreasing gradually to the top; they are stiff, and fold inward, of a dark green, ending in a sharp thorn. One of these plants has for some years produced bunches of male flowers between the leaves; but we are at present ignorant what the fruit is which these trees produce, but as the leaves are very different from all the sorts of Palms here known, I make no doubt of its being a distinct species.

The eleventh sort was discovered by the late Mr *Robert Millar*, growing naturally on the mountains near *Panama*, where the *Spaniards* call it Mountain Cabbage. The fruit of this tree, which was sent to *England* by the gentleman before-mentioned, were of the size and shape of middling Plumbs, covered with a thick shell; from these several plants were raised in the *English* gardens, which have made no great progress as yet. The leaves stand upon pretty long foot-stalks, which are broad at the top, and have a sharp ridge or angle underneath. The lobes or pinnæ are placed circularly, meeting in a point at their base, where they join the foot-stalk; they are divided to the bottom, and are two feet long, three inches broad in the middle, and fold backward; they are of a deep green on their upper side, and of a russet colour on their under side at first, but afterward become white. These are not so stiff as those of most other sorts, nor do they end in spines.

The twelfth sort was discovered by the late Dr. *Houssoun*, growing naturally in the sands near *Old Vera Cruz* in *America*. This hath a thick stem, which seldom rises more than two feet high. The leaves come out round the upper part of the stem, standing upon foot-stalks which are a foot and a half long; they are winged; the lobes or small leaves are about five inches long, and one and a half broad in the middle, drawing to a point at both ends; they are stiff, smooth, and entire, having a few small indentures at their points, and are placed alternate, of a pale green colour; there are fourteen or fifteen of these lobes ranged along the midrib or stalk. The fruit rises up from the side of the stem, upon a short thick foot-stalk, standing upright, and shaped like a club, having many red seeds about the size of large Peas, standing in separate cells round the central foot-stalk, to which they adhere. These plants have their male flowers on separate plants from the fruit, for all those plants which have flowered in *England* are of the male kind. The plants lose their leaves before the fruit is ripe annually. The first time when Dr. *Houssoun* saw these plants growing at *La Vera Cruz*, they were in full leaf, but on his return to the same place three months after, the fruit was then ripe, and all the leaves were fallen off; and this he afterwards observed the following season.

The thirteenth sort was discovered by the late Dr. *Houssoun* in the *Spanish West-Indies*. This rises with a very tall naked trunk, garnished at the top with long winged branches or leaves, whose lobes are spear-shaped and plaited; they are of a softer texture than any of the other sorts, and for the most part come out two from the same point, so stand by pairs on the same side of the midrib; they have two lobes

on a side a little above each other, but there is a great space between every four lobes. The flowers come out in long bunches from between the leaves, the male flowers hanging on long slender strings; but the fruit, which is about the size of a middling Plumb, is collected into large bunches.

The fourteenth sort grows naturally in the *Cape de Verd Islands*, from whence I had one of the plants brought me; as also in the *Madeiras*, from whence I have received the seeds. This is called Dragon-tree, because the inspissated juice of the plants becomes a red powder very like the eastern dragons-blood, and is frequently used instead of it in the shops; but the tree, from whence the true dragons-blood is taken, is of a very different genus from this. Dr. *Van Royen*, in the *Prodromus* of the *Leyden* garden, has ranged this among the *Yuccas*, I suppose, from the similitude of the plant to those of that genus; for, as the fruit of this is a berry not unlike those of the Bay-tree, and the seeds of the *Yucca* grow in capsules with three cells, they cannot be of the same genus; nor have we any account of the real characters of this plant, so as absolutely to determine the genus; therefore, as it has by several modern authors been ranged in this genus, I have continued it there. This rises with a thick trunk nearly equal in size the whole length, the inner part of which is pithy; next to this is a circle of strong fibres, and the outside is soft. The stalk or trunk rises twelve or fourteen feet high; there are the circular marks or rings left the whole length, where the leaves are fallen off; for as these half embrace the stalk with their base, so when they fall away, the vestigia where they grew remain. The top of the stalk sustains a large head of leaves, which come out singly all round it; they are shaped like those of the common Iris, but are much longer, being often four or five feet long, and an inch and a half broad at their base, where they embrace the stalk, and lessen gradually to the end, where they terminate in a point. These leaves are pliable, and hang down all round the stem; they are entire, and of a deep green, smooth on both surfaces, and greatly resemble those of the common yellow Iris. As this plant has not flowered in *England*, I can give no account of its flowers; but so far as I can judge from the berries which I have received, it may properly enough be ranged in this genus.

All these sorts of Palms are propagated by seeds, which should be sown in the same way as hath been directed for the first sort, and the plants should afterward be treated in the same manner, with this difference, that such of them as are natives of very warm countries, will require to be kept in a warmer air. The second, third, fourth, fifth, seventh, eighth, twelfth, and thirteenth sorts, should be constantly kept in the bark-bed in the stove, otherwise they will not make great progress in *England*; and when they do thrive, they grow in about twenty years too tall for most of the stoves which are at present built here, nor can we hope to see many of them produce their fruit in *England*; for the plants are preserved by the curious for their foliage, which being so singular and different from that of the *European* trees, renders them worthy of care.

The other sorts may be kept in a dry stove in winter in a moderate temperature of air, and in the heat of summer they may be exposed to the open air in a warm sheltered situation for about three months; but they should be removed into the stove, before the morning frosts come on in the autumn. When these plants are kept in a moderate degree of warmth, they should have but little water during the winter season; and in the summer, when they are exposed in the open air, they must not be often watered, unless the season is remarkably dry and warm, for too much moisture will soon destroy them. The other management of them is nearly the same as for the Date Palms, which is

not to cut their principal roots when they are shifted from one pot to another, nor to confine their roots too much; but as the plants grow in size, they should annually be removed into pots a size larger than those they were in the former year. The earth in which they are planted, should be light, so as to let the moisture easily pass off; for if it is strong, and detains the moisture, the tender fibres of the roots will rot.

PANAX *Lin. Gen. Plant.* 1031. Ginfeng, or Ninfeng.

The Characters are,

It hath male and hermaphrodite flowers on distinct plants; the male have simple globular umbels, composed of several coloured rays which are equal. The flower has five narrow, oblong, blunt petals, which are reflexed, sitting on the empalement, and five oblong slender stamina inserted in the empalement, terminated by single summits. The hermaphrodite umbels are simple, equal, and clustered; the involucre is small, permanent, and composed of several awl-shaped leaves. The flowers have five oblong equal petals, which are recurved, and five short stamina terminated by single summits which fall off, with a roundish germen under the empalement supporting two small erect styles, crowned by simple stigmas. The germen afterward becomes an umbellicated berry with two cells, each containing a single, heart-shaped, convex, plain seed.

The Species are,

1. PANAX *foliis ternis quinatis. Flor. Virg.* 147. Panax with trifoliolate Cinquefoil leaves; called Ninzin.

2. PANAX *foliis ternis ternatis. Flor. Virg.* 35. Panax with three trifoliolate leaves.

Both these plants grow naturally in North America; the first is generally believed to be the same as the Tartarian Ginfeng, the figures and descriptions of that plant, which have been sent to Europe by the missionaries, agreeing perfectly with the American plant.

This hath a fleshy taper root as large as a man's finger, which is jointed, and frequently divided into two smaller fibres downward. The stalk rises above a foot high, naked to the top, where it generally divides into three smaller foot-stalks, each sustaining a leaf composed of five spear-shaped lobes, which are sawed on their edges; they are of a pale green, and a little hairy. The flowers arise on a slender foot-stalk, just at the division of the foot-stalks, which sustain the leaves, and are formed into a small umbel at the top; they are of an herbaceous yellow colour, composed of five small petals, which are recurved. These appear the beginning of June, and are succeeded by compressed heart-shaped berries, which are first green, but afterward turn red, inclosing two hard, compressed, heart-shaped seeds, which ripen the beginning of August.

The Chinese hold this plant in great esteem, according to the accounts which have been transmitted to Europe by the missionaries. Father Jartoux in his letters says, that the most eminent physicians in China have written whole volumes upon the virtues of this plant, and make it an ingredient in almost all remedies, which they give to their nobility, for it is of too high price for the common people. They affirm that it is a sovereign remedy for all weakness occasioned by excessive fatigues, either of body or mind; that it cures weakness of the lungs and the pleurisy; that it stops vomitings; that it strengthens the stomach, and helps the appetite; that it strengthens the vital spirits, and increases the lymph in the blood; in short, that it is good against dizziness of the head, and dimness of sight, and that it prolongs life in old age.

This father also says, he has made trials of the root of this plant himself, and has in an hour after taken half one of the roots, found himself greatly recovered from weariness and fatigue, and much more vigorous, and could bear labour with greater ease than before.

This plant has been introduced to the English gardens from America, where it has been planted in a shady situation and a light soil, the plants have thriven and produced flowers, and ripened their seeds annually, but none of these seeds have grown; for I have several years sown them soon after they were ripe, without any success; I have also sown of the seeds which were sent me from America several times, in various situations, and have not raised a single plant from either; and by the accounts which the missionaries have sent from China, it appears they have had no better success with the seeds of this plant, which they say they have frequently sown in the gardens in China, but could not raise one plant; so that I believe there is a necessity for the hermaphrodite plants to have some male plants stand near them, to render the seeds prolific; for all those plants which I have seen, or saved the seeds from, were such as had hermaphrodite flowers; and though the seeds seem to ripen perfectly, yet their not growing, though I have waited three years, without disturbing of the ground, confirms me in this opinion.

The second sort grows naturally in the same countries, but whether it is possessed of the same qualities as the first I cannot say; I have seen but one plant of this sort in England, which was sent me a few years ago from Maryland, and did not live over the first summer, which was remarkably dry, and being planted in a dry soil, was the occasion of its death; the stalk of this was single, and did not rise more than four inches high, dividing into three foot-stalks, each sustaining a trifoliolate leaf, whose lobes were longer, narrower, and deeper indented on the edges, than those of the former. The flower-stalk rose from the divisions of the foot-stalk of the leaves, but before the flowers opened, the plant decayed, so I can give no farther account of it.

PANCRATIUM. *Dill. Hort. Elth.* 221. fol. 289. Sea Daffodil.

The Characters are,

The flowers are inclosed in an oblong spathe or sheath, and have a funnel-shaped, cylindrical nectarium of one leaf, spreading open at the top, with six spear-shaped petals, which are inserted on the outside of the nectarium, and six long stamina inserted in the brim of the nectarium, terminated by oblong prostrate summits. They have a three-cornered obtuse germen situated under the flower, supporting a long slender style, crowned by an obtuse stigma. The germen afterward becomes a roundish three-cornered capsule with three cells, filled with globular seeds.

The Species are,

1. PANCRATIUM *spathâ multiflorâ, petalis planis, foliis linguatis. Lin. Sp. Plant.* 291. Pancratium with a sheath containing many flowers, plain petals, and tongue-shaped leaves; the Sea Daffodil.

2. PANCRATIUM *spathâ multiflorâ, foliis ensiformibus, staminibus nectario longioribus. Flor. Leyd. Prod.* 34. Pancratium with many flowers in a sheath, sword-shaped leaves, and stamina longer than the nectarium; Lily Daffodil of Sclavonia.

3. PANCRATIUM *spathâ uniflorâ, petalis reflexis. Flor. Zeyl.* 126. Pancratium with one flower in a sheath, whose petals are reflexed.

4. PANCRATIUM *spathâ biflorâ. Hort. Cliff.* 133. Pancratium with two flowers in a sheath.

5. PANCRATIUM *spathâ multiflorâ, foliis ovatis nervosis. Lin. Sp. Plant.* 291. Pancratium with many flowers in a sheath, and oval veined leaves.

6. PANCRATIUM *spathâ multiflorâ, foliis linearibus, staminibus nectarii longitudine. Lin. Sp. Plant.* 291. Pancratium with many flowers in a sheath, narrow leaves, and stamina the length of the nectarium.

7. PANCRATIUM *spathâ multiflorâ, foliis carinatis angustioribus.* Pancratium with many flowers in a sheath, and narrow keeled-shaped leaves.

8. *PANCRATIUM spathâ multiflorâ, foliis carinatis latioribus.* Pancratium with many flowers in a sheath, and broader keel-shaped leaves.

9. *PANCRATIUM foliis ovatis, nervosis, spathâ multiflorâ, staminibus nectario longioribus.* Pancratium with oval veined leaves, and many flowers in a sheath, whose stamina are longer than the nectarium.

The first sort grows naturally on the sea-coast in *Spain*, and the south of *France*. This hath a large, coated, bulbous root, of an oblong form, covered with a dark skin; the leaves are shaped like a tongue, they are more than a foot long, and one inch broad, of a deep green, six or seven of them rising together from the same root, encompassed at bottom with a vagina or sheath; between these arise the stalk, which is a foot and a half long, naked, sustaining at the top six or eight white flowers, inclosed in a sheath, which withers and opens on the side, to make way for the flowers to come out. The germen are situated close to the top of the stalk, from these arise the tube of the flowers, which are three inches long; they are very narrow, swelling at the top, where the cup or nectarium is situated, on the outside of which is fastened the six segments or petals of the flower; these are narrow, and extend a great length beyond the nectarium; from the border of the nectarium arise six long slender stamina, terminated by oblong summits which are prostrate, and in the center arises a style the length of the stamina, terminated by an obtuse stigma. The flowers of this sort do not appear in *England* till the latter end of *August*, so are not succeeded by seeds here. The leaves of this sort are green all the winter, and decay in the spring, so the roots should be transplanted in *June*, after the leaves are decayed. This must be planted in a very warm border, and screened from severe frost, otherwise it will not live through the winter in *England*.

The second sort grows naturally in *Sclavonia*, and also in *Sicily*; this hath a large, coated, bulbous root, covered with a dark skin, sending out many thick strong fibres, which strike deep in the ground; the leaves are sword-shaped, a foot and a half long and two inches broad, of a grayish colour. The stalks are thick, succulent, and rise near two feet high, sustaining at the top six or seven white flowers shaped like those of the first sort, but the tube is shorter and the stamina are much longer. This flowers in *June*, and frequently produces seeds which ripen in *September*.

This sort is hardy, and will live through the winter in the full ground, being never injured but in very severe winters; and if, in such seasons, the surface of the ground is covered with tanners-bark, sea-coal ashes, straw or Peas haulin, to keep out the frost, there will be no danger of the roots suffering. It is propagated either by offsets from the roots, or from seeds; the former is the more expeditious method, for the offsets will flower very strong the second year; whereas those which are raised from seeds, seldom flower in less than four or five years.

The roots of this plant should not be removed oftener than every third year, if they are expected to flower strong; the best time to transplant them is in the beginning of *October*, soon after their leaves decay; they should not be kept long out of the ground, for as they do not lose their fibres every year, so if these are dried by long keeping out of the ground, it greatly weakens the roots. This loves a light sandy soil and a sheltered situation; the roots should be planted nine inches or a foot asunder every way, and five inches deep in the ground.

If the plants are propagated by seeds, they should be sown in pots filled with light earth soon after they are ripe; these pots should be placed under a hot-bed frame in winter, to screen them from frost, but the glasses must be taken off

every day in mild weather. The other management being the same as for the *Narcissus*, I need not repeat it here, so shall only mention, that the young roots will require a little protection in winter, till they have obtained strength.

The third sort grows naturally in *Ceylon*; this hath a pretty large bulbous root, the leaves are long and narrow, of a grayish colour, and pretty thick, standing upright; the stalk rises between them a foot and a half high, naked, sustaining one flower at the top, whose petals are reflexed backward; the nectarium is large, and cut at the brim into many acute segments; the stamina are long, and turn toward each other at their points, in which it differs from the other species. The flower has a very agreeable scent, but is of short duration; this is very rare in the gardens at present.

The fourth sort grows naturally at *La Vera Cruz*, from whence the late Dr. *Houfston* brought some of the roots. The leaves of this sort are about a foot long, and almost two broad, having three longitudinal furrows. The stalk rises about a foot high, then divides like a fork into two small foot-stalks, or rather tubes, which are narrow, green, and at first are encompassed by a thin spatha (or sheath) which withers and opens to give way to the flowers, which are white, and shaped like those of the other species, but have no scent.

The fifth sort was some years past in the *English* gardens, but I believe is now lost here; it grows naturally at *Amboyna*. The root of this sort is oblong, white, and sends out several thick fleshy fibres, which strike downward; the leaves stand upon very long foot-stalks, some of them are oval, and others heart-shaped, about five inches long, and almost as many broad, ending in points, having many deep longitudinal furrows; they are of a light green, and their borders turn inward. The stalk is thick, round, and succulent, rising near two feet high, sustaining at the top several white flowers, shaped like the other species, but the petals are broader; the tube is shorter, and the stamina are not so long as the petals. These flowers have a thin sheath or covering, which splits open longitudinally, to make way for the flowers.

The sixth sort grows naturally on moist boggy soils in *Georgia*, where Mr. *Catesby* discovered it. This hath a roundish bulbous root, covered with a light brown skin, from which arise several narrow dark green leaves, about a foot long; between these come out a thick stalk about nine inches high, sustaining six or seven white flowers, with very narrow petals, having large bell-shaped nectariums or cups, which are deeply indented on their brims; the stamina do not rise far above the nectarium, and are terminated by yellow summits.

The seventh sort grows naturally in the islands of the *West-Indies*, where it is called *White Lily*. This hath a pretty large bulbous root, a little flatted at the top, covered with a brown skin; the leaves are near a foot and a half long, a little more than one inch broad, of a dark green, and hollowed in the middle like the keel of a boat. The stalks rise near two feet high, they are thick, succulent, and naked, sustaining at the top eight or ten white flowers, shaped like those of the first sort, but are of a purer white, and have a strong sweet odour, like that of *Balsam of Peru*. The stamina of this are very long, spreading out wide each way; the pointal is of the same length, standing in the middle of the nectarium. These flowers are of a short duration, seldom continuing longer in beauty than three or four days, and in very hot weather not so long; when these fade, the germen, which are situated at the bottom of the tubes, turn to so many oblong bulbs, which are irregular in form, and, when ripe, drop off in the ground, where they put out fibres and become plants.

These foreign species are most, if not all of them, of this kind, bearing bulbs; whereas the two first have feed-vessels with three cells, inclosing many roundish black seeds, so that though they agree in the characters of flowers, yet in this particular they differ greatly.

The eighth sort grows naturally in the *West-Indies*, where it is not distinguished from the former; but as I have frequently propagated both by their bulbs which succeed the flowers, and have always found the plants so raised continue their difference, so I make no doubt of their being distinct species. This differs from the former, in the leaves being much longer and broader than that; for these are near two feet long, and more than three inches broad, and are hollowed like the keel of a boat. The flowers are larger, the petals longer, and the scent is not so strong as that of the former, and the roots flower in every season of the year. This seems to be the sort figured by Dr. *Trew*, in the twenty-seventh table of his *Decades of Rare Plants*, but if it is, the leaves in his figure are too flat.

The ninth sort grows naturally in the *West-Indies*; this hath a large, roundish, bulbous root, from which arise several oval leaves about a foot long, and six inches broad in the middle, drawing to a point at both ends; they are of a deep green, and have many longitudinal furrows. The stalk is thick, succulent, and naked; it rises a foot and a half high, sustaining at the top six or eight white flowers, of an agreeable sweet scent, shaped like those of the seventh sort, but are smaller; the petals are narrower, the tubes are shorter, and so are the spathæ or sheaths.

These seven sorts last mentioned are tender, so will not thrive in *England*, unless they are placed in a warm stove. The best way to have these plants in perfection, is, to plunge the pots into the bark-bed in the stove, where they will thrive and flower exceeding well; for though they may be preserved in a dry stove, yet those will not thrive so well, nor will their flowers be so strong, as when they are plunged in the tan-bed; nor will they flower oftener than once a year, whereas when they are in the tan-bed, the same roots will often flower two or three times in a year. I have had several of the species in flower at all seasons of the year, so there has not been a month when some of them were not in flower.

They are propagated by offsets from the roots, and also by the bulbs which succeed the flowers; if the latter are planted in small pots filled with light earth from a kitchen-garden, and plunged into a moderate hot-bed, they will soon put out roots and leaves, and with proper management, will become blowing roots in one year, so that they may be easily propagated; and if they are constantly kept in the tan-bed in the stove, they will put out offsets from their roots, and thrive as well as in their native countries.

PANICUM. *Tourn. Inst. R. H.* 515. tab. 298. Panic.

The Characters are,

There is one flower in each chaff; the chaff opens with three valves which are oval, ending in acute points. The petals open with two oval acute-pointed valves. The flowers have three short hair-like stamina, terminated by oblong summits, and a roundish germen, supporting two hair-like styles, crowned by feathered stigmas. The germen afterward becomes a roundish seed, fastened to the withered petals.

The Species are,

1. PANICUM spicâ simplici cernuâ, setis brevioribus, pedunculo hirsuto. Panic with a single nodding spike, short awns, and a hairy foot-stalk; German Panic.

2. PANICUM spicâ compositâ, spiculis glomeratis, setis immixtis, pedunculo hirsuto. *Lin. Sp. Plant.* 56. Panic with a compounded spike, whose smaller spikes grow in clusters intermixed with awns, and have a hairy foot-stalk; Italian Panic.

3. PANICUM spicâ simplici longissimâ, setis hispidis, pedunculo hirsuto. Panic with the longest single spike, prickly awns, and a hairy foot-stalk; Indian Panic with the longest spike.

4. PANICUM spicâ tereti, involuclis bifloris fasciculato-pilosis. *Flor. Zeyl.* 44. Panic with a taper spike, having two flowers in each cover, and hairs growing in clusters.

5. PANICUM spicâ simplici æquali, pedunculis bifloris. *Prod. Leyd.* 54. Panic with an equal single spike, and two flowers growing on each foot-stalk.

There are several other species of this genus, than are here enumerated, some of which grow naturally in *England*; but as they are not cultivated, so it would be swelling this work too much, if they were inserted here.

The first sort grows naturally in *Germany* and *Hungary*; of this there are three varieties, one with yellow grain, another with white, and the third has purple grains. This has been formerly cultivated for bread, in some of the northern countries. It rises with a jointed Reed-like stalk about three feet high, and the size of the common Reed, garnished at each joint with one Grass-like leaf a foot and a half long, and an inch broad at the base where broadest, ending in acute points. The stalks are terminated by compact spikes, which are about the thickness of a man's finger at their base, growing taper toward their points, closely set with small roundish grain, like that of Millet. This is an annual plant, which perishes soon after the seeds are ripe.

The second sort is frequently cultivated in *Italy*, and other warm countries. This rises with a Reed-like stalk near four feet high, which is much thicker than that of the former; the leaves are also broader, but of the same shape. The spikes are a foot long, and twice the thickness of those of the former, but not so compact, being composed of several roundish clustered spikes; the grain is also larger, but of the same form.

The third sort grows naturally in both *Indies*; this hath a Reed-like stalk as large as a man's thumb, rising upward of five feet high; the leaves are two inches broad, and more than two feet long, of the same form with those of the former sort; the spikes at the top are a foot and a half long, very compact, and thicker than a man's thumb at the base, growing taper toward the top. The seeds are much larger than those of the other sorts, and are in some white, and others yellow.

The fourth sort grows naturally in both *Indies*; this hath a strong Reed-like stalk, which rises six or seven feet high, garnished with leaves more than three feet long; they are near three inches broad at their base, lessening to a point at the end, having a smooth surface; the spikes arise at the wings of the stalk, they are single, but not so compact as those of the former, having soft awns or beards; they are about six inches long, and stand upon very long foot-stalks; the grain of this is pretty large.

The fifth sort grows naturally in *Peru*; this rises with a Reed-like stalk six feet high, which sends out two or three branches from the sides, and is garnished with long leaves two inches broad at their base; the stalks are of a purple colour, the leaves are also inclining to the same colour. The spikes come out from the wings of the stalks, and at the end of the branches; they are about four or five inches long, thicker than a man's thumb, and almost equal at the point with the base. They are of a pale blue colour, having pretty long awns or beards of the same colour, as are also the seeds, which are larger and rounder than those of the other sorts.

The two first sorts are sown in several parts of *Europe*, in the fields, as Corn, for the sustenance of the inhabitants, but it is reckoned not to afford so good nourishment as Millet; however, it is frequently used in some parts of *Germany* and

and *Italy*, to make cakes and bread, but the *German* is not so much esteemed as the *Italian* sort; but as it will ripen better in cold countries than that, it is generally cultivated where a better sort of grain will not succeed.

The seeds of these sorts may be sown in the spring, at the same time as Barley is sown, and may be managed exactly in the same way; but this should not be sown too thick, for these seeds are very small, and the plants grow stronger, therefore require much more room. The *German* sort doth not grow above three feet high, unless it is sown on very rich land; in which case it will rise to be four feet high, but the leaves and stems of this Corn are very large, so require to stand four or five inches apart, otherwise they will grow up weak, and come to little. These large growing Corns should be sown in drills at about eighteen inches apart, so that the ground may be hoed between the rows of Corn, to keep them clear from weeds, and the stirring of the ground will greatly improve the Corn. In *July* the Corn will ripen, when it may be cut down and dried, and then should be housed.

The *Italian* Panic grows much larger than the *German*, and produces much larger spikes; so this should be allowed more room to grow, otherwise it will come to little. This is also later before it ripens, so it is not very proper for cold countries.

The other sorts are natives of very warm countries, where they are used by the inhabitants to make bread. These grow very large, and require a good summer, otherwise they will not ripen in this country. The seeds of these kinds should be sown the latter end of *March*, or the beginning of *April*, on a bed of light rich earth, in a warm situation. They should be sown in drills about three feet asunder, and when the plants come up, they must be kept clear from weeds, and thinned where they are too close. When the plants are grown pretty tall, they should be supported by stakes, otherwise the winds will break them down; and when the Corn begins to ripen, the birds must be kept from it, otherwise they will soon destroy it. These sorts are preserved in some curious gardens for the sake of variety, but they are not worth cultivating for use in *England*. The two last sorts do not ripen here.

PANSIES. See *Viola Tricolor*.

PAPAVER. *Tourn. Inst. R. H.* 237. tab. 119. Poppy.

The Characters are,

The empalement of the flower is oval, indented, and composed of two almost oval, concave, obtuse leaves, which fall off. The flower has four large roundish petals which spread open, with a great number of hair-like stamens, terminated by oblong, compressed, erect summits. In the center is placed a large roundish germen, having no style, but is crowned by a plain, radiated, target-shaped stigma. The germen afterward becomes a large capsule, crowned by the plain stigma, having one cell, opening in many places at the top under the crown, and is filled with small seeds.

The Species are,

1. PAPAVER capsulis glabris globosis, caule piloso multifloro, foliis pinnatifidis incis. *Lin. Sp. Plant.* 507. Poppy with smooth globular heads, a hairy stalk with many flowers, and wing-pointed cut leaves; or common, red, Field Poppy.

2. PAPAVER capsulis subglobosis torosis hispida, caule folioso multifloro. *Lin. Sp. Plant.* 506. Poppy with globular capsules which are furrowed and prickly, and a leafy stalk, bearing many flowers.

3. PAPAVER capsulis clavatis hispida, caule folioso multifloro. *Lin. Sp. Plant.* 506. Poppy with nail-shaped prickly heads, and a leafy stalk bearing many flowers.

4. PAPAVER capsulâ hispida, scapo unifloro nudo hispido, foliis bipinnatis. *Lin. Sp. Plant.* 507. Poppy with prickly heads, a naked prickly stalk bearing one flower, and double-winged leaves.

5. PAPAVER capsulis glabris oblongis, caule multifloro lævi, foliis pinnatis incis. *Lin. Sp. Plant.* 508. Poppy with oblong smooth heads, a smooth stalk bearing many flowers, and cut winged leaves; yellow *Welch* Poppy.

6. PAPAVER capsulis hispida, scapo unifloro nudo hispido, foliis simplicibus pinnato sinuatis. *Hort. Upsal.* 136. Poppy with prickly heads, a naked rough stalk having one flower, and single leaves which are wingedly sinuated.

7. PAPAVER capsulis glabris, caulibus unifloris, scabris, foliis pinnatis serratis. *Hort. Upsal.* 136. Poppy with smooth heads, rough leafy stalks having one flower, and sawed winged leaves.

8. PAPAVER calycibus capsulisque glabris, foliis amplexicaulibus incis. *Lin. Sp. Plant.* 508. Poppy with smooth capsules and empalements, and cut leaves embracing the stalks.

9. PAPAVER capsulis ovatis glabris, foliis latioribus amplexicaulibus marginibus inciso-serratis. Poppy with oval smooth heads, and broader leaves embracing the stalks, which are cut on their edges like the teeth of a saw; commonly called *White Poppy*,

The first sort is the common red Poppy, which grows naturally on arable land in most parts of *England*; from the flowers of this sort is drawn a simple water, a tincture, a syrup, and a conserve of these flowers is also made for medicinal use. It is an annual plant; from the roots rise several rough branching stalks a foot and a half high, garnished with hairy leaves five or six inches long, deeply jagged almost to the midrib, those on the lower part of the leaves being the deepest. At the top of each stalk stand the flowers, which have oval hairy empalements, opening with two valves, and soon fall away. The flowers are composed of four large roundish petals, of a beautiful scarlet colour, and soon fall off. These appear in *June*, and are succeeded by oblong smooth heads, crowned by the flat target-shaped stigma, perforated in several places at the top, filled with small purplish coloured seeds.

The second sort grows naturally among the Corn in many parts of *England*; the leaves of this sort are much smaller than those of the first, and cut into much finer segments; the stalks are slender, a little more than a foot high, not so branching as the former. The flowers are not so large, and of a deep red colour, very soon falling away, seldom lasting more than a whole day; these are succeeded by oblong prickly heads, filled with small black seeds. It flowers in *June*.

The third sort grows naturally among Corn in some parts of *England*, but not in so great plenty as either of the former. The leaves of this are finer cut and smaller than those of the first sort, but are not so fine as those of the second; the stalks do not rise so high as either of the former, and seldom have many branches. The flowers are not half so large as either of the former, and are of a copper colour, falling away in a few hours. These appear in *May*, and are succeeded by long, slender, prickly heads which are channelled, filled with small, black, shrivelled seeds.

The fourth sort grows naturally on the *Alps*, among the rocks. The leaves of this are smooth and doubly winged, the segments are finely cut; the stalks rise about a foot high, sustaining one small yellow, or copper colour flower, which is succeeded by roundish prickly heads, filled with small seeds. This flowers about the same time as the former sort.

The fifth sort has a perennial root; it grows naturally in *Wales*, and also in some of the northern counties in *England*. I have found it growing plentifully near *Kirkby Lonsdale*, in *Westmoreland*. *Tournefort* also found this plant upon the *Pyrenean* mountains. The leaves of this sort are winged; the lobes are deeply cut on their edges. The stalks rise at

foot high; they are smooth, and garnished with a few small leaves, of the same shape as the lower. The upper part of the stalk is naked, sustaining one large yellow flower. These appear in *June*, and are succeeded by oblong smooth capsules, filled with small purplish seeds.

The sixth sort grows naturally on the confines of *Russia* near *Tartary*. The leaves of this sort are single, and sinuated almost to the midrib in form of a winged leaf; they are rough and hairy. The stalk rises near two feet high; it is slender, naked, sustaining one flower at the top, which is composed of four roundish petals of a pale yellow colour, each having a dark bottom or tail. The flowers have an agreeable scent, but are of a short duration. They come out in *June*, but are succeeded by long rough capsules, filled with small seeds.

The seventh sort grows naturally in *Armenia*. The root of this plant is composed of two or three strong fibres as thick as a man's little finger, which are a foot and a half long, of a dark brown on their outside, and full of a milky juice, which is very bitter and acrid. The leaves are winged, and sawed on their edges; they are a foot long, closely covered with bristly white hairs. The stalks rise two feet and a half high; they are very rough and hairy, garnished below with leaves like those at bottom, but smaller; the upper part is naked, sustaining at the top one very large flower, of the same colour with the common red Poppy. These appear in *May*, and are succeeded by oval smooth capsules, filled by purplish seeds.

The eighth sort is the common black Poppy, the seeds of which are sold in the shops by the title of Maw-seed. The sort with single flowers grows in the warm parts of *Europe* naturally; this is annual; the stalks rise three feet high; they are smooth, and divide into several branches, garnished with large leaves, which are smooth, and deeply cut or jagged on their edges, embracing the stalks with their base. The flowers grow on the top of the stalks; they are composed of four large roundish petals, of a purplish colour, with dark bottoms, and are succeeded by oval smooth capsules, filled with black seeds. It flowers in *June*, and the seeds ripen the latter end of *August*.

There are great varieties in the flowers of this sort, some having very large double flowers, which are variegated of several colours, some are red and white, others purple and white, and some are finely spotted like Carnations; so that during their short continuance in flower, there are few plants whose flowers appear so beautiful, but having an offensive scent, and being of short duration, they are not much regarded.

The ninth sort is the common white Poppy. This is cultivated in gardens for the heads, which are used in medicine. The stalks of this are large, smooth, and rise to the height of five or six feet; they branch out into several smaller branches, and are garnished with large grayish leaves, whose base embraces the stalks; they are jagged irregularly on their sides. The flowers terminate the stalks; these, when inclosed in the empalement, nod downward, but before the flowers open they are erect. The empalement of the flower is composed of two large oval leaves, of the same grayish colour as the other; these separate and soon drop off. The flower is composed of four large, roundish, white petals, which are of short duration, and are succeeded by large roundish heads, as big as Oranges, flattened at both ends, having indented crowns, and are filled with small white seeds. This flowers in *June*, and the seeds ripen in *August*.

There are several varieties of this sort, which differ in the colour of their flowers and multiplicity of petals; those with beautiful flowers are preserved in gardens for ornament, but that with the single flowers only is cultivated for

use. The seeds of this sort are used in emulsions, being cooling and good in fevers, and inflammatory distempers, as also for the strangury and heat of urine. Of the dry heads infused and boiled in wine, is made the Diocodium of the shops.

All the sorts of Poppy are propagated by seeds, but the fifth and seventh sorts, which have perennial roots, may also be propagated by offsets. The best time for sowing of the seeds is in *September*, when they will more certainly grow than those which are sown in the spring; and those sorts which are annual will make larger plants, and flower better than when they are sown in the spring. The best way is to sow the seeds of the annual kinds in the places where they are to remain, and to thin the plants where they are too close; those of the large kinds should not be left nearer to each other than a foot and a half, and the smaller sorts may be allowed about half that space. The culture they will require after this, is only to keep them clean from weeds.

Those who are curious to have fine Poppies in their gardens, carefully look over their plants when they begin to flower, and cut up all those plants whose flowers are not very double and well marked, before they open their flowers, to prevent their farina mixing with their finer flowers, which would degenerate them; and it is the not being careful of this, that causes the flowers to degenerate so frequently in many places, which is often supposed to be occasioned by the ground.

The yellow *Welsh* Poppy requires a cool shady situation, where the plants will thrive, and produce plenty of seeds annually. If the seeds are permitted to scatter, the plants will come up better than when sown by hand; but if they are sown, it should be always in the autumn, for the seeds of this, which are sown in the spring, rarely succeed.

The best time to transplant, and part the roots of this sort, is in the autumn, that the plants may be well established in their new quarters, before the dry weather comes on in the spring.

The eastern Poppy will thrive either in sun or shade, for I have several of these plants growing under trees, where they have thriven many years, and flower full as well as those in an open situation, but came later in the season. This will propagate very fast by its roots, so there is no necessity for sowing of the seeds, unless to procure new varieties. This sort should be transplanted at the same season as the former, and if the seeds are sown, it should be at the same time for the reasons before given.

PAPAVER CORNICULATUM. See Glaucium.

PAPAVER SPINOSUM. See Argemone.

PAPAYA. See Carica.

PARIETARIA. *Tourn. Inst. R. H.* 509. *tab.* 289. Pellitory.

The Characters are,

It hath hermaphrodite and female flowers upon the same plant. There are two hermaphrodite flowers contained in a six-leaved involucre. They have no petals, but four permanent awl-shaped stamina, with an oval germen supporting a slender coloured style, crowned by a pencil-shaped stigma. The germen afterward turns to an oval seed wrapped up in the empalement. The female flowers have no stamina, but in other respects are the same as the hermaphrodite.

The Species are,

1. *PARIETARIA foliis lanceolatis alternis.* Pellitory with spear-shaped leaves placed alternately; the officinal Pellitory.

2. *PARIETARIA foliis ovatis alternis.* Pellitory with oval leaves placed alternately; Pellitory with a Basil leaf.

The first sort grows naturally in *Germany* and *Holland*, but was not in *England* till the year 1727, when I brought it

it here. This is supposed to be the true sort, which is recommended by the ancients to be used in medicine; it hath a thick perennial root, composed of fleshy reddish fibres, from which arise many stalks a foot and a half high, garnished with hairy spear-shaped leaves. The flowers come out in small clusters on the side of the stalks; they are small, of an herbaceous colour, so make no figure. These appear in succession all the summer months, and the seeds ripen accordingly, which are cast out to a distance with an elasticity when ripe.

The second sort grows plentifully on old walls, and the sides of dry banks in many parts of *England*. This differs from the former in having shorter stalks, and smaller oval leaves. The flowers are also less, and are in smaller clusters; in other respects they are the same.

They may be propagated in plenty from a single plant, which, if permitted to scatter its seeds, will fill the ground about it with young plants, for the seeds are very difficult to collect, as they are thrown out of their covers as soon as they are ripe.

PARIS. *Lin. Gen. Plant.* 449. True-love, or One-berry.

The Characters are,

The empalement of the flower is composed of four leaves, which expand in form of a cross. The flower also hath four leaves, which spread open in the same manner. In the center of the flower is situated a roundish four-cornered germen, supporting four spreading styles, crowned by single summits. This is attended by eight stamina, each having an oblong summit fastened by threads on each side to the stamina. The germen afterward changes to a roundish berry, having four cells, which are filled with seeds.

We know but one Species of this genus, viz.

PARIS *foliis quaternis. Flor. Lapp.* 155. Herb Paris, True-love, or One-berry.

This plant grows wild in moist shady woods in divers parts of *England*, but especially in the northern counties; and it is with great difficulty preserved in gardens. The only method to procure it, is to take up the plants from the places where they grow wild, preserving good balls of earth to their roots, and plant them in a shady moist border, where they may remain undisturbed, in which situation they will live some years; but as it is a plant of little beauty, it is rarely preserved in gardens.

PARKINSONIA. *Plum. Nov. Gen.* 25. tab. 3:

The Characters are,

The empalement of the flower is of one leaf, indented in five parts at the top. The flower has five equal petals placed circularly; the four upper are oval, the under is kidney-shaped. It has ten declining stamina terminated by oblong summits, and a long taper germen with scarce any style, crowned by an obtuse stigma. The germen afterward becomes a long taper pod with swelling joints, in each of which is lodged one oblong seed.

We know but one Species of this plant, which is

PARKINSONIA *aculeata, foliis minutis, uni costæ adnexis. Plum. Nov. Gen.* 25. Prickly Parkinsonia with very small leaves, which are fastened to one middle rib.

This plant was discovered by father Plumier in *America*, who gave it this name in honour of Mr. John Parkinson, who published an universal history of plants in *English*, in the year 1640.

It is very common in the *Spanish West-Indies*, but of late years it has been introduced into the *English* settlements in *America* for the beauty and sweetness of its flowers. This, in the countries where it grows naturally, rises to be a tree of twenty feet high or more, and bears long slender bunches of yellow flowers, which hang down after the same manner as the Laburnum. These flowers have a most agreeable sweet scent, so as to perfume the air to a considerable distance round about the trees; for which reason, the inhabitants of the *West-Indies* plant them near their habitations.

And though this plant has not been introduced many years into the *English* settlements, yet it is now become so common in all the islands, that but few houses are without some of the trees near it; for it produces flowers and seeds in plenty in about two years from seed, so that it may soon be made common in all hot countries; but in *Europe* it requires a stove, otherwise it will not live through the winter.

This plant is propagated by seeds; which should be sown in small pots filled with light fresh earth early in the spring, and the pots must be plunged into a hot-bed of tanners bark, where, in about three weeks or a month's time, the plants will come up, when they should be kept clear from weeds, and frequently refreshed with water. In a little time these plants will be fit to transplant, which should be done very carefully, so as not to injure their roots. They must be each planted into a separate halfpenny pot filled with light fresh earth, and then plunged into the hot-bed again, observing to stir up the tan; and if it hath lost its heat, there should be some fresh tan added, to renew it again. Then shade the plants from the heat of the sun, until they have taken new root; after which time they should have fresh air admitted to them every day, in proportion to the warmth of the season. With this management the plants will grow so fast, as to fill the pots with their roots by the beginning of *July*, at which time they should be shifted into pots a little larger than the former; and plunged again into the bark-bed to forward their taking new root; after which it will be the best way to inure the plants by degrees to bear the open air, that they may be hardened before winter; for if they are kept too warm in winter, the plants will decay before the next spring. The only method by which I have succeeded in keeping this plant through the winter, was by hardening them in *July* and *August* to bear the open air; and in *September* I placed them on shelves in the dry stove, at the greatest distance from the fire, so that they were in a very temperate warmth; and there they retained their leaves all the winter, and continued in health, when those which were placed in a warmer situation, as also those in the green-house, were entirely destroyed.

PARNASSIA. *Tourn. Inst. R. H.* 246. tab. 127. Grass of Parnassus.

The Characters are,

The flower hath a spreading empalement, cut into five parts. The flower has five roundish concave petals, which have five heart-shaped concave nectariums, and five stamina terminated by depressed summits, with a large oval germen having no style, but four obtuse stigmas in their place. The germen afterward turns to an oval four-cornered capsule with one cell, containing several oblong seeds.

The Species are,

1. PARNASSIA *palustris* & *vulgaris. Inst. R. H.* Common Marsh Grass of Parnassus.

2. PARNASSIA *vulgaris, flore pleno.* Common Grass of Parnassus, with a double flower.

The former of these sorts grows wild in moist meadows in several parts of *England*, but particularly in the north. It grows on the other side of *Watford*, in the low meadows by *Cassio-berry*, where it is in pretty great plenty.

The other sort is an accidental variety of the former, which has been discovered wild, and transplanted into gardens. This is but rarely to be found, being in very few gardens at present.

These plants may be taken up from the natural places of their growth, with balls of earth to their roots, and planted into pots filled with pretty strong, fresh, undunged earth, and placed in a shady situation, where, if they are constantly watered, they will thrive very well, and flower every summer;

summer; but if the plants are planted in the full ground, it should be in a very moist shady border, otherwise they will not live; and these should be as duly watered as those in the pots in dry weather, to make them produce strong flowers.

They may be propagated by parting of their roots, which should be done in *March*, before they put out new leaves, but the roots should not be divided too small, for that will prevent their flowering the following summer. These roots should always be planted in pretty strong fresh earth, for they will not thrive in a light rich soil. In the spring they must be constantly watered, if the season should prove dry, otherwise they will not flower; nor should they be parted oftener than every third year, to have them strong. These plants flower in *July*, and their seeds are ripe the latter end of *August*.

PARONYCHIA. *Tourn. Inst. R. H. 507. tab. 281.* Mountain Knot Grass.

The Characters are,

The empalement of the flower is five-cornered. The flower has no petals, but has five hair-like stamina within the empalement, terminated by single summits, and an oval acute germen, sitting upon a short style, crowned by an obtuse stigma. The empalement afterward turns to a roundish capsule with one cell, opening with five valves, containing one large, roundish, acute-pointed seed.

The Species are,

1. PARONYCHIA floribus sessilibus axillaribus, bracteis nitidis, caulibus procumbentibus. Mountain Knot Grass, with flowers sitting close to the wings of the stalks, having neat bractæ and trailing stalks.

2. PARONYCHIA caulibus diffusis procumbentibus, floribus conglomeratis, bracteis nitidis. Mountain Knot Grass with diffused trailing stalks, flowers growing in clusters, whose bractæ are very neat.

There are two or three other species of this genus, which grow naturally in the south of *France* and *Italy*, which having little beauty, are rarely admitted into gardens, so it would be needless to enumerate them here.

The first sort here mentioned, grows naturally in *Spain*. This hath trailing stalks like those of common Knot Grass, which are a foot and a half long, putting out several side branches, which are garnished with small leaves like those of the common Knot Grass, but smaller, sitting close to the stalks. The flowers come out at the wings of the leaves, sitting close to the stalks; these have silvery neat bractæ, which inclose the flowers, which are so small as not to be visible, unless they are close to the sight. The flowers appear in *July*, but unless the season is very warm, the seeds do not ripen in *England*.

The second sort grows naturally in *Spain*. The stalks of this plant are larger, and the branches more diffused than those of the first sort, but trail upon the ground in the like manner. The flowers come out in close clusters upon short foot-stalks from the side of the branches, surrounded by leaves, shaped like those of the broad-leaved Knot Grass; the bractæ of these flowers are silvery and neat, like those of the first sort.

These plants seldom continue longer than two or three years, and rarely ripen seeds here, but in warm dry seasons; but cuttings of them will take root. The plants will rise from seeds in the open air, and will live abroad in mild winters, but in hard frosts they are destroyed.

PARSLEY. See Apium.

PARSNIP. See Pastinaca.

PARTHENIUM. *Lin. Gen. Plant. 939.* Bastard Feverfew.

The Characters are,

It hath a flower composed of hermaphrodite florets and female

half florets, which are inclosed in a common five leaved spreading empalement. The hermaphrodite flowers which form the disk, have one tubulous petal cut into five parts at the brim; they have five hair-like stamina the length of the tube. The germen is situated below the flower, and is scarce visible, supporting a slender style, having no stigma; these flowers are barren. The female flowers, which compose the rays or border, are stretched out on one side, like a tongue; these have a large heart-shaped compressed germen, with a slender style, crowned by two long spreading stigmas. These flowers are succeeded by one heart-shaped compressed seed.

The Species are,

1. PARTHENIUM foliis composito-multifidis. *Lin. Hort. Cliff.*

442. Parthenium with many-pointed compound leaves.

2. PARTHENIUM foliis ovatis crenatis. *Lin. Hort. Cliff.*

442. Parthenium with oval crenated leaves.

The first sort grows wild in great plenty in the island of *Jamaica*, and in some other of the *English* settlements in the *West-Indies*, where it is called wild Wormwood, and is used by the inhabitants as a vulnerary herb.

The second sort grows plentifully in several parts of the *Spanish West-Indies*, from whence the seeds have been brought to *Europe*.

The first is an annual plant, which may be propagated by sowing the seeds on a hot-bed early in the spring; and when the plants are come up, they should be transplanted on another hot-bed, at about five or six inches distance. When the plants have grown so as to meet each other, they should be carefully taken up, preserving a ball of earth to their roots, and each planted into a separate pot, filled with light rich earth; and if they are plunged into a moderate hot-bed, will greatly facilitate their taking fresh root; but where this conveniency is wanting, the plants should be removed to a warm sheltered situation, where they must be shaded from the sun until they have taken new root; after which time they may be exposed, with other hardy annual plants, in a warm situation, where they will flower in *July*, and their seeds will ripen in *August* and *September*.

The second sort is a perennial plant, which dies to the ground every autumn, and shoots up again the following spring. The seeds of this sort were sent me by my good friend *Dr. Thomas Dale*, from *South Carolina*, where the plants grow wild. This may be propagated by parting of the roots in autumn, and may be planted in the full ground, where it will abide the cold of our ordinary winters very well. This sort flowers in *July*, but seldom produces good seeds in *England*.

These plants make no great appearance, so are seldom cultivated but for the sake of variety.

PASQUE FLOWER. See Pulsatilla.

PASSERINA. *Lin. Gen. Plant. 440.* Sparrow-wort.

The Characters are,

The flower has no empalement; it has one withered petal, having a slender cylindrical tube swelling below the middle. It hath eight bristly stamina, sitting on the top of the tube, terminated by erect summits. It has an oval germen under the tube, having a slender style rising on one side of the germen, crowned by a beaded stigma, set with prickly hairs on every side. The germen afterward turns to an oval seed pointed at both ends, inclosed in a thick oval capsule of one cell.

The Species are,

1. PASSERINA foliis linearibus convexis quadrifariam imbricatis, ramis tomentosis. *Lin. Sp. Plant. 559.* Sparrow-wort with linear convex leaves imbricated four ways, and downy branches.

2. PASSERINA foliis carnosis extus glabris, caulibus tomentosis. *Lin. Sp. Plant. 559.* Swallow-wort with fleshy leaves, which are smooth on their outside, and downy stalks.

3. *PASSERINA foliis lanceolatis subciliatis erectis, ramis nudis. Lin. Sp. Plant. 559.* Sparrow-wort with spear-shaped erect leaves, having small hairs and naked branches.

4. *PASSERINA foliis linearibus oppositis, floribus terminalibus solitariis, ramis glabris. Lin. Sp. Plant. 560.* Sparrow-wort with linear leaves placed opposite, single flowers terminating the branches, and smooth stalks.

The first sort grows naturally at the *Cape of Good Hope*. This rises with a shrubby stalk five or six feet high, sending out branches the whole length; these, when young, grow erect, but as they advance in length, they incline toward an horizontal position; but more so, when the small shoots toward the end are full of flowers and seed-vessels, which weigh down the weak branches from their upright position. The branches are covered with a white down like meal, and are closely garnished with very narrow leaves, which are convex, and lie over each other in four rows like the scales of fish, so as that the young branches seem as if they were four-cornered. The flowers come out at the extremity of the young branches, from between the leaves, on every side; they are small and white, so make but little appearance, and are succeeded by small seed-vessels, which seem withered and dry.

This plant may be propagated by cuttings during any of the summer months; these may be planted in a bed of loamy earth, and closely covered with a bell or hand-glass to exclude the air, shading them every day from the sun, and refreshing them now and then with water. With this treatment the cuttings will have taken root in about two months, when they may be taken up, and each planted in a small pot, filled with soft loamy earth, placing them in the shade till they have taken new root; then they may be removed into a sheltered situation, where they may remain till *October*, when they must be placed in the green-house, for they will not live in the open air through the winter in *England*, but they require no other treatment, than Myrtles and other hardy green-house plants, which is only to screen them from frost. As this plant retains its verdure all the year, so it makes a pretty variety in the green-house in winter.

The second sort grows naturally in *Spain* and *Portugal*. This hath shrubby stalks, which rise to a greater height than the former; the branches grow more diffused than those of the former; they are covered with a mealy down, and are garnished with short, thick, succulent leaves, lying over each other like the scales of fish; they are smooth, and green on their outside, but downy on their inner. The flowers are small and white, like those of the former. This plant will live abroad in ordinary winters, if it is planted in a dry soil and a warm situation, but in hard frosts they are frequently destroyed, therefore one or two plants should be kept in pots, and sheltered in winter to preserve the species. This may be propagated by cuttings, in the same way as the former sort.

The third sort grows naturally in *Spain* and *Portugal*, as also at the *Cape of Good Hope*. This hath a shrubby stalk, rising five or six feet high, sending out many branches, which are naked to their ends, where they are garnished with oblong leaves standing erect, which have hairy points. The flowers are small, white, and come out between the leaves at the end of the branches, but are not succeeded by seeds in *England*. This may be propagated by cuttings as the two former, and requires the same treatment.

The fourth sort grows naturally at the *Cape of Good Hope*. It hath a low shrubby stalk, which seldom rises more than a foot high, dividing into many slender branches, which are smooth, and spread out on every side; these are garnished with very narrow leaves placed opposite; they are of a dark green, and have the appearance of those of the

Pir-tree, but are narrower. The flowers come out singly at the end of the branches; these are larger than those of the former, and their upper part is spread open almost flat; they are of a purple colour. This may be propagated by cuttings as the other sorts, and the plants must be treated as the first sort.

PASSIFLORA. Lin. Gen. Plant. 910. Passion-flower.

The Characters are,

The flower has a plain-coloured empalement of five leaves, and five half spear-shaped petals, which are large, plain, and obtuse. The nectarium hath a tripple crown; the outer, which is longer, is fastened to the inside of the petal, but is larger and compressed above. It has five awl-shaped stamina, fastened at their base to the column of the style annexed to the germen. The style is an erect cylindrical column, upon whose top sits an oval germen, with three smaller styles which spread out. The germen afterward becomes an oval fleshy fruit with one cell, sitting at the end of the style, filled with oval seeds, fastened longitudinally to the skin or shell.

The Species are,

1. *PASSIFLORA foliis trilobis serratis. Amœn. Acad. Vol. I. p. 230.* Passion-flower, with leaves having three-sawed lobes; commonly called three-leaved Passion-flower.

2. *PASSIFLORA foliis palmatis integerrimis. Amœn. Acad. Vol. I. p. 231.* Passion-flower with hand-shaped entire leaves; or the common Passion-flower.

3. *PASSIFLORA foliis trilobis cordatis æqualibus obtusis glabris integerrimis. Amœn. Acad. Vol. I. p. 224.* Passion-flower with heart-shaped leaves, having three equal lobes, which are smooth, obtuse, and entire.

4. *PASSIFLORA foliis trilobis integerrimis, lobis sub-lanceolatis, intermedio productiore. Amœn. Acad. Vol. I. p. 229.* Passion-flower with leaves having three entire lobes, which are somewhat spear-shaped, and the middle one longer than the others.

5. *PASSIFLORA foliis trilobis integerrimis glabris, cortice suberoso.* Passion-flower with leaves having three entire smooth lobes, and a Cork-like bark.

6. *PASSIFLORA foliis hastatis glabris, petalis forum angustioribus.* Passion-flower with halberd-pointed smooth leaves, and narrow petals to the flowers.

7. *PASSIFLORA foliis trilobis cordatis pilosis, involucri multifido capillaribus. Amœn. Acad. I. p. 228.* Passion-flower with leaves having three hairy lobes, and the involucre of the flower composed of many-pointed hairs.

8. *PASSIFLORA foliis hastatis pilosis amplioribus, involucri multifido-capillaribus.* Passion-flower with the largest halberd-pointed hairy leaves, and empalements composed of many-pointed hairs.

9. *PASSIFLORA foliis trilobis, basi utrinque denticulo reflexo. Amœn. Acad. I. p. 229.* Passion-flower with leaves having three lobes, indented on each side the base, and reflexed.

10. *PASSIFLORA foliis bilobis cordatis oblongis petiolatis. Lin. Sp. Plant. 957.* Passion-flower with oblong heart-shaped leaves, having two lobes standing upon foot-stalks.

11. *PASSIFLORA foliis bilobis cuneiformibus, basi biglandulosis, lobis acutis divaricatis. Amœn. Acad. I. 223.* Passion-flower with wedge-shaped leaves having two lobes, and two glands at their base, whose lobes are acute, and spread from each other.

12. *PASSIFLORA foliis bilobis obtusis, basi emarginatis petiolatis.* Passion-flower with leaves having two obtuse lobes, which are indented at the base, and have foot-stalks.

13. *PASSIFLORA foliis bilobis glabris rigidis, basi indivisis.* Passion-flower with stiff smooth leaves having two lobes, which are undivided at their base.

14. *PASSIFLORA foliis bilobis transversis amplexicaulibus. Amœn. Acad. I. p. 222.* Passion-flower with transverse leaves, having two lobes embracing the stalk.

15. *PASSIFLORA foliis cordato-oblongis integerrimis, caule triquetro, involucris integerrimis.* Passion-flower with heart-shaped, oblong, entire leaves, a three-cornered stalk, with entire covers to the flowers; commonly called *Granadilla* in the *West-Indies*.

16. *PASSIFLORA foliis oblongis integerrimis, involucris dentatis.* Passion-flower with oblong entire leaves, and the covers of the flowers indented; commonly called *Water Lemon* in the *West-Indies*.

17. *PASSIFLORA foliis indivisis ovatis integerrimis, petiolis aequalibus.* *Amœn. Acad. Vol. I. p. 219.* Passion-flower with undivided, oval, entire leaves, and equal foot-stalks.

18. *PASSIFLORA foliis indivisis serratis.* *Amœn. Acad. 1. p. 213.* Passion-flower with undivided sawed leaves.

19. *PASSIFLORA foliis indivisis oblongis integerrimis, floribus confertis.* *Amœn. Acad. 1. p. 221.* Passion-flower with undivided, oblong, entire leaves, and flowers growing in clusters.

The first sort grows naturally in *Virginia* and other parts of *North America*, and was the first known in *Europe* of all the species, but was not very common in the *English* gardens till of late years. The root of this plant is perennial, but the stalk is annual in *North America*, dying to the ground every winter, as it also does in *England*, unless it is placed in a stove. The stalks of this are slender, rising about four or five feet high, having tendrils or clasps at each joint, which fasten themselves about whatever plants stand near them, whereby the stalk is supported. At each joint comes out one leaf upon a short foot-stalk; these have for the most part three oblong lobes, which join at their base, but the two side lobes are sometimes divided part of their length into two narrow segments, so as to resemble a five-lobed leaf; they are thin, of a light green, and slightly sawed on their edges. The flowers are produced from the joints of the stalk at the foot-stalks of the leaves; these have long slender foot-stalks. The involucre of the flower is composed of five oblong blunt-pointed leaves, of a pale green; these open and disclose five more leaves or petals, which are white, having a fringe or circle of rays of a double order round the style, of a purple colour, the lower row being the longest. In the center of this arises the pillar-like style, with the roundish germen at the top, surrounded at the bottom, where it adheres to the style, with five flattish stamina, which spread out every way, and sustain each of them an oblong summit, which hangs downward, and on their under side are covered with a yellow farina. The flowers have an agreeable scent, but are of short duration, opening in the morning, and fade away in the evening, never opening again, but are succeeded by fresh flowers, which come out at the joints of the stalk above them. When the flowers fade, the roundish germen swells to a fruit as large as a middling *Apple*, which changes to a pale *Orange* colour when ripe, inclosing many oblong rough seeds inclosed in a sweetish pulp.

This sort is usually propagated by seeds, which are brought from *America*, for the seeds do not often ripen in *England*; though I have had sometimes several fruit perfectly ripe on plants, which were plunged in a tan-bed under a deep frame; but those plants, which are exposed to the open air, do not produce fruit here. The seeds should be sown upon a moderate hot-bed, which will bring up the plants much sooner than when they are sown in the open air, so they will have more time to get strength before winter. When the plants are come up two or three inches high, they should be carefully taken up, and each planted in a separate small pot filled with good kitchen-garden earth, and plunged into a moderate hot-bed to forward their taking new root; after which they should be gradually indred to bear the open air, to which they should

be exposed in summer, but in the autumn they must be placed under a garden-frame to screen them from the frost, but they should have the free air at all times in mild weather. The spring following some of these plants may be turned out of the pots, and planted in a warm border, where, if they are covered with tanners bark every winter to keep out the frost, they will live several years, their stalks decaying in the autumn, and new ones arise in the spring, which in warm seasons will flower very well. If those plants, which are continued in pots, are plunged into a tan-bed, some of them may produce fruit; and, if the stalks of these are laid down into pots of earth plunged near them, they will take root, so that the plants may be easily propagated this way.

The second sort has not been many years in *England*, but is now the most common. This grows naturally in the *Brazils*, yet is hardy enough to thrive in the open air here, and is seldom injured except in very severe winters, which commonly kills the branches to the ground, and sometimes destroys the roots; this rises in a few years to a great height, if they have proper support. I have seen some of these plants, whose branches were trained up more than forty feet high. The stalks will grow almost as large as a man's arm, and are covered with a purplish bark, but do not become very woody. The shoots from these stalks are often twelve or fifteen feet long in one summer; they are very slender, so must be supported, otherwise they will hang to the ground, intermix with each other, and appear very unsightly. These are garnished at each joint with one hand-shaped leaf, composed of five smooth entire lobes. Their foot-stalks are near two inches long, and have two small leaves or ears embracing the stalks at their base; and from the same point comes out a long clasper, which twists round the neighbouring plants, whereby the stalks are supported. The flowers come out at the same joints as the leaves; these have foot-stalks almost three inches long; they have an outer cover composed of three concave oval leaves, of a paler green than the leaves of the plant, which are little more than half the length of the empalement, which is composed of five oblong blunt leaves, of a very pale green; within these are five petals, nearly of the same shape and size with the empalement, standing alternately between them. In the center of the flower arises a thick club-like column about an inch long, on the top of which sits an oval germen, from whose base spreads out five awl-shaped horizontal stamina, which are terminated by oblong broad summits fastened in the middle to the stamina, hanging downward; these may be moved round without separating from the stamina; their under surface is charged with yellow farina, and, on the side of the germen, arise three slender purplish styles near an inch long, spreading from each other, terminated by obtuse stigmas. Round the bottom of the column are two orders of rays, the inner, which is the shortest, inclines upward to the column, the outer, which is near half the length of the petals, spreads flat upon them; these rays are composed of a great number of thread-like filaments, of a purple colour at bottom, but are blue on the outside. These flowers have a faint scent, and continue but one day; after they fade, the germen on the top of the column swells to a large oval fruit, about the size and shape of the *Mogul Plumb*, and when ripe is of the same pale yellow colour, inclosing a sweetish disagreeable pulp, in which are lodged oblong seeds. This plant begins to flower early in *July*, and there is a succession of flowers daily, till the frost in autumn puts a stop to them.

It may be propagated by seeds, which should be sown in the same manner as those of the first sort, and the plants treated in the same way till the following spring, when they

should be turned out of the pots, and planted against a good aspected wall, where they may have height for their shoots to extend, otherwise they will hang about and entangle with each other, so make but an indifferent appearance; but where buildings are to be covered, this plant is very proper for the purpose. After they have taken good root in their new quarters, the only care they will require is to train their shoots up against the wall, as they extend in length, to prevent their hanging about; and if the winter proves severe, the surface of the ground about their roots should be covered with mulch to keep the frost from penetrating of the ground; and if the stalks and branches are covered with mats, Peas haulm, straw, or any such light covering it will protect them in winter; but this covering must be taken off in mild weather, otherwise it will cause the branches to grow mouldy, which will be more injurious to them than the cold. In the spring the plants should be trimmed, when all the small weak shoots should be entirely cut off, and the strong ones shortened to about four or five feet long, which will cause them to put out strong shoots for flowering the following year.

This plant is also propagated by laying down the branches, which in one year will be well-rooted, so may be taken off from the old plants and transplanted, where they are designed to remain. The cuttings of this will also take root, if they are planted in a loamy soil not too stiff, in the spring, before they begin to shoot. If these are covered with bell or hand glasses to exclude the air, they will succeed much better than when they are otherwise treated; but when the cuttings put out shoots, the air should be admitted to them, otherwise they will draw up weak and spoil, they must be afterward treated as the layers.

Those plants, which are propagated by layers or cuttings, do not produce fruit so plentifully as the seedling plants, and I have found the plants, which have been propagated two or three times, either by layers or cuttings, seldom produce fruit, which is common to many other plants.

If in very severe winters the stalks of these plants are killed to the ground, the roots often put out new stalks the following summer, therefore they should not be disturbed; and where there is mulch laid on the ground about their roots, there will be little danger of their being killed, although all the stalks should be destroyed.

There is a variety of this; the lobes of the leaves are much narrower, and are divided almost to the bottom. The flowers come later in the summer; the petals of the flowers are narrower, and of a purer white, but I believe it is only a feminal variation of the other, so not worthy of being enumerated.

The third sort grows naturally in *Virginia*, and also in *Jamaica*. This hath a perennial creeping root, sending up many weak stalks about three or four feet high, which are garnished with leaves shaped very like those of Ivy, and are almost as large, but of a pale green and very thin consistence. The flowers come out from the wings of the stalk, upon slender foot-stalks, an inch and a half long, and at their base arise very slender tendrils, which clasp round any neighbouring support. The flowers are of a dirty yellow colour, and not larger than a sixpence when expanded, so make no great appearance. This may be propagated by its creeping roots, which may be parted in *April*, and planted where they are to remain. This sort will live in a warm border, if treated in the same way as is directed for the first sort. Some of these plants lived many years in the *Chelsea* garden, in a border to a south-west aspect, but in the year 1740 they were killed by the frost.

The fourth sort grows naturally in *Jamaica*. This hath a perennial root, from which arise several slender stalks four or five feet high, which have joints four or five inches

afunder; at each of these come out one leaf, a tendril, and a flower. The leaves have three lobes. The flowers are smaller than those of the last mentioned, and are of a greenish colour; these are succeeded by oval fruit, about the size of small Olives, which turn purple when they are ripe.

The fifth sort grows naturally in most of the *West-India* islands; this rises with a weak stalk to the height of twenty feet. As the stalks grow old, they have a thick fungous bark, like that of the Cork-tree, which cracks and splits. The smaller branches are covered with a smooth bark, and garnished with smooth leaves at each joint, sitting upon very short foot-stalks; these have three lobes, the middle one being much longer than those on the sides, so that the whole leaf has the form of the point of those halberds used by the yeomen of the guards. The flowers are small, of a greenish yellow colour, and are succeeded by small oval fruit, of a dark purple colour when ripe.

The sixth sort grows naturally in the *West-Indies*. This hath a perennial root, from which arise several slender stalks, which rise eight or ten feet high, garnished with smooth green leaves, standing upon slender foot-stalks. They are but slightly indented into three lobes, which end in acute points, and are shaped like the points of halberds, the middle one standing oblique to the foot-stalk. The flowers come out from the wings of the leaves on very short foot-stalks; they are of a pale yellow. The petals of the flowers are very narrow, and longer than those of the two former sorts; the fruit is smaller, and of an oval form, changing to a dark purple when ripe.

The seventh sort grows naturally in most of the islands in the *West-Indies*, where the inhabitants of the *British* islands call it Love in a Mist. The root of this is annual; the stalks rise five or six feet high, when they are supported; they are channelled and hairy. The leaves are heart-shaped, divided into three lobes, the middle lobe being much the longest; they are covered with short brown hairs. The tendrils come out at the same place as the leaves, as do also the flowers, whose foot-stalks are long, hairy, and pretty strong. The empalement of the flower is composed of slender hairy filaments, which are wrought like a net; these are longer than the petals of the flower, and turn up round them, so that the flowers are not very conspicuous at a distance; these are white, and of a short duration; their structure is the same with the other sorts, and they are succeeded by roundish oval fruit, about the size of an ordinary Golden Pippin, of a yellowish green colour, inclosed with the netted empalement. This plant is propagated by seeds, which should be sown upon a hot-bed early in the spring, and when the plants are fit to remove, they should be each transplanted into a small pot filled with light kitchen-garden earth, and plunged again into a hot-bed, observing to shade them from the sun till they have taken new root; after which time they must be treated in the same way as other plants from the same country, shifting them into larger pots as their roots increase; and when the plants are too tall to remain under the glasses of the hot-bed, they should be removed into an airy glass-case, where they should have the free air admitted to them in warm weather, but screened from the cold. In this situation the plants will flower in *July*, and their seeds will ripen in the autumn. The whole plant has a disagreeable scent when touched.

There is a variety of this, if it is not a distinct species, with hairy leaves not so broad as those of the former. The whole leaf is shaped more like the point of a halberd, and those leaves, which grow toward the upper part of the stalks, have very small indentures, so approach near to simple leaves without lobes. The flowers are also smaller, but of the same form, and the roots are of shorter duration, so that I am inclined to believe it is a distinct species.

The eighth fort has some appearance of the seventh, so that many persons have supposed it was only an accidental variety of it, but there can be no doubt of its being a different species. The stalks of this rise upward of twenty feet high, and will continue two or three years; the leaves are larger, but of the same shape, and hairy; the tendrils of this fort are very long, as are also the foot-stalks of the flowers, which are smooth, not hairy as the former; the empalement of the flowers is netted, but not so long as in the former fort; the flowers are larger, and the rays are of a light blue colour; the fruit is much less and rounder than those of the other, and when ripe changes to a deep yellow colour.

The ninth fort was discovered by the late Dr. *Houssoun*, growing naturally at *La Vera Cruz*. This is a perennial plant; the stalks rise twenty feet high, dividing into many slender branches, which are covered with a soft hairy down. The leaves are shaped like the point of a halberd, of a light green; they are soft and silky to the touch, standing oblique to the foot-stalks. The flowers come out at the wings of the leaves like the other species; these are not half so large as those of the second fort, but are of the same form. The petals are white, and the rays or filaments are purple, with a mixture of yellow. The fruit of this is small, roundish, and yellow when ripe.

The tenth fort grows naturally in *Jamaica*. This is a perennial plant; the stalks are slender, and rise to twenty feet high when they are supported, and divide into many weak branches; the leaves, flowers, and tendrils, come out at each joint. The leaves have three longitudinal veins, which join at the base to the foot-stalk, but the two outer diverge toward the borders of the leaf in the middle, drawing inward again at the top. The leaves are of a deep green on their upper side, but are pale on their under, and stand upon short foot stalks; the foot-stalks of the flowers are very slender, of a purplish colour. The flowers are shaped like those of the other species, but when expanded are not more than an inch and a half diameter, of a soft red colour, and little scent. The fruit is small, oval, and, when ripe, changes to a purple colour.

The eleventh fort was discovered by the late Mr. *Robert Millar* growing naturally near *Carthagena* in *New Spain*. This hath slender striated stalks, of a brownish red colour, dividing into many slender branches, which are garnished with leaves, shaped like the wings of a bat when extended; they are about seven inches in length, measuring from the two extended points, which may rather be termed the breadth, for from the base to the top they are not more than two inches and a half. The foot-stalk is set half an inch from the base of the leaf, from which come out three ribs or veins; two of them extend each way to the two narrow points of the leaf, the other rises upright to the top, where is the greatest length of the leaf, if it may be so termed. The figure of this leaf is the most singular of any I have yet seen: the flowers come out at the joints of the stalk like the others, upon short slender foot-stalks; they are about three inches diameter when expanded. The petals and rays are white; the rays are twisted and slender, extending beyond the petals. The fruit of this I have not seen entire.

The twelfth fort was discovered by the late Dr. *Houssoun*, growing naturally at *La Vera Cruz* in *New Spain*. This hath slender angular stalks, which rise twenty feet high, sending out many branches, which are garnished with moon-shaped leaves, and have two blunt lobes, spreading asunder each way, so as to have the appearance of a half-moon. The flowers and tendrils come out from the same joints of the stalks. The flowers are of a pale colour and small, but shaped like those of the other forts; these are succeeded by oval fruit of a purple colour, about the size of small oval Grapes.

The thirteenth fort has some resemblance of the twelfth, but the stalks are rounder and become ligneous. The leaves are almost as stiff as those of the Bay-tree, and are not so deeply divided as those of the former. The flowers stand upon long foot-stalks, which are horizontal; they are small, white, and shaped like those of the other fort. The fruit is oval, small, and of a purple colour, fitting close to the petals of the flowers, which are permanent.

The fourteenth fort grows naturally in most of the islands in the *West-Indies*. This is by *Tournefort* separated from this genus, and titled by him *Murucua*, which is the *Brazilian* name for it. This hath slender climbing stalks, which are channelled, putting out tendrils at the joints, which fasten themselves about the neighbouring plants for support, and climb to the height of ten or twelve feet, garnished with leaves, which are cut into two lobes at their base, but at the top are only a little hollowed at a distance from each point, rising again in the middle opposite the foot-stalk. The base of the two lobes spread and meet, so that they appear as if they embraced the stalk, but when they are viewed near, they are found divided to the short crooked foot-stalk, which does scarcely appear. There are two purplish veins arising from the foot-stalk, which extend each way to the points of the lobes; the tendrils, which come out with the leaves, are long, tough, and of a purple colour. The flowers are produced toward the end of the branches, coming out by pairs on each side; they have purple foot-stalks, sustaining one flower at the top, whose empalement is composed of five purple leaves, which form a kind of tube, and within are five very narrow purple petals. The column in the center of the flower is of the same length as the petals, but the stamina are extended an inch above. When the flowers fade, the germen swells to an oval purple fruit, the size of the small red Gooseberry, inclosing a soft pulp, in which are lodged the seeds.

The fifteenth fort grows naturally in the *West-Indies*, where the inhabitants call it *Granadilla*. The fruit of this fort is commonly eaten there, being served up to their tables in deserts. This hath a thick, climbing, herbaceous, triangular stalk, sending out slender tendrils at each joint, which fasten to the bushes and hedges for support, rising to the height of fifteen or twenty feet, garnished at each joint with one large oval leaf. There are two large stipulæ or ears joined to the stalks, which encompass the foot-stalks of the flowers and leaves, as also the base of the tendril. The leaves are of a lively green, having one strong nerve or midrib running longitudinally, from which arise several small veins, which diverge to the sides, and incurve again toward the top. The flowers stand upon pretty long foot-stalks, which have two small glandules in the middle; the cover of the flower is composed of three soft velvety leaves, of a pale red, with some stripes of a lively red colour; the petals of the flower are white, and the rays are blue. These flowers are large, so make a fine appearance during their continuance, but they are like the other species, of short duration, however there is a succession of flowers for some time on the plants. After the flowers are past, the germen swells to a roundish fruit, the size of a middling Apple, of a yellow colour when ripe, having a thicker rind than any of the other forts, inclosing a sweetish pulp, in which are lodged many oblong flat seeds, of a brownish colour, a little rough to the touch.

The sixteenth fort grows naturally in the *West-Indies*. This hath climbing tough stalks, which put out clasps at every joint like the others, which fasten to the neighbouring trees and hedges for support, and rise upward of twenty feet high, sending out many side branches. The leaves are four or five inches long, and two broad, of a pretty thick consistence, and a bright green on their upper side, but pale

pale on their under. The flowers come out at the joints of the stalks; the buds of the flowers are as large as pigeons eggs, before they begin to expand. The cover of the flower is composed of three large, oval, green leaves, which are indented on their edges, and hollowed like a spoon; within these is the empalement of the flower, which is composed of five oblong leaves, of a pale green on their outside, but whitish within. The petals of the flower are white, and stand alternately with those of the empalement, but are not more than half their breadth, and are marked with several small, brownish, red spots. The rays of the flower are of a Violet colour; the column in the center is yellowish, as is also the round germen at the top, but the three styles are of a purple colour. These flowers have an agreeable odour, and when they fade, the germen swells to the size of a pullet's egg, nearly of the same shape, which turns yellow when ripe. The rind is soft and thick; the pulp has an agreeable acid flavour, which quenches thirst, abates the heat of the stomach, gives an appetite, and recruits the spirits, so is commonly given in fevers. The seeds are heart-shaped and brownish.

The seventeenth sort grows naturally in the *Bahama* islands; this hath slender, climbing, three cornered stalks, which send out tendrils at each joint, fastening themselves to any neighbourly support. The stalks climb to the height of twelve or fourteen feet, and are garnished with oblong oval leaves. Their foot stalks are slender, from which arise three longitudinal veins, one running through the middle of the leaf, the other two diverge to the sides, drawing toward each other again at the point. The flowers come out from the wings of the stalk upon slender foot-stalks; the empalement of the flower is composed of five oblong, narrow, purple leaves, and within are five narrower petals of the same colour, which turn backward after they have been some time expanded. The column in the middle of the flower is very long and slender, supporting a round germen, from whose base spread out five slender stamina, terminated by oblong hanging summits; from the top of the germen arise three slender styles, which spread asunder, crowned by roundish summits. When the flowers fade, the germen swells to an oval fruit, about the size of a sparrow's egg, which changes to a purple colour when ripe, filled with oblong seeds inclosed in a soft sweet pulp.

The nineteenth sort was discovered by the late Dr. *Houffoun*, at *La Vera Cruz* in *New Spain*. This hath slender climbing stalks, sending out many small branches, which climb to the height of twenty-five or thirty feet, when they meet with neighbouring support, to which they fasten themselves by their tendrils. The stalks by age become ligneous toward the bottom; their joints are not far asunder. The leaves stand upon short slender foot-stalks; they are smooth, entire, and of a lively green colour. The flowers come out from the wings of the leaves, standing upon long foot-stalks; the empalement of the flower is composed of five oblong leaves, green on their outside, but whitish within. The flower has five oblong white petals situated alternately to the leaves of the empalement, which spread open; the rays are of a bluish purple colour, inclining at the bottom to red; the column in the center is short and thick; the germen on the top is oval, and, after the flowers fade, swells to the size of a pullet's egg, and changes to a pale yellow when ripe, having many oblong seeds inclosed in a soft pulp. The flowers of this kind have an agreeable odour, but are of short duration, seldom continuing twenty hours open; but there is a succession of flowers on the plants, from *June* to *September*, and sometimes the fruit will ripen here.

All the perennial sorts which are natives of the hot parts

of *America*, require a stove to preserve them here, without which they will not thrive; for although some of the sorts will live in the open air during the warm months in summer, yet they make but little progress; nor will the plants produce many flowers, unless the pots in which they are planted, are plunged into the tan-bed of the stove, and their branches are trained against an espalier. The best way to have them in perfection, is to make a border of earth on the back-side of the tan-bed, which may be separated by planks to prevent the earth from mixing with the tan; and when the plants are strong enough, they should be turned out of the pots, and planted in this border; adjoining to which, should be a trelliage erected to the top of the stove; against this the stalks of the plants must be trained, and as they advance they will form a hedge to hide the wall of the stove, and their leaves continuing green all the year, together with their flowers, which will be very plentifully intermixed in summer, will have a very agreeable effect.

As there will be only a plank partition between the earth and the tan, so the earth will be kept warm by the tan-bed, which will be of great service to the roots of the plants. This border should not be less than two feet broad and three deep, which is the usual depth of the pit for tan; so that where these borders are intended, the pits should not be less than eight feet broad, that the bark-bed, exclusive of the border, may be six feet wide. If the border is fenced off with strong ship planks, they will last some years, especially if they are well painted over with a composition of melted pitch, brick-dust and oil, which will preserve them found a long time; and the earth should be taken out carefully from between the roots of the plants, at least once a year, putting in fresh; with this management, I have seen these plants in great perfection. But where there has not been this conveniency, I have turned the plants out of the pots, and planted them into the tan, where it was half rotten, into which they have rooted exceedingly, and have thriven for two or three years as well as could be desired; but when their roots extended to a great distance in the tan-bed, they have been injured by renewing of the bark; when it has fermented pretty violently, the roots have been scalded, and the plants have been killed, so that the other method is more eligible.

As these sorts do not often perfect their seeds here, so they may be propagated by laying down their branches, which, if done in *April*, they will put out roots by the middle of *August*, when they may be separated from the old plants, and either planted in pots to get strength, or into the border of the stove, where they are to remain.

Some of these sorts may also be propagated by cuttings; these should be planted in pots about the middle or latter end of *March*, and plunged into a moderate hot-bed, observing to screen them from the sun, and refresh them with water gently, as often as the earth may require it; and in about two months or ten weeks, they will put out roots, and may then be treated as the seedling plants.

PASSION-FLOWER. See *Passiflora*.

PASTINACA. *Journ. Inst. R. H.* 319. tab. 170. Parsnep.

The Characters are,

It hath an umbellated flower; the principal umbel is composed of many smaller, and these are likewise composed of several rays. They have no involucreum, and the empalement is scarce visible; the umbel is uniform. The flowers have five spear-shaped incurved petals, and five hair-like stamina. The germen is situated under the flower, supporting two reflexed styles. The germen afterward becomes an elliptical, plain, compressed fruit, dividing in two parts, having two bordered elliptical seeds.

The Species are,

1. PASTINACA foliis simpliciter pinnatis hirsutis. Parsnep with single, winged, hairy leaves; wild Parsnep.

2. PAS-

2. *PASTINACA foliis simpliciter pinnatis glabris.* Parsnep with single, winged, smooth leaves; Garden Parsnep.

3. *PASTINACA foliis decompositis pinnatis.* Hort Cliff. 105. Parsnep with decomposed winged leaves; or Opopanax.

The first sort grows naturally on the side of banks, and on dry ground in many parts of *England*. This is a biennial plant, the first year shooting out hairy leaves which spread on the surface of the ground, which are singly winged; and the lobes are irregularly cut. The following year the stalks rise four or five feet high, these are channelled, hairy, and garnished with winged leaves like those at the bottom, but smaller; the stalk branches out toward the top, each branch being terminated by a large umbel of yellow flowers, which are succeeded by compressed fruit, having two flat bordered seeds.

The root and seed of this sort is sometimes used in medicine, but it is seldom cultivated in gardens, the markets being supplied from the fields; yet the druggists commonly sell the seeds of the garden kind for it, which they may purchase at an easy price when it is too old to grow, but then the seeds can have no virtue left.

The second sort hath smooth leaves of a light or yellowish green colour, in which this differs from the former; the stalks also rise higher, and are deeper channelled; the foot-stalks of the umbels are much longer, and the flowers are of a deeper yellow colour. These two sorts have been thought only varieties; the Garden Parsnep they have supposed to differ from the wild only by culture; but I have cultivated both many years, and have never found that either of the sorts have varied; the seeds of each having constantly produced the same sort as they were taken from, so that I am certain they are distinct species.

This sort is cultivated in kitchen gardens, the roots of which are large, sweet, and accounted very nourishing. They are propagated by seeds, which should be sown in *February* or *March*, in a rich mellow soil, which must be well dug, that their roots may run downward, the greatest excellency being the length and bigness of the roots. These may be sown alone, or with Carrots, as is practised by the kitchen-gardeners near *London*; some of whom also mix Leeks, Onions, and Lettuce, with their Parsneps; but this I think very wrong, for it is not possible, that so many different sorts can thrive well together, except they are allowed a considerable distance; and if so, it will be equally the same to sow the different sorts separate. However, Carrots and Parsneps may be sown together very well, especially where the Carrots are designed to be drawn off very young; because the Parsneps generally spread most towards the latter end of summer, which is after the Carrots are gone, so that there may be a double crop upon the same ground.

When the plants are come up, you should hoe them out, leaving them about ten inches or a foot asunder; observing at the same time to cut up all the weeds, which, if permitted to grow, would soon overbear the plants and choke them. This must be repeated three or four times in the spring, according as you find the weeds grow; but in the latter part of summer, when the plants are so strong as to cover the ground, they will prevent the growth of weeds, so that after that season they will require no farther care.

When the leaves begin to decay, the roots may be dug up for use, before which time they are seldom well tasted; nor are they good for much late in the spring, after they are shot out again; so that those who would preserve these roots for spring use, should dig them up in the beginning of *February*, and bury them in sand, in a dry place, where they will remain good until the middle of *April*, or later. These roots are excellent for hogs.

If you intend to save the seeds of this plant, you should make choice of some of the longest, straitest, and largest

roots, which should be planted about two feet asunder, in some place where they may be defended from the strong south and west winds; for the stems of these plants commonly grow to a great height, and are very subject to be broken by strong winds, if exposed thereto; they should be constantly kept clear from weeds, and if the season should prove very dry, you should give them some water twice a week, which will cause them to produce a great quantity of seeds, which will be much stronger than if they were wholly neglected. Toward the latter end of *August* or the beginning of *September*, the seeds will be ripe; at which time you should carefully cut off the heads, and spread them upon a coarse cloth for two or three days, to dry; after which, the seeds should be beaten off, and put up for use; but you should never trust to these seeds, after they are a year old, for they will seldom grow beyond that age.

The leaves of the Garden Parsnep are dangerous to handle, especially in a morning, while the dew remains upon them, at which time, if they are handled by persons who have a soft skin, it will raise it in blisters. I have known some gardeners, when they have been drawing up Carrots from among Parsneps in a morning, when their leaves were wet with dew, draw up the sleeves of their shirts to their shoulders, to prevent their being wet; by doing of which they have had their arms, so far as they were bare, covered over with large blisters; and these were full of a scalding liquor, which has proved very troublesome for several days.

The third sort rises with a green rough stalk seven or eight feet high, garnished with large, decomposed, winged leaves, which are very rough to the touch, and of a dark green colour; the juice is very yellow, which flows out where either the leaf or stalk is broken; the stalks are divided upward into many horizontal branches, each being terminated by a large umbel of yellow flowers. These appear in *July*, and are succeeded by plain seeds which are bordered, and a little convex in the middle, which ripen in the autumn. The Opopanax of the shops, is thought to be the concrete juice of this plant.

PASTURE.

Pasture ground is of two sorts: the one is low meadow land, which is often overflowed, and the other is upland, which lies high and dry. The first of these will produce a much greater quantity of Hay than the latter, and will not require manuring or dressing so often; but then the Hay produced on the upland is much preferable to the other, as is also the meat which is fed in the upland more valued than that which is fatted in rich meadows; though the latter will make the fatter and larger cattle, as is seen by those which are brought from the low rich lands in *Lincolnshire*. But where people are nice in their meat, they will give a much larger price for such as hath been fed on the downs, or in short upland pasture, than for the other. Besides this, dry pastures have an advantage over the meadows, that they may be fed all the winter, and not so subject to poach in wet weather; nor will there be so many bad weeds produced, which are great advantages, and do, in a great measure, recompence for the smallness of the crop.

The first improvement of upland pasture is, by fencing it, and dividing it into small fields of four, five, six, eight, or ten acres each, planting timber trees in the hedge rows, which will screen the Grass from the drying pinching winds of *March*, which prevent the Grass from growing in large open lands; so that if *April* proves a cold dry month, the open land produces very little Hay; whereas in the sheltered fields the Grass will begin to grow early in *March*, and will cover the ground, and prevent the sun from parching the roots of the grass, whereby it will keep growing, so as to afford a tolerable crop, if the spring should prove dry. But

in fencing of land it must be observed (as was before directed) not to make the inclosures too small, especially where the hedge rows are planted with trees; because when the trees are advanced to a considerable height, they will spread over the land; and, where they are close, will render the Grass sour; so that instead of being an advantage, it will greatly injure the pasture.

The next improvement of upland pastures is, to make the turf good, where either from the badness of the soil, or for want of proper care, the Grass hath been destroyed by Rushes, bushes, or mole hills. Where the surface of the land is clayey and cold, it may be improved by paring it off, and burning it in the manner before directed, under the article of LAND; but if it is a hot sandy land, then chalk, lime, marle, or clay, are very proper manures to lay upon it; but this should be laid in pretty good quantities, otherwise it will be of little service to the land.

If the ground is over-run with bushes or Rushes, it will be a great advantage to the land, to grub them up toward the latter part of the summer; and after they are dried to burn them, and spread the ashes over the ground just before the autumnal rains: at which time the surface of the land should be levelled, and sown with Grass seed, which will come up in a short time, and make good Grass the following spring. So also where the land is full of mole-hills, these should be pared off, and either burnt for the ashes, or spread immediately on the ground, when they are pared off, observing to sow the bare patches with Grass seed, just as the autumnal rains begin.

Another improvement of upland pastures is the feeding of them every other year; for where this is not practised, the land must be manured at least every third year; and where a farmer hath much arable land in his possession, he will not care to part with his manure to the pasture. Therefore every farmer should endeavour to proportion his pasture to his arable land, especially where manure is scarce, otherwise he will soon find his error; for the pasture is the foundation of all the profit, which may arise from the arable land.

These upland pastures seldom degenerate the Grass which is sown on them, if the land is tolerably good; whereas the low meadows, which are overflowed in winter, in few years turn to a harsh rushy Grass, but the upland will continue a fine sweet Grass for many years without renewing.

There is no part of husbandry, of which the farmers are in general more ignorant, than that of the pasture; most of them suppose, that when an old pasture is ploughed up, it can never be brought to have a good sward again; so their common method of managing their land after ploughing, and getting two or three crops of Corn is, to sow with their crop of Barley, some Grass seeds (as they call them); that is, either the red Clover, which they intend to stand two years after the Corn is taken off the ground, or Rye Grass mixed with Trefoil; but as all these are at most but biennial plants, whose roots decay soon after their seeds are perfected, so the ground having no crop upon it, is again ploughed for Corn; and this is the constant round which the lands are employed in, by the better sort of farmers; for I have never met with one of them, who had the least notion of laying down their land to Grass for any longer continuance; therefore the seeds which they usually sow, are the best adapted for this purpose.

But whatever may have been the practice of these people, I hope to prove, that it is possible to lay down land, which has been in tillage, with Grass, in such manner as that the sward shall be as good, if not better than any natural Grass, and of as long duration. But this is never to be expected, in the common method of sowing a crop of Corn with the

Grass seeds; for wherever this hath been practised, if the Corn has succeeded well, the Grass has been very poor and weak; so that if the land has not been very good, the Grass has scarcely been worth standing; for the following year it will produce but little Hay, and the year after the crop is worth little, either to mow or feed. Nor can it be expected it should be otherwise, for the ground cannot nourish two crops; and if there were no deficiency in the land, yet the Corn being the first, and most vigorous of growth, will keep the Grass from making any considerable progress; so that the plants will be extremely weak, and but very thin, many of them which came up in the spring being destroyed by the Corn; for wherever there are roots of Corn, it cannot be expected there should be any Grass. Therefore the Grass must be thin, and, if the land is not in good heart, to supply the Grass with nourishment, that the roots may branch out after the Corn is gone, there cannot be any considerable crop of Hay.

Therefore, when ground is laid down for Grass, there should be no crop of any kind sown with the seeds; the land should also be well ploughed, and cleaned from weeds; otherwise the weeds will come up the first, and grow so strong, as to overbear the Grass, and if they are not pulled up, will entirely spoil it. The best season to sow the Grass seeds upon dry land is about the beginning of *September*, if there is an appearance of rain; for the ground being then warm, if there happen some good showers of rain after the seed is sown, the grass will soon make its appearance, and get sufficient rooting in the ground before winter, so will not be in danger of having the roots turned out of the ground by the frost, especially if the ground is well rolled before the frost comes on, which will press it down, and fix the earth close to the roots. Where this hath not been practised, the frost has often loosened the ground so much, as to let in the air to the roots of the Grass, and done it great damage, and this has been brought as an objection to the autumnal sowing of Grass; but it will be found to have no weight, if the above direction is practised; nor is there any hazard in sowing the Grass at this season, but that of dry weather after the seeds are sown; for if the Grass comes up well, and the ground is well rolled in the end of *October* or the beginning of *November*, and repeated again the beginning of *March*, the sward will be closely joined at bottom, and a good crop of Hay may be expected the same summer. In very open exposed cold lands, it is proper to sow the seeds three weeks earlier than is here mentioned, that the Grass may have time to get good rooting, before the cold season comes on to stop its growth; for in such situations, vegetation is over early in the autumn, so the Grass being weak, may be destroyed by frost: but if the seeds are sown in *August*, and a few showers follow soon after to bring up the Grass, it will succeed much better than any which is sown in the spring, as I have several years experienced, on some places as much exposed as most in *England*. But where the ground cannot be prepared for sowing at that season, it may be performed the middle or latter end of *March*, according to the seasons being early or late; for in backward springs, and in cold land, I have often sowed the Grass in the middle of *April* with success; but there is danger in sowing late, of dry weather, and especially if the land is light and dry; for I have seen many times the whole surface of the ground removed by strong winds at that season, so that the seeds have been driven in heaps to one side of the field. Therefore whenever the seeds are sown late in the spring, it will be proper to roll the ground well soon after the seeds are sown, to settle the surface, and prevent its being removed.

The sort of seeds which are the best for this purpose, are the best sort of upland Hay seeds, taken from the cleanest pastures,

pastures, where there are no bad weeds; if this seed is sifted to clean it from rubbish, three, or at most four bushels, will be sufficient to sow an acre of land. The other sort is the *Trifolium pratense album*, which is commonly known by the names of white Dutch Clover, or white Honeyfuckle Grass. Eight pounds of this seed will be enough for one acre of land. The Grass seed shall be sown first, and then the Dutch Clover seed may be afterward sown; but they should not be mixed together, because the Clover seeds being the heaviest, will fall to the bottom, and consequently the ground will be unequally sown with them.

After the seeds are sown, the ground should be lightly harrowed to bury the seeds; but this should be performed with a short toothed harrow, otherwise the seeds will be buried too deep. Two or three days after sowing, if the surface of the ground is dry, it should be rolled with a Barley roller, to break the clods and smooth the ground, which will settle it, and prevent the seeds from being removed by the wind.

When the seeds are come up, if the land should produce many weeds, these should be drawn out before they grow so tall as to overbear the Grass; for where this has been neglected, the weeds have taken such possession of the ground, as to keep down the Grass and stave it; and when these weeds have been suffered to remain until they have shed their seeds, the land has been so plentifully stocked with them, as entirely to destroy the Grass; therefore it is one of the principal parts of husbandry, never to suffer weeds to grow on the land.

As the white Clover is an abiding plant, so it is certainly the very best sort to sow, where pastures are laid down to remain; for as the Hay seeds which are taken from the best pastures, will be composed of various sorts of Grass, some of which may be but annual, and others biennial, so when those go off, there will be many and large patches of ground left bare and naked, if there is not a sufficient quantity of the white Clover, to spread over and cover the land. Therefore a good sward can never be expected, where this is not sown; for in most part of the natural pastures, we find this plant makes no small share of the sward; and is equally good for wet and dry land, growing naturally upon gravel and clay, in most parts of *England*; which is a plain indication how easily this plant may be cultivated to great advantage, in most sorts of land throughout this kingdom.

After the ground has been sown in the manner before directed, and brought to a good sward, the way to preserve it good is, by constantly rolling the ground with a heavy roller, every spring and autumn, and in summer after rain, as hath been before directed. This piece of husbandry is rarely practised by farmers, but those who do, find their account in it, for it is of great benefit to the Grass. Another thing should also be carefully performed, which is, to cut up Docks, Dandelion, Knapweed, and all such bad weeds, by their roots, every spring and autumn; this will increase the quantity of good Grass, and preserve the pastures in beauty. Dressing of these pastures every third year, is also a good piece of husbandry, for otherwise it cannot be expected the ground should continue to produce good crops. Besides this, it will be necessary to change the seasons of mowing, and not to mow the same ground every year; but to mow one season, and feed the next; for where the ground is every year mown, it must be constantly dressed, as are most of the Grass grounds near *London*, otherwise the ground will be soon exhausted.

PAVIA. Boerb. Ind. alt. 2. p. 260. The scarlet flowering Horse Chestnut.

The Characters are,

The flower has a small empalement of one leaf, indented in five

parts at the top. It has five roundish petals, waved and plaited on their borders, narrow at their base, where they are inserted in the empalement. It hath eight stamina, which are declined, as long as the petals, terminated by rising summits; and a roundish germen sitting upon an awl shaped style, crowned by an acuminated stigma. The germen afterward becomes an oval, Pear-shaped, leathery capsule with three cells, in which is sometimes one, and at others two, almost globular seeds.

There is but one Species of this genus, viz.

PAVIA. Boerb. Ind. alt. 2. p. 260. The scarlet Horse Chestnut.

This plant grows naturally in *Carolina* and the *Brazils*; from the first the seeds were brought to *England*, where the plants have been of late years much cultivated in the gardens. In *Carolina* it is but of humble growth, seldom rising more than eight or ten feet high; the stalk is pretty thick and woody, sending out several branches, garnished with hand shaped leaves, composed of five or six spear-shaped lobes, which unite at their base, where they join the foot-stalk; they are sawed on their edges, and have long foot-stalks. The flowers are produced in loose spikes at the end of the branches, standing upon long naked foot-stalks, which sustain five or six flowers, which are tubulous at bottom, but spread open at the top, where the petals are irregular in size and length, having an appearance of a lip flower; they are of a bright red colour, and have seven or eight stamina the length of the petals. When the flowers fade, the germen swells to a Pear-shaped fruit, with a thick russet cover having three cells, one of which, and sometimes two, are pregnant with globular seeds.

It may be propagated by sowing the seeds in the spring, upon a warm border of light sandy earth; and when the plants come up, they should be carefully cleared from weeds, but they must not be transplanted until the spring following; for as these seedling plants are tender while they are young, so they should be covered with mats the two first winters: this should be carefully performed in autumn, when the early frosts begin; for as the tops of the young plants are very tender, so a small frost at that time will pinch them; and when the tops are killed, they generally decay to the ground; when this happens, they seldom make good plants after. Therefore this should be constantly observed for two years, or three at most, by which time the plants will have gotten strength enough to resist the frost, when they should be removed just before they begin to shoot, and placed either in a nursery to be trained up, or where they are to remain; observing, if the season be dry, to water them until they have taken root, as also to lay some mulch upon the surface of the ground, to prevent the sun and wind from drying it too fast; as the plants advance, so the lateral branches should be pruned off, in order to reduce them to regular stems.

This tree may be propagated by budding or grafting it upon the common Horse Chestnut, which is the common method practised by the nursery-men; but the trees thus raised, seldom make a good appearance long, for the stock of the common Horse Chestnut will be more than twice the size of the other, and frequently put out shoots below the graft, and sometimes the grafts are blown out of the stocks, after ten years growth; but these stocks render the trees hardy, and of a larger growth.

PAULLINIA. Lin. Gen. Plant. 446.

The Characters are,

The flower has a permanent empalement, composed of four small oval leaves. It hath four oblong oval petals, twice the size of the empalement, and eight short stamina, with a turbinated germen, having three short slender styles, crowned by spreading stigmas. The germen afterward turns to a large three-cornered capsule with three cells, each containing one almost oval seed.

The

The Species are,

1. PAULLINIA *foliis ternatis, petiolis teretiusculis, foliolis ovato-oblongis*. *Lin. Sp. Plant.* 365. Three-leaved Paullinia with taper foot-stalks, and oblong oval lobes.

2. PAULLINIA *foliis biternatis, petiolis marginatis, foliolis ovatis integris*. *Lin. Sp. Plant.* 366. Paullinia with nine lobes in each leaf, bordered foot-stalks, and oval entire lobes.

3. PAULLINIA *foliis ternatis, foliolis cuneiformibus, obtusis subdentatis*. *Lin. Sp. Plant.* 365. Three-leaved Paullinia, with trifoliate leaves having wedge-shaped lobes, which are indented.

4. PAULLINIA *foliis biternatis, foliolis ovatis subsinuatis*. *Lin. Sp. Plant.* 366. Paullinia with double trifoliate leaves, having oval sinuated lobes.

5. PAULLINIA *foliis pinnatis, foliolis incis, petiolis marginatis*. *Hort. Cliff.* 52. Paullinia with winged leaves whose lobes are cut, and bordered foot-stalks.

6. PAULLINIA *foliis ternatis, foliolis ovatis subdentatis, petiolis marginatis*. *Burm.* Three-leaved twining Cururu.

7. PAULLINIA *foliis pinnatis tomentosis, foliolis ovatis incis, petiolis marginatis*: Paullinia with winged woolly leaves, whose lobes are oval, cut on their edges, and bordered foot-stalks.

8. PAULLINIA *foliis bipinnatis*. *Lin. Sp. Plant.* 366. Paullinia with double winged leaves.

9. PAULLINIA *foliis biternatis, foliolis oblongo-ovatis emarginatis, petiolis marginatis*. Paullinia with twice trifoliate leaves, whose lobes are oblong, oval, and indented at the top, and bordered foot-stalks.

These plants all grow naturally in the *West-Indies*. They have climbing stalks with tendrils at each joint, by which they fasten themselves to the neighbouring trees, and rise to the height of thirty or forty feet, garnished at each joint with one leaf, which in some of the species is composed of three lobes like Trefoil, in others of five lobes, and some have nine lobes. These are in some species entire, in others they are indented at the point, and some are cut on their edges; in some species their surface is smooth, in others they are hairy. The flowers come out in long bunches like those of Currants, they are small and white, so make no figure; these are succeeded by three-cornered capsules having three cells, which in the Cururu of *Plumier*, contain roundish seeds, but those of the Serjana have winged seeds like those of the Maple reversed, being fastened at the extremity of the wing to the capsule, the seed hanging downward.

As these plants are so tender as not to live through the winter in *England*, unless they are placed in a warm stove, and requiring a large share of room, they are seldom propagated in *Europe*, unless in botanick gardens for the sake of variety, for their flowers have very little beauty to recommend them.

PEACH. See *Perfica*.

PEAR. See *Pyrus*.

PEAS. See *Pisum*.

PEAS EVERLASTING. See *Lathyrus*.

PEDICULARIS, Rattle, Cocks Comb, or Loufewort.

There are four different kinds of this plant, which grow wild in pastures in several parts of *England*, and in some low meadows are very troublesome weeds, especially one sort with yellow flowers, which rises to be a foot high, or more, and is often in such plenty as to be the most predominant plant; but this is very bad food for cattle, and when it is mowed with the Grass for Hay, renders it of little value. The seeds of this plant are generally ripe by the time the Grass is mowed, so that whenever persons take Grass seed for sowing, they should be very careful, that none of this seed is mixed with it. As these plants are never cultivated, I shall not trouble the reader with their several varieties.

PEGANUM. *Lin. Gen. Plant.* 530. Wild *Assyrian Rue*.

The Characters are,

The flower has a permanent empalement. It has five oblong oval petals, which spread open, and fifteen awl-shaped stamina about half the length of the petals, whose bases spread into a nectarium under the germen, and are terminated by erect oblong summits. It has a three-cornered roundish germen, elevated at the base of the flower, which afterward becomes a roundish three-cornered capsule, having three cells filled with oval acute-pointed seeds.

We have but one Species in the *English gardens* at present, *viz.*

PEGANUM *foliis multifidis*. *Hort. Upsal.* 144. Peganum with many-pointed leaves.

This plant grows naturally in *Spain* and *Syria*; it has a root as large as a man's little finger, which by age becomes woody. The stalks decay every autumn, and new ones arise in the spring; these grow about a foot long, and divide into several small branches, which are garnished with oblong thick leaves cut into several narrow segments; they are of a dark green, and of a gummy bitterish taste. The flowers are produced at the end of the branches, sitting close between the leaves, and are composed of five roundish white petals, which open like a Rose, having fifteen awl-shaped stamina. In the center is situated a roundish three-cornered germen, which afterward becomes a roundish three-cornered capsule, having three cells, which contain several oval acute-pointed seeds.

It is propagated by seeds, which should be sown thinly on a bed of light earth, the beginning of *April*, and when the plants come up, they must be constantly kept clean from weeds, which is all the culture they will require till the end of *October*, or the beginning of *November*, when their stalks decay. At which time, if the bed is covered with tanners bark, ashes, saw-dust, or such like covering to keep out the frost, it will be a secure way to preserve the roots, which when young are somewhat tender. The following *March* the roots may be taken up, and transplanted into a warm situation and a dry soil, where they will continue several years.

PELECINUS. See *Biserrula*.

PELLITORY OF SPAIN. See *Anthemis*.

PELLITORY OF THE WALL. See *Parietaria*.

PENNY-ROYAL. See *Pulegium*.

PENTAPETES. *Lin. Gen. Plant.* 757.

The Characters are,

The flower has a double empalement, the outer being small and composed of three leaves, the inner is cut into five parts, which are reflexed. It has five oblong petals which spread open, and fifteen narrow stamina joined in a tube at their base. It has a roundish germen, with a cylindrical style the length of the stamina, crowned by a thick stigma. The germen afterward becomes an oval ligneous capsule with five cells, filled with oblong seeds.

We have but one Species of this genus at present in the *English gardens*, *viz.*

PENTAPETES *foliis hastato-lanceolatis serratis*. *Lin. Sp. Plant.* 698. Pentapetes with halberd-pointed, spear-shaped, sawed leaves.

This plant grows naturally in *India*, from whence I have several times received the seeds; it is annual, and dies in the autumn, soon after it has ripened seeds. It hath an upright stalk from two to three feet high; garnished with leaves of different forms; the lower leaves are large, and cut on their sides towards the base into two side lobes; the middle is extended two or three inches farther in length, so that the leaves resemble the points of halberds in their shape; they are slightly sawed on their edges, and are of a lucid green on their upper side, standing upon pretty long foot-stalks. The leaves, which are on the upper part of the branches, are much narrower, and some of them have very small indentures on their sides; these sit close to the stalks, and are

placed alternately. From the wings of the stalks the flowers come out; they are for the most part single, but sometimes there are two arising at the same place. The foot-stalk of the flower is short and slender. The exterior empalement of the flower is composed of three short leaves; the interior is of one leaf, cut at the top into five acute segments, and are almost as long as the petal. The flower is of one petal, cut into five obtuse segments. In the center of the flower arises a short thick column, to which adhere fifteen short stamina. Between the stamina is situated a roundish germen, supporting a style the length of the stamina, which is crowned by a thick stigma. These are all joined at their base into a sort of column. The flowers are of a fine scarlet colour, and are succeeded by roundish capsules with five cells, each cell inclosing three or four oblong seeds, which ripen in the autumn.

The seeds of this plant must be sown upon a hot bed in *March*, and when the plants are fit to transplant, there should be a new hot-bed prepared to receive them, into which should be plunged some small pots filled with good kitchen-garden earth; in each of these should be one plant put, giving them a little water to settle the earth to their roots; they must also be shaded from the sun till they have taken new root, then they should be treated in the same way as other tender exotick plants. When the plants are advanced in their growth so as to fill the pots with their roots, they should be shifted into larger, and plunged into another hot-bed, where they may remain as long as they can stand under the glasses of the bed, without being injured; afterward they must be removed either into the stove or a glass-case, where they may be screened from the cold, and in warm weather have plenty of fresh air admitted to them. With this management the plants will flower early in *July*, and there will be a succession of flowers continued till the end of *September*, during which time they make a good appearance. The seeds ripen gradually after each other in the same succession as the flowers were produced, so they should be gathered as soon as their capsules begin to open at the top.

PENTAPHYLLOIDES. See *Potentilla*.

PEONY. See *Pæonia*.

PEPO. See *Cucurbita*.

PERESKIA *Plum. Nov. Gen. 37. tab. 26. Gooseberry.*

The Characters are,

It hath a Rose-shaped flower consisting of several leaves, which are placed orbicularly, whose cup afterward becomes a soft, fleshy, globular fruit, beset with leaves. In the middle of the fruit are many fat roundish seeds inclosed in a mucilage.

We have but one Species of this plant, viz.

PERESKIA *aculeata, flore albo, fructu flavescente. Plum. Nov. Gen. 37.* Prickly Pereskia with a white flower, and a yellowish fruit.

This plant grows in some parts of the *Spanish West-Indies*, from whence it was brought to the *English* settlements in *America*, where it is called a *Gooseberry*, and by the *Dutch* it is called *Blad Apple*. It hath many slender branches, which will not support themselves, so must be supported by stakes, otherwise they will trail on the ground. The branches, as also the stem of the plant, are beset with long whitish spines, which are produced in tufts. The leaves are roundish, very thick, and succulent, and the fruit is about the size of a *Walnut*, having tufts of small leaves on it, and hath a whitish mucilaginous pulp.

It may be propagated by planting of the cuttings during any of the summer months, which should be planted in pots filled with fresh light earth, and plunged into a moderate hot-bed of tanners bark, observing to shade them from the sun in the heat of the day. In about two months the cuttings will have made good roots, when they may be carefully taken out of the pots, and each planted in a separate

pot, and plunged into the hot-bed again, where they may remain during the summer season; but at *Michaelmas*, when the nights begin to be cold, they should be removed into the stove, and plunged into the bark-bed. During the winter season, the plants must be kept warm; in summer they must have a large share of air, but they should constantly remain in the stove, for though they will bear the open air in summer, in a warm situation, yet they will make no progress, if they are placed abroad; nor do they thrive near so well in the dry stove, as when they are plunged in the tan, so that the best way is to set them next a trellace, at the back of the tan-bed, to which their branches may be fastened, to prevent their trailing on other plants. This plant has not as yet produced either flowers or fruit in *England*; but as there are several plants pretty well grown in the gardens of the curious, we may expect some of them will flower in a short time.

PERICLYMENUM. *Tourn. Inst. R. H. 608. tab. 578.* Honey-suckle.

The Characters are,

The empalement of the flower is cut into five parts sitting upon the germen. The flower is of one petal, having an oblong tube, cut at the top into five segments, which turn backward. It has five awl-shaped stamina almost the length of the petal, and a roundish germen situated below the flower, which afterward becomes an umbilicated berry with two cells, each containing one roundish seed.

The Species are,

1. PERICLYMENUM *floribus capitatis terminalibus, foliis omnibus connatis sempervirentibus.* Honey-suckle with flowers growing in heads at the end of the branches, and leaves joined round the stalk, which are ever-green; commonly called *Trumpet Honey-suckle*.

2. PERICLYMENUM *racemis lateralibus oppositis, floribus pendulis, foliis lanceolatis integerrimis.* Honey-suckle with flowers in long bunches growing opposite, hanging down, and entire spear-shaped leaves.

3. PERICLYMENUM *corymbis terminalibus, foliis ovatis verticillatis petiolatis.* Honey-suckle with round bunches of flowers at the end of the branches, and oval leaves growing in whorls, having foot-stalks.

4. PERICLYMENUM *corymbis terminalibus, foliis ovatis acutis.* Honey-suckle with round bunches of flowers terminating the branches, and oval acute-pointed leaves.

5. PERICLYMENUM *capitulis ovatis imbricatis terminalibus, foliis omnibus distinctis.* Honey-suckle with oval imbricated heads terminating the stalk, and the leaves distinct; or the *German Honey-suckle*.

6. PERICLYMENUM *floribus verticillatis terminalibus sessilibus, foliis summis connato-perfoliatis.* Hort. Cliff. 45. Honey-suckle with whorls of flowers sitting close at the ends of the branches, and the upper leaves surrounding the stalk; or *Italian Honey-suckle*.

7. PERICLYMENUM *floribus corymbosis terminalibus, foliis hirsutis distinctis, viminibus tenuioribus.* Honey-suckle with a corymbus of flowers terminating the stalks, hairy leaves growing distinct, and very slender branches; commonly called *English Honey-suckle*, or *Woodbine*.

8. PERICLYMENUM *floribus verticillatis terminalibus sessilibus, foliis connato-perfoliatis sempervirentibus glabris.* Honey-suckle with whorled flowers sitting close, terminating the stalks, and smooth ever-green leaves surrounding the stalks; or *ever-green Honey-suckle*.

The first sort grows naturally in *Virginia*, and many other parts of *North-America*, but has been long cultivated in the *English* gardens by the title of *Virginia Trumpet Honey-suckle*. Of this there are two varieties, if not distinct species, one being much hardier than the other. The old sort, which came from *Virginia*, has stronger shoots; the leaves are of

a brighter green; the bunches of flowers are larger, and deeper coloured than of the other, which came from *Carolina*. These plants have the appearance of the common Honeyfuckle, but the shoots are weaker than any of those, except the wild sort called Woodbine; they are of a purplish red colour, and smooth. The leaves are of an oblong oval shape inverted, and closely surround the stalk; of a lucid green on their upper side, but pale on their under. The flowers are produced in bunches at the end of the branches, having long slender tubes, which are enlarged at the top, where they are cut into five almost equal segments. The outside of the flower is of a bright scarlet, and the inside yellow.

These plants should be planted against walls or pales, to which their branches should be trained for support, otherwise they will fall to the ground; for they cannot be reduced to heads like many of the Honeyfuckles, because their branches are too weak and rambling, and are liable to be killed in severe winters; therefore they should be planted to a warm aspect, where they will begin to flower the latter end of *June*, and there will be a succession of flowers till the autumn. They are propagated by laying down their young branches, which will easily take root, and may be afterward treated like the Honeyfuckle.

The second sort grows naturally in *Jamaica*. This hath many slender branches, which cannot support themselves, but trail upon any neighbouring bushes. They grow eight or ten feet long, are covered with a brown bark, and garnished with spear-shaped leaves, of a lucid green on their upper side, but pale on their under, standing by pairs opposite. The flowers come out from the side of the branches at each joint; they are ranged on each side the foot-stalk in long bunches like Currants. The bunches come out opposite; the flowers are small, of a yellowish green, and are succeeded by small berries of a snow white, from whence the plant is called Snowberry Bush in *America*.

The third sort grows naturally in some of the islands in the *West-Indies*. This rises with a shrubby stalk ten or twelve feet high, sending out many slender branches, covered with a light brown bark, garnished with oval leaves, four of them coming out at each joint in whorls round the stalk; they stand upon short foot stalks, and have one strong midrib, with several veins running from the midrib to the sides. The flowers come out in round bunches at the end of the branches; they are of a deep coral colour on their outside, but of a pale red within. This was found growing in *Jamaica* by the late Dr. *Houssoun*, who brought it to *England*.

The fourth sort grows naturally in the kingdom of *Chili*; father *Feuille* found it near the city of *Conception*; it was afterward found by the late Dr. *Houssoun* growing at a little distance from *Cartagena* in *New Spain*. This hath a shrubby stalk near four inches thick, covered with a gray bark, dividing into many branches, which rise about twelve feet high, garnished with stiff leaves, placed opposite, of a lucid green on their upper side, but pale on their under. The flowers are produced in round bunches at the end of the branches; they are of a deep red colour, cut into four segments at the top. These are succeeded by oval berries the size of small Olives, inclosing a hard seed.

The branches of this shrub are used for dying a black in the *Spanish West-Indies*, which is permanent, and cannot be washed out. This dye is made with the wood of the shrub cut into small pieces, and mixed with a plant called Pangué, and a black earth called Robbo, boiling them in common water till it becomes of a proper consistence.

The three sorts last mentioned are too tender to thrive in this country without artificial heat; they are propagated by seeds, which must be procured from the countries where they naturally grow. These should be sown in pots, and plunged into a moderate hot-bed, where they may remain

till the autumn, for the plants rarely come up the first year, so the pots should be removed into the stove for the winter season, and the following spring placed on a fresh hot-bed, which will bring up the plants; when they are fit to remove, they should be each planted in a separate small pot filled with light earth, and plunged into a fresh hot-bed, shading them from the sun, till they have taken new root; after which they must be treated in the manner as other tender plants from those countries. As the plants obtain strength, they should be more hardily treated, by placing them abroad in a sheltered situation for two months or ten weeks, in the warmest part of the summer, and in the winter they may be placed in the dry stove, kept to a moderate temperature of warmth; where they will thrive, and produce their flowers in the autumn.

The fifth sort is the common *Dutch* or *German* Honeyfuckle, which has been generally supposed the same with the *English* wild sort called Woodbine, but is undoubtedly a very different species, for the shoots of this are much stronger. The plants may be trained with stems, and formed into heads, which the wild sort cannot, their branches being too weak and trailing for this purpose. The branches of this are smooth, of a purplish colour, garnished with oblong oval leaves, of a lucid green on their upper side, but pale on their under, having very short foot-stalks; they are placed by pairs, but are not joined at their base. The flowers are produced in bunches at the end of the branches, each flower arising out of a scaly cover, which cover after the flowers fade, forms an oval head, whose scales lie over each other, like those of fish. The flowers are of a reddish colour on their outside, and yellowish within, of a very agreeable odour. This sort flowers in *June*, *July*, and *August*. There are two other varieties of this species, one is called the long blowing, and the other the late red Honeyfuckle.

The sixth sort is commonly called the *Italian* Honeyfuckle. Of this there are two or three varieties, the early white Honeyfuckle is one; this is the first which flowers, always appearing in *May*. The branches of this are slender, covered with a light green bark, garnished with oval leaves of a thin texture, placed by pairs sitting close to the branches, but those which are situated toward the end of the branches, join at their base, so that the stalk seems as if it came through the leaves. The flowers are produced in whorled bunches at the end of the branches; they are white, and have a very fragrant odour, but are of short duration, so that in about a fortnight they are entirely over, and soon after the leaves appear as if blighted and sickly, making an indifferent appearance the whole summer, which has rendered them less valued than the others. The other variety is the yellow *Italian* Honeyfuckle, which is the next in succession to the white. The shoots of this are much like those of the former, but have a darker bark; the leaves are also of a deeper green; the flowers are of a yellowish red, and appear soon after the white; they are not of much longer duration, and are succeeded by red berries, containing one hard seed inclosed in a soft pulp, which ripens in the autumn.

The seventh sort is the common wild *English* Honeyfuckle or Woodbine; this grows naturally in the hedges in many parts of *England*. The branches are very slender and hairy, trailing over the neighbouring bushes, and twining round the boughs of trees; the leaves are oblong, hairy, and distinct, not joined at their base; they are placed by pairs opposite; the flowers are produced in long bunches at the end of the branches. There are two varieties, one with white, and the other yellowish red flowers. These appear in *July*, and there is a succession of flowers on the plants till the autumn.

There is also a variety of this with variegated leaves, and one with cut leaves somewhat like the leaves of Oak, and one of these with variegated leaves; but, as these are accidental varieties, I have not enumerated them.

The eighth sort is supposed to grow naturally in *North America*. This hath strong branches, covered with a purple bark, which are garnished with lucid green leaves embracing the stalks, which continue their verdure all the year. The flowers are produced in whorled bunches at the end of the branches; there are frequently two, and sometimes three of these bunches rising one out of another; they are of a bright red on their outside, and yellow within, of a strong aromatic flavour. This sort begins to flower in *June*, and there is a succession of flowers till the frost puts a stop to them, so that it is the most valuable of all the sorts.

All the sorts of Honeyuckles are propagated either by layers or cuttings: when they are propagated by layers, the young shoots only should be chosen for that purpose. These should be layed in the autumn, and by the following autumn they will have taken root, when they should be cut off from the plants, and either planted where they are to remain, or into a nursery to be trained up, either for standards, which must be done by fixing down stakes to the stem of each plant, to which their principal stalk should be fastened, and all the other must be cut off; the principal stalk must be trained to the intended height of the stem, then it should be shortened, to force out lateral branches, and these should be again stopped to prevent their growing too long; by the constant repeating this as the shoots are produced, they may be formed into a sort of standard; but if any regard is had to their flowering, they cannot be formed into regular heads, for by constantly shortening their branches, the flower-buds will be cut off, so that few flowers can be expected; and as it is an unnatural form for these trees, so there should be but few of them reduced to it, for when they are planted near other bushes, in whose branches the shoots of the Honeyuckles may run and mix, they will flower much better, and have a finer appearance than when they are more regularly trained; therefore, when the plants are in the nursery, if two or three of the principal shoots are trained up to the stakes, and the others are entirely cut off, they will be fit to transplant the following autumn, to the places where they are to remain; for though they may be transplanted of a greater age, yet they do not thrive so well as when they are removed while they are young.

When these plants are propagated by cuttings, they should be planted in *September*, as soon as the ground is moistened by rain. The cuttings should have four joints, three of which should be buried in the ground, and the fourth above the surface, from which the shoots are to be produced. These may be planted in rows, at about a foot distance row from row, and four inches asunder in the rows, treading the earth close to them; and as the ever-green and late red Honeyuckles, are a little more tender than the other sorts, so if the ground between the rows where these are planted, is covered with tanners bark, or other mulch, to keep out the frost in winter, and the drying winds of the spring, it will be of great advantage to the cuttings; and if the cuttings of these sorts have a small piece of the two years wood at their bottom, there will be no hazard of their taking root. The plants which are raised from cuttings, are preferable to those which are propagated by layers, as they have generally better roots.

These plants will grow in almost any soil or situation (except the second, third, fourth, and the last mentioned, which will not thrive where they are too much exposed to the cold in winter); they thrive best in a soft sandy loam, and will retain their leaves in greater verdure in such ground, than if planted in a dry gravelly soil, where in warm dry

seasons their leaves often shrink, and hang in a very disagreeable manner; nor will those sorts, which naturally flower late in the autumn, continue so long in beauty on a dry ground, unless the season should prove moist and cold, as those in a gentle loam, not too stiff or wet.

There are few sorts of shrubs which deserve cultivation better than most of these, for their flowers are very beautiful, and perfume the air to a great distance with their odour, especially in the mornings and evenings, and in cloudy weather, when the sun does not exhale their odour, and raise it too high to be perceptible; so that in all retired walks, there cannot be too many of these intermixed with the other shrubs. I have seen these plants intermixed in hedges, planted either with Alder or Laurel, where the branches have been artfully trained between those of the hedge; from which the flowers have appeared dispersed from the bottom of the hedge to the top, and being intermixed with the strong green leaves of the plants, which principally compose the hedge, they have made a fine appearance; but the best sorts for this purpose, are the ever-green and long-blowing Honeyuckles, because their flowers continue in succession much longer than the other sorts.

PERIPLOCA. *Tourn. Inst. R. H. 93. tab. 22. Virginian Silk.*

The Characters are,

The flower hath a permanent empalement, cut into five points. The flower has one plain petal, cut into five narrow segments, with a small nectarium going round the center of the petal, and the five incurved filaments, which are not so long as the petal, with five short stamina. It has a small bisid germen with scarce any style, which afterward becomes two oblong bellied capsules with one cell, filled with seeds crowned with down, lying over each other like the scales of fish.

The Species are,

1. PERIPLOCA floribus internè hirsutis. *Lin. Sp. Plant. 211. Virginia Silk* with flowers hairy on their inside.
2. PERIPLOCA caule hirsuto. *Lin. Sp. Plant. 211. Virginian Silk* with a hairy stalk.
3. PERIPLOCA foliis oblongo-cordatis pubescentibus, floribus alaribus, caule fruticoso scandente. *Virginia Silk*, with oblong heart-shaped leaves, which are covered with soft hairs, and flowers proceeding from the sides of the stalks, which are shrubby and climbing.
4. PERIPLOCA foliis oblongo-ovatis, siliquis teretibus articulatis, caule scandente. *Virginia Silk* with oblong oval leaves, taper jointed pods, and a climbing stalk.
5. PERIPLOCA foliis ovato-lanceolatis, floribus terminalibus, siliquis articulatis, caule fruticoso scandente. *Virginia Silk* with oval spear-shaped leaves, flowers terminating the stalks, taper jointed pods, and a shrubby climbing stalk.
6. PERIPLOCA foliis lanceolatis acuminatis, floribus umbellatis axillaribus, caule fruticoso scandente. *Virginia Silk* with spear-shaped acute-pointed leaves, flowers growing in umbels from the sides of the stalks, and a shrubby climbing stalk.
7. PERIPLOCA foliis subcordatis obtusis, infernè incanis, caule hirsuto scandente. *Virginia Silk*, with heart-shaped obtuse leaves, which are hoary on their under side, and a hairy climbing stalk.

The first sort grows naturally in *Syria*, but is hardy enough to thrive in the open air in *England*. It hath twining shrubby stalks, covered with a dark bark, which twist round any neighbouring support, and will rise more than forty feet high, sending out slender branches from the side, which twine round each other, and are garnished with oval spear-shaped leaves near four inches long, and two broad in the middle, of a lucid green on their upper side, but pale on their under, standing by pairs, upon short foot-stalks. The flowers come out toward the end of the small branches in bunches; they are of a purple colour, and hairy on their inside,

inside, composed of one petal, cut into five segments almost to the bottom, which spread open in form of a star, and within is situated a nectarium, which goes round the five short stamina and germen, which is hairy. The germen afterward turns to a double long taper pod or capsule, filled with compressed seeds, lying over each other like the scales of fish, having a soft down fixed to their top. This plant flowers in *July* and *August*, but rarely ripens its seeds in *England*.

It is easily propagated by laying down of the branches, which will put out roots in one year, and may then be cut from the old plant, and planted where they are to remain. These may be transplanted either in autumn, when their leaves begin to fall, or in the spring before they begin to shoot, and must be planted where they may have support, otherwise they will trail on the ground, and fasten themselves about whatever plants are near them.

The second sort grows naturally in *Africa*. This hath many slender stalks, which twine about each other, or any neighbouring support, and will rise near three feet high, putting out several small side branches, which are hairy, as are also the leaves, standing by pairs upon very short foot-stalks. The flowers come out in small bunches from the side of the stalks; they are small, of a worn-out purplish colour, and of a sweet scent, being cut into five narrow segments almost to the bottom. It flowers in the summer months, but does not produce seeds here. There is a variety of this with smooth leaves and stalks, from the same country.

The third sort was discovered by the late Dr. *Houfoun*, growing naturally at *La Vera Cruz* in *America*. This rises with a strong woody stalk to the height of five or six feet, covered with a gray bark, putting out many weak branches, which twist themselves about any neighbouring support, and rise to the height of twenty feet; they are garnished with heart-shaped leaves, of a yellowish green, covered with silky hairs, which are soft to the touch, and stand by pairs upon pretty long foot-stalks. The flowers come out in small bunches from the wings of the leaves; they are small, white, and of the open bell-shape; these are succeeded by swelling taper pods, filled with seeds crowned with long feathery down.

The fourth sort grows naturally at *Campeachy*. This hath slender, shrubby, climbing stalks, which fasten round the neighbouring trees, and rises to the height of thirty feet, covered with a purplish bark, garnished with oblong oval leaves, of a lucid green, and pretty thick texture; these stand upon short foot-stalks opposite. The flowers are in small bunches, standing upon very long foot-stalks; they are white, and are succeeded by very slender taper pods, near a foot long, having small swelling joints an inch apart; in each of these are lodged three or four flat oval seeds, with a plume of down on their top.

The fifth sort grows naturally in *Jamaica*. This hath shrubby climbing stalks like the former, which twine about the neighbouring trees, and rise ten or twelve feet high, putting out a great number of small branches, which are garnished with oval spear shaped leaves, of a lucid green, standing on short foot-stalks opposite. The flowers are produced at the end of the branches, three or four together, upon the same short foot-stalk; these have a short tube, which is cut into five segments at the top, which spread open; they are yellow, and are succeeded by slender pods between four and five inches long, which have swelling joints where the seeds are lodged, and a brown feathery down on their top. The joints of these pods do not swell so much as those of the other, nor are the spaces between the joints so slender.

The sixth sort grows naturally in *Jamaica*. This hath

slender climbing stalks covered with a green bark, which twine about the neighbouring trees, and rise thirty feet high; the joints are far asunder; at each are placed two spear-shaped leaves opposite, standing upon short foot-stalks, of a light green, ending in acute points. The flowers come out from the side of the stalks in a sort of umbel, standing upon foot-stalks between two and three inches long; they are of a pure white, and smell very sweet, and are cut into five segments almost to the bottom; these are succeeded by taper pods about two inches long, ending in acute points, filled with oblong seeds, crowned with long down.

The seventh sort grows naturally at the *Cape of Good Hope*. This hath very slender twining stalks, which twilt about each other, and any of the neighbouring plants, rising four or five feet high; they are hairy, garnished with leaves almost heart-shaped, hoary on their under side, but of a lucid green on the upper, standing by pairs on short foot-stalks. The flowers come out in clusters from the side of the stalk; they are small, and cut into five segments, which spread open flat; they are of a worn out purple colour, and have a strong sweet scent. These appear in *July* and *August*, but are not succeeded by seeds in *England*.

The second and last mentioned sorts are hardy enough to thrive in this country, with a little protection from the frost in winter. If these are sheltered under a common frame, or placed in a green-house during the winter season, and placed abroad with other hardy exotic plants in summer, they will thrive and flower very well; but as all the plants of this genus have a milky juice, so they should not have much wet, especially in cold weather, lest it rot them. They are easily propagated by laying down of their branches, which in one year will be rooted enough to transplant; these should be planted in a light sandy loam not rich, and the pots must not be too large, for when they are over-potted they will not thrive.

The third, fourth, fifth, and sixth sorts, are tender; these will not thrive in *England*, unless they are placed in a warm stove. They may be propagated by laying down of their branches, in the same manner as the former; or from seeds, when they can be procured from the places where they naturally grow. These should be sown upon a good hot-bed, and when the plants come up, they must be treated in the same manner as other tender exotic plants.

If these plants are constantly kept plunged in the tan-bed of the stove, they will thrive and flower much better than in any other situation, but the stove should not be kept too warm in winter; and in the summer, the plants should have a large share of free air admitted to them; for when they are kept too close, their leaves will be covered with insects, and the plants will become sickly in a short time.

PERIWINKLE. See *Vinca*.

PERSEA. *Plum. Nov. Gen. 44. tab. 20.* The Avocado, or Avogato Pear.

The Characters are,

The flower hath no empalement, but is composed of six petals, ending in acute points, which spread open. It hath six stamina, about half the length of the petals, terminated by roundish summits, and a short style crowned by a pyramidal germen, which afterward becomes a large fleshy pyramidal fruit, inclosing an oval seed, having two lobes.

We know but one Species of this plant, viz.

PERSEA. *Clas. Hist.* The Avocado, or Avogato Pear.

This tree grows in great plenty in the *Spanish West-Indies*, as also in the island of *Jamaica*, and hath been transplanted into most of the *English* settlements in the *West-Indies*, on account of its fruit; which is not only esteemed by the inhabitants as a fruit to be eaten by way of dessert, but is very necessary for the support of life. The fruit of itself is very insipid, for which reason they generally eat it with the juice

of Lemons and sugar, to give it a piquancy. It is very nourishing, and is reckoned a great incentive to venery. Some people eat this fruit with vinegar and pepper.

This tree, in the warm countries where it is planted, grows to the height of thirty feet or more, and has a trunk as large as our common Apple trees; the bark is smooth, and of an Ash colour; the branches are beset with pretty large, oblong, smooth leaves, like those of Laurel, which are of a deep green colour, and continue on the tree throughout the year. The flowers and fruit are, for the most part, produced toward the extremity of the branches. The fruit is as large as one of the largest Pears, inclosing a large seed with two lobes included in a thin shell.

In *Europe* this plant is preserved as a curiosity, by those persons who delight in collecting exotick plants; and though there is little hope of its producing fruit, yet for the beauty of its shining green leaves, which continue through the winter, it deserves a place in every curious collection of plants.

It is propagated by seeds, which should be obtained as fresh as possible, from the countries of its growth; and if they are brought over in sand, they will be more likely to grow, than such as are brought over dry. These nuts or seeds should be planted in pots, filled with light earth, and plunged into a hot-bed of tanners bark. In about five or six weeks the plants will come up, when they must, while young, be treated very tender; but when they have grown about four inches high, they should be carefully transplanted; and if there are two or more plants in one pot, they must be parted, being careful to preserve a ball of earth to the root of each, and planted into separate small pots, then plunged into a hot-bed of tanners bark, observing to shade them until they have taken new root; after which time they should have fresh air admitted to them, in proportion to the warmth of the season. Towards *Michaelmas* the plants must be removed into the stove, and plunged into the bark-bed, where, during the winter season, they would be kept warm, and must be gently watered twice a week. In the spring the plants should be shifted into pots a size larger than the former, and the bark-bed should be then renewed with fresh tan, which will set the plants in a growing state early, whereby they will make a fine progress the following summer. These plants should be kept in the stove, for they are too tender to bear the open air in this country, except in the warmest part of summer.

PERSICA. *Tourn. Inst. R. H. 624. tab. 402.* The Peach-tree.

The Characters are,

The flower has a tubulous empalement of one leaf, cut into five obtuse segments. It hath five oblong obtuse petals, which are inserted in the empalement, and about thirty erect slender stamina, which are shorter than the petals, and are also inserted in the empalement. In hath a roundish hairy germen, which afterward becomes a roundish, woolly, large, succulent fruit, with a longitudinal furrow, inclosing an oval nut with a netted shell, having many punctures.

There are a great variety of these trees cultivated in the gardens of those who are curious in collecting the several sorts of fruit: I shall therefore first beg leave to mention only two or three sorts, which are cultivated for the beauty of their flowers; after which, I shall enumerate the several varieties of good fruit which have come to my knowledge.

1. PERSICA vulgaris, flore pleno. *Tourn. Inst. R. H. 625.* Common Peach-tree with double flowers.

2. PERSICA Africana nana, flore incarnato simplici. *Tourn. Inst. R. H. 625.* Dwarf Almond with single flowers, vulgò.

3. PERSICA Africana nana, flore incarnato pleno. *Tourn. Inst. R. H. 625.* Double flowering Dwarf Almond, vulgò.

The first of these trees is a very great ornament in a gar-

den early in the spring, the flowers being very large, double, and of a beautiful red or purple colour. This may be planted in standards, and, if intermixed amongst other flowering trees of the same growth, makes a very agreeable variety; or it may be planted against the walls of the pleasure-garden, where the beautiful appearance of its flowers early in the spring will be more acceptable in such places than the choicest fruits, which must be exposed to servants, and others, so that they seldom can be preserved in large families until they are ripe. This tree may be propagated by budding it on the Almond or Plum stocks, in the same manner as the other sort of Peaches, and should be planted in a good fresh soil that is not over moist.

The other two sorts are of humbler growth, seldom rising above three or four feet high; these may be budded upon Almond stocks, or propagated by layers; they will also take upon Plum stocks, but they are very apt to canker, after they have stood four or five years upon those stocks, especially that with double flowers, which is tenderer than the other, which sends out suckers from the root, whereby it may be propagated in great plenty.

These shrubs make a very agreeable variety amongst low flowering trees, in wilderness walks. The single sort flowers in the beginning of *April*, and the double is commonly a fortnight later.

I shall now proceed to mention the several sorts of good Peaches which have come to my knowledge; and though perhaps a greater number of sorts may be found in some catalogues of fruits, yet I doubt whether many of them are not the same kinds called by different names; for, in order to determine the various kinds, it is necessary to observe the shape and size of the flowers, as well as the different parts of the fruit; for this does sometimes determine the kind, when the fruit alone is not sufficient; besides, there is a vast difference in the size and flavour of the same Peach, when planted on different soils and aspects; so that it is almost impossible for a person who is very conversant with these fruits to distinguish them, when brought from various gardens.

1. The white Nutmeg (called by the *French*, *L'Avant Pêche Blanche*). This tree has sawed leaves, but generally shoots very weak, unless it is budded upon an Apricot stock; the flowers are large and open, the fruit is small and white, as is also the pulp at the stone, from which it separates; it is a little musky and sugary, but is only esteemed for its being the first sort ripe. It is in eating the end of *July*, and soon becomes mealy.

2. The red Nutmeg (called by the *French*, *L'Avant Pêche de Troyes*). This tree has sawed leaves; the flowers are large and open; the fruit is larger and rounder than the white Nutmeg, and is of a bright vermilion colour; the flesh is white, and very red at the stone; it has a rich musky flavour, and parts from the stone. This Peach is well esteemed; it ripens the beginning of *August*.

3. The early or small Mignon (called by the *French*, *La Double de Troyes*, or *Mignonette*). This tree has small contracted flowers; the fruit is of a middling size, and round; it is very red on the side next the sun; the flesh is white, and separates from the stone, where it is red; the juice is vinous and rich. It is ripe the beginning of *August*.

4. The yellow Alberge. This tree has smooth leaves; the flowers are small and contracted; the fruit is of a middling size, somewhat long; the flesh is yellow and dry; it is seldom well flavoured, but should be perfectly ripe before it is gathered, otherwise it is good for little. It is ripe early in *August*.

5. The white *Magdalen*. This tree has sawed leaves; the flowers are large and open; the wood is generally black at the pith; the fruit is round, of a middling size; the flesh

is white to the stone, from which it separates; the juice is seldom high flavoured; the stone is very small. This ripens early in *August*.

6. The early Purple (called by the *French*, *La Pourprée bâtive*). This tree has smooth leaves; the flowers are large and open; the fruit is large, round, and of a fine red colour; the flesh is white, but very red at the stone; is very full of juice, which has a rich vinous flavour, and is by all good judges esteemed an excellent Peach. This is ripe the middle of *August*.

7. The large or *French Mignon*. The leaves of this tree are smooth; the flowers are large and open; the fruit is a little oblong, and generally swelling on one side; it is of a fine colour; the juice is very sugary, and of a high flavour; the flesh is white, but very red at the stone, which is small. This is ripe in the middle of *August*, and is justly esteemed one of the best Peaches; it separates from the stone. This sort of Peach is tender, and will not thrive on a common stock, so is generally budded upon some vigorous shooting Peach, or an Apricot, by the nursery-men, which enhances the price of the trees. But the best method is to bud this Peach into some old healthy Apricot, which is planted to a south or south east aspect, and to cut away the Apricot when the buds have taken, and made shoots: upon some trees which I have seen thus managed, there has been a much greater quantity of fairer, and better flavoured fruit, than I have ever observed in any other management, and the trees have been much more healthy.

8. The *Chevreuse*, or *Belle Chevreuse*. This tree has smooth leaves; the flowers are small and contracted; the fruit is of a middling size, a little oblong, of a fine red colour; the flesh is white, but very red at the stone, from which it separates; it is very full of a rich sugary juice, and ripens toward the end of *August*. This is a very good bearer, and may be ranged with the good Peaches.

9. The red *Magdalen* (called by the *French* about *Paris*, *Madeleine de Courson*). The leaves of this tree are deeply sawed; the flowers are large and open; the fruit is large and round, of a fine red colour; the flesh is white, but very red at the stone, from which it separates; the juice is very sugary, and of an exquisite flavour. It is ripe the end of *August*, and is one of the best sort of Peaches.

10. The early *Newington* (or *Smith's Newington*). This is very like, if not the same, with what the *French* call *Le Pavie blanc*. This tree has sawed leaves; the flowers are large and open; the fruit is of a middling size, of a fine red on the side next the sun; the flesh is firm and white, but very red at the stone, to which it closely adheres. It hath a sugary juice, and is ripe the end of *August*.

11. The *Montauban*. This tree has sawed leaves; the flowers are large and open; the fruit is of a middling size, of a deep red, inclining to purple next the sun, but of a pale colour toward the wall; the flesh is melting and white to the stone, from which it separates; the juice is rich, and the tree is a good bearer. It ripens the middle of *August*, and is well esteemed.

12. The *Malta* (which is very like, if not the same, with the *Italian Peach*). This tree has sawed leaves; the flowers are large and open; the fruit is of a middling size, of a fine red next the sun; the flesh is white and melting, but red at the stone, from which it separates; the stone is flat and pointed; the tree is a good bearer. This ripens the end of *August*.

13. The *Noblest*. This tree has sawed leaves; the flowers are large and open; the fruit is large, of a bright red next the sun; the flesh is white and melting, and separates from the stone, where it is of a faint red colour; the juice is very rich in a good season. It ripens the end of *August*.

14. The *Chancellor*. The leaves of this tree are smooth; the flowers are small and contracted; the fruit is shaped somewhat like the *Belle Chevreuse*, but is rounder; the flesh is white and melting, and separates from the stone, where it is of a fine red colour; the skin is very thin, and the juice is very rich. It ripens about the end of *August*, and is esteemed one of the best sort of Peaches. This tree is very tender, and will not succeed on common stocks, so is budded twice as the *Mignon*; and if budded on Apricots, as was directed for that sort, will thrive much better than in any other method.

15. The *Bellegarde* (or as the *French* call it, the *Gallande*). This tree has smooth leaves; the flowers are small and contracted; the fruit is very large and round, of a deep purple colour on the side to the sun; the flesh is white, melting, and separates from the stone, where it is of a deep red colour; the juice is very rich. This ripens the beginning of *September*, and is an excellent Peach, but at present not very common.

16. The *Liste* (or as the *French* call it, *La petite Violette bâtive*). This tree has smooth leaves; the flowers are small and contracted; the fruit is of a middling size, of a fine Violet colour toward the sun; the flesh is of a pale yellow and melting, but adheres to the stone, where it is very red; the juice is very vinous. This ripens the beginning of *September*.

17. The *Bourdine*. This tree has smooth leaves; the flowers are small and contracted; the fruit is large, round, and of a fine red colour next the sun; the flesh is white, melting, and separates from the stone, where it is of a fine red colour; the juice is vinous and rich. This ripens the beginning of *September*, and is greatly esteemed by the curious. The tree bears plentifully, and will produce fruit in standards very well.

18. The *Rossiana*. This tree has smooth leaves; the flowers are small and contracted; the fruit is large, a little longer than the *Alberge*; the flesh is yellow, and separates from the stone, where it is red; the juice is rich and vinous. This ripens the beginning of *September*, and is esteemed a good Peach. This is the same with what some call the purple, and others the red *Alberge*, it being of a fine purple colour on the side next the sun.

19. The *Admirable*. This tree hath smooth leaves; the flowers are small and contracted; the fruit is large, round, and red on the side next the sun; the flesh is white, melting, and separates from the stone, where it is of a deep red colour; the juice is sugary and rich. This ripens the beginning of *September*. This is by some called the early *Admirable*, but is certainly what the *French* call *L'Admirable*, and they have no other of this name which ripens later.

20. The *old Newington*. This tree has sawed leaves; the flowers are large and open; the fruit is fair and large, of a beautiful red colour next the sun; the flesh is white, hard, and closely adheres to the stone, where it is of a deep red colour; the juice is very rich and vinous. This is esteemed one of the best sort of Pavies: It ripens about the middle of *September*.

21. The *Rambouillet* (commonly called the *Rumbullion*). This tree has smooth leaves; the flowers are large and open; the fruit is of a middling size, rather round than long, deeply divided by a sulcus or furrow in the middle; it is of a fine red colour next the sun, but of a light yellow next the wall; the flesh is melting, of a bright yellow colour, and separates from the stone, where it is of a deep red; the juice is rich, and of a vinous flavour. This ripens the middle of *September*, and is a good bearer.

22. The *Bellis* (which I believe to be what the *French* call *La Belle de Vitry*). The leaves of this tree are sawed; the flowers are small and contracted; the fruit is of a mid-

dle size, round, and of a pale red next the sun; the flesh is white, and adheres to the stone, where it is red; the juice is vinous and rich. This ripens in the middle of *September*.

23. The *Portugal*. This tree has smooth leaves; the flowers are large and open; the fruit is large, and of a beautiful red colour towards the sun; the skin is generally spotted; the flesh is firm, white, and closely adheres to the stone, where it is of a faint red colour; the stone is small, but full of deep furrows; the juice is rich and vinous. This ripens the middle of *September*.

24. *La Teton de Venus* (or *Venus's Breast*), so called from its having a rising like a dug, or bubbly. This tree has smooth leaves; the flowers are small and contracted; the fruit is of a middling size, resembling the Admirable, of a pale red colour next the sun; the flesh is melting, white, and separates from the stone, where it is red; the juice is sugary and rich. This ripens late in *September*.

25. *La Pourprée* (or as the *French* call it, *Pourprée tardive*, *i. e.* the late Purple). This tree has very large leaves, which are sawed; the shoots are very strong; the flowers are small and contracted; the fruit is large, round, and of a fine purple colour; the flesh is white, melting, and separates from the stone, where it is red; the juice is sugary and rich. This ripens late in *September*.

26. The *Nivette*. This tree has sawed leaves; the flowers are small and contracted; the fruit is large, somewhat longer than round, of a bright red colour next the sun, and of a pale yellow on the other side; the flesh is melting, full of a rich juice, and is very red at the stone, from which it separates. This is esteemed one of the best Peaches. It ripens in the middle of *September*.

27. The Royal (*La Royale*). This tree has smooth leaves; the flowers are small and contracted; the fruit is large, round, and of a deep red on the side next the sun, and of a paler colour on the other side; the flesh is white, melting, and full of a rich juice; it parts from the stone, where it is of a deep red colour. This ripens the middle of *September*, and, when the autumn is good, is an excellent Peach.

28. The *Perfique*. This tree has sawed leaves; the flowers are small and contracted; the fruit is large, oblong, and of a fine red colour next the sun; the flesh is melting, and full of a rich juice; it separates from the stone, where it is of a deep red colour. The stalk has a small knot upon it; this makes a fine tree, and is a good bearer. It ripens the end of *September*. Many gardeners call this the *Nivette*.

29. The monstrous Pavy of *Pomponne* (called by the *French*, *La Pavie rouge de Pomponne*). The leaves of this tree are smooth; the flowers are large and open; the fruit is very large and round, many times fourteen inches in circumference; the flesh is white, melting, and closely adheres to the stone, where it is of a deep red colour; the outside is a beautiful red next the sun, and of a pale flesh colour on the other side. This ripens the end of *October*, and, when the autumn is warm, is an excellent Peach.

30. The *Catharine*. This tree hath smooth leaves; the flowers are small and contracted; the fruit is large, round, and of a dark red colour next the sun; the flesh is white, hard, and full of a rich juice. It closely adheres to the stone, where it is of a deep red colour. It ripens the beginning of *October*, and in very good seasons is an excellent Peach, but being so very late ripe, there are not many situations where it ripens well.

31. The Bloody Peach (called by the *French*, *La Sanguinolle*). This Peach is of a middling size, of a deep red next the sun; the flesh is of a deep red quite to the stone, and from thence is, by some gardeners, called the Mulberry Peach. This fruit rarely ripens in *England*, so is not often planted, but it bakes and preserves excellently; for

which, as also the curiosity, one or two trees may be planted, where there is extent of walling.

There are some other sorts of Peaches which are kept in some of the nurseries, but those which are here enumerated, are the sorts most worth planting, and in this list the choicest only should be planted; but I shall just mention the names of those sorts omitted, for the satisfaction of the curious.

The *Sign*; the *Bordeaux*; the *Swalch* or *Dutch*; the *Carlisse*; the *Eton*; the *Pêche de Pau*; yellow Admirable; the Double Flower. This last sort is generally planted more for the beauty of the flowers, than for the goodness of the fruit, of which some years the standard trees produce great plenty; but they are late ripe, and have a cold, watery, insipid juice. The Dwarf Peach is also preserved in some places as a curiosity. This is a very tender tree, making very weak shoots, which are very full of flower-buds. The fruit is not so large as a nutmeg, and not good, nor will the tree be of long duration, so it is not worth cultivating.

And indeed, from these thirty-one above-named, there are not above ten of them which I would advise to be planted; because, when a person can be furnished with those which are good, or has the best of the season, it is not worth while to plant any which are middling or indifferent, for the sake of variety; therefore the sorts which I should prefer, are these after-mentioned.

The early Purple; the *Grosse Mignon*; *Belle Chevreuse*; red *Magdalen*; *Chancellor*; *Bellegarde*; *Bourdine*; *Rossanna*; *Rambouillet*, and *Nivette*. These are the sorts best worth planting, and, as they succeed each other, they will furnish the table through the season of Peaches; and, where there is room, and the situation very warm, one or two trees of the *Catharine* Peach should have place, for in very warm seasons it is an excellent fruit.

The *French* distinguish those we call Peaches into two sorts, *viz.* Pavies and Peaches; those are called Peaches which quit the stone, and those, whose flesh closely adheres to the stone, are called Pavies. These are much more esteemed in *France* than the Peaches, though in *England* the latter are preferred to the former by many persons.

All the different sorts of Peaches have been originally obtained from the stones, which, being planted, produce new varieties, as do the seeds of all other fruits; so that where persons have garden enough to allow room for propagating these fruits from seeds, there is no doubt but some good sorts may be obtained; though it is true, there will be many of them good for nothing, as is the case of most fruits and flowers which are produced from seeds, amongst which there may be some valuable kinds, superior to those from whence the seeds were taken, yet there is always a great number which are little worth; but where persons are so curious as to plant the stones of these fruits, great regard should be had to the sorts; and if the fruits were permitted to remain upon the trees until they dropped off, the kernels would be fitter for planting, and more likely to grow. The best sorts for sowing are those whose flesh is firm, and cleaves to the stone; and from amongst these you should choose such as ripen pretty early, and have a rich vinous juice; from which sorts some good fruit may be expected.

These stones should be planted in autumn, on a bed of light dry earth, about three inches deep, and four inches asunder; and in the winter the beds should be covered with mulch, to protect them from the frost, which, if permitted to enter deep into the ground, may destroy them. In the spring, when the plants come up, they should be carefully cleared from weeds, which should also be observed throughout the summer. In this bed they should remain until the following spring, when they should be carefully taken up, so as not to break their tender roots, and transplanted into a nursery,

nursery, in rows three feet asunder, and one foot distant plant from plant in the rows, observing to lay a little mulch upon the surface of the ground about their roots, to prevent its drying too fast; and if the spring should prove very dry, you should give them a little water once a week, until they have taken root; after which, they should be constantly kept clear from weeds, and the ground between the rows carefully dug every spring, to loosen it so as that the tender fibres may strike out on every side.

In this nursery they may continue one or two years according to the progress they make; after which they should be transplanted where they are to remain, to produce fruit.

In removing these trees, you should observe to prune their downright roots (if they have any) pretty short, and to cut off all bruised parts of the roots, as also all the small fibres, which generally dry, and, when left upon the roots after planting again, grow mouldy and decay, so that they are injurious to the new fibres which are shot out from the roots, and very often prevent the growth of the trees; but you should by no means prune their heads, for the plants, which are produced from stones, are generally of a more spongy texture, and so more liable to decay when cut, than those which are budded upon other stocks. Besides, as these trees are designed for standards (for it is not proper to plant them against walls, until you see the produce of the fruit, to shew which of them deserve to be cultivated), so they will not require any other pruning, but only to cut out decayed branches, or such as shoot out very irregular from the sides, for more than this is generally very injurious to them.

When they have produced fruit, you will soon be a judge of their goodness, therefore such of them as you dislike, may be destroyed, but those which are good, may be propagated by inoculating them upon other stocks, which is the common method now practised to propagate these fruits, therefore I shall now proceed to treat of that more particularly; in the doing of which, I shall set down the method now commonly practised by the nursery-gardeners, and then propose some few things of my own as an improvement thereon, for such persons who are very curious to have good fruit. But first,

You should be provided with stocks of the Muscle and white Pear Plums, which are generally esteemed the two best sorts of Plums for stocks to inoculate Peaches and Nectarines upon; as also some Almond and Apricot stocks, for some tender sorts of Peaches, which will not grow upon Plum stocks. These should be all produced from the stone (as hath been already directed in the article NURSERY), and not from suckers, for the reasons there laid down. These stocks should be transplanted, when they have had one year's growth in the seed-bed, for the younger they are transplanted, the better they will succeed, and hereby they will be prevented from sending tap roots deep in the ground; for by shortening those which seem so disposed, it will cause them to put out horizontal roots. These stocks should be planted at the distance above-mentioned, *viz.* the rows three feet asunder, and one foot apart in the rows. This is wider than most nursery-men plant them, but I shall give my reasons hereafter for this.

When these stocks have grown in the nursery two years, they will be strong enough to bud; the season for which is commonly any time in *July*, when the rind will easily separate from the wood; when you should make choice of some good cuttings of the sorts of fruit you intend to propagate, always observing to take from healthy trees, and such as generally produce a good quantity of well tasted fruit; for it is very certain, that any sort of fruit may be so far degenerated, where this care is wanting, as not to be like the same kind. Besides, whenever a tree is unhealthy, the buds

taken from that tree will always retain the distemper, in a greater or less degree, according as it hath imbibed a greater or less quantity of the distempered juice. Thus, for instance, where a Peach or Nectarine tree hath been greatly blighted, so as that the shoots have grown busled, and the leaves curled up to a great degree, that distemper is seldom recovered again by the greatest care, or at least not without several years good management; for let the seasons prove ever so favourable, these trees will continually shew the same distemper, which many persons are so weak as to suppose a fresh blight; whereas in reality it is no other but the remains of the former sickness, which are spread and intermixed with all the juices of the tree, so that whatever buds are taken from such trees, will always retain a part of the distemper.

Upon the care which is taken in the choice of the buds, the whole success depends; therefore a person, who is curious to have good fruit, cannot be too careful in this particular, for, in general, no more is regarded by those nursery-men who are the most careful in propagating the several sorts of fruit trees, than the taking their buds or grafts from the true kinds of fruit trees; but there is still more care required to have sound healthy trees, especially in this of Peach and Nectarines; for if the buds are taken from young plants in the nursery, which have not produced fruit, the shoots of which are generally very strong and vigorous, these buds will have so vicious a habit, as rarely to be corrected, and brought into good order; for they will shoot more like the Willow than the Peach, the joints being extended to great a distance from each other, the shoots very gross, and the wood pithy; therefore, where the practice of taking the buds from nursery trees is long continued, there can be little hopes of the trees so raised. I would therefore recommend it to every curious person, to procure their buds from such trees as have been long growing, whose fruit are well flavoured, and the trees perfectly sound; as also never to make choice of the strongest or most luxuriant shoots of these trees, but such shoots as are well-conditioned, and whose buds grow pretty close together. For although these do not make so strong shoots the following year, as those which are taken from luxuriant branches, yet they will be better disposed to bear fruit, and will make much better trees.

The cuttings, with which you are thus to be provided, should always be taken from the trees either in a morning or evening, or else in a cloudy day; for if they are cut off when the sun is very hot, the shoots will perspire so freely, as to leave the buds destitute of moisture, which is often the cause of their miscarrying; and the sooner they are used, when cut from the trees, the better they will take. The manner of this operation being explained under the article INOCULATION, I shall not repeat in this place. The management of these trees, during their remaining time in the nursery, is likewise fully set down under that article. I shall therefore proceed to give some directions for the choice of these trees, when they are to be procured from a nursery. The first care should be to find out a person of character to deal with, on whose integrity you may depend, for having the trees of those kinds which you propose, and either see them taken up, or let some person you can confide in do it for you, because as most of the nursery-men have dealings with each other, if the person applied to has not the sort of fruit desired in his own nursery, he procures them from another; and, if the gardener from whom he gets them, is not as honest and careful as himself, it is a great chance if the trees prove to be of the right kinds.

The trees should also be chosen in the autumn, before others have drawn out the best; for those who go first to the nurseries, if they have skill, will always draw the finest plants. In the choice of the trees, you should observe the

stocks upon which they have been budded, that they are of the right sort, whether Plum or Apricot; that they are found and young; not such as had been budded the preceding year and failed, nor those which have been cut down. If the size of the stock is near that of a man's finger, it will be better, than if they are larger; these should be clear of mofs or canker. The buds should be of one year's growth only, and not such as have been cut down in the spring, and made a second shoot, nor should those trees be chosen, whose shoots are very strong and luxuriant, but such as have clean shoots of a very moderate size, whose joints are not too far asunder; and those trees which stand in the outside rows, or near the ends of the rows, where they have most air, are generally such; for, where they stand close in the nursery, their shoots are drawn up in length; their joints are much farther asunder, and their buds or eyes flat; for which reason, I have before advised the planting of the stocks at a greater distance than the nursery-men generally allow them; and if a careful discreet nursery-man would be at the trouble and expence in the raising of his Peach trees, according to this method, he would better deserve three shillings *per tree*, than one in the manner they are usually raised; for every person who is at the expence of building walls for fruit, should not think of saving a few shillings in the purchase of their trees; because, if they are bad, or not of the right kinds, there is a great loss of time and expence to no purpose, and the disappointment will be so great, after waiting three or four years, as to discourage many from making farther trials, thinking themselves liable to the same ill success.

When the trees are chosen in the nursery, the next care must be to have them carefully taken up out of the ground, so as not to break or tear the roots, nor injure their bark; for, as these trees are very apt to gum in those places where they are wounded, there cannot be too much care taken of this. If the trees are to be transported to a distant place, their roots should be closely wrapped either with Haybands, Straw, or Peas haulm, and mats sewed over these, to prevent the air from drying of their roots and branches. If the leaves of the trees are not fallen when they are taken up, they should be carefully stripped off, before the trees are packed up; for, when there are many of these left, they are very apt to heat, if they are long in their passage, and often occasion a mouldiness very hurtful to the branches.

We come next to the preparing of the ground to receive the trees. The best earth for Peach trees is such as is taken from a pasture ground, that is neither too stiff and moist, nor over dry, but of a middling nature, such as is termed hazel loam. This should be dug from the surface of the ground about ten inches deep, taking the turf with it, and should be laid in heaps eight or ten months at least; but that which is prepared one year or more is still better before it is used, that it may have the winter's frost, and summer's heat to mellow it, during which time it should be often turned, to rot the turf, and break the clods, whereby it will be rendered very light, and easy to work, and about the beginning of *September* you should carry it into the garden, and make the borders, which must be raised in height, proportionable to the moisture of the garden; if the ground is very wet, it will be advisable to lay some rubbish in the bottom of the border, to drain off the moisture, and to prevent the roots of the trees from running downward; and in this case it will be proper to make some under-drains at the bottom of the border, to convey off the superfluous moisture, which, if detained about the roots of the trees, will greatly prejudice them; then raise the border of earth at least a foot, or in very wet land two feet, above the level of the ground, so that the roots of the trees may always remain dry; but if the ground is pretty dry, the borders should not be raised

above six or eight inches higher than the surface, which will be sufficient to allow for their sinking.

As to the breadth of these borders, that cannot be too great; but they should never be less than eight feet broad, where fruit trees are planted, for when the borders are made narrow, the roots of the trees will be so confined in four or five years time, that they will seldom thrive well after. The depth of these borders should not be greater than two feet and a half; for where they are prepared to a great depth, it only entices the roots of the trees downward, which may be the cause of their future barrenness, for their roots, being got down below the influences of the sun and showers, imbibe a great quantity of crude juices, which only add to the luxuriant growth of the trees; besides, whatever fruit are produced from such trees, are not near so well tasted, as are those which grow upon those trees, whose roots lie near the surface, and enjoy the kindly benefit of the sun's heat, to correct and digest whatever crudities there may be in the earth.

Where the natural soil of the garden is shallow, and either chalk, clay, or gravel lies near the surface, these should not be dug out like pits to receive the earth for the border, as is by some practised, for this will be no better than planting the trees in tubs or cases, for their roots will be confined to these pits; so that when they are extended to the sides, and can get no farther, the trees will blight and decay; and if it is clay on the sides, the wet will be detained, as in a basin, and the earth of the border will be like mud in very wet seasons, so unfit for the roots of these trees. Therefore, whenever it so happens that the ground is of either of the sorts before-mentioned, it will be the best way to raise the borders of a proper thickness of good earth over these, rather than to sink down into them; for when the roots of the trees lie near the surface of the ground, they will extend to a great distance in search of nourishment, but if they get below the staple of the land, they can find nothing but sour crude pasture very unfit for vegetation.

Your borders being thus prepared should lie about three weeks or a month to settle, by which time the season for planting will be come, which should be performed as soon as the leaves begin to decay, that the trees may put out new roots, before the frost comes on to prevent them. Your ground being ready, and the trees brought carefully to the place, the next work is to prepare them for planting, which is to be formed in the following manner: you must shorten all the roots, and cut off smooth any broken or bruised roots, as also all the small fibres should be taken off, for the reasons before given; and where any of the roots cross each other, the worst of them must be cut out, that they may not injure the other.

Having thus prepared your trees, you should measure out their distance, which ought never to be less than twelve feet; but where the ground is very good, they should be planted fourteen feet asunder. This, I doubt not, will be thought too great a distance by many persons, especially since it is contrary to the general practice at this time; but I am satisfied, whoever shall try the experiment, will find it no more than is sufficient for these, where they are rightly managed; for if they take kindly to the soil, their branches may be so trained, as to furnish all the lower part of the wall in a few years, which is what should be principally regarded, and not, as is too often the practice, run up the shoots in height, and leave all the lower part of the tree destitute of bearing wood, so that in a few years there will not be any fruit upon the lower part of the trees; which also must be the case where they are planted too close, because there being no room to extend the branches on either side, they are obliged to lead them upright, which produces the before-mentioned ill effect.

There may be also some persons, who may think this distance too small for these trees, because Plums, Cherries, and most other sorts of fruit trees require much more room; but when it is considered that Peach and Nectarine trees produce their fruit only upon the former year's wood, and not upon spurs, as Cherries, Plums, and Pears do; therefore the shoots of these trees must be annually shortened in every part of them, to obtain bearing wood, whereby the trees may be kept in much less compass than those of other sort of fruit, and every part of the wall may be constantly supplied with bearing branches; for when the trees are planted at a great distance, the branches are often extended to such lengths, as to leave the middle of the trees naked, for there are never any good shoots produced from the old branches of these trees.

In the disposition of the trees, it will not be amiss to plant those sorts of Peaches near each other, which ripen about the same time, for by so doing the fruit may be better guarded from men and insects, and this will save a great deal of trouble in gathering of the fruit; for if a person is obliged to go from one part of the garden to another, or perhaps to look over all the walls of the garden every time the fruit is gathered, it is a great loss of time, which may be avoided by this first care in planting of the trees.

But to return to planting; after you have marked out the places where each tree is to stand, you must with your spade make a hole wide enough to receive the roots of the tree; then you should place it down, observing to turn the bud outwards, that the wounded part of the stock may be hid, and let the stem of the tree be placed about four or five inches from the wall, with its head inclining thereto; then fill in the earth with your hands, observing to break the clods, that the earth may fall in between the roots, so as no void spaces may be left about them. You should also gently shake the tree with your hands, to settle the earth down the better between the roots; then with your foot gently press down the earth about the stem, but do not tread it down too hard, which is many times a very great fault; for when the ground is inclinable to bind, the treading of it close doth often render the ground so hard, as that the tender fibres of the roots cannot strike into it, whereby the tree remains at a stand for some time, and if the earth be not loosened in time, it frequently dies; so that whenever you observe the earth of your borders to be bound, either by great rains, or from any other cause, you should with a fork loosen it again, observing always to do it in dry weather, if in winter or spring; but in summer it should be done in a moist season.

Although I have here given directions for the choice of trees from the nursery, after the usual method of planting these trees, which is that of taking such as have made one year's shoot, yet I would prefer those which were budded the preceding summer, and have made no shoot; for if the bud is sound and plump, and the bark of the stock well closed, where the bud is inserted, there will be no danger of its growing; and when the bud has made a shoot the following spring the length of five or six inches, if it is stopped by pinching off the top, it will put out lateral branches, which may be trained to the wall, and this will prevent any cutting off the head, as must be done to those trees which have had one year's growth in the nursery; for these trees do not care for those large amputations, especially some of the more tender sorts; and by this method of planting these trees in bud no time will be lost, when it is considered that the trees which have shot, must be cut down, and there is a hazard of their shooting again; therefore I am convinced from experience, that it is the best method.

After you have thus planted your trees, which have made

their shoots in the nursery, you should fasten their heads to the wall, to prevent their being shaken by the wind, which would disturb their roots, and break off the tender fibres soon after they were produced, to the no small prejudice of the trees; you should also lay some mulch upon the surface of the ground about their roots, before the frost sets in, to prevent it from penetrating the ground, which would injure, if not destroy the small fibres; but this mulch should not be layed upon the ground too early, lest it prevent the autumnal rains from penetrating to the roots.

These things being duly observed, they will require no farther care till the beginning or middle of *March*, according as the season is early or late; you must cut off the heads of the new planted trees, leaving only four or five eyes above the bud; in doing of which, you must be very careful not to disturb their roots; to prevent which, you should place your foot down close to the stem of the tree, and take fast hold of that part of the stock below the bud with one hand, to hold it steady, while with the other hand you gently slope off the head of the tree with a sharp knife at the intended place, which should always be just above an eye; this should be done in dry weather, for if there should be much rain soon after, there will be some danger that the wet will enter the wounded part, and damage the tree; nor should it be done in frosty weather, for the same reason; for that would enter the wounded part, and prevent its healing over. After you have headed the trees, you should gently loosen the earth of the borders, for the fibres of the roots to strike out; but you must be very careful in doing of this, not to injure their new roots, which would damage them; and if the mulch which was laid about their roots in autumn be rotten, you may dig it into the border at some distance from the roots of the trees; and when the dry weather comes on, you should pare off some turf from a pasture ground, which should be laid upon the surface of the border about the roots of the trees, turning the Grass downward, which will preserve a gentle moisture in the earth, better than any other sort of mulch; and this will not harbour insects, as most sorts of dung and litter do, to the no small detriment of the trees.

Those trees which are planted in bud, and have not made any shoots, should have their stocks cut down at this season just above the bud, for the buds will rarely shoot unless this is performed; and the nearer they are cut to the bud, the sooner will the head of the stock be covered by the buds; for although it may be necessary to leave a part of the stock above the bud, in those trees which are in the nursery, to which the shoots made by the buds may be fastened, to prevent their being broken by the wind, yet as these are planted against the wall, to which the shoots may be fastened, there will be no want of any part of the stock.

In watering of these new planted trees, which should not be done unless the spring proves very dry, you should observe to do it with a nozzle on the watering pot, so as to let it out in drops; for when it is hastily poured down, it causes the ground to bind; and if you water over the head of the tree, it will be of great service to it. Your waterings should not be repeated too often, nor should they be given in great quantity, both which are very injurious to new planted trees.

In the middle of *May*, when these trees will have put out several shoots six or eight inches in length, you should nail them to the wall; observing to train them horizontally, rubbing off all foreright shoots, or such as are weak, whereby those which are preserved will be much stronger; but if there are not more than two shoots produced, and those very strong, you should at the same time nip off their tops, which will cause each of them to push out two or more shoots, whereby the wall will be better supplied with branches;

you must also continue to refresh them with water in dry weather, during the whole season, otherwise they will be apt to suffer; for their roots having but little hold of the ground the first year after transplanting, if the season should prove very dry, it will greatly retard their growth, if due care be not taken to water them.

In the beginning of *October*, when you observe the trees have done shooting, you should prune them; in doing of which, you must shorten the branches in proportion to the strength of the tree; which, if strong, may be left eight inches long, but if weak, should be shortened to four or five; then you should train them horizontally to the wall (as was before directed), so that the middle of the trees may be void of branches, for that part of the tree will be easily furnished with wood afterwards; whereas, if the shoots are trained perpendicularly to the wall, those which are the strongest will draw the greatest share of the sap from the roots, and mount upwards; so that the side branches will be deprived of their nourishment and grow weaker, until they many times decay; and this is the reason, that we see so many Peach trees with one or two upright shoots in the middle, and the two sides wholly unfurnished with branches, whereby the middle of each tree cannot produce any fruit, that being filled with large wood, which never produces any bearing shoots. Nor can the two sides of the trees be regularly filled with fruitful branches, when this defect happens to them; therefore this method should be carefully observed in the training up young trees, for when they are permitted to run into disorder at first, it will be impossible to reduce them into a regular healthful state afterwards, the wood of these trees being too soft and pithy to admit of being cut down (as may be practised on many other hardy fruit trees, which will shoot out vigorously again); whereas these will gum at the places where they are wounded, and in a few years entirely decay.

The spring following, when the trees begin to shoot, you should carefully look over them, to rub off all fore-right shoots, or such as are ill placed, and train those which are designed to remain horizontally to the wall, in their due order as they are produced, for this is the principal season when you can best order the trees as you would have them; whereas, if they are neglected until *Midsummer*, as is the common practice, a great part of the nourishment will be exhausted by fore-right shoots, and other useless branches, which must afterwards be cut off; and hereby the remaining shoots will be rendered very weak, and perhaps some part of the wall be entirely unfurnished with branches; which might have been easily supplied in the beginning of *May*, by stopping some of the stronger shoots in such parts of the tree where there is a necessity for more branches; which would cause each of them to shoot out two or more side branches below the ends of the shoots, which may be guided into the vacant parts of the tree as they are produced, so as that every part may be regularly furnished with proper wood, which is the greatest beauty and excellency of wall trees; but you should always forbear stopping the shoots in summer, where there is not a necessity for branches to fill the wall; for there cannot be a greater fault committed, than that of multiplying the number of shoots, so as to cause a confusion, whereby the branches will be too weak to produce good fruit; besides, when they are too close laid in against the wall, the air is excluded from the shoots by the great number of leaves, so that they are never duly ripened; and consequently, what fruit is produced thereon, cannot be so well tasted as those which are produced upon such trees where the shoots receive all the advantages of sun and air to bring them to maturity.

In the pruning of Peach and Nectarine trees (which re-

quire the same management) the two following rules should be strictly observed, *viz.* First, That every part of the tree be equally furnished with bearing wood; and secondly, That the branches are not laid in too close to each other, for the reasons before laid down (with some others, which will be hereafter intersetted). As to the first, it must be observed, That all these trees produce their fruit upon the young wood, either of the preceding year, or at most, the two years shoots, after which age they do not bear; therefore the branches should be shortened so, as to cause them to produce new shoots annually in every part of the tree; which cannot be done in the ordinary method of pruning, where persons neglect their trees at the season when they are most capable of management, which is in *April*, *May*, and *June*; at which time the luxuriant growth of branches may be checked by pinching, and new shoots produced where they are wanting, by stopping the neighbouring branches; which shoots, being produced at that season, will have time enough to ripen and gain strength, before the autumn comes on; whereas all those shoots which are produced after the middle of *June*, will be crude and pithy; and though they may sometimes produce a few blossoms, yet those rarely bring fruit. Therefore those persons who only regard their wall trees at two different seasons, *viz.* the winter and *Midsummer* pruning, cannot possibly have them in good order; for when all the branches which were produced in the spring, are permitted to remain until the middle or latter end of *June* (as is the common practice), some of the most vigorous will draw the greatest part of the nourishment from the weaker branches, which, when the strong ones are taken off, will be too weak to produce fair fruit; and hereby the strength of the tree is exhausted, to nourish the useless branches which are annually cut off again; and thus are too many trees managed, and at the same time complaints made of their luxuriancy; because two or three shoots, by drawing the greatest share of the nourishment, grow very strong and woody (whereas, if the nourishment had been equally distributed to a regular quantity of branches, there would be no sign of their too great strength); but by often cutting off these vigorous branches, the trees are entirely destroyed, or at least rendered so weak as not to be able to produce fruit. It is therefore of the greatest consequence to wall trees, especially of these sorts, to go over them two or three times in the months of *April* and *May*, to rub off all irregular shoots, and to train in the branches that are left in due order to the wall, that each shoot may have an equal advantage of sun and air, both of which are absolutely necessary to ripen and prepare the wood for the next year's bearing; therefore the oftener the trees are looked over to divert them of these useless branches, from the time they first begin to shoot in the spring till the autumn, the better will the wood be ripened for the succeeding year.

And by duly observing this in summer, there will not be occasion for so much cutting, as is often practised on Peach trees, to their great injury; for their wood branches are generally soft, tender, and pithy, which, when greatly wounded, are not healed over again so soon as many other sorts of trees.

The distance which the branches of these trees should be allowed against the wall, must be proportioned to the size of the fruit or the length of the leaves; for if we observe how the branches of trees are naturally disposed to grow, we shall always find them placed at a greater or less distance, as their leaves are larger or smaller. And there is no surer guide to a curious artist than nature, from whence a gardener should always be directed in every part of his profession, since his business is to aid and assist nature, where she is not capable of bringing her productions to maturity;

or where there is room, to make considerable improvements by art; which cannot be any otherwise effected, than by gently assisting her in her own way.

But to return to pruning of these trees: The branches being carefully trained in, as before directed, in the spring and summer seasons, we come now to treat of the winter pruning, which is commonly performed in *February* or *March*. But the best season for this work is in *October*, when their leaves begin to fall, which will be early enough for their wounds to heal, before the frost comes on, so that there will be no danger of their being hurt hereby; and the branches of the trees being proportioned to the strength of the roots at that season, all the ascending sap in the spring will be employed to nourish only those useful parts of the branches which are left; whereas, if they are left unpruned till *February*, the sap in the branches being then in motion, as may be observed by the swelling of the buds, the greatest part of it will be drawn up to the extreme parts of the branches, to nourish such blossoms as must be afterwards cut off; and this may be easily known, by observing the strongest shoots at that season, when you will find the extreme buds to swell faster than most of the lower ones; for there being no leaves then upon the branches to detain the sap to nourish the lower buds, the upper ones will always draw from those below.

But suppose it were no advantage to the trees to prune them at this season (which I think no one will have reason to doubt after making the trial), but that it only succeeds as well as the spring pruning; yet there is a great advantage in doing of it in autumn, for that being a much more leisure season with gardeners than the spring, they will have more time to perform it carefully; and then they will not have too many things come together, which may require to be immediately executed; for the spring being the principal season for cropping their kitchen gardens and attending their hot-beds, if they are disengaged from the business of pruning at that time, it will be of great advantage, especially where there is a great quantity of walling. And here is also another benefit in pruning at this season, which is, the having the borders at liberty to dig and make clean before the spring, so that the garden may not appear in litter at that season.

In pruning of these trees, you should always observe to cut them behind a wood bud, which may be easily distinguished from the blossom buds, which are shorter, rounder, and more turgid than the wood buds; for if the shoot have not a leading bud where it is cut, it is very apt to die down to the next leading bud; so that what fruit may be produced above that, will come to nothing, there being always a necessity of a leading bud to attract the nourishment; for it is not sufficient that they have a leaf bud, as some have imagined, since that will attract a small quantity of nourishment, the great use of the leaves being to perspire away such crude juices as are unfit to enter the fruit. The length you should leave these branches, should be proportioned to the strength of the tree, which, in a healthy strong tree, may be left ten inches or more, but in a weak one, they should not be more than six inches; however, in this you must be guided by the position of a leading bud, for it is better to leave a shoot three or four inches longer, or cut it two or three inches shorter than we would choose to do, provided there be one of these buds, it being absolutely necessary for the future welfare of the branches; you should also cut out entirely all weak shoots, though they may have many blossom buds upon them; for these have not strength enough to nourish the fruit, so as to give it a kindly flavour, but they will weaken the other parts of the tree.

In nailing the shoots to the wall, you must be careful to place them at as equal distances as possible, that their leaves,

when come out, may have room to grow, without shading the branches too much; nor should you ever nail them upright if it can be avoided; for when they are thus trained, they are very subject to shoot from the uppermost eyes, and the lower part of the shoots will thereby become naked.

There is not any thing in the business of gardening, which has more exercised the thoughts of the curious, than how to preserve their tender sorts of fruit from being blighted in the spring of the year, and yet there has been little written upon this subject, which is worth notice: some have proposed mattresses of Straw or Reeds to be placed before the fruit trees against walls, to prevent their being blasted; others have directed the fixing horizontal shelters in their walls, to prevent the perpendicular dew or rain from falling upon the blossoms of the fruit trees, which they suppose to be the chief cause of their blighting; but both these contrivances have been far from answering the expectations of those persons who have put them in practice, as I have elsewhere shewn; therefore it may not be improper to repeat some things in this place, which I have before mentioned, in relation to this matter. And,

First, I have already said, that the blights which are so often complained of, do not always proceed from any external cause or inclemency in the season, but from a distemper or weakness in the trees; for if we observe the trees at that season, where they are most subject to what is called a blight, we shall find the branches very small, weak, and not half ripened, as also trained in very close to each other; these branches are, for the most part, full of blossom buds (which is chiefly occasioned by their want of strength). These buds do indeed open, and to persons not skilled in fruit trees, shew a great prospect of a plentiful crop of fruit; whereas the whole strength of the branches is spent in nourishing the flowers, and being unable to do more, the blossoms fall off, and the small efforts of the leaf buds are checked, so that many times the greatest part of the branches die away, and this is called a great blight; whereas at the same time it may be often observed, that some trees of a different sort, nay, even some of the same sort, which were stronger, though placed in the same soil, exposed to the same aspect, and subject to the same inclemency of air, have escaped very well, when the weak trees have appeared to be almost dead; which is a plain indication, that it proceeds from some cause within the tree, and not from any external blight. All this will therefore be remedied, by observing the foregoing directions in the pruning and management of the trees, so as never to over-burden them with branches, nor to suffer any part of the trees to exhaust the whole nourishment from the root, which will cause the other parts to be very weak; but to distribute the nourishment equally to every shoot, that there may be none too vigorous, at the same time that others are too weak; and by continually rubbing off useless or fore-right shoots as they are produced, the strength of the trees will not be spent, to nourish such branches as must be afterwards cut out, which is too often seen in the management of these trees. And,

Secondly, It sometimes happens, that the roots of these trees are buried too deep in the ground, which, in a cold or moist soil, is one of the greatest disadvantages that can attend these tender fruits; for the sap which is contained in the branches, being by the warmth of the sun put strongly into motion early in the spring, is exhausted in nourishing the blossoms; and a part of it is perspired through the wood branches, so that its strength is lost before the warmth can reach to their roots, to put them into an equal motion in search of fresh nourishment, to supply the expence of the branches; for want of which, the blossoms fall off and decay, and the shoots seem to be at a stand, until the farther

advance

advance of the warmth penetrates to the roots, and sets them in motion; when suddenly after, the trees, which before looked weak and decaying, make prodigious progress in their shoots; and before the summer is spent, are furnished with much stronger branches than those trees which have the full advantage of sun and showers, and that are more fruitful and healthy. If therefore this be the case, there is no way of helping this, but by raising up the trees, if they are young; or if they are too old to remove, it is the better way to root them out, and make new borders of fresh earth, and plant down young trees; for it is a great vexation to be at the trouble and expence of pruning and managing these trees, without having the pleasure of reaping any advantage from them, which will always be the case where the trees are thus injudiciously planted. Or,

Thirdly, This may proceed from the trees wanting nourishment, which is many times the case, where they are planted in a hard gravelly soil, in which it is the common practice to dig borders three or four feet wide, and three feet deep into the rock of gravel, which is filled with good fresh earth, into which the trees are planted, where they will thrive pretty well for two years, until their roots reach the gravel, where they are confined, as if planted in a pot; and, for want of proper nourishment, the branches continually decay every year. This cannot be helped, where the trees have been growing some years, without taking them entirely up, or by digging away the gravel from their roots, and adding a large quantity of fresh earth, that may afford them a supply of nourishment a few years longer; but trees so planted, cannot by any art be continued long in health.

But if the unfruitfulness of the trees does not proceed from any of the before-mentioned causes, and is the effect of unkindly seasons; then the best method yet known is, in dry weather, when little dew falls, to sprinkle the branches of the trees gently with water soon after the blossoming season, and while the young-set fruit is tender; which should always be done before noon, that the moisture may evaporate before the night comes on; and if in the night you carefully cover the trees with mats, canvas, or some such light covering, it will be of great service to them: however, where the trees are strong and vigorous, they are not so liable to suffer by a small inclemency, as are those which are weak; so that there will be few seasons in which there may not be hopes of a moderate quantity of fruit from them, though there should be no covering used; for where these coverings are used, if it is not performed with great care and diligence, it is much better to have no covering, but trust to the clemency of the season; for if the coverings are kept too close, or continued too long, the trees will receive more injury hereby, than from being constantly exposed; or if after they have been covered for some time, and then incautiously removed, so as to expose the trees too suddenly to the open air, they will suffer more thereby, than if they had not been covered. However, I must repeat in this place what has been before mentioned under another article, of a management which has been generally attended with success, which is, the putting up two feather-edge deal boards joined together, over the top of the trees, so as to form a penthouse to cast off perpendicular wet. These should be fixed up when the trees begin to blossom, and should remain till the fruit is well set, when they should be taken down, to admit the dew and rain to the leaves and branches of the trees, which must not be longer kept off; and where the wall is long, and exposed to currents of wind, if at the distance of forty feet from each other are fixed some cross Reed hedges, to project about ten feet from the wall; these will break the force of the wind, and prevent its destroying of the blossoms; and these may be

removed away, as soon as the danger is over. Where these things have been practised, they were generally attended with success; and as there will be no trouble of covering and uncovering in this method, after they are fixed up, there can be no danger of neglect, as very often is the case when the trouble is great, or to be often repeated.

When your fruit is set, and grown to the bigness of a small nut, you should go over the trees and thin them, leaving them at least five or six inches asunder; for when they are permitted to remain in bunches, as they are often produced, the nourishment which should be employed wholly to the fruits designed to stand, will be equally spent amongst the whole number, a great part of which must be afterwards pulled off; so that the sooner this is done, the better it will be for the remaining fruit; and if it should sometimes happen, that a part of those left, by any accident, should be destroyed, yet the remaining ones will be much the larger and better tasted for it, and the trees will gain more strength, for a moderate quantity of fruit is always preferable to a great crop; the fruit, when but few, will be much larger, better tasted, and the trees in a condition to bear well the succeeding year; whereas, when they are overcharged with fruit, it is always small, ill tasted, and the trees are generally so much weakened thereby, as not to be in a condition for bearing well for two or three years after; so that upon the whole, it is much better to have a smaller number of fruit than is commonly esteemed a crop, than to have too many, since the fruit and also the trees, are benefited thereby. The quantity of fruit to be left on large full grown trees, should never be greater than five dozen upon each; but on middling trees, three or four dozen will be enough.

If the season should prove hot and dry, it will be proper to draw up the earth round the stem of each tree, to form a hallow basin of about six feet diameter, and cover the surface of the ground in this basin with mulch; and once in a week or fortnight, according to the heat and drought of the season, pour down eight or ten gallons of water to the root of each tree; or where there is an engine, which will disperse the water in gentle easy drops like rain, if the same, or a larger quantity of water, is sprinkled all over the branches of the trees, and this, soaking down to the roots, will keep the fruit constantly growing, which will prevent their falling off the trees, as they generally do where this method is not practised; and the fruit being thus constantly nourished, will be much better tasted, and hereby the trees will be maintained in vigour; so that it is what I can from long experience recommend, as one of the most necessary things to be practised by all lovers of good fruit. But this should not be continued longer than while the fruit are growing, for afterward it will be hurtful to the trees and fruit, for a dry autumn ripens both wood and fruit better than a moist latter season.

It is a common opinion which has for some years prevailed, even among persons of good understanding, that Peach trees are not long lived, therefore should be renewed every twenty years; which is a great mistake, for I have eaten some of the finest Peaches of various kinds, from trees which had been planted above fifty years: and I am convinced by experience, that when the trees are budded upon proper stocks, carefully planted and managed, they may be continued fruitful and healthy sixty years and upward; and the fruit produced on these old trees, will be much better flavoured than any of those upon young ones; but I suppose the foundation of the above opinion was taken from the *French*, who generally bud their Peaches upon Almond stocks, which are of short duration, these seldom lasting good more than twenty years; but this being seldom practised in *England*, the case is widely different; nor indeed should we fetch our examples from that nation,

nation, where the professors of the art of gardening are at least a century behind the *English*; and, from their present disposition, seem unlikely to overtake them; for they depart from nature in almost every part of gardening, and are more pleased with introducing their little inventions of pruning and managing their fruit trees, according to their own fancy, than they are careful to draw their instructions from nature, from whence the true art is to be obtained; so that in very few instances gardeners should deviate from nature, unless it be in those particulars, where art may be practised to the greatest advantage, which is in the procuring many sorts of esculent plants and fruits, earlier and better flavoured than can be obtained without, in which the *French* are extremely deficient; and herein they trust too much to nature, and use too little art.

I must recommend the dunging of the borders for fruit trees every other year, with this caution, always to use such dung for their borders, as is well rotted, and to dig it into the borders in *November*, that the rain may wash down the salts before the spring comes on; and where the ground is very loose or sandy, it will be the best way to make use of neats dung, which is cooler than that of horses, but for cold strong land the latter is to be preferred.

If the ground is well-trenched every year about the roots, it will be of great service to them; and where the soil is subject to bind very close, if it is forked two or three times in a year to loosen the surface, it will greatly help the trees. The borders should not be crowded with any large growing plants, which will draw away the nourishment from the trees; therefore when any sort of kitchen herbs are planted on these borders, they should be only such as are of small growth, and which may be taken off early in the spring; and if this is carefully observed, the cultivating small things on these borders can do no harm, because the ground will be stirred the oftener, on account of these small crops, than perhaps it would have been, when no use was to be made of the borders. These rules which are here laid down, if properly observed, will direct any curious person how to have plenty of good fruit, as also to preserve the trees in vigour a great number of years.

PERSICARIA. *Tourn. Inst. R. H. 509. tab. 290.* Arse-smart.

The Characters are,

The flower hath no empalement. It hath one petal, which is permanent, and cut into five segments, which spread open; it has in some species five, and in others six short stamina, terminated by roundish summits, and a three-cornered germen, supporting two or three short slender styles crowned by single stigmas. The germen afterward becomes a roundish acute-pointed seed, wrapped up in the petal of the flower.

The Species are,

1. PERSICARIA *foliis lanceolatis, floribus hexandris, stylo bifido.* Arse-smart with spear-shaped leaves, flowers with six stamina, and a bifid style; Water Pepper.

2. PERSICARIA *floribus hexandris digynis, spicis ovatis oblongis, foliis lanceolatis acutis.* Arse-smart with flowers having six stamina and two styles, oblong oval spikes of flowers, and acute-pointed spear-shaped leaves; Spotted Arse-smart.

3. PERSICARIA *floribus octandris tryginis racemosis, foliis lanceolatis, caule divaricato patulo.* Arse-smart with bunches of flowers having eight stamina and three styles, spear-shaped leaves, and spreading stalks.

4. PERSICARIA *foliis ovato-lanceolatis acutis, floribus pentandris, caule erecto.* Arse-smart with oval, spear-shaped, acute-pointed leaves, flowers having five stamina, and an erect stalk.

There are several other species of this genus, some of which grow naturally in *England*, but as they are common weeds, they are not admitted into gardens, therefore it

would be to little purpose enumerating them. The two first here mentioned are troublesome weeds, the first growing in moist ground by the sides of ditches and ponds in most parts of *England*; the roots of this are perennial, and creep far in the ground, so as to overspread large tracts of land. The other is an annual plant, which grows plentifully on dunghills, and in moist ground every where; but as these two plants are used in medicine, I have mentioned them here to introduce the other. The first sort has been accounted an extraordinary plant against the stone. Mr. *Boyle* having in his book of the usefulness of experimental philosophy, given a mighty character of the distilled juice of this plant, for its virtues against that distemper.

The third sort grows naturally in *Siberia*. This hath a perennial creeping root, composed of many strong ligneous fibres. The stalks rise about three feet high, and divide into many confused branches, which are generally bent at each joint; these are garnished with narrow, spear-shaped, smooth leaves, of a light green, ending in acute points. The flowers are produced in loose spikes branching out from the end of the stalks; they are white, and of the same construction with the other species, but have eight stamina and three styles.

The seeds of the fourth sort were sent to *Europe* by Dr. *Tournefort*, who saw it first growing in the prince of *Teflis*'s garden in *Georgia*, and afterward in the garden of the *Monks* of the three churches near mount *Ararat*, but he could not learn where it grew naturally. They cultivate this plant in the gardens of *Georgia* and *Armenia*, not only for the beauty of its flowers, but also for the virtues, with which the plant is possessed, which are nearly the same with those attributed to the *European* Arse-smart.

This plant is annual, decaying with the first frosts in the autumn; it rises from the scattered seeds much better than if sown, but where it is sown, it should always be done in the autumn, soon after the seeds are ripe. The plants rise with a strong upright stalk to the height of eight or ten feet, and grow to the size of an ordinary walking stick; the lower part of the stalk becomes ligneous and tough; the joints are like those of the Reed or Cane. At each joint is placed one leaf; these stand alternately on the stalk; the lower leaves, which are the largest, are often more than a foot long, and six inches broad in the middle, lessening toward the end, and terminating in a long acute point, having a strong longitudinal midrib, with several transverse veins running from it toward the edges. The upper surface is of a bright green, a little hairy; the under of a pale green, and much more hairy; the lower leaves have pretty long foot-stalks, which are broad at their base, and half surround the stalks. The upper part of the stalk branches out into many divisions, each being terminated by two or three close spikes of purple flowers, which are seven or eight inches long, and have their points hanging downward; these flowers have no empalement according to Mr. *Ray* and others, or no petals according to *Tournefort*, the former calling the covers to the parts of generation, petals, if they are coloured, and the latter terming those covers, the empalement, where there are no other, whether they are green or coloured. This plant begins to shew its flowers toward the latter end of *July*, and continues in beauty, till the frost in the autumn puts a stop to them.

PERVINCA. See Vinca.

PETASITES. *Tourn. Inst. R. H. 451. tab. 258.* Butterbur.

The Characters are,

It hath a flower composed of several hermaphrodite florets, which are included in one common cylindrical empalement, which are tubulous or funnel-shaped, of one petal, cut into five segments at the brim; they have each five small hair-like stamina, terminated

nated by cylindrical summits, and a short germen, crowned with down, supporting a slender style crowned by a thick stigma. The germen afterwards becomes an oblong compressed seed, crowned with a hairy down.

The Species are,

1. *PETASITES thyrso ovato sessili, foliis obcordatis angulatis serratis.* Butter-bur with a short oval spike of flowers, and heart-shaped, angular, sawed leaves; common Butter-bur.

2. *PETASITES thyrso fastigiato, scapo crassissimo folioso, foliis inaequaliter serratis, pediculis tenuioribus.* Butter-bur with a close compact spike, a very thick leafy stalk, leaves unequally sawed, and slender foot-stalks; smaller Butter-bur.

3. *PETASITES foliis cordato-hastatis serratis infernè tomentosis.* Butter-bur with heart-shaped, halberd-pointed, sawed leaves, which are woolly on their under.

4. *PETASITES scapo longissimo, thyrso oblongo, pedunculis longissimis, foliis cordatis amplioribus.* Butter bur with a very long flower-stalk, an oblong spike of flowers, the longest foot-stalks, and the largest heart-shaped leaves.

5. *PETASITES scapo subnudo unifloro, foliis cordato-orbiculatis crenatis.* Butter-bur with a stalk almost naked, having one flower, and round, heart-shaped, crenated leaves.

The first here mentioned is the common Butter-bur or Pestilent Wort, which grows naturally by the side of rivers and ditches in most parts of England. This hath a root composed of large fleshy fibres, as big as a man's finger, which creep near the surface of the ground, but do not strike deep, nor have they many small fibres. From these, early in the spring, arise hollow thick stalks five or six inches high, terminated by an oval spike of purplish flowers sitting close to the stalk. Each flower is composed of four or five hermaphrodite florets, inclosed in one common empalement; these appear in March, and when they fade, are each succeeded by one compressed seed crowned with hairy down. It is never cultivated in gardens, but being a medicinal plant, I have mentioned it.

The roots of this are sudorifick, alexipharmick, and good for all kinds of fevers, and malignant, infectious, and pestilential distempers; they are cordial, preventing fainting and shortness of breath. A good quantity of this root is put into the Treacle water.

The fourth sort was found growing naturally in Oxfordshire by Mr. Jacob Bobart, gardener of the physick garden at Oxford. The flower-stalks of this are thicker, and rise more than two feet high; the spikes of flowers are a foot long; each flower stands on long foot-stalks, and the leaves of the plant are larger, and have longer foot-stalks than those of the common sort, and the flowers come later in the spring. This is kept in botanick gardens to increase the variety of plants, but is rarely admitted into any other.

The three other sorts grow naturally on the Alps and other mountainous places in Europe; they are of much less growth than either of the former, especially the fifth sort, whose leaves are small and round. The flower-stalks are not more than four inches high; they are almost naked, and sustain a single yellowish flower on the top. The others have short spikes of flowers; those of the second sort are collected in little bunches, and form a thick roundish spike, but those of the third sort are more like the first.

PETIVERIA. Plum. Nov. Gen. 50. tab. 39. Guiney Henweed.

The Characters are,

The flower hath a permanent empalement. It hath four small white petals, placed in form of a cross, which soon fall off, and six awl-shaped erect stamina, terminated by single summits. In the center is situated an oblong compressed germen, with four awl-shaped styles. The germen afterwards becomes one oblong seed, narrow at the bottom and taper, but broad, and indented at the top, resembling an inverted shield armed with the acute style, which is reflexed.

We know but one Species of this plant, viz.

PETIVERIA. Hort. Cliff. 141. commonly called Guiney Henweed.

It is a very common plant in Jamaica, Barbadoes, and most of the other islands in the West-Indies, where it grows in such plenty, as to become a very troublesome weed. The roots are strong, and strike deep in the ground; the stalks are jointed, and rise from two to three feet high, garnished with oblong veined leaves, of a deep green, placed alternately upon short foot-stalks. The flowers are produced in slender spikes at the end of the branches; they are very small, so make no figure.

In Europe this plant is preserved in the gardens of those persons, who are curious in botany; but there is little beauty in it, and having a strong rank scent upon being handled, renders it less valuable. It is propagated by seeds, which must be sown on a hot-bed early in the spring, and when the plants are come up, they should be each transplanted into a separate pot, and plunged into a moderate hot-bed to bring them forward. When they have obtained a good share of strength, they should be inured to bear the open air by degrees, into which they may be removed toward the latter end of June, placing them in a warm situation, where they may remain till autumn, when they should be removed into the stove, and in winter must have a moderate degree of warmth, otherwise they will not live in this country.

PETREA. Houfl. Gen. Nov. Lin. Gen. Plant. 682.

The Characters are,

The flower hath an empalement of one leaf, cut into five obtuse segments. It hath one petal, with a short tube, cut above into five almost equal segments, which are expanded. It hath four short stamina, situated in the tube, two of which are a little longer than the other, terminated by single summits, and four germen supporting a short style, crowned by an obtuse stigma. The germen afterwards become four seeds wrapped up in a fringed cover.

We have but one Species of this genus, viz.

PETREA frutescens foliis lanceolatis rigidis, flore racemoso pendulo. Shrubby Petrea with stiff spear shaped leaves, and flowers growing in long hanging bunches.

This plant was first discovered by the late Dr. Houfloun, growing naturally at La Vera Cruz in New Spain. It rises with a woody stalk to the height of fifteen or sixteen feet, which is covered with a light gray bark, sending out several long branches; these have a whiter bark than the stem, and are garnished with leaves at each joint, which on the lower part of the branches are placed by threes round them, but higher up they stand by pairs; they are stiff, and their surface rough; of a light green, having a strong dark midrib, with several transverse veins running from the midrib to the borders, which are entire. The flowers are produced at the end of the branches growing in loose bunches, which are nine or ten inches long, each flower standing upon a slender foot stalk about an inch long; the empalement of the flower is composed of five narrow obtuse leaves about an inch long, which are of a fine blue colour, so are much more conspicuous than the petals, which are white, and not more than half the length of the empalement. After the flower is past, the four germen in the center become so many oblong seeds wrapped up in a fringed cover.

This is propagated by seeds, which must be obtained from the places where the trees grow naturally, and these are very few good; for, from the seeds which the Dr. sent to England, there were but two plants raised, though the seeds were distributed to several persons. The seeds must be sown in a good hot-bed, and when the plants come up, they should be each planted in a separate small pot filled with light loamy earth, and plunged into a hot-bed of tanners bark, and afterwards placed in the bark bed in the stove,

rove, where they should constantly remain, and be treated like other plants of the same country.

PETROSELINUM. See Apium.

PEUCEDANUM. *Tourn. Inst. R. H.* 318. *tab.* 169. Hogs-fennel, or Sulphur-wort.

The Characters are,

It hath an umbelliferous flower. The cover of the large umbel is composed of many linear reflexed leaves. The empalement of the flower is small and indented in five parts. The petals of the great umbel are uniform. Each flower is composed of five oblong incurved petals, which are entire; they have each five hair-like stamina, with an oblong germen situated under the flower, supporting two small styles crowned by obtuse stigmas. The germen afterward turns to an oval fruit channelled on each side, splitting in two parts, containing two seeds convex on one side, compressed on the other, with three raised furrows, and a broad membraneous border indented at the top.

The Species are,

1. PEUCEDANUM *foliis tripartitis filiformibus longioribus umbellis circinatis.* Hogs-fennel with leaves which are divided by threes, and these are again divided into three linear parts.

2. PEUCEDANUM *foliis tripartitis filiformibus linearibus umbellis difformibus.* Hogs-fennel with leaves cut into three parts, which are long, slender, and have irregular umbels; Greater Italian Hogs-fennel.

3. PEUCEDANUM *foliis quinquies tripartitis filiformibus brevioribus, umbellâ maximâ.* Hogs-fennel with five leaves divided by threes, which are very slender and short, and a very large umbel.

4. PEUCEDANUM *foliis tripartitis capillaribus, caule ramossimo patulo, umbellis difformibus.* Hogs-fennel with very narrow hair-like leaves divided by threes, a very branching spreading stalk, and irregular umbels.

The first sort is said to grow naturally in England, but I have not been lucky enough to find it, though I have searched the places where it is mentioned to have been found; it grows in several parts of Germany in marshy meadows. This hath a perennial root, from which arise the foot-stalks of the leaves which are channelled; these are naked at bottom, but about four or five inches from the root branches into three smaller foot-stalks, and these again divide into three, and each of these divisions sustain three narrow leaves, which when bruised emit a strong scent like sulphur. The stalks rise near two feet high; these are channelled, and divide into two or three branches, each being terminated by a large regular umbel of yellow flowers, composed of several small umbels, which are circular.

The second sort grows naturally on the mountains, and also in the low valleys by the sides of rivers in Italy. The root of this is perennial; the foot-stalks of the leaves are large and furrowed, dividing into three small branches, which are again divided into three, and these end with three long narrow lobes or small leaves, which are much longer than those of the other sort. The stalks, which sustain the umbels, rise near three feet high, and divide toward the top into several small branches, each sustaining an umbel, composed of several smaller rays or umbels, which stand upon very long foot stalks. The flowers of this are yellow, and shaped like those of the former, but are much larger, as are also the seeds, but have the same form as the other.

The third sort grows naturally in the forest of Fontaine-bleau, and many other parts of France. It hath a strong perennial root, from which come out leaves, which branch into three divisions, and these divide again into three smaller; each of these smaller divisions are garnished with five short narrow leaves. The stalks are strong, round, and not so deeply channelled as either of the former, sustaining a very large umbel of yellow flowers, shaped like

those of the former sorts; the seeds are shorter, but of the same shape as those.

The fourth sort grows naturally on St. Vincent's rock near Bristol. This is a biennial plant, which perishes soon after it has perfected its seeds. The leaves of this sort are short and very narrow, spreading near the surface of the ground; the stalks rise near a foot high, but are branched almost from the bottom; these branches are almost horizontal, and are garnished with a few narrow short leaves, of a lucid green. Each stalk is terminated by a small umbel of flowers, which are of an herbaceous yellow colour and small. These are succeeded by small channelled seeds.

These sorts are preserved in botanick gardens for the sake of variety; they are all propagated, by seeds, which should be sown in the autumn soon after they are ripe; for those which are sown in the spring seldom succeed, or if the plants come up, it is rarely before the following spring. When the plants come up, they must be kept clean from weeds, and the autumn following they may be transplanted where they are to remain; they love a moist soil and a shady situation, but will not thrive under the drip of trees. The roots of the three first sorts will continue several years, and every year produce flowers and seeds. The fourth sort will rarely ripen seeds in a garden, so that I have been obliged to procure them from the place where it grows naturally.

PHACA. *Lin. Gen. Plant.* 798. Bastard Milk-vetch.

The Characters are,

The flower hath a tubulous empalement, cut into five small indentures at the brim. It is of the butterfly kind, having a large oval erect standard, with two oblong wings, which are shorter, and a short compressed obtuse keel. It hath ten stamina, nine of which are joined in one body, and the other stands separate. In the center is situated an oblong germen, supporting an awl-shaped style, crowned by a single stigma. The germen afterward becomes an oblong swelling pod, whose upper suture is depressed toward the under, having one cell, containing several kidney-shaped seeds.

The Species are,

1. PHACA *caulescens pilosa, leguminibus tereti-cymbiformibus.* *Lin. Sp. Plant.* 755. Phaca with a hairy stalk, and taper boat-shaped pods.

2. PHACA *caulescens erecta glabra, leguminibus semi-ovatis.* *Lin. Sp. Plant.* 755. Phaca with an upright smooth stalk, and half oval pods.

The first sort is a native of Portugal and Spain. This has been long preserved in some curious gardens in England, but the other is more rare at present.

The roots of the first sort, which grow naturally in Portugal, will abide many years, and run very deep into the ground; but the branches decay every autumn, and the roots produce fresh stalks every spring, which will rise near four feet high, and grow ligneous. The flowers are produced in short spikes from the wings of the leaves; but unless the season proves very warm, they rarely flower in England, for which reason the plants are not much esteemed.

The second sort, which is a native of Siberia, hath smooth stalks, which do not rise so high as the former; the flowers are smaller, the pods are much shorter, and hang downwards.

Both these sorts are propagated by seeds, which should be sown in the place where the plants are to remain; for as they shoot their roots very deep into the earth, so it is very difficult to transplant them with any safety, especially after they have remained any considerable time in the seed-bed. The plants should be left about six feet asunder, that there may be room to dig the ground between them every spring, which is all the culture they require, except the keeping them clean from weeds.

PHALANGIUM. See Anthericum.

PHASEOLOIDES. See Glycine.

PHASEOLUS. Tourn. Inst. R. H. 412. tab. 232. Kidney-bean.

The Characters are,

The empalement of the flower is of one leaf. The flower is of the butterfly kind; it hath a heart-shaped, obtuse, inclined standard, reflexed on the sides; the wings are oval, the length of the standard, and a narrow spiral keel twisted contrary to the sun. It hath ten stamina, nine joined in one body, and the other standing separate, and an oblong, compressed, hairy germen, supporting a slender, inflexed, spiral style, crowned by an obtuse hairy stigma. The germen after-ward becomes a long pod, with a thick shell, ending in an obtuse point, inclosing oblong, compressed, kidney-shaped seeds.

It would be to little purpose to enumerate all the varieties of this plant, which have come to our knowledge in this place, since America does annually furnish us with so many new sorts, as that there is no knowing what varieties there may be produced in England: besides, as they are not likely to be much cultivated here, since some of the old sorts are preferable to any of the new ones, for the use of the kitchen-garden; therefore I shall only mention a few sorts, which are cultivated for their flowers, or as curiosities, and then mention those which are most esteemed for the table.

1. PHASEOLUS caule volubili, floribus laxè spicatis, alis longitudine vexillo. Lin. Sp. Plant. 725. Kidney-bean with a twining stalk, and flowers growing in loose spikes, whose wings are as long as the standard.

2. PHASEOLUS caule volubili, vexillis carinâque spiralliter convolutis. Lin. Sp. Plant. 725. Kidney-bean with a twining stalk, whose standard and keel are spirally twisted; commonly called Caracalla in Portugal.

3. PHASEOLUS caule volubili, vexillis revolutis patulis, leguminibus linearibus strictis. Lin. Sp. Plant. 724. Kidney-bean with a twining stalk, a spreading standard which is twisted backward, and narrow close pods.

4. PHASEOLUS caule volubili, pedunculis subcapitatis, seminibus tetragono-cylindricis pulverulentis. Hort. Upsal. 214. Kidney-bean with a twining stalk, foot-stalks ending in flowers growing in heads, and four-cornered, cylindrical, dust-coloured seeds.

5. PHASEOLUS caule volubili, floribus racemosis geminis, bracteis calyce brevioribus, leguminibus pendulis. Lin. Sp. Plant. 724. Kidney-bean with a twining stalk, branching flowers growing by pairs, bractæ which are shorter than the empalement, and hanging pods; commonly called the Scarlet-bean.

6. PHASEOLUS caule volubili, floribus racemosis, siliquis brevibus pubescentibus. Kidney-bean with a twining stalk, flowers growing in long bunches, and short hairy pods.

The first sort is an annual plant. The seeds of this were brought from Carolina, where it grows naturally. The stalks twine about any support, like the common Kidney-bean; they are hairy, and rise four or five feet high; the leaves are shaped like those of the common Kidney-bean, but are narrower. The flowers are produced in loose spikes, standing upon long foot stalks; they are large, and of a purple colour, turning to a blue before they fade.

The seeds of this sort should be sown on a warm border about the latter end of April, and when the plants begin to run up, they must be supported either with sticks, or fastened to a hedge or wall, to prevent their trailing on the ground, and constantly kept clean from weeds. If they are close to a wall or hedge, exposed to a good aspect, they will ripen their seeds in England, otherwise they frequently fall in bad seasons.

The second sort grows naturally in the Brazils. This is a perennial root with twining stalks, which rise to the height of twelve or fourteen feet; the leaves are shaped like those

of the common Kidney-bean, but are smaller. The flowers are produced in slender spikes; they are of a purplish colour, and have an agreeable odour; these are succeeded by slender pods, which are compressed, containing several oval compressed seeds. This is propagated by seeds, which should be sown in a moderate hot-bed in the spring; and when the plants come up, they must be transplanted into pots, filled with light fresh earth, and plugged into a hot-bed, to facilitate their taking root; after which they should be inured to bear the open air by degrees, into which they should be removed the end of June or beginning of July, placing them in a sheltered situation; and as they advance in their growth, and fill the pots with their roots, they should be removed into larger pots, which must be filled up with fresh light earth.

The third sort grows naturally in America, and is preserved in some curious gardens for variety, but is a plant of no great beauty. This may be propagated by sowing the seeds in the spring upon a hot-bed; and when they come up, they must be planted in pots, and treated as the former sort.

The fourth sort was brought from America, and is preserved in some curious gardens, for the sake of its long flowering. This is an abiding plant, and should be managed as was directed for the third sort, but this requires a stove to preserve it through the winter in England.

The fifth sort has been long cultivated in the English gardens for the beauty of its scarlet flowers. This hath twining stalks, which, if properly supported, will rise to the height of twelve or fourteen feet; the leaves are smaller than those of the common Kidney-bean. The flowers grow in large spikes, and are much larger than those of the common Kidney-bean, and of a deep scarlet colour; the pods are large and rough, and the seeds are purple, marked with black. This sort requires no other treatment than the common sort, but the stalks should have tall stakes put down by them to twine round, otherwise they will fall on the ground, which will soon cause them to rot.

Although this sort is chiefly cultivated for the beauty of its flowers at present, yet I would recommend it as the best sort for the table; and whoever will make trial of this, I dare say must prefer it to all the other kinds yet known.

The fifth sort grows naturally in the warmest part of America, so will not thrive in England out of a stove; and as the chief beauty of it is in the seeds, which are half scarlet, and the other half black, so these may be procured from abroad better than raised here.

I shall now mention those sorts of Kidney-beans, which are cultivated in the English gardens to supply the table, which are few in comparison of the number already known; though these are not many of them valuable, and are only cultivated because they require less care, or will come a little forwarder in the season, for they are inferior in taste to the others; however, as there are some persons who esteem them for their qualities before-mentioned, so I shall put them down in the order of their ripening for use.

The three sorts which are usually cultivated for early crops, are the small white Dwarf, the Dwarf black, which is called the Negro-bean, and the Liver Colour-bean. The stalks of these are never very long, so may be planted much nearer together than the larger growing kinds, and they require but little support; so these are planted on hot-beds under frames, or in pots which are placed in stoves, to come early in the spring, for which purpose they are better adapted than any of the other; but they are not to be compared with some of the others for goodness, but as they may be had at a time when the others cannot be so well obtained, so they are generally cultivated in the gardens; and where there are not the convenience of stoves or frames for raising them very early, they are planted in

warm borders near hedges, walls, or pales, where they will be fit for use a fortnight earlier than the other sorts.

The next to these are the *Battersea* and *Canterbury* Kidney-beans; these do not ramble far, and produce their flowers near the root, so bear plentifully for some time: the *Battersea* Bean is the forwarder of the two, but the other will continue bearing much longer; they are both better flavoured than either of the three former sorts, but when they begin to be large, are very stringy and tough.

There are two or three sorts of Kidney-beans cultivated with erect stalks, which want no support, as they do not put out any twining stalk. These are much cultivated by the gardeners for that reason, as also for their producing a great plenty of pods; but they are inferior in goodness to all the other, especially that sort with black and white seeds, whose pods have a rank flavour, and, when boiled, become soft and mealy, so this should never be propagated by persons of taste.

The best sorts for the table are the scarlet blossom Bean before-mentioned, and a white Bean of the same size and shape, which appears to be only a variety of the scarlet, as it differs in no other respect, but the colour of the flowers and seeds, being equal in size and flavour. And next to these is the large *Dutch* Kidney-bean, which grows as tall as either of these, so must be supported by stakes, otherwise their stalks will trail upon the ground and spoil. The sort with scarlet flowers is preferable to this in goodness, and is also hardier; and although it will not come so early as some of the dwarf kinds, yet as it will continue bearing till the frost puts a stop to it in the autumn, so it is much preferable to either of them; for the pods of this sort when old, are seldom stringy, and have a better flavour than the young pods of those sorts, and will boil greener; and where this is sown in the same situation and soil as the *Battersea* Bean, it will not be a fortnight later.

All the sorts of Kidney-beans are propagated by seeds, which are too tender to be sown in the open air before the middle of *April*; for if the weather should be cold and wet after they are in the ground, they will soon rot; or if the morning frost should happen after the plants come up, they will be destroyed; therefore the best way to have early Kidney-beans, where there is no conveniency of frames for raising them, is to sow the seeds in rows pretty close, upon a moderate hot-bed, the latter end of *March* or the beginning of *April*. If the heat of the bed is sufficient to bring up the plants, it will be enough; this bed should be arched over with hoops, that it may be covered with mats every night, or in bad weather. In this bed the plants may stand till they have put out their trifoliate leaves, then they should be carefully taken up, and transplanted in warm borders near hedges, pales, or walls. If the season proves dry at the time of removing them, the plants should be gently watered to forward their taking new root, and afterward they must be managed in the same way as those which are sown in the full ground. These transplanted Beans will not grow so strong as those which are not removed, nor will they continue so long in bearing, but they will come at least a fortnight earlier than those which are sown in the full ground.

The first crop intended for the full ground, should be put in about the middle of *April*; but these should have a warm situation and a dry soil, otherwise the seeds will rot in the ground; or if the weather should prove so favourable as to bring up the plants, yet there will be danger of their being killed by morning frosts, which frequently happen the beginning of *May*.

The second crop, which should be one of the three large sorts last mentioned, should be sown about the middle of *May*. These will come into bearing before the early kinds

are over, and if they are of the scarlet sort, will continue fruitful till the frost destroys the plants in the autumn, and these will be good as long as they last. The manner of planting them is, to draw shallow furrows with a hoe, at about three feet distance from each other, into which you should drop the seeds about two inches asunder; then with the head of a rake draw the earth over them, so as to cover them about an inch deep.

If the season be favourable, the plants will begin to appear in about a week's time after sowing, and soon after will raise their heads upright; therefore, when the stems are advanced above ground, you should gently draw a little earth up to them, observing to do it when the ground is dry, which will preserve them from being injured by sharp winds; but you should be careful not to draw any of the earth over their seed leaves. After this, they will require no farther care but to keep them clear from weeds until they produce fruit, when they should be carefully gathered two or three times a week; for if they are permitted to remain upon the plants a little too long, the beans will be too large for eating, and the plants would be greatly weakened thereby.

The large sorts of Kidney-beans must be planted at a greater distance row from row; for as these grow very tall, so if the rows are not at a farther distance, the sun and air will be excluded from the middle rows, therefore these should not be less than four feet and a half distance row from row; and when the plants are about four inches high, the poles should be thrust into the ground by the side of the plants, to which they will fasten themselves, and climb to the height of eight or ten feet, and bear plenty of fruit from the ground upward. The *Dutch* and *French* preserve great quantities of the large *Dutch* Beans for winter use, which they stew and make good with gravy and other sauces.

There are some persons who raise these in hot-beds, in order to have them early. The only care to be taken in the management of these plants, when thus raised, is to allow them room, and give them as much air as can be conveniently, when the weather is mild, as also to let them have but a moderate heat; for if the bed be over hot, they will either burn, or be drawn up so weak as never to come to good.

The best way of saving the seeds of these plants, is to let a few rows of them remain ungathered in the height of the season; for if you gather from the plants for some time, and afterwards leave the remaining for seed, their pods will not be near so long and handsome, nor will the seed be so good. In autumn, when you find they are ripe, you should in a dry season pull up the plants, and spread them abroad to dry; after which you may thresh out the seed, and preserve it in a dry place for use.

PHILADELPHUS. *Lin. Gen. Plant.* 540. Pipe tree, or Mock Orange.

The Characters are,

It hath a permanent empalement, cut into five acute parts sitting upon the germen. It hath four or five roundish plain petals, and twenty awl-shaped stamina. The germen is situated under the flower, supporting a slender style divided in four parts, which afterward becomes an oval acute-pointed capsule, having four cells filled with small oblong seeds.

The Species are,

1. PHILADELPHUS *foliis ovato-lanceolatis acutè dentatis.* Philadelphus with oval spear-shaped leaves which are acutely indented; the white Syringa, or Mock Orange.

2. PHILADELPHUS *foliis ovatis subdentatis, flore solitario pleno.* Syringa or Mock Orange, with oval leaves which are somewhat indented, and double flowers standing singly on the sides of the branches.

3. PHILADELPHUS *foliis integerrimis*. *Lin. Sp. Plant.* 470. Philadelphus with entire leaves.

The first sort has been long cultivated in the *English* gardens as a flowering shrub, but the place where it naturally grows is uncertain. This sends up a great number of slender stalks from the root, which have a gray bark, branching out from their side, garnished with oval spear-shaped leaves; they have several acute indentures on their edges, their surface rough, and of a deep green on their upper side, but pale on their under, and have the taste of a fresh Cucumber. The flowers come out from the side and at the end of the branches, in loose bunches, each standing on a short distinct foot-stalk; they have four oval petals which spread open, with a great number of stamina within, surrounding the style. The flowers are white, and have a strong scent, which at some distance resembles that of Orange flowers, but when near is too powerful for most persons. This shrub rises seven or eight feet high.

There is a variety of this with variegated leaves, which some people preserve in their gardens; but as the stripes generally disappear when the plants are in health, so it makes little appearance.

The second sort is of humble growth, seldom rising above three feet high; the leaves are shorter than those of the former, and approach near to an oval form; they are but little indented on their edges. The flowers come out singly from the side of the branches, and have a double or treble row of petals, of the same size and form as the other, and the flowers have the same scent; but this sort flowers very rarely, so is not much esteemed.

Both these are extreme hardy, and will thrive in almost any soil or situation, but will grow taller in light good ground, than in that which is stiff. They are usually propagated by suckers, which are sent out from their roots in great plenty; they should be taken from the old plants in autumn, and planted in a nursery to grow one or two years till they have obtained strength, and then they should be transplanted to the place where they are designed to remain. They are commonly disposed in wilderness work, among other shrubs of the same growth, where they add to the variety.

The third sort grows naturally in *Carolina*, and is as yet very rare in *Europe*. This rises with a shrubby stalk about sixteen feet high, sending out slender branches from the sides opposite, which are garnished with smooth leaves shaped like those of the Pear tree, which are entire, standing opposite on pretty long foot-stalks. The flowers are produced at the end of the branches, they are large, each having four oval petals which spread open, and have large empalements, composed of four acute-pointed leaves. The petals are white, and within these stand a great number of short stamina, terminated by yellow summits.

This shrub is very rare in *England*, for it will not rise from seeds; I have sown the seeds which were sent me by the late Dr. Dale from *Carolina*, two or three times without any success, and others have done the same, which occasions its present scarcity in *England*; but when the plants are procured from abroad, they may be propagated by laying down their branches. I had one of the shrubs which was sent me by the gentleman before-mentioned, which had thriven in the *Chelsea* garden near two years; and some of the branches which were laid down had put out roots, but they were all destroyed by cold in the winter 1740.

PHILLYREA. *Tourn. Inst. R. II.* 496. *tab.* 367. Phillyrea, or Mock Privet.

The Characters are,

The flower has a small permanent empalement cut into five parts at the brim. It has one petal with a very short tube, cut into

five parts which turn backward, and two short stamina standing opposite, terminated by single erect summits. It has a roundish germen supporting a slender style, crowned by a thick stigma. The germen afterward turns to a globular berry with one cell, inclosing one roundish seed.

The Species are,

1. PHILLYREA *foliis ovato-lanceolatis integerrimis*. Phillyrea with oval, spear-shaped, entire leaves; commonly called the true Phillyrea.

2. PHILLYREA *foliis ovatis subintegerrimis*. Phillyrea with oval leaves which are almost entire; called broad-leaved Phillyrea.

3. PHILLYREA *foliis cordato-ovatis serratis*. *Hort. Cliff.* 4. Phillyrea with oval heart-shaped leaves which are sawed; or broad-leaved prickly Phillyrea.

4. PHILLYREA *foliis lanceolatis integerrimis*. *Hort. Cliff.* 4. Phillyrea with spear-shaped entire leaves; Privet-leaved Phillyrea.

5. PHILLYREA *foliis lanceolato-ovatis integerrimis, floribus confertis axillaribus*. Phillyrea with spear-shaped, oval, entire leaves, and flowers growing in clusters from the sides of the branches; Olive-leaved Phillyrea.

6. PHILLYREA *foliis lineari-lanceolatis integerrimis, floribus confertis axillaribus*. Phillyrea with narrow, spear-shaped, entire leaves, and flowers growing in clusters from the sides of the branches; narrow-leaved Phillyrea.

7. PHILLYREA *foliis linearibus*. Phillyrea with very narrow leaves; commonly called Rosemary-leaved Phillyrea.

The first sort here mentioned, is the most common in the *English* gardens, where it is known by the title of true Phillyrea; so called, to distinguish it from the *Alaternus*, which is called simply Phillyrea, by the gardeners. This rises with a strong upright stem, to the height of eighteen or twenty feet, dividing into several branches, covered with a smooth grayish bark, garnished with oval spear-shaped leaves placed opposite, which are entire, firm, and of a light green. The flowers come out from the wings of the stalk on each side, they are of an herbaceous white colour, and grow in small clusters. They are succeeded by globular berries with one cell, inclosing a single seed of the same form.

The second sort rises to an equal height with the first, but the branches are more diffused, and have a darker bark; the leaves are oval, and of a darker green, a little sawed on their edges. The flowers come out from the wings of the branches, growing in long bunches; they are of an herbaceous white colour as the former, and are succeeded by berries of the same form.

The third sort rises with an upright stem as high as the two former, sending out several strong branches which grow erect, covered with a gray bark, garnished with oval heart-shaped leaves, which are firm, of a lucid green, and sawed on their edges, each serrature ending in a spine. The flowers and seeds of this are like those of the two former sorts.

The fourth sort is of humbler growth than either of the former, seldom rising more than ten feet high; the branches are weaker, and spread wider than those, and are covered with a light brown bark; they are garnished with stiff spear-shaped leaves, of a light green, and sit close to the branches. The flowers are produced in small clusters at the wings of the branches on each side; they are small, and whiter than those of the former, and are succeeded by small berries which ripen in the autumn.

The fifth sort rises about the same height as the fourth, the branches are stronger and spread out wider; the bark is of a lighter colour; the leaves are stiff, smooth, and entire, standing on very short foot-stalks, of a lucid green, and terminate in a point. The flowers come out in clusters

upon pretty long foot-stalks, at the wings of the young branches; they are small, white, and have round berries succeeding them, which ripen in autumn.

The sixth sort rises with a woody stalk ten or twelve feet high, sending out branches by pairs, which are covered with a brown bark spotted with white, and are garnished with smooth, stiff, narrow, spear-shaped leaves, which are entire, sitting close to the branches, of a light green, and point upward. The flowers come out in large clusters at each joint of the branches, to which they sit close like the whorled flowers, almost surrounding the stalk; they are small, white, and are succeeded by small berries which ripen in autumn.

The seventh sort is of humbler growth than either of the former, seldom rising more than five or six feet high, sending out slender branches opposite; the leaves are of a dark green, stiff, very narrow, and entire. The flowers are small, white, and grow in clusters from the side of the branches. The berries of this sort are very small, and rarely ripen in *England*.

These plants all grow naturally in the south of *France*, *Spain*, and *Italy*, but are hardy enough to thrive in the open air in *England*; and are never injured except the winters are very severe, which sometimes causes their leaves to fall, and kills a few of the weaker branches, but these are repaired by new shoots the following summer; so that there are but few of the ever-green trees which are hardier than these, or that deserve more to be cultivated for pleasure.

The three first sorts are very proper to intermix with other ever-green trees of the same growth to form clumps in parks, or to plant round the borders of woods, which are filled with deciduous trees, where in the summer time the dark shade of these ever-greens will make a fine contrast with the brighter green leaves of the deciduous trees, and in winter, when the latter are destitute of leaves, they will have a fine effect; and these will be a fine harbour for birds. They may be trained up to stems, so as to be out of the reach of cattle, therefore may be planted in open places, where, if they are fenced against cattle till they are grown up, they may be afterwards exposed.

The other sorts, which are of humbler growth, must be confined to gardens or other inclosures, where they may be secured from cattle, hares, rabbits, &c. otherwise they will soon be destroyed.

These plants are propagated either from seeds or layers, but the latter, being the most expeditious method in *England*, is chiefly preferred. The best time to lay them down is in autumn, when you should dig the ground round the stems of the plants intended to be layed, making it very loose; then making choice of a smooth part of the shoot, you should make a slit upward (in the manner as is practised in laying of Carnations), and then bend the branch gently down to the ground, making a hollow place with your hand to receive it; and having placed the part which was slit in the ground, so as that the slit may be open, you should fasten it down with a forked stick, that it may remain steady, covering that part of the branch with earth about three inches thick, observing to keep the upper part erect. You must keep them clear from weeds the spring and summer following, which, if suffered to grow up amongst them, will prevent their taking root.

The autumn following most of these plants will be rooted, at which time they may be taken off, and carefully planted in a nursery, where they may be trained up three or four years in the manner you intend them to grow, during which time you should dig the ground between the rows, and cut about the roots of the plants every year, which will cause them to strike out strong fibres, so as to support a good ball of earth when they are removed; you should

also support their stems with stakes, in order to make them straight, otherwise they are very apt to grow crooked and unrightly.

When the plants have been thus managed three or four years, you may transplant them into the places where they are designed to remain. The best time for this work is the latter end of *September*, or the beginning of *October*; but in removing them, you should dig round their roots, and cut off all downright or strong roots, which have shot out to a great distance, that you may the better preserve a ball of earth to each plant, otherwise they are subject to miscarry; and when you have placed them in their new quarters, you should lay some mulch upon the surface of the ground to prevent its drying. You should also support the plants with stakes, until they have taken fast hold of the earth, to prevent their being turned out of the ground, or displaced by the winds. These trees delight in a middling soil, which is neither too wet and stiff; nor too dry, though the latter is to be preferred to the former, provided it be fresh.

Those sorts with small leaves are commonly two years before they take root, when laid; therefore they should not be disturbed, for the raising them out of the ground greatly retards their rooting.

PHILLYREA OF THE CAPE. See *Maurocena*.

PHLOMIS. *Tourn. Inst. R. H. 177. tab. 82.* The Sage tree, or *Jerusalem Sage*.

The Characters are,

The flower hath a permanent empalement with an oblong tube, having five angles. It is of the lip kind. The tube is oblong; the upper lip is oval, forked, and inflexed; the under is cut into three segments, the middle one being large and obtuse. It hath four stamina hid under the upper lip, two being longer than the other, and a germen divided into four parts, supporting a style the length of the stamina. The germen afterward becomes four oblong cornered seeds sitting in the empalement.

The Species are,

1. PHLOMIS foliis subrotundis tomentosis crenatis, caule fruticoso. Phlomis with roundish, woolly, crenated leaves, and a shrubby stalk.
2. PHLOMIS foliis lanceolatis tomentosis integerrimis, caule fruticoso. Phlomis with spear-shaped woolly leaves which are entire, and a shrubby stalk.
3. PHLOMIS foliis oblongo-ovatis petiolatis tomentosis, floribus capitatis, caule fruticoso. Phlomis with oblong, oval, woolly leaves having foot stalks, flowers growing in large heads, and a shrubby stalk.
4. PHLOMIS involucris setaceis hispida, foliis ovato-oblongis scabris, caule herbaceo. *Hort. Upsal. 171.* Phlomis with bristly prickly involucrum, oblong, oval, rough leaves, and an herbaceous stalk.
5. PHLOMIS involucris hispida subulatis, foliis cordatis scabris, caule herbaceo. *Hort. Upsal. 171.* Phlomis with awl-shaped prickly involucrum, rough heart-shaped leaves, and an herbaceous stalk.
6. PHLOMIS foliis lanceolatis tomentosis, foralibus ovatis, involucris setaceis lanatis. *Lin. Sp. Plant. 585.* Phlomis with spear-shaped woolly leaves, those under the flowers oval, and bristly woolly involucrum.
7. PHLOMIS foliis ovato-lanceolatis crenatis, subtus tomentosus, involucris setaceis. Phlomis with oval spear-shaped leaves which are woolly on their under side, and have a bristly involucrum.
8. PHLOMIS foliis cordatis acutis subtus tomentosus, involucris frillatis tripartitis. Phlomis with acute-pointed heart-shaped leaves, which are woolly on their under side, and the covers of the flowers divided into three parts.
9. PHLOMIS foliis cordatis rugosis subtus tomentosus, involucris lanatis, caule herbaceo. Phlomis with rough heart-shaped leaves, which are woolly on their under side, woolly

woolly covers to the flowers, and an herbaceous stalk.

10. *PHLOMIS foliis lanceolatis crenatis subtus tomentosis, involucri lanatis, caule fruticoso.* Phlomis with spear-shaped crenated leaves which are woolly on their under side, woolly covers to the flowers, and a shrubby stalk.

11. *PHLOMIS foliis radicalibus cordatis utrinque tomentosis villosis.* *Lin. Sp. Plant.* 585. Phlomis whose lower leaves are heart-shaped, woolly, and hairy on every side.

12. *PHLOMIS involucri lanceolatis, foliis cordatis subtus tomentosis, caule suffruticoso.* Phlomis with spear-shaped involucriums, heart-shaped leaves which are woolly on their under side, and a shrubby stalk; whitest, shrubby, *Spanish Jerusalem Sage*, with an iron-coloured flower.

13. *PHLOMIS involucri subulatis, foliis cordato-ovatis subtus tomentosis, caule fruticoso.* Phlomis with awl-shaped involucriums, oval heart-shaped leaves which are woolly on their under side, and a shrubby stalk.

14. *PHLOMIS foliis alternatim pinnatis, foliolis laciniatis, calycibus lanatis.* *Lin. Sp. Plant.* 585. Phlomis with leaves alternately winged, whose lobes are cut, and woolly emplacements to the flowers.

The first fort grows naturally in *Spain* and *Sicily*; it hath a pretty thick shrubby stalk, covered with a loose bark, rising five or six feet high, dividing into many irregular, woolly, cornered branches. Their joints are pretty far asunder; at each of these are placed two roundish leaves opposite on short foot-stalks, woolly on their under side. The flowers are yellow, and come out in thick whorls round the stalks, having two lips; the upper lip is forked, bending over the under, which is divided into three parts; the middle is broad, and stretched out beyond the two small side segments.

The second fort hath a shrubby stalk like the first, but does not rise so high. The branches are weaker; the leaves are spear-shaped and oval, being longer and narrower than the former; the whorls of flowers are smaller, but the flowers are of the same shape and colour.

These two forts have been long propagated in the *English* gardens by the title of Sage tree, or *Jerusalem Sage*. The plants were formerly kept in pots, and housed in winter with other exotick plants, but of late years they have been planted in the open air, where they are seldom injured by cold, unless in very severe winters; so they are intermixed with other shrubs of the same growth in quarters of wilderness work, where they add to the variety.

These plants should have a dry soil and a warm sheltered situation, otherwise they will not live in the open air. They may be planted among *Cistuses* of all the different kinds, the shrubby *Moon Trefoil*, ever-green *Cytisus*, *Wormwood tree*, and some other exotick shrubs of the same countries, which require a warm situation and a dry soil, being too tender for open plantations which are exposed to strong cold winds; and as they are not of very long duration, they are better when separated from trees and shrubs, which continue many years; for these rarely live above twelve or fourteen years in dry ground, and not more than half so long in cold moist land, or where they are not well sheltered.

They are propagated by slips or cuttings, which if planted in a bed of light earth in *April*, just before the plants begin to shoot, and covered with mats to screen them from the sun every day, as also to observe when the ground is dry to give them water gently, they will get roots in about two months or ten weeks, when they may be carefully taken up, and transplanted into a nursery, where they may remain one year, and then be transplanted to the places where they are designed to stand, for these plants will not bear transplanting at a greater age.

The third fort hath a shrubby stalk like the former, but seldom rising more than four or five feet high, sending out branches on every side, garnished with broader hoary leaves than either of the former; they are of an oblong oval form, and have pretty long foot-stalks; they are whiter than those of the former. The flowers grow in large whorls or heads, which generally terminate the branches; they are larger than those of the other forts, and the upper lip is very hairy. The plants are equally hardy with the other, and may be propagated by slips or cuttings in the same way as is before directed for them.

The fourth fort grows naturally in the south of *France* and *Italy*; this hath a perennial root, and an annual stalk which rises about two feet high. When the roots are large, they send up a great number of square stalks, which are covered with a hairy down, garnished with oblong, oval, rough leaves sitting close to the stalks. The flowers grow in whorls round the stalks, having stinging bristly covers; they are of a bright purple colour, so make a pretty appearance.

This may be propagated by parting of the roots; the best time for doing of this is in the autumn, when the stalks begin to decay, that they may get root before the frost comes on, but they should not be parted oftener than every third year, if they are expected to have many flowers. This fort is hardy, so may be planted in exposed places, but not in moist ground.

The fifth fort grows naturally in *Tartary*; this hath a perennial root. The stalks are purple, have four corners, and rise five or six feet high, garnished with heart-shaped leaves placed opposite, deeply crenated on their edges. The flowers are purple, and grow in whorls round the stalks; their covers are awl-shaped, and set with stinging hairs. It is propagated by seeds, which should be sown upon an east border in the spring, and when the plants come up, they must be kept clean from weeds the following summer, and in the autumn they should be transplanted where they are to remain.

The sixth fort grows naturally in the south of *France*, in *Spain*, and *Italy*. The root is perennial, the stalk is annual. This sends out long, narrow, woolly leaves from the roots in tufts, which are enveloped at their base by a common covering; they are soft to the touch, and lie upon the ground. The stalks are slender, and near two feet long; their joints are far asunder; at each of these stand two oval leaves opposite, which embrace the stalk with their base. The whorls of flowers are also encompassed by these leaves, and within them is situated a radiated bristly involucrium, which cover the yellow flowers, shaped like those of the other forts. The stalks decay in the autumn, but the lower leaves continue all the year. It may be propagated by slips in the spring, and the plants require a dry soil and a warm situation.

The seventh fort grows naturally in *Portugal* and *Spain*. This hath a shrubby stalk which rises four or five feet high, sending out slender branches, which have four angles covered with a white bark, garnished with oval spear-shaped leaves crenated on their edges, woolly on their under side, standing on very short foot-stalks. The flowers come out in whorls at each joint; they have bristly involucriums, and are of a deep purple colour. It may be propagated by cuttings in the same way as the three first forts, and the plants require the same treatment.

The eighth fort grows naturally in the *Levant*; this hath a perennial root and an annual stalk. The leaves are heart-shaped, ending in acute points; they are downy on their under side, and have five strong veins. The stalks rise a foot and a half high, garnished at each joint with two leaves placed opposite, of the same form as the lower, but smaller.

The flowers grow in whorls round the stalks; they are of a worn out purple colour; their involucrum is cut into segments, and are closely shut.

The seeds of the ninth sort were sent from *Smyrna* by the late consul *Sberard*, to the *Chelsea* garden. This has a perennial root, and an annual stalk. The lower leaves are very woolly and heart-shaped, standing upon long woolly foot-stalks. The stalks, which are woolly, rise a foot high; the flowers are large, yellow, and grow in whorls round them; they have very long tubulous empalements, covered with down. This sort had survived many winters in the open air in the *Chelsea* garden, but in the year 1740 they were all destroyed.

The seeds of the tenth sort were also sent from *Smyrna* by the same gentleman, and several of the plants were raised in the *Chelsea* garden. This hath shrubby stalks, which rise about three feet high, covered with a yellowish down, sending out many slender irregular branches, garnished with narrow spear-shaped leaves, which are covered with a yellowish down on their under side. The flowers are produced in heads at the end of the branches; their involucrum is very downy; the flowers are smaller than those of either of the three first sorts, and are of a dirty yellow colour. This approaches near to the second sort, but the leaves are much smaller, the branches are slenderer, and are covered with a yellow down, especially toward the end of the branches. The whorls of flowers are not near so large, and are generally produced at the end of the branches.

This sort may be propagated by cuttings in the same way as the three first sorts, and the plants may be treated in the like manner, with this difference only, of planting them in a warmer situation, for it will not bear so much cold, though in a warm border the plants have lived several years abroad in the *Chelsea* garden.

The eleventh sort grows naturally in the *Archipelago*, and also in *Spain*, from both which countries I have received the seeds. It hath an annual stalk, but the root is perennial, as are also the lower leaves, which do not arise from the root immediately, but stand in clusters upon short trailing woolly branches; they have very long downy foot-stalks; they are heart shaped, and downy on both sides. The stalks are slender, and rise a foot high, garnished with oval spear-shaped leaves, which gradually decrease in size to the top. The stalks generally send out two side branches opposite, near the bottom, and from this division to the top are garnished with thin whorls of yellow flowers, which are not closely joined together, as in the other species, but each flower stands separate. Their empalements are oval, very downy, and closely shut up. This sort may be propagated by slips in the same manner as the sixth sort, and the plants should be treated in the like way.

The twelfth sort grows naturally in *Spain* and *Portugal*. This hath a shrubby stalk, which is a little ligneous, and rises about two feet and a half high; covered with a thick white down. There are many of the stalks which rise from the same root, garnished with heart-shaped leaves; from the lower part of the stalks, at each joint, there are two short shoots come out opposite, which have four or six small leaves of the same shape with the others. The flowers, which are of an iron colour, are produced in small whorls toward the upper part of the stalk, and have downy spear-shaped involucrum.

This sort multiplies by its spreading roots, so that they may be divided every other year; the best time for doing of this is about the middle of *September*, that the offsets may get root before the frost comes on, but there should be some mulch laid about their roots, to prevent the frost from penetrating the ground. It may also be propagated by cuttings in the same way as the three first sorts, during

the spring and summer months. The plants require the same treatment as the tenth sort, for they are not so hardy as the three first sorts; therefore if there is some tanners bark, or other mulch laid on the surface of the ground about their roots every winter, it will be a means of preserving the roots, so that if a severe winter should kill the stalks, the roots will put out new ones the spring following.

The thirteenth sort grows naturally in *Spain* and *Portugal*. This rises with several shrubby stalks from three to four feet high, which divide into several four-cornered branches, covered with a woolly down, garnished with leaves, which on the lower part of the stalks are heart-shaped, but upward they are of an oval spear-shape, woolly on their under side; they stand opposite upon short foot-stalks. The flowers come out in whorls round the stalks; they have awl-shaped involucrum, ending in acute points, and covered with down; they are of a bright purple colour, but are not succeeded by seeds in this country. This sort is propagated by slips or cuttings in the same way as the three first sorts, and the plants should be treated in the like manner as hath been before directed for the tenth sort.

The fourteenth sort grows naturally in the *Levant*. This hath a perennial root, and an annual stalk, but the lower leaves continue all the year; these are alternately winged, and the small lobes are cut on their edges. The stalks rise a foot and a half high, garnished with leaves of the same shape with the lower, but are smaller. The flowers come out in whorls round the stalks, like those of the other sorts, whose empalements are downy; they are of a worn-out purple colour, and appear in *June*, but the seeds do not ripen here.

It is propagated by offsets from the root in the same way as the eighth sort, but these are sent out sparingly also, and the plants require the same treatment. It is at present very rare in *England*, for the severe frost in the year 1740 destroyed all the plants here, which had survived all the winters for twenty years before in the open air.

All the species of this genus are ornamental plants, when properly disposed in gardens, so deserve a place, for there is generally a succession of flowers on them for two or three months, and their hoary down leaves, when intermixed with plants, whose leaves are green, make a pretty contrast.

PHLOX. *Lin. Gen. Plant.* 197. *Lychnidea*, or *Bastard Lychnis*.

The Characters are,

The flower has a cylindrical empalement, which is permanent, with five acute indentures at the top. It has one funnel-shaped petal, with a cylindrical tube, incurved at the base, plain at the top, where it is cut into five equal roundish segments, which spread open. It hath five short stamina, situated within the tube, two of which are longer than the tube. It hath a conical germen, supporting a slender style, crowned by an acute trifid stigma. The germen afterward turns to an oval capsule, with three cells sitting in the empalement, each cell containing a single seed.

The Species are,

1. PHLOX *foliis lineari-lanceolatis glabris acuminatis, caule erecto ramoso, corymbo terminali.* Phlox with smooth, narrow, spear-shaped leaves, ending in acute points, and upright branching stalks, terminated by flowers, which grow in a corymbus.

2. PHLOX *foliis lanceolatis sessilibus glabris crassis, caule erecto, floribus verticillatis terminalibus.* Phlox with smooth, thick, spear-shaped leaves, sitting close to the stalks, and upright stalks, terminated by flowers growing in whorls.

3. PHLOX *foliis cordato-lanceolatis levibus.* *Lin. Sp. Plant.* 152. Phlox with heart spear-shaped leaves, which are smooth.

4. PHLOX *foliis lato-lanceolatis, inferioribus alternis, caule ramoso.* *Lin. Sp. Plant.* 152. Phlox with broad spear-shaped leaves,

leaves, which are placed alternately at bottom, and a branching stalk.

5. *PHLOX foliis lanceolatis margine scabris, corymbis compositis.* *Lin. Sp. Plant.* 151. Phlox with spear-shaped leaves, having rough borders, and flowers disposed in compound corymbuses.

6. *PHLOX foliis lanceolatis villosis, caule erecto, corymbo terminali.* *Lin. Sp. Plant.* 152. Phlox with hairy spear-shaped leaves, and an upright stalk, terminated by a corymbus of flowers.

7. *PHLOX foliis ovatis, floribus solitariis.* *Lin. Sp. Plant.* 152. Phlox with oval leaves and solitary flowers.

The first sort grows naturally in *Virginia*, and in some other parts of *North America*. This hath a perennial root, which sends up several stalks, in number proportionable to the size of the roots, near a foot and a half high, which divide into three or four small branches toward the top, terminated by a corymbus of flowers. The leaves on the lower part of the stalks are placed opposite; they are smooth, and set close to the stalks; the leaves on the upper part of the stalks are placed alternate. The flowers grow almost in form of an umbel, standing on short foot-stalks; their empalements are tubulous, have ten angles or furrows, and are cut at the top into five acute segments; the tube of the flower is twice the length of the empalement, and is divided at the top into five roundish segments, which spread open; these are of a light purple colour.

The second sort grows naturally in *Carolina*. This hath a perennial root, from which arise several smooth stalks near two feet high, garnished with stiff shining leaves placed opposite; they are spear-shaped, entire, and their edges are reflexed; the upper part of the stalk has generally two slender side branches, and is terminated by a head of flowers, which grow in whorls round the stalks, but the whorls are so nearly placed, as to appear one corymbus at some distance. The empalement of the flower is short, and deeply cut into five acute segments; the tube of the flower is long, and at the top is cut into five roundish segments, which spread open. These flowers are of a deeper purple colour than those of the former.

The third sort grows naturally in *Maryland*. This hath a perennial root, from which arise several upright stalks, of a purplish colour, closely covered with white spots; these grow about three feet high, garnished with heart, spear-shaped, smooth leaves. Toward the upper part of the stalks, are sent out small branches opposite, each being terminated by a small bunch of flowers; but the principal stalk is terminated by a long loose spike of flowers, composed of small bunches, arising from the wings of the stalk at each joint, each cluster having one common foot-stalk; the flowers are of a bright purple colour, but are rarely succeeded by seeds in *England*.

The fourth sort grows naturally in *North America*. This has a perennial root, from which arise several slender stalks, which are apt to incline to the ground, if they are not supported; these divide into several small branches, which spread from each other; the lower part of the stalks are garnished with broad spear-shaped leaves, placed alternate, sitting close to the stalks; but on the smaller branches they are narrower, and placed opposite. The flowers grow in loose bunches at the end of the branches; they have short empalements, which are cut into five narrow acute segments; the tube of the flower is long and slender, the segments at the top are broad and heart-shaped, inverted. They are of a light blue, but are rarely succeeded by seeds in *England*.

The fifth sort grows naturally in *North America*. This hath a perennial root and an annual stalk, which is smooth, of a light green, and rises about two feet high, sending out

a few side branches, garnished with spear-shaped leaves, placed opposite, sitting close to the stalks; they are of a dark green, and their edges are a little rough. The flowers are disposed in a corymbus at the top of the stalks; these are composed of many smaller bunches of flowers, which have each a distinct foot-stalk, and support a great number of flowers, which stand upon short slender foot-stalks; the empalement of the flower is short, cut almost to the bottom into five narrow acute segments; the tube of the flower is long, slender, and is cut at the top into five oval segments, which spread open. The flowers are of a pale purple colour, and are often succeeded by seeds, which ripen in the autumn.

The sixth sort grows naturally in *Virginia*. This hath a perennial root, from which arise a few single stalks about a foot high, garnished with narrow spear-shaped leaves, ending in acute points, which are a little hairy. The flowers are produced in a loose corymbus at the top of the stalk; their empalements are cut into acute segments almost to the bottom; the tube of the flower is slender, pretty long, and is cut at the top into five oval segments, which spread open. The flowers are of a light purple colour, but are seldom succeeded by seeds in *England*.

The seventh sort grows naturally in *Maryland*, and other parts of *North America*. This hath a perennial root, from which comes out two or three slender stalks about nine inches high, garnished with oval, rough, hairy leaves, placed opposite, upon very short foot-stalks. The flowers come singly at the top of the stalk; they have very slender tubes, but are cut into five roundish segments, which spread open. They are of a light purple colour, but are not succeeded by seeds in *England*.

These plants are hardy, so will thrive in the open air in *England*. They delight in a moist rich soil not too stiff, in which they will grow tall, and produce much larger bunches of flowers, than in dry ground; for when the soil is poor and dry, they frequently die in summer, unless they are duly watered.

They are generally propagated by parting their roots, because they do not often produce seeds in *England*. The best time for this is in autumn, when their stalks begin to decay. These roots should not be divided into small heads, if they are expected to flower well the following summer; nor should they be parted oftener than every other year, because when they are often removed and parted, it will greatly weaken the roots, so that they will send out but few stalks, and those will be so weak as not to rise their usual height; the bunches of flowers will also be much smaller.

The first, second, and fifth sorts, propagate pretty fast by their spreading roots, but the others increase but slowly this way, therefore the best method to propagate them is by cuttings; if the three first sorts are desired in plenty, they may be easily obtained by this method. The best time to plant the cuttings, is about the latter end of *April*, or the beginning of *May*, when the shoots from the roots are about four inches high; these should be cut off close to the ground, and their tops should be shortened; then they must be planted on a border of light loamy earth, and shaded from the sun until they have taken root; or if they are planted close together, and covered with bell or hand-glasses, shading them every day from the sun, they will put out roots in five or six weeks; but when they begin to shoot, the glasses should be gradually raised to admit the free air to them. As soon as they are well rooted, the glasses should be taken off, and the plants inured to the open air; then they should be soon after removed into a bed of good soil, planting them about six inches distance every way, observing to shade them from the sun, and water them duly till

till they have taken new root; after which, if they are kept clean from weeds, they will require no other care till autumn, when they should be transplanted into the borders of the flower garden, where they are designed to remain.

PHYLICA. *Lin. Gen. Plant.* 236. Bastard Alaternus.

The Characters are,

The flowers are collected in a disk, sitting in a common receptacle, each having a permanent empalement, composed of three narrow oblong leaves. They have one perforated petal, with an erect conical tube, cut into five parts at the brim, with an acute scale at each division, which join them together, and five small stamina inserted under the scale, terminated by single summits. The germen is situated at the bottom of the petal, supporting a single style, which afterward becomes a roundish capsule with three lobes, having three cells, each inclosing a single roundish seed, gibbous on one side, and angular on the other.

The Species are,

1. PHYLICA *foliis linearibus verticillatis.* *Lin. Sp. Plant.* 195. Phylica with linear leaves, growing in whorls.

2. PHYLICA *foliis lineari-subulatis, summis birsutis.* *Pred. Leyd.* 199. Phylica with narrow awl-shaped leaves, which are hairy at the top.

3. PHYLICA *foliis ovatis sparsis.* *Lin. Sp. Plant.* 195. Phylica with oval leaves growing scatteringly.

The first sort grows naturally at the *Cape of Good Hope*. It also grows wild about *Lisbon*, where there are large extents of ground covered with it like the heaths in *England*. This is a low bushy plant, seldom rising more than three feet high; the stalks are shrubby and irregular, dividing into many spreading branches. The young branches are closely garnished with short, narrow, acute-pointed leaves, placed in whorls round the stalks, to which they sit close; they are of a dark green, and continue all the year. At the end of every shoot the flowers are produced in small clusters, sitting close to the leaves; they are of a pure white, and begin to appear in the autumn, continuing in beauty all the winter, and decay in the spring, which renders the plant more valuable.

The second sort grows naturally at the *Cape of Good Hope*. This hath an erect shrubby stalk, which rises near three feet high, covered with a purplish bark; the leaves are narrow, short, and acute-pointed, sitting close to the branches in alternate order; they are thick, nervous, and of a dark green on their upper side, but hoary on their under. The flowers are collected in small heads at the end of the branches; they are white, woolly, and fringed on their borders, cut into six acute segments at the top. These appear the beginning of winter, and continue long in beauty.

The third sort is a native of the same country as the former. This rises with a shrubby erect stalk five or six feet high; the stalks, when old, are covered with a rough purplish bark, but the younger branches have a woolly down; these are garnished with thick oval leaves, about the size of those of the Box-tree; they are veined, smooth, and of a lucid green on their upper side, but are hoary on their under. The flowers are collected in small heads at the end of the branches; they are of an herbaceous colour, so make no great appearance. These appear at the same time with the former.

As these plants do not produce seeds in *England*, so they are propagated by cuttings, which, if properly managed, will take root freely. There are two seasons for planting these cuttings, the first is the latter end of *March* before the plants begin to shoot; if these are planted in pots, and plunged into a very moderate hot-bed, covering them close with bell or hand-glasses, observing to shade them from the sun in the middle of the day, and to refresh them gently with water, they will put out roots in two months; then they should be inured to the open air, and after they have

obtained strength, they should be taken out of these pots, and each planted in a separate small pot, filled with soft loamy earth, and placed in a shady situation until they have taken new root, when they may be removed to a sheltered situation, where they may remain till autumn.

The other season for planting of these cuttings, is about the beginning of *August*. At this time they may be planted in pots, which may be either plunged into an old hot bed, or the full ground, covering them close with bell or hand-glasses, as before, and treating them in the same way; these will put out roots in about two months, but it will then be too late in the season to transplant them, so they must remain in the same pots till spring.

These plants are too tender to thrive in the open air in *England*, so they must be kept in pots, and housed in winter; for although the first sort will live through the winter in a warm sheltered situation, when the seasons prove favourable, yet when severe frosts happen, they are always destroyed, but they require no artificial heat to preserve them, if they are sheltered under a hot-bed frame in winter, when they are young, and after they are grown large, kept in a green-house where they may enjoy the free air in mild weather, and treated in the same way as other hardy exotick plants from the same country; in the summer they must be placed abroad in a sheltered situation; with which management the plants will thrive and continue several years, and as they flower in the winter, they make a good appearance in the green-house during that season.

PHYLLANTHUS. *Lin. Gen. Plant.* 932. Sea-side Laurel.

The Characters are,

It hath male and female flowers in the same plant; the empalements of the flowers in both sexes are permanent, bell-shaped, and of one leaf, cut into six parts, which spread open. The flowers have no petals according to some, or no empalements according to others. The male flowers have three short stamina, which join at their base, but spread asunder at their top, and are terminated by twin summits. The female flowers have an angular nectarium surrounding the germen, which afterward becomes a roundish capsule with three furrows, having three cells, each containing a single roundish seed.

The Species are,

1. PHYLLANTHUS *foliis lanceolatis serratis, crenis floriferis.* *Hort. Cliff.* 439. Phyllanthus with spear-shaped sawed leaves, having flowers growing on their edges.

2. PHYLLANTHUS *foliis pinnatis floriferis, floribus pedunculatis, caule herbaceo erecto.* *Lin. Sp.* Phyllanthus with winged leaves, bearing flowers upon foot-stalks, and an upright herbaceous stalk.

3. PHYLLANTHUS *foliis pinnatis floriferis, floribus sessilibus, caule herbaceo procumbente.* *Lin. Sp.* Phyllanthus with winged leaves, bearing flowers sitting close, and a trailing herbaceous stalk.

4. PHYLLANTHUS *foliis pinnatis floriferis, caule arboreo, fructu baccato.* *Lin. Syst.* 1265. Phyllanthus with winged leaves, bearing flowers, a tree-like stalk, and the fruit a berry.

5. PHYLLANTHUS *caule arboreo, foliis ovatis obtusis integerrimis.* *Lin. Syst.* 1264. Tree Phyllanthus with oval, obtuse, entire leaves.

The first sort grows naturally upon the rocks near the sea, in all the islands of the *West-Indies*, where the inhabitants title it Sea-side Laurel. This is seldom found growing on the land, which occasions its scarcity in *Europe*; for the roots strike so deep into the crevices of the rocks, as to render it almost impracticable to transplant the plants, and it is very difficult to propagate by seeds; for unless they are sown soon after they are ripe, they will not grow, and the greatest part of the seed proves abortive, so that it is

very rare in *Europe*. There was formerly a plant of this sort in the gardens at *Hampton-Court*, but this, with many other fine plants, has been destroyed by the ignorance of the gardeners. I also saw a fine plant of this sort in the *Amsterdam* garden.

This grows with a woody stalk about fifteen or sixteen feet high; the leaves come out without any order; upon the edges of the leaves the flowers are produced, but especially toward the upper part, where they are placed very closely, so as almost to form a sort of border to the leaves; which, together with the shining green colour of the leaves, makes a very beautiful appearance; the leaves continue green all the year, which renders the plant more valuable.

It requires to be placed in a moderate stove in the winter, otherwise it will not live in *England*; but in summer it may be placed in the open air, in a warm sheltered situation. With this management the plant was in great vigour in the physick garden at *Amsterdam*.

The second sort is an annual plant, with an herbaceous stalk about a foot high, which branches out, and has winged leaves, composed of many oval lobes, under which the flowers are produced upon foot-stalks, ranged along the midrib; they are small, of an herbaceous colour, and as they are situated under the leaf, so make no great appearance; however, the plants are cultivated by those who delight in botany.

The third sort is also annual; the stalks trail on the ground, and are garnished with winged leaves, having oblong lobes; under which the flowers are ranged along the midrib, as in the other species, so make little appearance.

The fourth sort is the *Nilicamarum* of the *Hortus Malabaricus*, and the *Nux Emblia* of the shops. This hath a woody tree-like stalk, spreading into many branches, garnished with narrow linear leaves, in shape like those of the deciduous Cypress; but as the plants have not produced flowers in *England*, so I can give no farther account of the tree.

The fifth sort grows naturally in the *West-Indies*, where it becomes a tree of middling stature: the leaves are almost oval, of a light green on their upper side, but grey on their under, being very entire. The flowers have not appeared in *England*, so nothing can be said of them; but the fruit which came over were the size of Walnuts, having three swelling cells, in each of which should be lodged a single seed, but two of them are generally barren; and those which seem to have fair seeds, upon examination, will be found hollow without any germ.

The second and third sorts grow naturally in both *Indies*: as they are annual, so their seeds may be sown upon a hot-bed in the spring; when the plants come up, and are fit to remove, they should be each put into a separate small pot, and plunged into a hot-bed of tanners bark, shading them from the sun till they have taken new root; after which their management should be the same as for other plants of the same countries: with this care they will perfect their seeds in autumn, which must be carefully watched, otherwise their husks will open, and scatter the seeds into such pots as are near them, where if the ground is not disturbed, the plants will come up the following spring.

The fourth sort grows naturally in the *East-Indies*, where it rises with a ligneous stalk to the height of twelve or fourteen feet; but the plants which have been raised in *England*, have not exceeded three or four, though there are some of ten years growth; for they frequently lose their leading shoot in winter, and put out lateral branches, which also are apt to lose their tops in winter; so the plants do not advance much, nor have any of them attempted to shew their flowers here, though the plants are in good health.

This and the fifth sort have been raised from seeds, which were sown upon a hot-bed, and the plants were put into pots, and plunged into a tan-bed in summer, and in winter removed into the bark-stove, where they have been constantly kept, for they were found to be too tender to live through the winter in a less degree of heat. Their cuttings, which have been planted, have failed, and their branches being too strong to make layers, they have not been propagated any other way than from the seeds.

PHYLLIS. *Lin. Gen. Plant.* 286. *Simpla Nobla*.

The Characters are,

The empalement of the flower is composed of two leaves sitting on the germen. The flower has five obtuse spear-shaped petals, which turn backward. It hath five short hair-like stamina, terminated by oblong summits. The germen, which is situated under the flower, has no style, but is crowned by two awl-shaped reflexed hairy stigmas, and afterward turns to an oblong angular fruit, containing two parallel seeds, convex on their outside, plain on the other, and broad at the top.

We have but one Species of this genus in the *English* gardens, viz.

PHYLLIS *stipulis dentatis*. *Prod. Leyd.* 92. *Phyllis* with indented stipulæ; or *Simpla Nobla* of the *Canaries*.

This plant grows naturally in the *Canary Islands*. It rises with a soft shrubby stalk about two or three feet high, which is seldom thicker than a man's finger, of an herbaceous colour, and full of joints. These send out several small side branches toward the top, garnished with spear-shaped leaves, of a lucid green on their upper side, but pale on their under, having a strong whitish midrib, with several deep veins running from it to the sides. The flowers are produced at the end of the branches in loose panicles; they are small, and of an herbaceous colour at their first appearance, but before they fade, change to a brown or worn-out purple; they are cut into five parts to their base, where they are connected, and fall off without separating, so should be termed a flower of one petal. These segments are reflexed backward so as to cover the germen, which is situated under the flower, and afterward becomes a short turbinated, obtuse, angular fruit, which splits in two parts when ripe, each containing one seed, flat on the inside, convex on the outside, and angular.

It is propagated by seeds, which must be sown on a bed of fresh light earth the beginning of *April*; the plants will come up by the beginning of *May*; when they are fit to transplant, they should be put into separate pots, and placed in a shady situation until they have taken root; after which time they should be placed in a sheltered situation, where they may have the morning sun, and in summer will require to be frequently watered. In winter they must be sheltered from the frost, but require to have as much free air as possible in mild weather; the second year the plants will flower, so if in the spring some of the plants are shaken out of the pots, and put into the full ground, they will perfect their seeds much better than those which remain in the pots.

As these plants seldom continue in health above four or five years, it will be proper to raise a supply of young plants to succeed them.

PHYSALIS. *Lin. Gen. Plant.* 223. *Winter Cherry*.

The Characters are,

The flower hath a swelling permanent empalement, which is five cornered, and cut at the top into five acute points. The flower hath one wheel-shaped petal with a short tube, and a large brim, which is five cornered and plaited. It has five small awl-shaped stamina, which join together, and a roundish germen, supporting a slender style, crowned by an obtuse stigma. The germen afterward turns to an almost globular berry with two cells, inclosed

in the large inflated empalement, filled with compressed kidney-shaped seeds.

The Species are,

1. *PHYSALIS foliis geminis*. Lin. Sp. Plant. 183. Physalis with two leaves at a joint; the common Winter Cherry.

2. *PHYSALIS foliis cordatis integerrimis obtusis scabris, corollis glabris*. Lin. Sp. Plant. 183. Physalis with rough, obtuse, entire, heart-shaped leaves, and smooth petals.

3. *PHYSALIS radice perenni, caule procumbente, foliis ovatis acutè dentatis, petiolis longissimis*. Physalis with a perennial root, a trailing stalk, and oval leaves which are acutely indented, and have very long foot-stalks.

4. *PHYSALIS caule herbaceo, foliis ovato-lanceolatis acutè dentatis*. Tab. 206. fig. 1. Winter Cherry with an herbaceous stalk, and oval spear-shaped leaves which are acutely indented.

5. *PHYSALIS caule suffruticoso, foliis ovatis tomentosiss integerrimis*. Physalis with a shrubby stalk, and oval downy leaves which are entire.

6. *PHYSALIS caule fruticoso, foliis ovatis tomentosiss*. Lin. Vir. Cliff. 16. Physalis with a shrubby stalk, and oval woolly leaves.

7. *PHYSALIS caule fruticoso, ramis rectis, floribus confertis*. Lin. Sp. Plant. 180. Physalis with a shrubby stalk, erect branches, and flowers growing in clusters.

8. *PHYSALIS caule fruticoso, ramis flexuosis, floribus confertis*. Lin. Sp. Plant. 182. Physalis with a shrubby stalk, flexible branches, and flowers growing in clusters.

9. *PHYSALIS foliis ovato-lanceolatis integerrimis oppositis, caule fruticoso*. Tab. 206. fig. 2. Physalis with oval, spear-shaped, entire leaves which are placed opposite, and a shrubby stalk.

10. *PHYSALIS ramosissima, foliis villosis-viscosis pedunculis nutantibus*. Lin. Sp. Plant. 183. The most branching Physalis with hairy viscous leaves, and nodding foot-stalks.

11. *PHYSALIS ramosissima, ramis angulatis glabris*. Lin. Sp. Plant. 183. The most branching Physalis with angular smooth branches.

12. *PHYSALIS ramosissima, foliis ovatis acuminatis subdentatis petiolis longioribus*. Very branching Physalis with oval acute-pointed leaves, which are somewhat indented, and have longer foot-stalks.

13. *PHYSALIS ramosissima patula, ramis villosis, foliis ovatis acuminatis subdentatis*. The most branching spreading Physalis with woody branches, and oval acute-pointed leaves which are somewhat indented.

14. *PHYSALIS caule erecto ramoso, foliis ovatis serrato-dentatis, petiolis pedunculisque longissimis*. Physalis with an erect branching stalk, oval, indented, sawed leaves, and the foot-stalks of the leaves and flowers very long.

15. *PHYSALIS caule erecto ramoso, foliis ovato-lanceolatis viscosis, fructu maximo cordato*. Physalis with an erect branching stalk, oval, spear-shaped, viscous leaves, and a large heart-shaped fruit.

16. *PHYSALIS caule erecto ramoso, ramis angulatis, foliis sinuatis, calycibus acutangulis*. Physalis with an erect branching stalk, angular branches, sinuated leaves, and empalements having acute angles.

The first sort is the common winter Cherry, which is used in medicine; this grows naturally in Spain and Italy. The roots of this are perennial, and creep in the ground to a great distance, if they are not confined; these shoot up many stalks in the spring, which rise about a foot high or better, garnished with leaves of various shapes; some are angular and obtuse, others are oblong and acute-pointed; they have long foot-stalks. The flowers are produced from the wings of the stalks standing upon slender foot-stalks; they have one white petal which has a short tube, and is cut at the brim into five angles spreading open. In the

center of the tube is situated a roundish germen, supporting a slender style crowned by an obtuse stigma; this is accompanied by five stamina of the same length, terminated by oblong, erect, yellow summits which join together. The flowers are succeeded by round berries about the size of small Cherries, inclosed in an inflated bladder which turns red in the autumn, when the top opens and discloses the red berry, which is soft, pulpy, and filled with flat kidney-shaped seeds. Soon after the fruit is ripe, the stalks decay to the root.

This plant is easily propagated either by seeds or parting of the roots, the latter being the most expeditious method is generally practised. These roots may be transplanted and parted, any time after the stalks decay, till the roots begin to shoot in the spring; they love a shady situation, and should be confined, otherwise they will ramble to a great distance in one year, and when the stalks stand at a distance, they make no appearance. Their only beauty is in the autumn, when the fruit is ripe, at which time their red bladders, opening and disclosing the Cherry-shaped fruit, make a pretty appearance.

The second sort grows naturally at Buenos Ayres; this hath a creeping root, by which it multiplies very fast, sending up a great number of smooth stalks about two feet high, which divide toward their tops into small spreading branches, garnished with heart-shaped or oval leaves, standing upon pretty long foot-stalks. The flowers come out from the wings of the stalks toward the top, and have long slender foot-stalks; they are of a dirty yellow colour with purple bottoms, and are succeeded by viscous berries about the size of those of the common sort, of an herbaceous yellow colour, inclosed in a swelling bladder of a light green colour.

This plant is easily propagated by parting of the roots either in the spring or autumn, but is too tender to live abroad through the winter in England, so should be planted in pots and sheltered under a hot-bed frame in winter, where they may enjoy the free air at all times in mild weather.

The seeds of the third sort were sent me from Virginia, where the plant grows naturally; this hath a perennial root, but these roots do not creep in the ground like the two former. The stalks of this grow two feet long, and spread on the ground if they are not supported; these are garnished with oval leaves standing alternately upon very long foot-stalks; they are of a pale green having several acute indentures on their edges. The flowers come out from the wings of the larger stalk upon very short foot-stalks; they are larger than those of the common sort, and of a pale yellow colour. These are succeeded by very small yellowish berries which ripen in the autumn, when the season proves warm, but in cool moist summers they come to nothing.

This sort is propagated by seeds, which should be sown upon a warm border about the latter end of March, and when the plants come up, they should be thinned where they are too close, and kept clean from weeds till autumn, when the plants must be transplanted where they are to remain, which should be in a warm situation, where they will live through the winter in mild seasons, but are killed by severe frost if they are not screened.

The seeds of the fourth sort were sent me from Philadelphia by Dr. Bensl, who found the plants growing there naturally. This hath a perennial root composed of strong fibres, from which arise two or three hairy stalks about nine or ten inches high, dividing into several branches garnished with oval, spear-shaped, hairy leaves, of a pale green, having several acute indentures on their edges. The flowers come out from the side of the branches at the base of the foot-stalks of the leaves; these have long slender foot-stalks; they have very short tubes, but are larger than most of the species of this genus, of a sulphur colour with a dark

purple bottom. These are succeeded by oval yellowish berries, which ripen in the autumn. This sort may be propagated by seeds in the same way as the third, and the plants require the same treatment.

The fifth sort grows naturally at *Curassao* in the *West-Indies*. This hath a perennial creeping root, from which arise several slender stalks about a foot high, which become somewhat ligneous, but do not last above two years; the leaves are small, oval, and hairy: the flowers come out from the wings of the stalk toward the top, standing upon slender foot-stalks; these are of a sulphur colour, and have dark purple bottoms, but are seldom succeeded by berries in *England*.

This is easily propagated by parting of the roots in the spring, but the plants are too tender to live through the winter in *England* without artificial warmth, so the pots should be placed in a moderate warmth in winter, but during the months of *July*, *August*, and *September* they may be placed in the open air in a warm situation.

The sixth sort grows naturally at *Curassao*. This rises with a shrubby downy stalk about two feet high, dividing into several branches covered with a thick soft down, garnished with oval woolly leaves. The flowers come out at the end of the branches, at the base of the foot-stalks of the leaves; they are small, of a yellow colour, and sit close to the branches, but are not succeeded by berries in *England*.

This sort may be propagated by cuttings, which must be planted in small pots filled with light loamy earth, and plunged into a moderate hot-bed the beginning of *July*; when they are rooted, they may be removed into the open air, placing them in a sheltered situation. After they have obtained strength, they should be shaken out of the pots and separated, planting each in a distinct pot; then place them in the shade till they have taken new root, when they may be removed to their former situation, where they may remain till the end of *September*, and then be removed into the stove, where they should be placed in a moderate temperature of warmth during the winter season.

The seventh sort grows naturally in *Crete*, *Sicily*, and *Spain*. This rises with a shrubby stalk near three feet high, dividing into several branches which grow erect, and are garnished with oval spear-shaped downy leaves. The flowers come out in clusters on the side of the branches; they are small, of an herbaceous white colour sitting very close to the branches, and are succeeded by small berries, almost as large as those of the first sort, which when ripe are red.

This plant is propagated by seeds, which may be sown on a bed of light earth the beginning of *April*, and when the plants are two or three inches high, they should be taken up, and each planted in a separate small pot, and placed in the shade till they have taken new root; then they may be removed to a sheltered situation, where they may remain till the beginning of *October*; at which time they should be removed into the green-house, for the plants are too tender to live through the open air in winter, so they must be treated like other green-house plants, but should be sparingly watered in winter. These plants will continue several years if they are not too tenderly treated.

The eighth sort grows naturally at *Malabar*, and also at the *Cape of Good Hope*. This rises to the height of five or six feet, sending out long flexible branches, covered with a gray bark, garnished with oblong oval leaves which are often placed opposite. The flowers are produced in clusters at the base of the foot-stalks of the leaves; they are small, of an herbaceous yellow colour, and are succeeded by round purplish berries having ten cells, each including one seed.

This is propagated by seeds, which should be sown upon a moderate hot-bed, and the plants afterward treated in the same way as the last.

The ninth sort grows naturally at *Campeachy*. This hath a shrubby stalk, which rises ten or twelve feet high, covered with a gray hairy bark, garnished with oval spear-shaped leaves, placed alternately, of a pale green, and downy. The flowers come out from the wings of the stalks toward the end of the branches, sometimes one, and at others two are produced at the same joint opposite; they stand upon short nodding foot-stalks. The flowers are small, of a pale dirty yellow colour, having purple bottoms; these are succeeded by small, spherical, red berries, included in an oval dark purple bladder.

This may be propagated by seeds in the same way as the last mentioned, and the plants require the same treatment, but are not so hardy, therefore they must be kept in a moderate stove in winter, but in the middle of summer they should be placed in the open air, in a sheltered situation, for about three months. It may also be propagated by cuttings, which, if planted in pots during the summer months, and plunged into a gentle warmth, will take root freely, and may be treated in the same way as is before directed for the sixth sort.

The tenth sort is an annual plant, which grows naturally in *Virginia*. This branches out at bottom on every side; the branches frequently trail upon the ground; they are angular, and full of joints, garnished with hairy, viscous, heart-shaped leaves, standing upon pretty long foot-stalks, acutely indented on their edges. The flowers are produced on the side of the branches upon short, slender, nodding foot-stalks, of an herbaceous yellow colour with dark bottoms, which are succeeded by large swelling bladders, of a light green, inclosing berries as large as common Cherries, which are yellowish when ripe.

If the seeds of this sort are permitted to scatter, the plants will come up in the spring, and require no other care but to thin them, and keep them clean from weeds; or if the seeds are sown in the spring on a common border, the plants will rise very well, and need no other care.

The eleventh sort is also an annual plant, which grows naturally in the islands of the *West-Indies*. This rises with an upright branching stalk from two to three feet high. The branches are smooth, angular, and garnished with spear-shaped leaves, ending in acute points, sharply indented on their edges. The flowers come out toward the end of the branches upon short slender foot-stalks; they are very small, of a dirty white colour, and are succeeded by berries the size of common Cherries, covered with an angular bladder; they are of a yellowish colour when ripe.

This sort is propagated by seeds, which should be sown on a moderate hot bed; when the plants come up, and are a little advanced, they should be planted on a fresh hot-bed to bring them forward, and treated in the same way as the *Capicum*. When they are grown strong, and are hardened to bear the open air, they may be transplanted with balls of earth to their roots into a warm border, where their seeds will ripen.

The twelfth sort grows naturally in the *West-Indies*. This is an annual plant, with very branching stalks, which seldom rise above a foot high. The leaves are oval, of a deep green, and have long foot-stalks; the flowers are small, white, and stand upon short foot-stalks; the berries are small, and green when ripe.

The seeds of the thirteenth sort were sent me from *Barbadoes*. This is a low annual plant, seldom rising more than nine or ten inches high. The branches are hairy, and spread out almost horizontally; the leaves are oval, ending in acute points, and are a little indented; the flowers are small, white, and are succeeded by large fruit, inclosed in a long acute-pointed bladder.

The fourteenth sort was discovered at *La Vera Cruz*. This is an annual plant, with an upright branching stalk near two feet high, garnished with oval leaves, indented on their edges like a saw. They have long foot-stalks, and change to a purplish colour in the autumn. The flowers are small, white, standing upon very long foot-stalks, and are succeeded by large berries almost as large, and of the shape of Heart-cherries, of a yellowish green, with some purple stripes.

The fifteenth sort grows naturally in the same country. This is an annual plant, with a smooth, erect, branching stalk near three feet high, garnished with oval, spear-shaped, viscous leaves, standing on long foot-stalks. The flowers are small, of a pale yellow, and are succeeded by large heart-shaped fruit, of a pale yellow when ripe. The four last mentioned sorts are propagated by seeds in the same manner as the eleventh, and the plants require the same treatment.

The sixteenth sort grows naturally in *Peru*. This is an annual plant, rising with a strong, herbaceous, angular stalk four or five feet high, of a purplish colour, dividing into several angular branches, garnished with oblong leaves, which are deeply sinuated on their sides, of a deep green. The foot-stalks of the flowers are short; the empalement of the flower is large, bell-shaped, and deeply cut into five segments; the flower is large, of the open bell-shape, of a light blue colour, and is succeeded by berries about the size of common Cherries, inclosed in a large swelling bladder, having five sharp angles. If the seeds are permitted to scatter, the plants will come up the following spring, or if the seeds are sown on a bed of rich earth in the spring, the plants will rise easily, and may be afterward transplanted to the borders of the pleasure-garden, where they must be allowed room, for if the ground is good, the plants will grow very large.

Father *Feuillee*, who first discovered this plant in *Peru*, and has given a figure and description of it, recommends it greatly for its virtues, and says the *Indians* make great use of the berries to bring away gravel, and to relieve persons, who have a stoppage of urine, and gives the manner of using them, which is, to bruise four or five of the berries either in common water, or white wine, giving it the patient to drink, and the success is astonishing.

PHYTOLACCA. *Tourn. Inst. R. H. 299. tab. 154. American Night-shade.*

The Characters are,

The flower hath no petals; though the cover of the parts of generation being coloured, is by some termed petals; there are five of these which are concave, open, and permanent. It has for the most part ten stamina, which are the same length as the petals, terminated by roundish summits, and ten compressed orbicular germen, joined together on their inside, but are divided on their outside, upon which sit ten very short styles, which are reflexed. The germen afterward turns to an orbicular depressed berry, with ten longitudinal deep furrows, having ten cells, each containing a single smooth seed.

The Species are,

1. PHYTOLACCA *foliis integerrimis, radice perenni*. Phytolacca with entire leaves, and a perennial root; commonly called *Virginian Poke*, or *Porke Physick*.

2. PHYTOLACCA *foliis ovato-lanceolatis, floribus sessilibus*. Phytolacca with oval spear-shaped leaves, and flowers sitting close to the stalks.

3. PHYTOLACCA *spicis florum longissimis, radice annua*. *Tab. 207.* Phytolacca with the longest spikes of flowers, and an annual root.

The first sort grows naturally in *Virginia*, and also in *Spain* and *Portugal*. It hath a very thick fleshy root, as large as a man's leg, divided into several thick fleshy fibres.

When the roots are become large, they send out several stalks, which are herbaceous, as large as a good walking stick, of a purple colour, and rise to the height of six or seven feet, dividing into many branches at the top, garnished with large entire leaves, rounded at their base, but terminate in a point, and are placed without order, having short foot-stalks; in the autumn the leaves change to a purplish colour. From the joints of the branches, and at their divisions, come out the foot stalks of the flowers about five inches long; the lower part is naked, but the upper half sustains a number of flowers ranged on each side like common Currants. The flowers have five purplish petals, or covers, within which stand the ten stamina and styles. After the flowers are faded, the germen turns to a depressed berry with ten furrows, having ten cells, filled with smooth seeds.

It may be propagated by sowing the seeds in the spring upon a bed of light earth; and when the plants come up, they should be transplanted into the borders of large gardens, allowing them space to grow, for they must not be planted too near other plants, lest they overbear and destroy them, as they grow to be very large, especially if the soil be very good. When they have taken root, they will require no farther care, but only to clear them from weeds, and in the autumn they will produce their flowers and fruit; the stems of these plants constantly decay in the winter, but their roots will abide in the ground, and come up again the succeeding spring.

Parkinson says, that the inhabitants of *North America* make use of the juice of the root as a familiar purge; two spoonfuls of the juice will work strongly. Of late there have been some quacks, who pretend to cure cancers with this herb, but I have not met with one instance of its having been serviceable in that disorder. The inhabitants of *North America* boil the young shoots of this plant, and eat it like Spinach. The juice of the berries stain paper and linen of a beautiful purple colour, but it will not last long. If there could be a method of fixing the dye, it might be very useful.

The second sort grows naturally in the *Spanish West-Indies*, where the inhabitants constantly use it for their table. This plant is biennial, seldom continuing longer than two years, and when it flowers and produces plenty of seeds the first year, the plants frequently die before the following spring. This hath an herbaceous stalk about two feet high, dividing at the top into two or three short branches, garnished with oval spear-shaped leaves; they are of a deep green, and have foot-stalks an inch and a half long, placed without order. The foot-stalks of the flowers come out from the side of the branches opposite to the leaves; they are seven or eight inches long; the lower part about two inches in length is naked; the remaining part is garnished with white flowers, sitting close to the stalks; these are succeeded by flat berries, having many deep furrows divided into so many cells, each containing one smooth seed.

Dr. Linnaeus has supposed these two species were the same, but whoever sees the two plants growing, or attends to their descriptions, cannot doubt of their being different.

The third sort grows naturally in *Malabar*. This plant is annual, always perishing soon after it has perfected seeds, so that in this particular it differs greatly from the first: it rises with an herbaceous stalk from three to four feet high, which has several longitudinal furrows, and changes the latter part of summer to a purplish colour. It divides at the top into three or four branches, garnished with spear-shaped, dark, green leaves, standing upon short foot-stalks; sometimes alternately, at others they are placed opposite. The foot-stalks of the flowers come out from the side of the branches opposite to the leaves, the lower part being naked, as in the other sorts; the other part is garnished with larger flowers

flowers than those of the other sorts, white on their inside, of an herbaceous colour on their edges, and purplish on their outside, standing upon short foot-stalks; these have not always the same number of stamina, some of them have but eight, and others nine, which are terminated by roundish summits. The flowers are succeeded by orbicular, compressed soft berries, divided by deep furrows on their outside into ten cells, each containing one smooth shining black seed; the racemus of flowers is very narrow at the top, where it is commonly inclined.

These two sorts are not so hardy as the first, so their seeds should be sown upon a moderate hot-bed in the spring, and when the plants are fit to remove, they should be transplanted to another hot-bed to bring them forward; then they should be treated in the same way as other tender exotic plants; the beginning of July they may be transplanted out upon a warm border, or into pots: they will require to be watered duly in dry weather, and kept clean from weeds. As these plants perfect their seeds every autumn, they may be easily preserved.

PIERCEA. *Solanoides*. *Tournef. Art. Par.* 1706.

The Characters are,

The flower has no petals; the empalement which incloses the parts of generation is composed of four oblong, oval, coloured leaves. It hath four stamina, which stand erect and close together, terminated by small summits. In the center is situated a large roundish germen, supporting a short style, crowned by an obtuse stigma. The germen afterward turns to a roundish berry, sitting upon the reflexed empalement, having one cell, inclosing a rough seed of the same form.

I have taken the freedom of inscribing this genus of plants to the Right Hon. Hugh Piercy, Earl of Northumberland, who is not only a great encourager of botanical studies, but greatly skilled in the science himself.

The title of *Solanoides* was applied to this plant, in the Memoirs of the Academy of Sciences for the year 1706. Dr. Linnæus has supposed this to be the same with Plumier's *Rivinia*, so he has continued that title to this plant, and believed Plumier was mistaken, when he drew eight stamina to the flower, but Plumier's *Rivinia* is totally different from this plant, and the flowers of it have eight stamina, as he has represented it; so Linnæus is mistaken.

The Species are,

1. PIERCEA *foliis ovato-lanceolatis glabris*. Piercea with oval, spear-shaped, smooth leaves.

2. PIERCEA *foliis cordatis pubescentibus*. Piercea with heart-shaped downy leaves.

These plants grow naturally in most of the islands in the West-Indies, but the first is the most common there. It rises with a slender herbaceous stalk three or four feet high, which by age becomes a little ligneous at the bottom. It divides into many angular herbaceous branches, garnished with oval spear-shaped leaves, of a bright green, with slender foot stalks. The foot-stalks of the flowers come out from the side of the branches, at the base of the foot-stalks of the leaves, sustaining a great number of small white flowers, ranged along the upper part on both sides. These are succeeded by small red berries full of a red juice, inclosing one hard seed of the same form.

The second sort spreads more than the first; the leaves are smaller, heart-shaped, and covered with short hairy down; the spikes of flowers are not so long, and are not so closely placed together, and have longer foot-stalks.

These plants are propagated by seeds, which should be sown soon after they are ripe, for if they are kept long out of the ground, they seldom grow the same year. They should be sown in pots, filled with light earth, and plunged into a moderate hot-bed. When the plants come up two inches high, they should be each planted in a small half-

penny pot, and plunged into a moderate hot-bed; then they must be treated in the same way as other exotic plants. When the plants have obtained strength, they should be removed into the stove, and may be placed on shelves, and there they must constantly remain, for they are too tender to thrive in the open air in England in the warmest part of the year.

The juice of the berries of this plant will stain paper and linen of a bright red colour, and I have made many experiments with it to colour flowers, which have succeeded extremely well in the following manner. I pressed out the juice of the berries, and mixed it with common water, putting it into a phial, shaking it well together for some time, till the water was thoroughly tinged; then I cut off the flowers, which were white and just fully blown, and placed their stalks into the phial, and in one night the flowers have been finely variegated with red. The flowers, which I made the experiments on, were the Tuberose, and the double white Narcissus.

PILOSELLA. See Hieracium.

PIMPINELLA. *Lin. Gen. Plant.* 328. Burnet Saxifrage.

The Characters are,

It hath an umbellated flower; the principal umbel is composed of many rays or smaller umbels, neither of these have any involucrems; the greater umbel is uniform. The flowers have five heart-shaped inflexed petals, nearly equal, and five stamina longer than the petals, terminated by roundish summits. The germen is situated under the flower, supporting two short styles, crowned by obtuse stigmas. The germen afterward becomes an oblong oval fruit, divided in two parts, containing two oblong seeds, plain on the inside, convex on the other, and furrowed.

The Species are,

1. PIMPINELLA *foliis pinnatis, foliolis cordatis serratis, summis simplicibus trifidis*. Burnet Saxifrage, whose lower leaves are winged, and single three-pointed leaves at the top; greater Burnet Saxifrage.

2. PIMPINELLA *foliis pinnatis, foliolis radicalibus subrotundis, summis linearibus*. *Lin. Sp. Plant.* 263. Burnet Saxifrage with winged leaves, whose bottom lobes are roundish, but those at the top linear.

3. PIMPINELLA *foliis pinnatis, foliolis radicalibus pinnatifidis, summis linearibus trifidis*. Burnet Saxifrage with winged leaves, whose lobes of the bottom leaves are wing-pointed, and the upper ones linear and trifid; or lesser Burnet Saxifrage.

4. PIMPINELLA *foliis pinnatis hirsutis, foliolis radicalibus cordatis inæqualiter serratis, summis linearibus quinquesidis*. Burnet Saxifrage with hairy winged leaves, whose lobes of the bottom leaves are heart-shaped unequally sawed, and the upper ones linear and five-pointed; or German Burnet Saxifrage.

5. PIMPINELLA *foliis pinnatis lucidis, foliolis radicalibus lanceolatis, pinnato-serratis, summis linearibus pinnatifidis*. Burnet Saxifrage with shining winged leaves, the lobes of whose bottom leaves are spear-shaped and sawed, and the upper ones linear and wing-pointed; or largest Burnet Saxifrage of Austria.

6. PIMPINELLA *foliis radicalibus pinnatis crenatis, summi cuneiformibus incis. Lin. Sp. Plant.* 164. Burnet Saxifrage, whose lower leaves are winged, and indented on their edges, and the upper ones wedge-shaped and cut; or foreign Parsley with roundish leaves.

7. PIMPINELLA *foliis radicalibus trifidis incis. Lin. Sp. Plant.* 264. Pimpinell with trifid, cut, lower leaves; or common Anise.

The first sort grows naturally in chalky woods, and on the side of the banks near hedges, in several parts of England. The lower leaves of this sort are winged; the lobes are sharply sawed on their edges, and sit close to the midrib,

of a dark green. The stalks are more than a foot high, dividing into four or five branches; the lower part of the stalk is garnished with winged leaves, shaped like those at the bottom, but are smaller; those upon the branches are short and trifid; the branches are terminated by small umbels of white flowers, which are composed of smaller umbels or rays. The flowers have five heart-shaped petals, which turn inward, and are succeeded by two narrow, oblong, channelled seeds.

The second sort grows naturally in dry pastures in many parts of *England*. The lower leaves of this are composed of four pair of lobes, terminated by an odd one; they are indented on their edges; the stalks rise near a foot high, sending out three or four slender branches, garnished with very narrow leaves. The umbels of flowers are smaller than those of the first, as are also the flowers and seeds.

The third sort grows naturally in dry gravelly pastures in several parts of *England*. The lower leaves of this sort have five or six pair of lobes, terminated by an odd one. The stalks are slender, and rise about a foot high, sending out a few small branches, which have a narrow trifid leaf placed at each joint, and are terminated by small umbels of white flowers, composed of several rays, standing upon pretty long foot-stalks.

The seeds of the fourth sort were sent me from *Paris* by Dr. *Bernard de Jussieu*. The lower leaves of this sort are composed of six or seven pair of heart-shaped lobes, terminated by an odd one; they are hairy, and of a pale green. The stalk rises near two feet high, dividing into several branches, which have one narrow five-pointed leaf at each joint, and are terminated with umbels of white flowers, like those of the first sort.

The seeds of the fifth sort I gathered in Dr. *Boerhaave's* private garden near *Leyden*, who had received the seeds of it from *Austria*. The lower leaves have five pair of lobes, terminated by an odd one; they are deeply cut in regular jags opposite, in form of a winged leaf, of a lucid green, and have long foot-stalks. The stalks rise more than two feet high, dividing at the top into two or three slender branches, garnished at each joint with one wing-pointed narrow leaf. The umbels of flowers are very like the first.

All these sorts have perennial roots; they are propagated by seeds, which, if sown in the autumn, will more certainly succeed, than when they are sown in the spring. When the plants come up, they will require no other culture, but to thin them where they are too close, and keep them clean from weeds; the second year they will flower and produce ripe seeds, and the roots will abide some years.

The first sort is directed for medicinal use, but the herb-women either bring the third sort to market for it, or what is worst, substitute *Burnet* and *Meadow Saxifrage* in its stead. It enters the *pulvis ari compositis*, and is esteemed good for the gravel.

The last sort is the common Anise. This is an annual plant, which grows naturally in *Egypt*, but is cultivated in *Malta* and *Spain*, from which countries the seeds are annually brought to *England*. From these seeds there is a distilled water, and an oil drawn for medicinal use. The pastrycooks also make great use of these seeds in several of their compositions, to give them an aromack taste and smell. The lower leaves of this plant are divided into three lobes, which are deeply cut on their edges; the stalk rises a foot and a half high, dividing into several slender branches, garnished with narrow leaves, cut into three or four narrow segments, terminated by pretty large loose umbels, composed of many smaller umbels or rays, which stand on pretty long foot-stalks. The flowers are small, and of a yellowish white; the seeds are oblong and swelling.

The seeds of this should be sown the beginning of *April* upon a warm border, where the plants are to remain; when they come up, they should be thinned, and kept clean from weeds, which is all the culture this plant requires, but it is too tender to be cultivated in *England* for profit.

PINASTER. See Pinus.

PINGUICULA, Butterwort.

This plant is found growing upon bogs in many parts of *England*, but is never cultivated in gardens, so I shall pass it over with barely mentioning it.

PINUS. *Tourn. Inst. R. H. 585. tab. 355.* The Pine-tree.

The Characters are,

The male flowers are collected in a scaly conical bunch, having many stamina, which are connected at their base, terminated by erect summits, included in the scales, which supply the want of petals and empalement. The female flowers are collected in a common oval cone, and stand at a distance from the male on the same tree. Under each scale of the cone is produced two flowers, which have no petals, but a small germen, supporting an awl-shaped style, crowned by a single stigma. The germen afterward becomes an oblong oval nut, crowned with a wing, included in the rigid scale of the cone.

The Species are,

1. PINUS foliis geminis crassiusculis glabris, conis pyramidalis acutis. Pine-tree with two thick smooth leaves in each sheath, and pyramidal acute cones; or Pineaster.

2. PINUS foliis geminis tenuioribus glaucis, conis subrotundis obtusis. Pine-tree with two narrower gray leaves coming out of each sheath, and roundish blunt cones; the cultivated Pine-tree, commonly called the Stone Pine.

3. PINUS foliis geminis brevioribus glaucis, conis parvis mucronatis. Pine-tree with two shorter gray leaves proceeding out of each sheath, and small acute-pointed cones; called Scotch Fir or Pine.

4. PINUS foliis geminis brevioribus latiusculis glaucis, conis minimis. Pine-tree with two shorter broad leaves in each sheath, which are gray, and the smallest cones; commonly called Tartarian Pine.

5. PINUS foliis sepius ternis tenuioribus viridibus, conis pyramidalis, squamis obtusis. Pine with three narrow green leaves often in each sheath, and pyramidal cones with blunt scales; called Mugho.

6. PINUS foliis quinis laevibus. *H. Scan. 32. Lin. Sp. Plant. 1000.* Pine-tree with five smooth leaves in each sheath; called Cembro.

7. PINUS foliis geminis longioribus glabris, conis longioribus tenuioribusque. Pine-tree with two longer smooth leaves in each sheath, and longer narrower cones; the maritime Pine.

8. PINUS foliis geminis tenuissimis, conis obtusis, ramis patulis. *Tab. 208.* Pine-tree with two narrow leaves in each sheath, obtuse cones, and spreading branches; *Aleppo* Pine.

9. PINUS foliis geminis brevioribus, conis parvis, squamis acutis. Pine-tree with two shorter leaves in each sheath, and small cones with acute scales; commonly called *Jersey* Pine.

10. PINUS foliis ternis, conis longioribus squamis rigidioribus. Pine-tree with three leaves, and longer cones, having rigid scales; commonly called three-leaved *Virginian* Pine.

11. PINUS foliis longioribus tenuioribus ternis, conis maximis laxis. Pine-tree with three longer narrower leaves, and the largest loose cones; called the *Frankincense*-tree.

12. PINUS *Virginiana* praelongis foliis tenuioribus, cono echinato glacili. *Pluk. Alm. 297.* *Virginian* Pine with longer and narrower leaves, and a slender prickly cone; called three-leaved *Bastard* Pine.

13. PINUS foliis quinis scabris. *Lin. Sp. Plant. 1001.* Pine-tree with five rough leaves in each sheath; commonly called *Lord Weymouth's* Pine.

14. *PINUS foliis ternis longissimis.* Pine-tree with the longest leaves, growing by threes out of each sheath; or three-leaved Marsh *American* Pine.

There are some other species of this genus in *America*, which have not been sufficiently examined to ascertain their differences; and it is probable some of the *European* kinds, which are now supposed to be only varieties of the sorts here enumerated, may be distinct species; but as I have had no opportunity of seeing their cones, so I have omitted them here.

The first sort here enumerated is the Pineaster, or wild Pine, which grows naturally on the mountains in *Italy* and the south of *France*, where there are forests of these trees, which, if suffered to stand, grow to a large size; but they are frequently cut for making of pitch; and in the south of *France*, the young trees are cut for stakes to support their vines. This grows to a large size; the branches extend to a considerable distance, and while the trees are young, they are fully garnished with leaves, especially where they are not so close as to exclude the air from those within; but as they advance in age, the branches appear naked, and all those which are situated below, become unsightly in a few years, for which reason they have not been much in esteem of late years; for as the wood of the *Scotch* Fir is much preferable to this, and the branches being generally better garnished with leaves, so the latter has been more generally propagated than the former. The leaves of this are of a dark green, and their points are obtuse. The cones are seven or eight inches long, pyramidal, and have pointed scales; the seeds are oblong, a little flattened on their sides, and have narrow wings on their tops.

The second sort, which is generally called the Stone Pine, is very common in *Italy*; but I much doubt of the country where it grows naturally, for so far as I have been able to learn, there are none of these trees growing in any part of *Italy*, but where they have been planted, or where the seeds have scattered from planted trees; and I have frequently received the seeds of a Pine from *China*, which were taken out of the cones so like those of this sort, as not to be distinguished from them; but these have never grown, either by their being too old, or from their having been taken out of the cones; for if the seeds of Pines are kept in the cones, they will grow at ten or twelve years old; but when they are out of their cones, they seldom grow well after two years, and some sorts do not grow after one. The leaves of this are not quite so long as those of the former sort, and are of a grayish or sea-green colour; the cones are not more than five inches long, but are very thick, roundish, and the scales end in an obtuse point; the seeds are more than twice the size of those of the former. The kernels of these are frequently served up in deserts to the table during the winter season in *Italy*, and formerly they were used in medicine here, but of late years the Pistachia Nuts have been generally substituted in lieu of them. The wood of this tree is white, not so full of resin as many of the other sorts, so is never cultivated for its timber, but chiefly for the beauty of its leaves and for the nuts, which are much esteemed in the south of *France*, and in *Italy*.

The third sort is generally known here by the title of *Scotch* Pine, from its growing naturally in the mountains of *Scotland*; but it is common in most parts of *Europe*. *Monf. du Hamel*, of the Royal Academy of Sciences at *Paris*, mentions his having received cones of this tree from *St. Domingo* in the *West-Indies*, so concludes that it grows indifferently in torrid, frozen, and temperate zones. It is by *John Bauhin* titled, *Pinus sylvestris, Genevensis vulgaris*; so that it grows commonly in the mountains near that city, and all through *Denmark*, *Norway*, and *Sweden*. The wood of this tree is the red or yellow deal, which is the most durable of

any of the kinds yet known. The leaves of this tree are much shorter and broader than those of the former sorts, of a grayish colour, growing two out of each sheath; the cones are small, pyramidal, and end in narrow points; they are of a light colour, and the seeds are small.

This sort grows well upon almost every soil; I have planted numbers of the trees upon Peat-bogs, where they have made great progress. I have also planted them in clay, where they have succeeded far beyond expectation; and upon sand, gravel, and chalk, they likewise thrive as well; but as they do not grow near so fast upon gravel and sand, as upon moist ground, so the wood is much preferable; for those trees which have been cut down upon moist soils, where they have made the greatest progress, when they have been sawn out into boards, have not been valuable, the wood has been white, and of a loose texture; whereas those which have grown upon dry gravelly ground, have proved nearly equal to the best foreign deals; and I doubt not but those plantations, which of late years have been made of these trees, will, in the next age, not only turn greatly to the advantage of their possessors, but also become a national benefit.

The fourth sort grows naturally in *Tartary*, from whence I received the seeds. This hath a great resemblance to the *Scotch* Pine, but the leaves are broader, shorter, and their points are more obtuse; they emit a strong balsamick odour when bruised; the cones of this are very small, as are also the seeds, some of which were black, and others white; but whether they are from different trees or the same, I could not learn, for the seeds were taken out of the cones, but in the parcel there was one entire cone.

The fifth sort grows naturally upon the mountains in *Switzerland*. This hath very narrow green leaves, which grow sometimes by pairs, and at others there are three coming out of each sheath; they generally stand erect; the cones are of a middle size, and pyramidal; the scales are flat, having each a small obtuse rising, but are very compact, till they are opened by the warmth of the sun. The seeds of this are much less than those of the Pineaster, but larger than those of the *Scotch* Pine.

The sixth sort grows naturally in *Switzerland*, and is by some persons supposed to be the same as the *Siberian*, but is different; for the cones of this are short and roundish, and the scales are close, whereas those of the *Siberian* Pine are long, the scales are loose; the leaves have a near resemblance to each other, but when compared, those of this tree are smooth, and the other are rough. The plants, which have been raised from the *Switzerland* seeds, have made much greater progress than those from the *Siberian* seeds; the latter are with difficulty kept alive in *England*. The leaves are long and narrow, smooth to the touch, of a light green, and five of them come out from the same sheath; the branches are closely garnished with them; the cones are about three inches long; the scales are pretty close; the seeds are pretty large, and their shells are easily broken.

The seventh sort grows in the maritime parts of *Italy*. This hath long smooth leaves, growing by pairs in each sheath; the cones are very long and slender; the seeds are about the size of those of the Pineaster.

The eighth sort grows naturally near *Aleppo*. This is a tree of middling growth in its native soil, and in *England* there are none of any large size; for most of the plants, which were growing here before the year 1740, were killed by the frost that severe winter. This tree branches out on every side near the root; the branches at first grow horizontally, but turn their ends upward; their bark is smooth, and of a dark gray colour. The leaves are long and very narrow, of a dark green, and grow by pairs in each sheath;

if they are bruised, they emit a strong resinous odour. The cones come out from the side of the branches; they are not much more than half the length of those of the Pineaster, but are full as large at their base; the scales are flatted, and the point of the cone obtuse. The seeds are much less than those of the Pineaster, but of the same shape.

The ninth sort grows naturally in *North America*. This never rises to any great height, and is the least esteemed in the country of all the sorts. While the plants are young, they make a pretty good appearance, but when they get to the height of seven or eight feet, they become ragged and unsightly, so are not worth cultivating.

The tenth sort grows naturally in *Virginia*, and other parts of *North America*, where it rises to a great height; and so far as we can judge by the growth of those trees which are now here, it seems likely to become a large tree in *England*. The leaves of this are long, three generally standing in each sheath; the cones of this sort come out in clusters round the branches; they are as long as the cones of the Pineaster, and have rigid scales; the seeds are winged, and nearly as large as those of the Pineaster.

The eleventh sort grows naturally in *North America*. This hath very long narrow leaves, growing by threes out of each sheath; the cones are as large as those of the Stone Pine, but the scales are looser, and the cones more pointed. The scales of this open horizontally, and discharge the seeds. This sort was sent over from *America* to Mr. Ball of *Exeter*, and also to Dr. Compton, Bishop of *London*, by the title of Frankincense Pine.

The twelfth sort grows naturally in *Virginia*. The cones of this have been brought to *England* of late years, by the title of Bastard three-leaved Pine. The leaves of this sort are long and narrow; sometimes there are three growing in each sheath, and at others but two; the cones are long, slender, and their scales terminate in sharp points; they are rather longer than those of the Pineaster, and not so thick.

The thirteenth sort grows naturally in *North America*, where it is called the white Pine. It is one of the tallest trees of all the species, often growing a hundred feet high in those countries, as I have been credibly informed; the bark of this tree is very smooth and delicate, especially when young; the leaves are long and slender, five growing out of each sheath; the branches are pretty closely garnished with them, so make a fine appearance; the cones are long, slender, and very loose, opening with the first warmth of the spring; so that if they are not gathered in winter, the scales open and let out the seeds. The wood of this sort is esteemed for making of masts for ships; it is in *England* titled Lord *Weymouth's*, or *New England Pine*. As the wood of this tree was generally thought of great service to the navy, there was a law made in the ninth year of *Queen Anne*, for the preservation of the trees, and to encourage their growth in *America*; and it is within forty years past these trees began to be propagated in *England* in any plenty, though there were some large trees of this sort growing in two or three places long before, particularly at Lord *Weymouth's* at *Longleet*, and Sir *Wyndham Knatchbull's* in *Kent*; and it has been chiefly from the seeds of the latter that the much greater number of these trees now in *England* have been raised; for although there has annually been some of the seeds brought from *America*, yet those have been few in comparison to the produce of the trees in *Kent*; many of the trees, which have been raised from the seeds of those trees, now produce plenty of good seeds, particularly those in the gardens of the late Duke of *Argyle* at *Whitton*, which annually produce large quantities of cones, which his grace when living most generously distributed to all the curious.

This sort and the *Scotch Pine* are the best worth culti-

vating of all the kinds for the sake of their wood; the others may be planted for variety in parks, &c. where they may make a good appearance in winter, when other trees are destitute of leaves.

All the sorts of Pines are propagated by seeds, which are produced in hard woody cones; the way to get the seeds out of those cones which are close, is to lay them before a gentle fire, which will cause the cells to open, and then the seeds may be easily taken out. If the cones are kept entire, the seeds will remain good some years, so that the surest way to preserve them, is to let them remain in the cones, until the time for sowing the seeds; if the cones are kept in a warm place in summer, they will open, and emit the seeds, but if they are not exposed to much heat, many of the sorts will remain entire some years, especially those which are close and compact; and the seeds, which have been taken out of cones of seven years old, have grown very well, so that these may be transported to any distance, provided the cones are well ripened, and properly put up.

The best time for sowing the seeds of Pines, is about the end of *March*; when the seeds are sown, the place should be covered with nets to keep off birds, otherwise, when the plants begin to appear with the husk of the seed on their tops, the birds will pick off the heads of the plants, and destroy them.

Where the quantity of seeds to be sown is not great, it will be a good way to sow them either in boxes or pots, filled with light loamy earth, which may be removed from one situation to another, according to the season of the year; but if there is a large quantity of the seeds, so as to require a good space to receive them, they should be sown on an east or north-east border, where they may be screened from the sun, whose heat is very injurious to these plants at their first appearance above ground. Those seeds, which are sown in pots or boxes, should also be placed in a shady situation, but not under trees; and if they are screened from the sun with mats at the time when the plants first come up, it will be a good method to preserve them.

Most of the sorts will come up in about six or seven weeks after they are sown, but the seeds of the Stone or cultivated Pine, and two or three of the others, whose shells are very hard, frequently lie in the ground a whole year; so that when the plants do not come up the first year, the ground should not be disturbed, but kept clean from weeds, and the following spring the plants will rise. This frequently happens in dry seasons, and when they are sown in places a little too much exposed to the sun.

When the plants appear, they must be constantly kept clean from weeds, and in very dry seasons, if they are now and then gently refreshed with water, it will forward their growth; but this must be done with great care and caution, for if they are hastily watered, it will wash the tender plants out of the ground, or lay them down flat, which often rots their shanks, and when this is too often repeated, it will have the same effect, so that unless it is judiciously performed, it will be the best way to give them none, but only screen them from the sun.

If the plants come up too close, it will be a good method to thin them gently about the beginning of *July*. The plants, which are drawn up, may then be planted on other beds, which should be prepared ready to receive them, for they should be immediately planted as they are drawn up, because their tender roots are soon dried and spoiled at this season of the year. This work should be done (if possible) in cloudy or rainy weather, and then the plants will draw out with better roots, and will soon put out new fibres again, but if the weather should prove clear and dry, the plants should be shaded every day from the sun with mats, and now and then gently refreshed with water. In drawing

up of the plants, there should be great care taken not to disturb the roots of the plants left remaining in the seed-beds, &c. so that if the ground be hard, the beds should be well watered some time before the plants are thinned, to soften and loosen the earth; and if, after the plants are drawn out, the beds are again gently watered to settle the earth to the roots of the remaining plants, it will be of great service to them, but it must be done with great care, so as not to wash out their roots, or lay down the plants. The distance, which should be allowed these plants, is four or five inches row from row, and three inches in the rows.

In these beds the plants may remain till the spring twelve months after, by which time they will be fit to transplant where they are to remain for good, for the younger plants are, when planted out, the better they will succeed; for although some sorts will bear transplanting at a much greater age, yet young plants planted at the same time will in a few years overtake the large ones, and soon outstrip them in their growth; and there is an advantage in planting young, by saving the expence of staking, and much watering, which large plants require. I have several times seen plantations of several sorts of Pines, which were made of plants six or seven feet high, and at the same time others of one foot high planted between them, which in ten years were better trees than the old ones, and much more vigorous in their growth; but if the ground, where they are designed to remain, cannot be prepared by the time before-mentioned, the plants should be planted out of the beds into a nursery, where they may remain two years, but not longer, for it will be very hazardous removing these trees at a greater age.

The best season to transplant all the sorts of Pines, is about the latter end of *March*, or the beginning of *April*, just before they begin to shoot; for although the *Scotch Pine*, and some of the most hardy sorts, may be transplanted in winter, especially when they are growing in strong land, where they may be taken up with balls of earth to their roots, yet this is what I would not advise for common practice, having frequently seen it attended with bad consequences, but those which are removed in the spring rarely fail.

Where these trees are planted in exposed situations, they should be put pretty close together, that they may shelter each other, and when they have grown a few years, part of the plants may be cut down to give room for the others to grow; but this must be gradually performed, lest by too much opening the plantation at once, the air should be let in among the remaining trees with too great violence, which will stop their growth.

Where-ever large plantations are designed to be made, the best method will be to raise the plants either upon a part of the same land, or as near to the place as possible, and also upon the same sort of soil; a small piece of ground will be sufficient to raise plants enough for many acres, but, as the plants require some care in their first raising, if the neighbouring cottagers, who have many of them small inclosures adjoining to their cottages; or where this is wanting, a small inclosure should be made them for the purpose of raising the plants, and they are furnished with the seeds and directions for sowing them, and managing the young plants, till they are fit for transplanting, the women and children may be usefully employed in this work, and the proprietors of land agreeing with them to take their plants, when raised, at a certain price, it would be a great benefit to the poor, and hereby they would be engaged to have a regard for the plantations when made, and prevent their being destroyed.

The *Scotch Pine*, as was before observed, being the hardiest of all the kinds, and the wood of it the most useful, is the sort which best deserves care. This will thrive upon the most barren lands, where scarce any thing else except heath

and furze will grow, so that there are many thousand acres of such land lying convenient for water carriage, which at present is of little benefit to any body, that might, by plantations of these trees, become good estates to their proprietors, and also a national benefit; and as the legislators have taken this into their consideration, and already passed some laws for the encouraging these plantations, as also for their preservation and security, so it may be hoped that this will be undertaken by the gentlemen who are possessed of such lands in all the different parts of the kingdom, with proper spirit; for although they may not expect to receive much profit from these plantations in their own time, yet their successors may with large interest, and the pleasure which these growing trees will afford them, by beautifying the present dreary parts of the country, will in some measure recompense them for their trouble and expence, and by creating employment for the poor, lessen those rates which are now so high in many parts of *England*, as scarce to be borne.

The expence of making these plantations is what most people are afraid of, so would not engage in it, but the greatest of the expence is that of fencing them from the cattle, &c. for the other is trifling, as there will be no necessity for preparing the ground to receive the plants, and the charge of planting an acre of land with these plants, will not be more than thirty shillings where labour is dear, exclusive of the plants, which may be valued at forty shillings more. I have planted many acres of land with these trees, which was covered with heath and furze, and have only dug holes between to put in the plants, and afterward laid the heath or furze, which was cut, upon the surface of the ground about their roots, to prevent the ground drying, and few of the plants have failed. These plants were most of them four years old from seed, nor was there any care taken to clean the ground afterward, but the whole left to shift, and in five or six years the Pines have grown so well, as to overpower the heath and furze, and destroy it.

The distance which I have generally planted these plants in all large open situations, was about four feet, but always irregular, avoiding planting in rows as much as possible, and in the planting, the great care is not to take up the plants faster than they can be planted, so that some men have been employed in digging up of the plants, while others were planting. Those who take up the plants, must be looked after to see they do not tear off their roots, or wound their bark; and as fast as they are taken up, their roots should be covered to prevent their drying, and put into their new quarters as soon as possible. In planting them, care should be had to make the holes large enough for their roots, as also to loosen and break the clods of earth, and put the finest immediately about their roots, then to settle the earth gently with the foot to the roots of the plant. If these things are duly observed, and a proper season chosen for performing it, there will be very little hazard of their succeeding, but I have seen some plantations made with plants, which were brought from a great distance, and had been so closely packed up, as to cause a heat, whereby most of the plants within had their leaves changed yellow, and few of them have grown, which has discouraged others from planting, not knowing the true cause of their failure.

After the plantations are made, the only care they require for five or six years, will be to secure the plants from cattle, hares, and rabbits, for if these are admitted to them, they will make great destruction in a short time, for if the branches are knawed by hares or rabbits, it will greatly retard the growth of the plants, if not destroy them.

In about five or six years after planting, the branches of the young trees will have met, and begin to interfere with each

each other, therefore they will require a little pruning, but this must be done with great caution. The lower tier of branches only should be cut off; this should be performed in *September*, at which time there will be no danger of the wounds bleeding too much, and the turpentine will harden over the wounds as the season grows cold, so will prevent the wet from penetrating of them. These branches should be cut off close to the stem of the plants, and care should be taken in the doing of this, not to break any of the remaining branches of the young trees. This work should be repeated every other year, at each time taking off only the lower tier of branches, for if the plants are much trimmed, it will greatly retard their growth, as it does in general that of all trees; but as these trees never put out any new shoots where they are pruned, so they suffer more from amputation than those which do.

In those parts of *France*, where they have forests of these trees, the proprietors always give the faggots to those who prune their young trees first, for their labour, so it costs them no money. At the second pruning, the proprietor has one-third of the faggots, and the dressers have the other two for their work, and afterward the faggots are equally divided between the workmen and proprietors, but there must be great care taken that they do not cut off more than should be.

In about twelve or fourteen years these will require no more pruning, for their upper branches will kill those below where they have not air; but soon after this, if the plants have made good progress, it may be necessary to thin them; but this should be gradually performed, beginning in the middle of the plantation first, leaving the outside close to screen those within from the cold, so by degrees coming to them at last, whereby those, which were first thinned, will have had time to get strength, so will not be in danger of suffering from the admission of cold air. When these plantations are thinned, the trees should not be dug up, but their stems cut off close to the ground, for their roots never shoot again, but decay in the earth, so there can no harm arise by leaving them, and hereby the roots of the remaining plants are not injured. The trees which are now cut, will be fit for many purposes; those which are strait, will make good putlocks for the bricklayers, and serve for scaffolding poles, so that there may be as much made by the sale of these, as will defray the whole expence of the planting, and probably interest for the money into the bargain.

As the upright growth of these trees renders their wood the more valuable, they should be left pretty close together, whereby they will draw each other up, and grow very tall. I have seen some of these trees growing, whose naked stems have been more than seventy feet high, and as strait as a walking cane, and from one of these trees there were as many boards sawed, as laid the floor of a room near twenty feet square. If these trees are left eight feet asunder each way, it will be sufficient room for their growth, therefore if at the first thinning a fourth part of the trees are taken away, the other may stand twelve or fourteen years longer, by which time they will be of a size for making ladders, and standards for scaffolding, and many other purposes, so that from this sale, as much may be made, as to not only pay the remaining part of the expence of planting, if any should be wanting in the first, but rent for the land with interest, and the standing trees for fortunes of younger children. This may be demonstrated by figures, and there has been several examples of late years, where the profits have greatly exceeded what is here mentioned.

The fifth sort is called in *Switzerland* Torch Pine; the peasants there make use of the wood of this tree instead of torches for burning. This tree grows to a great height in

its native soil, and is well furnished with branches. The wood is pretty full of resin, and when first cut is of a reddish colour. This is used by the inhabitants in their buildings.

The sixth sort of Pine makes but slow progress in *England*, so is not worth cultivating for profit, unless upon the summits of the northern mountains, where upon the peaty Moors, this, and the *Siberian Pine*, are likely to succeed much better than in any other part of *Britain*, for they naturally grow among snow.

The eighth sort is never a large tree in its native country, and in *England* it grows more like a shrub than a tree, and is often greatly injured by cold in winter, and by severe frosts sometimes killed; so that this is only kept for the sake of variety in the *English* gardens.

The ninth and tenth sorts are used indifferently by the inhabitants of *North America* for their buildings, and the same purposes as the other sorts of Pine.

There are some varieties of these in *America*, if they are not distinct species. Some of them ripen their cones the first year, but others are two years, and some three before they are ripe; but as these have not been well distinguished by those who reside in that country, and there are few of the sorts so large as to produce cones, so their differences cannot as yet be ascertained.

The eleventh and twelfth sorts I believe are indifferently called red Pine in *North America*, where their wood is greatly esteemed; the *French* at *Canada* have built a sixty gun ship entirely of this wood, called the *Saint Laurent*. I have had a little of this wood from *America*, which was very like that of the *Scotch Pine*, but had rather more resin. It may not be amiss to make trial of some of these sorts in plantations, to see which of them may deserve to be propagated; for in some places where they are growing, they thrive very well, but these will not succeed so well on dry land as moist.

The thirteenth sort is called the white Pine in most parts of *North America*; of this I believe there are two varieties, if not distinct species, but as they have not been well examined by persons of skill, we cannot take upon us to determine this, for *Monf. Gaultier's* description of one species is very different from that of the *Weymouth Pine*, and yet he has applied the title of white Pine to both.

This sort deserves to be propagated for its beauty, which is superior to all the sorts of Pines yet known in *England*. The bark of the young trees, and the branches are perfectly smooth; the branches are well garnished with leaves; these are long, and of an agreeable green, so that in summer they have a beauty, and in winter they make a better appearance than any of the sorts. The wood of this tree is very useful, especially for masts of ships, as the trees grow very tall and strait, and are pliable, so do not break with the wind, therefore the legislators thought proper to pass a law for the preservation and increase of these trees in *America*; but as these trees will thrive in *England*, they may be propagated in many places where the soil is proper for them. This sort grows best upon a moist light soil, but it should not be too wet; it will also thrive on a loamy soil, if it is not too much approaching to clay. The seeds of this sort should be sown with a little more care than those of the *Scotch Pine*, because their stems are not so strong, therefore are more apt to go off while young; so if these are sown in the full ground, the bed should be screened with mats from the sun every day, but exposed to the dews every night. When the plants come up, they should be treated in the same way, as is before directed for the *Scotch Pine*; and if all the plants of this kind are transplanted into beds in *July*, it will be a secure way to preserve them, but as these plants will grow larger than those of the *Scotch Pine*, they should be planted farther asunder; their rows should

be six inches distant, and in the rows they should be four inches apart. This will allow them room to grow till the spring twelve month following, when they may be either transplanted where they are to remain, or into a nursery where they may stand two years to get strength, but the sooner they are planted where they are to stand, the less danger there will be of their succeeding, and the larger they will grow; for although they will bear transplanting at a greater age, yet when they are planted young, they will make much greater progress, and grow to a greater size.

The soil in which this sort of tree thrives best is, a soft Hazel loam not too wet, in which I have frequently measured shoots of one year, which were two feet and a half long, and have for some years continued growing so much; they should have a sheltered situation, for I have observed where the trees have been much exposed to the south-west winds, they have not made near so great progress as those which grew in shelter; and where there have been plantations of these trees, those on the outside have not kept pace with the middle, nor have their leaves retained their verdure so well.

The fourteenth sort grows naturally on Swamps in many parts of *North America*, where I have been informed they grow to the height of twenty five or thirty feet. Their leaves are a foot or more in length, growing in tufts at the end of the branches, so have a singular appearance, but I have not heard the wood was of any use but for fuel, and there are few places here where these plants do well, for in very severe frosts their leading shoots are often killed, and in dry ground they will not thrive; so that unless the soil is adapted for them, it is to little purpose planting them.

From the wild Pine or Pineaster is procured the common turpentine, which is chiefly used by the farriers, and from it is distilled the oil of turpentine. The finer and more valuable part, which comes first, is called the spirit, what is left at the bottom of the still is the common resin.

The kernels of the nuts of the manured or stone Pine, are of a balsamick nourishing nature, good for consumptions, coughs, and hoarseness, restorative, and of service after long illnesses.

PIPER. *Lin. Gen. Plant.* 42. Pepper, or Lizard's-tail.

The Characters are,

The flowers are closely fastened to a single stalk, and have no complete sheath; these have no petals nor stamina, but have two summits opposite to the root of the germen, which are roundish; they have a large oval germen, but no style, crowned by a prickly triple stigma. The germen afterward becomes a roundish berry with one cell, containing one globular seed.

The Species are,

1. PIPER *foliis obverse ovatis enerviis. Lin. Sp. Plant.* 30. Pepper with obverse oval leaves, having no veins; or Low Lizard's-tail with a fleshy roundish leaf.

2. PIPER *foliis cordatis petiolatis, caule herbaceo. Lin. Sp. Plant.* 30. Pepper with heart-shaped leaves, having foot-stalks, and an herbaceous stalk.

3. PIPER *foliis lanceolatis-ovatis quinquenerviis rugosis. Lin. Sp. Plant.* 29. Pepper with rough, spear-shaped, oval leaves, having five veins.

4. PIPER *foliis lanceolatis nervosis rigidis sessilibus.* Pepper with stiff, spear-shaped, veined leaves sitting close to the branches.

5. PIPER *foliis peltatis orbiculato-cordatis obtusis repandis, spicis umbellatis. Lin. Sp. Plant.* 30. Pepper with target-formed leaves, which are orbicular, heart-shaped, obtuse, recurved, and have spikes growing in umbels.

6. PIPER *foliis lanceolato-ovatis nervosis, spicis brevibus.* Pepper with spear-shaped, oval, veined leaves, and short spikes.

7. PIPER *foliis ovato-lanceolatis tomentosiss, caule arboref-*

cente. Pepper with oval, spear-shaped, woolly leaves, and a tree-like stalk.

8. PIPER *foliis ovato-lanceolatis, nervis alternis, spicis uncinatis. Lin. Sp. Plant.* 29. Pepper with oval spear-shaped leaves, having alternate veins, and crooked spikes.

9. PIPER *foliis ovato-lanceolatis, acuminatis nervis alternis, spicis gracilis uncinatis.* Pepper with oval, spear-shaped, acute-pointed leaves, having alternate veins, and slender crooked spikes.

10. PIPER *foliis cordato-ovatis nervosis acuminatis, spicis reflexis.* Pepper with oval, heart-shaped, nerved, acute-pointed leaves, and reflexed spikes.

11. PIPER *foliis cordatis subseptinerviis venosis. Flor. Zeyl.* 29. Pepper with heart-shaped leaves, which are veined, and have almost seven nerves.

12. PIPER *foliis cordatis quinquenerviis reticulatis. Lin. Sp. Plant.* 29. Pepper with heart-shaped netted leaves, having five veins.

13. PIPER *foliis ovato-lanceolatis acuminatis glabris trinerviis.* Pepper with oval, spear-shaped, acute-pointed, smooth leaves, having three veins.

14. PIPER *foliis lanceolato-ovatis rugosis, nervis alternis.* Pepper with spear-shaped, oval, rough leaves, having alternate veins.

The first sort grows naturally in many of the islands in the *West-Indies*. This sends out from the root many succulent herbaceous stalks almost as large as a man's little finger; they are jointed, and divide into many branches, never rising above a foot high, but generally spread near the ground, putting out roots at each joint, so propagate very fast, and soon cover a large space of ground. The leaves are very thick, succulent, broad, smooth, and entire. The foot-stalk, which sustains the spike or tail, comes out at the end of the branches; this is also very succulent, the whole length including the spike is about seven inches. The spike is strait, erect, about the size of a goose quill, and closely covered with small flowers, which require a glass to be distinguished, so have no beauty; but the whole spike much resembles the tail of a lizard, for which *Plumier* gave it that title.

These spikes appear great part of the year, but they rarely have any seeds in *England*; the plants increase very fast by their stalks, which put out roots. It requires a warm stove to preserve it in *England*, and should have but little wet, especially in winter. If the plants are plunged into the tan-bed in the stove, the stalks will put out roots into the tan, so may be cut off to make new plants.

The second sort grows naturally in the *West-Indies*; this is annual. The stalks are herbaceous and succulent; they rise about seven or eight inches high; the leaves are heart-shaped; the spikes of flowers, which are slender, come out at the end of the stalks; the flowers are very small, and sit close to the foot-stalk. These appear in *July*, and are succeeded by very small berries, each containing a small seed like dust. If these seeds are permitted to scatter on the pots near it, the plants will come up without trouble; or if the seeds are saved, and sown upon a hot-bed in the spring, the plants will rise easily. These should be transplanted into separate pots, and plunged into a hot-bed of tanners bark, treating them in the same way as other tender plants, but they should not have much wet.

The third sort grows naturally in *Jamaica* and *Barbadoes*. This hath several crooked stems, which rise to the height of twelve or fourteen feet, jointed, hollow, and pithy; these divide into many small branches, which are garnished with spear-shaped, oval, rough leaves, with five longitudinal veins. The spikes come out at the end of the branches, having many small flowers sitting close to the foot-stalk, which are succeeded by small berries.

The fourth sort grows naturally in *Jamaica*. The stalks of this are slender, and frequently trail upon the ground, putting roots out from their joints like the first; they are garnished with stiff spear-shaped leaves, with one strong midrib, and on the backside have several veins running from that to the sides. The spike of flowers is very slender, and shaped like those of the former sorts.

The fifth sort grows naturally in *Jamaica*. This hath a pretty thick spongy stalk, which rises fifteen feet high, dividing into several branches, which are jointed, and pithy. The leaves are almost round; the foot-stalk is fastened to the under side, so that the upper surface has a mark like a navel, where the stalk joins, and from that center run out the veins to the side. The leaves are shaped like a heart, but the other part is round; the stalk being fixed toward the middle, the leaves have the appearance of a target. The spikes are small, and grow in form of an umbel.

The sixth sort grows naturally at *La Vera Cruz* in *America*. This hath shrubby jointed stalks, which rise nine or ten feet high, dividing into several branches, which are garnished with spear-shaped oval leaves; they are veined and rough, of the same consistence with Laurel leaves. The spikes of flowers come out from the side of the branch at the joints, opposite to the leaves; they are not more than one inch and a half long, about the thickness of a small quill, and are closely set with flowers like the other sorts.

The seventh sort grows naturally at *La Vera Cruz*. This hath hollow pithy stalks, which rise twelve or fourteen feet high, dividing into many crooked branches, having swelling joints, garnished with oval spear-shaped leaves, having many veins, and are covered with a woolly down. The spikes of flowers come out from the side of the branches, opposite to the leaves; they are slender, and turn downward.

The eighth sort grows naturally in *Jamaica*. This hath many hollow stalks, which rise about five feet high; the joints are close and protuberant; they divide into smaller branches, which are garnished with oval, spear-shaped, rough, veined leaves. The spikes of flowers come out from the side of the branches, opposite to the leaves; they are slender, and are closely set with small flowers their whole length. This is called *Spanish Elder* in the *West-Indies*.

The ninth sort was sent me by Mr. *Robert Millar* from *Panama*, near which place he found it growing naturally. This hath several pithy stalks, which rise about five feet high, divided into many small branches, garnished with oval spear-shaped leaves, ending in acute points. The spikes of flowers are very slender, and incurved.

The tenth sort was sent me from *Carthagena*. This rises with several shrubby stalks fifteen feet high, dividing into many slender branches, with protuberant joints, garnished with heart-shaped, oval, smooth leaves, ending in acute points, of a dark green on their upper side, but pale on their under. The spikes of flowers come out from the side of the branches; they are extremely slender, and are reflexed at the end like a scorpion's tail.

The eleventh sort grows at *Panama*. This hath hollow shrubby stalks, which rise about four feet high, divided into many small branches, garnished with heart-shaped leaves, ending in long acute points. The spikes come out from the side of the branches; they are slender, bending in the middle like a bow, and are closely set with small herbaceous flowers, which are succeeded by small berries, inclosing a small single seed.

The twelfth sort grows naturally in *Jamaica*. This rises with a shrubby pithy stalk about five feet high, sending out several side branches, which have protuberant joints, garnished with heart-shaped leaves, full of small veins, which form a sort of net work. The spikes come out from the side of the branches, opposite to the leaves; they are slender,

a little bending in the middle, and are closely set with very small herbaceous flowers.

The thirteenth sort grows naturally at *Campeachy*. This hath many shrubby stalks, which rise about ten feet high, divided into several crooked branches toward the top, which have swelling joints, garnished with oval, spear-shaped, acute-pointed leaves, of a lucid green. The spikes come out from the side of the stalks, opposite to the leaves; they are pretty long, slender, and a little incurved. The flowers and seeds are like the other species.

The fourteenth sort grows naturally at *Campeachy*. This hath a shrubby stalk, which rises ten or twelve feet high, dividing toward the top into a great number of small hollow branches, garnished with spear-shaped, oval, rough leaves; some of them have long, and others very short foot-stalks; they are of a deep green on their upper side, but pale on their under, ending in acute points. The spikes come out from the side of the stalks, opposite to the leaves; they are long, slender, and are closely set with very small flowers like the other species.

The twelve last mentioned sorts are abiding plants, which require a warm stove to preserve them in *England*. They may be propagated by seeds, if they can be procured fresh from the countries where the plants grow naturally; these should be sown upon a good hot-bed in the spring, and when the plants come up, and are fit to transplant, they should be each put into a separate small pot, filled with light fresh earth, and plunged into a hot-bed of tanners bark, shading them every day from the sun, till they have taken fresh root; then they must be treated in the same way as other tender exotick plants, admitting fresh air to them daily, in proportion to the warmth of the season, to prevent their drawing up weak; and when the nights are cold, the glasses of the hot-bed should be covered with mats to keep them warm. As the stalks of most of these plants are tender when young, so they should not have much wet, which would rot them, and when water is given to them, it must be with caution; not to beat down the plants, for when that is done, they seldom rise again.

In autumn the plants must be plunged into the tan-bed of the bark-stove, and during the winter they must be sparingly watered; they require the same warmth as the Coffee-tree. In summer they require a large share of fresh air in hot weather, but they must be constantly kept in the stove, for they are too tender to bear the inclemency of our weather in summer.

PISONIA. *Plum. Nov. Gen. 7. tab. 11. Lin. Gen. Plant. 984.* Fingrigo, vulgò.

The Characters are,

The male flowers grow upon different plants from the fruit. The male flowers are funnel-shaped; the tube is short; the brim is expanded, and cut into five acute parts; they have five awl-shaped stamina, which are longer than the petal, terminated by obtuse summits. The female flowers are of the same form; they sit upon the germen, which is situated under the receptacle, supporting a cylindrical style longer than the petal, crowned by five oblong spreading stigmas. The germen afterwards turns to an oval capsule, having five angles and one cell, containing one smooth, oblong, oval seed.

We have but one Species at present in *England*, viz.

PISONIA aculeata. *Lin. Sp. Plant. 1026.* Prickly Pisonia, called Fingrigo in the *West-Indies*.

The male plants differ so much in appearance from the female, that those who have not seen them rise from the same seeds, would suppose they were different species, I shall therefore give short descriptions of each.

The male plants have stalks as thick as a man's arm, which rise ten or twelve feet high; the bark is of a dark brown colour, and smooth; these send out many branches opposite,

opposite, which are much stronger than those of the female. To do not hang about so loose. They are garnished with obverse, oval, stiff leaves, standing opposite on short foot-stalks. From the side of the branches come out short cursons or spurs like those of the Pear-tree, having each two pair of small leaves at bottom, and from the top comes out the foot-stalk of the flowers, which is slender, dividing at the top into three; each of these sustain a small corymbus of herbaceous yellow flowers, having five stamina standing out beyond the petal, terminated by obtuse summits.

The stalks of the female plants are not so strong as those of the male, so require support. These rise eighteen or twenty feet high, sending out slender weak branches opposite, armed with short strong hooked spines, and garnished with small oval leaves, standing opposite on the larger branches, but on the smaller they are alternate, and have short foot-stalks. The flowers are produced in small bunches at the end of the branches, sitting upon the germen; they are shaped like those of the male, but have no stamina; in the center is situated a cylindrical style, crowned by five spreading stigmas. The germen afterward turns to a channelled, five-cornered, glutinous capsule, armed with small crooked spines, each containing one oblong, oval, smooth seed.

These plants are very common in the *Savannas*, and other low places in the island of *Jamaica*, as also in several other islands in the *West-Indies*; where it is very troublesome to whoever passes through the places of their growth, fastening themselves by their strong crooked thorns, to the clothes of persons; and their seeds being glutinous and burry, also fasten themselves to whatever touches them; so that the wings of the ground-doves and other birds, are often so loaded with the seeds, as to prevent their flying, by which means they become an easy prey.

In *Europe* this plant is preserved in the gardens of some curious persons for variety; it is propagated by seeds, which should be sown in pots filled with light rich earth, and plunged into a hot-bed of tanners bark; and when the plants come up, they should be transplanted into separate pots, and plunged into the hot-bed again, where they may remain till *Michaelmas*, when they should be removed into the stove, and plunged into the bark-bed, and treated in the same manner as hath been directed for several tender plants of the same country.

PISTACIA. *Lin. Gen. Plant.* 982. Turpentine-tree, Pistachia Nut, and Mastick-tree.

The Characters are,

The male and female flowers grow upon separate trees; the male flowers are disposed in loose sparsed katkins, having small five pointed empalements, but no petals; they have five small stamina, terminated by oval, four-cornered, erect summits. The female flowers have small trifid empalements, but no petals; they have each a large oval germen, supporting three reflexed styles, crowned by thick prickly stigmas. The germen afterward turns to a dry berry or nut, inclosing an oval smooth seed.

The Species are,

1. **PISTACIA** *foliis impari pinnatis, foliolis subovatis recurvis.* *Lin. Mat. Med.* 454. *Sp. Plant.* 1025. Pistachia with unequal winged leaves, whose lobes are somewhat oval and recurved; or the Pistachia-tree.

2. **PISTACIA** *foliis subternatis.* *Hort. Cliff.* 456. Pistachia with trifoliate leaves; or three-leaved Turpentine-tree.

3. **PISTACIA** *foliis pinnatis ternatisque, suborbiculatis.* *Lin. Sp. Plant.* 1025. Pistachia with winged and trifoliate leaves, which are almost round.

4. **PISTACIA** *foliis impari pinnatis, foliolis ovato-lanceolatis.* *Hort. Cliff.* 456. Pistachia with unequal winged leaves, whose lobes are oval and spear-shaped; or common Turpentine-tree.

5. **PISTACIA** *foliis abruptè pinnatis, foliolis lanceolatis.* *Hort. Cliff.* 456. Pistachia with abrupt winged leaves, and spear shaped lobes; or common Mastick-tree.

6. **PISTACIA** *foliis abruptè pinnatis, foliolis lineari lanceolatis.* Pistachia with abrupt winged leaves, and narrow spear-shaped lobes; or narrow-leaved Mastick-tree of *Marseilles*.

7. **PISTACIA** *foliis impari pinnatis, foliolis lanceolato-ovatis acuminatis.* Pistachia with unequal winged leaves, whose lobes are spear shaped, oval, and acute-pointed.

8. **PISTACIA** *foliis pinnatis deciduis, foliolis oblongo ovatis.* Pistachia with winged deciduous leaves, having oblong oval lobes; commonly called Birch-tree in *Jamaica*.

9. **PISTACIA** *foliis impari pinnatis, foliolis lanceolatis, exterioribus majoribus.* Pistachia with unequal winged leaves, whose lobes are spear-shaped, and the outer ones the largest.

The first sort is the Pistachia Nut-tree, whose fruit is much better known in *England* than the tree. This grows naturally in *Arabia*, *Persia*, and *Syria*, from whence the nuts are annually brought to *Europe*. In those countries it grows to the height of twenty-five or thirty feet; the bark of the stem and old branches is of a dark russet colour, but that of the young branches is of a light brown; these are garnished with winged leaves, composed sometimes of two, and at others of three pair of lobes, terminated by an odd one; these lobes approach toward an oval shape, and their edges turn backward; if these are bruised, they emit an odour like the shell of the nut. Some of these trees produce male flowers, others have female, and some, when old, have both on the same tree. The male flowers come out from the side of the branches, in loose bunches or katkins; they are of an herbaceous colour, having no petals, but have each five small stamina, crowned by large four-cornered summits, filled with farina; when that is discharged, the flowers fall off. The female flowers come out in clusters from the side of the branches; these have no petals, but have each a large oval germen, supporting three reflexed styles, and are succeeded by oval nuts. This tree flowers in *April*, but the fruit seldom ripens in *England*. It is propagated by the nuts, which should be planted in pots filled with light kitchen-garden earth, and plunged into a moderate hot-bed to bring up the plants; when these appear, they should have a large share of air admitted to them, to prevent their drawing up weak; and by degrees they must be hardened to bear the open air, to which they should be exposed the beginning of *June*, and may remain abroad till autumn, when they should be placed under a hot-bed frame to screen them from the frost in winter, for while they are young, they are too tender to live through the winter in *England* without protection, but they should always be exposed to the air in mild weather; the plants shed their leaves in autumn, so should not have much wet in winter; and in the spring, before they begin to shoot, they must be transplanted each into a separate small pot; and if they are plunged into a very moderate hot-bed, it will forward their putting out new roots; but as soon as they begin to shoot, they must be gradually hardened, and placed abroad again: the plants may be kept in pots three or four years, till they have got strength, during which time they should be sheltered in winter; afterward they may be turned out of the pots, and planted in the full ground, some against high walls to a warm aspect, and others in a sheltered situation, where they will bear the cold of our ordinary winters very well, but in severe frosts they are often destroyed. The trees flower and produce fruit in *England*, but the summers are rarely warm enough to ripen the nuts.

The second sort grows naturally in *Sicily* and the *Levant*, where it is a tree of middling size, covered with a rough brown bark, dividing into many branches, garnished with leaves, which for the most part have three, but some have four

four oval lobes; they stand upon long foot-stalks, and are of a dark green colour. The male flowers grow upon different trees from the female, and are like those of the former sort, but of a yellowish green colour. The female flowers of this sort I have not seen, so can give no account of them; these are succeeded by fruit like that of the former, but much smaller. This is propagated by seeds in the same manner as the former, and the plants should be treated in the same way, but require more protection in winter. There were several plants of this kind in the *English* gardens before the year 1740, which had lived abroad some years against walls, but that severe winter killed most of them.

The third sort grows in *Italy* and the south of *France*, but is supposed to have been transplanted there from some other country. This is a tree of a middling size, covered with a light gray bark, sending out many side branches, garnished with leaves, which have sometimes five, and at others but three roundish lobes, standing upon pretty long foot-stalks, of a light green colour. The male flowers grow upon separate trees from the fruit, as in the other sorts; the fruit of this is small, but eatable. This is propagated by the nuts in the same way as the first, and the plants are equally hardy.

The fourth sort grows naturally in *Barbary*, and also in *Spain* and *Italy*. This is a tree of middling size, covered with a brown bark, dividing into many branches, whose bark is very smooth while young; they are garnished with winged leaves, composed of three or four pair of oval spear-shaped lobes, terminated by an odd one. The flowers are male and female on different trees, as the former: the male flowers of this have purplish stamina; they appear in *April*, but I have not seen any of the female trees in flower. This is propagated by seeds, but unless they are sown in autumn soon after they are ripe, they seldom grow the first year, but remain in the ground a whole year; and unless the seeds are taken from such trees as grow near a male, the seeds will not grow, as I have several times experienced.

The plants of this sort may be treated in the same manner as the first, and are as hardy. There is a tree of this sort now growing in the gardens of the bishop of *London* at *Fulham*, against a wall, which was planted there above fifty years ago, which has endured the winters without cover; and some trees of this kind, which were planted in the open air, in the garden of his grace the Duke of *Richmond*, at *Goodwood* in *Suffex*, had survived several winters without any protection. From these trees the common turpentine of the shops was formerly taken, but there is little of that now imported, but that from some of the Cone-bearing trees is generally substituted for it.

The fifth sort is the common Maltick-tree, which is better known in the gardens by its *Latin* title of *Lentiscus*. This grows naturally in *Spain*, *Portugal*, and *Italy*, and being ever-green, the plants have been preserved in the *English* gardens, to adorn the green-house in winter. This in its native countries rises to the height of eighteen or twenty feet, covered with a gray bark, sending out many branches, which have a reddish brown bark, garnished with winged leaves, composed of three or four pair of small spear shaped lobes, without an odd one at the end. The midrib which sustains the lobes, has two narrow borders or wings, running from lobe to lobe; these lobes are of a lucid green on their upper side, but pale on their under. The male flowers come out in loose clusters from the side of the branches; they are of an herbaceous colour, appearing in *May*, and soon fall off. These are generally upon different plants from the fruit, which also grows in clusters, and are small berries of a black colour when ripe.

The plants of this sort are generally propagated by laying down of their young branches, which, if properly managed,

will put out roots in one year, and may then be cut off from the old plants, and each transplanted into separate small pots. These must be protected in winter, and in summer placed abroad in a sheltered situation, and treated in the same way as other hardy kinds of green-house plants. It may also be propagated by seeds in the same way as the Turpentine-tree, but if the seeds are not taken from trees growing in the neighbourhood of the male, they will not grow; and if they are kept out of the ground till spring, the plants rarely appear till the spring following. When these plants have obtained strength, some of them may be turned out of the pots, and planted against warm walls, where, if their branches are trained against the walls, they will endure the cold of our ordinary winters very well, and with a little shelter in severe winters they may be preserved.

The sixth sort grows naturally about *Marseilles*, and in some other places in the south of *France*, where it rises to the same height as the former, from which it differs in having one or two pair of lobes more on each leaf; the lobes are much narrower, and of a paler colour. This difference holds in the plants which are propagated by seeds, so may be pronounced a distinct species. It is propagated in the same way as the former sort, and is equally hardy.

The seventh sort grows naturally in many of the islands in the *West-Indies*, where it rises to a middling stature, dividing into many branches, covered with a purplish bark, and garnished with winged leaves, composed of two or three pair of spear-shaped, oval, acute-pointed lobes, terminated by an odd one; they are very thin and tender, and have long foot-stalks. The male flowers come out at the end of the branches; they are disposed in a single racemus (or long bunch); they are of a purplish colour, and have yellow summits. The fruit grows upon separate trees from the male flowers; they are shaped like the nuts of Pistachia, but are smaller, and not eatable.

The eighth sort grows naturally in *Jamaica*, and also in most of the other islands in the *West-Indies*, where it rises to the height of thirty or forty feet, covered with a loose brown bark, which falls off in large pieces; the stems are large; and divide into many branches toward the top, which are crooked and unsightly; these are garnished with winged leaves, composed of five or six pair of oblong, oval, smooth lobes, terminated by an odd one. The flowers come out at the end of the branches, in long loose bunches of a yellowish colour; these grow on different trees, or on different parts of the same tree from the fruit, which also hangs in long bunches, and is about the size of a middling Pea, having a dark skin, covering a nut about the size of a common Cherry-stone, and of the same colour.

These two trees are tender, so will not thrive in this country, unless they are kept in a warm stove. They are propagated by seeds, which must be taken from such trees as grow in the neighbourhood of the males, otherwise they will not grow, as I have too often found true. These should be sown in pots filled with light earth, and plunged into a good hot-bed of tanners bark; and when the plants are come up fit to remove, they should be each planted in a separate small pot, and plunged into a fresh hot-bed, treating them in the same way as other tender plants from the same countries, and in autumn they should be removed into the stove, plunging the pots into the tan-bed; during the winter they must have but little water, especially if they cast their leaves, which is generally the case after the first winter; for the young plants frequently retain their leaves the whole year, but afterward they are destitute of leaves for two months, in the latter part of winter. The plants should constantly remain in the stove, but in warm weather they must have a large share of air admitted to them.

The ninth sort is the true Mastick-tree of the *Lewant*, from which the Mastick is gathered. This has been confounded with the common *Lentiscus*, by most botannick writers; and *Townesfort*, who was on the spot where the Mastick is collected, has not distinguished the species; though he says, the leaves of the trees in the *Lewant*, are larger than those of the common sort, but takes no notice of their being unequally winged. The seeds of this tree were sent me by *Monf. Richard*, gardener to the king of *France* at *Verfailles*, who received them from the island of *Cbio* in the *Lewant*; the bark of the tree is brown; the leaves are composed of two or three pair of spear-shaped lobes, terminated by an odd one; the outer lobes are the largest, the others gradually diminish, the innermost being the least; these turn of a brownish colour toward autumn, when the plants are exposed to the open air; but if they are under glasses, they keep green. The leaves continue all the year, but are not so thick as those of the common sort, nor are the plants so hardy. It is propagated by seeds in the same way as the common *Lentiscus*, but the plants while young should be kept in a gentle temperature of warmth in winter, and require a warm sheltered situation in summer. When they have obtained strength, they may be kept in a warm green-house in winter, but should have little water during that season.

PISUM. *Tourn. Inst. R. H.* 394. tab. 215. Pea.

The Characters are,

The flower hath an empalement cut into five points, the two upper being broadest; it hath four petals, and is of the butterfly kind. The standard is broad, heart-shaped, reflexed, and indented, ending in a point. The two wings are shorter, roundish, and close together; the keel is compressed, half-moon-shaped, and shorter than the wings. It hath ten stamina in two bodies, the upper single one is plain and awl-shaped, the other nine are cylindrical below the middle, awl-shaped above and cut; these are joined together. It has an oblong compressed germen, with a triangular rising style. The germen afterward becomes a large long taper pod, terminated by a sharp rising point, opening with two valves, having one row of roundish seeds.

The Species are,

1. PISUM stipulis infernè rotundatis crenatis, petiolis teretibus, pedunculis multifloris. *Hort. Upsal.* 215. Pea, whose lower stipulæ are roundish, indented, with taper foot-stalks, and many flowers on a foot-stalk; greater Garden Pea.

2. PISUM caule erecto ramoso, foliis bijugatis, foliolis rotundioribus. Pea with an erect branching stalk, and leaves having two pair of round lobes; Dwarf Pea.

3. PISUM stipulis quadrifidis acutis, pedunculis multifloris terminalibus. Pea with four-pointed acute stipulæ, and foot-stalks bearing many flowers, which terminate the stalks; the Rose or Crown Pea.

4. PISUM petiolis supra planiusculis, caule angulato, stipulis sagittatis, pedunculis multifloris. *Flor. Suec.* 608. Pea with foot-stalks, which are plain on their upper side, an angular stalk, arrow-pointed stipulæ, and foot-stalks bearing many flowers.

5. PISUM caule angulato procumbente, foliolis inferioribus lanceolatis acutè dentatis, summis sagittatis. Pea with an angular trailing stalk, whose lower leaves are spear-shaped, sharply indented, and those at the top arrow-pointed; commonly called *Cape Horn* Pea.

6. PISUM petiolis decurrentibus membranaceis diphyllis, pedunculis unifloris. *Hort. Cliff.* 370. Pea with membranaceous running foot-stalks, having two leaves, and one flower upon a foot-stalk.

There is a great variety of garden Peas now cultivated in *England*, which are distinguished by the gardeners and seedsmen, and have their different titles; but as great part of these have been seminal variations, so if they are not very

carefully managed, by taking away all those plants which have a tendency to alter, before the seeds are formed, they will degenerate into their original state, therefore all those persons who are curious in the choice of their seeds, look carefully over those which they design for seeds at the time when they begin to flower, and draw out all the plants which they dislike from the other. This is what they call Roguing their Peas, meaning hereby, the taking out all the bad plants from the good, that the farina of the former may not impregnate the latter; to prevent which, they always do it before the flowers open; by thus diligently drawing out the bad, reserving those which come earliest to flower, they have greatly improved their Peas of late years, and are constantly endeavouring to get forwarder varieties; so that it would be to little purpose in this place, to attempt giving a particular account of all the varieties now cultivated; therefore I shall only mention their titles by which they are commonly known, placing them according to their time of coming to the table, or gathering for use.

The Golden Hotspur.	Nonpareil.
The Charlton.	Sugar Dwarf.
The Reading Hotspur.	Sickle Pea.
Masters's Hotspur.	Marrowfat.
Essex Hotspur.	Rose, or Crown Pea.
The Dwarf Pea.	Rouncival Pea.
The Sugar Pea.	Gray Pea.
Spanish Morotto.	Pig Pea, with some others.

The *English* Sea Pea is found wild upon the shore in *Suffex*, and several other counties in *England*, and is undoubtedly a different species from the common Pea.

The fifth sort hath a biennial root, which continues two years. This was brought from *Cape Horn* by *Lord Anson's* cook, when he passed that *Cape*, where these Peas were a great relief to the sailors. It is kept here as a curiosity, but the Peas are not so good for eating as the worst sort now cultivated in *England*; it is a low trailing plant; the leaves have two lobes on each foot-stalk; those below are spear-shaped, and sharply indented on their edges, but the upper leaves are small and arrow-pointed. The flowers are blue, each foot-stalk sustaining four or five flowers; the pods are taper, near three inches long, and the seeds are round, about the size of Tares.

The sixth sort is annual. This grows naturally among the Corn in *Sicily* and some parts of *Italy*, but is here preserved in botannick gardens for the sake of variety. It hath an angular stalk rising near three feet high; the leaves stand upon winged foot-stalks, each sustaining two oblong lobes. The flowers are of a pale yellow colour, shaped like those of the other sorts of Pea, but are small, each foot-stalk sustaining one flower; these are succeeded by pods about two inches long, containing five or six roundish seeds, which are a little compressed on their sides. These are by some persons eaten green, but unless they are gathered very young they are coarse, and at best not so good as the common Pea. It may be sown and managed in the same way as the garden Pea.

I shall now proceed to set down the method of cultivating the several sorts of garden Peas, so as to continue them throughout the season.

It is a common practice with the gardeners near *London*, to raise Peas upon hot-beds, to have them very early in the spring; in order to which, they sow their Peas upon warm borders, under walls or hedges, about the middle of *October*; and when the plants come up, they draw the earth up gently to their stems with a hoe, the better to protect them from frost. In these places they let them remain until the latter end of *January*, or the beginning of *February*, observing to earth

earth them up from time to time, as the plants advance in height (for the reasons before given); as also to cover them in very hard frost with Peas haulm, Straw, or some other light covering, to preserve them from being destroyed; then, at the time before-mentioned, they make a hot-bed (in proportion to the quantity of Peas intended) which must be made of good hot dung well prepared and properly mixed together, that the heat may not be too great. The dung should be laid from two to three feet thick, according as the beds are made earlier or later in the season; when the dung is equally levelled, then the earth (which should be light and fresh, but not over-rich) must be laid thereon about six or eight inches thick, laying it equally all over the bed. This being done, the frames (which should be two feet high on the back side, and about fourteen inches in front) must be put on, and covered with glasses; after which it should remain three or four days, to let the steam of the bed pass off, before you put the plants therein; observing every day to raise the glasses, to give vent for the rising steam to pass off; then when you find the bed of a moderate temperature for heat, you should, with a trowel, or some other instrument, take up the plants as carefully as possible, to preserve the earth to their roots, and plant them into the hot-bed in rows, about two feet asunder, and the plants about an inch distant from each other in the rows, observing to water and shade them until they have taken root; after which you must be careful to give them air, at all times when the season is favourable, otherwise they will draw up very weak, and be subject to grow mouldy and decay. You should also draw the earth up to the shanks of the plants, as they advance in height, and keep them always clear from weeds. The water they should have, must be given them sparingly, for if they are too much watered, it will cause them to grow too rank, and sometimes rot off the plants at their shanks, just above ground. When the weather is very hot, you should cover the glasses with mats in the heat of the day, to screen them from the violence of the sun, which is then too great for them: but when the plants begin to fruit, they should be watered oftener, and in greater plenty than before; for by that time the plants will have nearly done growing, and the often refreshing them will occasion their producing a greater plenty of fruit.

The sort of Pea, which is generally used for this purpose, is the Dwarf, for all the other sorts ramble too much to be kept in frames; the reason for sowing them in the common ground, and afterwards transplanting them on a hot-bed, is to check their growth, and cause them to bear in less compass; for if the seeds were sown upon a hot-bed, and the plants continued thereon, they would produce such luxuriant plants as are not to be contained in the frames, and would bear but little fruit.

The next sort of Pea, which is sown to succeed those on the hot-bed, is the Hotspur, of which there are reckoned several sorts; as the Golden Hotspur, the *Charlton* Hotspur, the Master's Hotspur, the *Reading* Hotspur, and some others; which are very little differing from each other, except in their early bearing, for which the Golden and *Charlton* Hotspurs are chiefly preferred; though if either of these sorts are cultivated in the same place for three or four years, they are apt to degenerate, and be later in fruiting; for which reason, most curious persons procure their seeds annually from some distant place; and in the choice of these seeds, if they could be obtained from a colder situation and a poorer soil, than that in which they are to be sown, it will be much better than on the contrary, and they will come earlier in the spring.

These must also be sown on warm borders, toward the latter end of *October*; and when the plants are come up,

you should draw the earth up to their shanks in the manner before directed, which should be repeated as the plants advance in height (always observing to do it when the ground is dry) which will greatly protect the stems of the plants against frost; and if the winter should prove very severe, it will be of great service to the plants to cover them with Peas haulm, or some other light covering, which should be constantly taken off in mild weather, and only suffered to remain on during the continuance of the frost; for if they are kept too close, they will draw up very weak and tender, and thereby be liable to be destroyed with the least inclemency of the season.

In the spring you must carefully clear them from weeds, and draw some fresh earth up to their stems, but do not raise it too high to the plants, lest by burying their leaves you should rot their stems, as is sometimes the case, especially in wet seasons. You should also observe to keep them clear from vermin, which, if permitted to remain amongst the plants, will increase so plentifully, as to devour the greatest part of them. The chief of the vermin, which infect Peas, are the slugs, which lie all the day in the small hollows of the earth, near the stems of the plants, and in the night time come out, and make terrible destruction of the Peas; and these chiefly abound in wet soils, or where a garden is neglected, and over-run with weeds; therefore you should make the ground clear every way round the Peas to destroy their harbours, and afterwards in a fine mild morning very early; when these vermin are got abroad from their holes, you should slack a quantity of lime, which should be sown hot over the ground pretty thick, which will destroy the vermin, where-ever it happens to fall upon them, but will do very little injury to the Peas, provided it be not scattered too thick upon them. This is the best method I could ever find to destroy these troublesome vermin.

If this crop of Peas succeeds, it will immediately follow those on the hot-bed; but for fear this should miscarry, it will be proper to sow two more crops at about a fortnight or three weeks distance from each other, so that there may be the more chances to succeed. This will be sufficient until the spring of the year, when you may sow several more crops of these Peas at a fortnight distance from each other. The late sowings will be sufficient to continue the early sort of Peas through the season, but it will be proper to have some of the large sort of Peas to succeed them for the use of the family; in order to which you should sow some of the *Spanish* Morotto, which is a great bearer, and a hardy sort of Pea, about the middle of *February*, upon a clear open spot of ground. These must be sown in rows about four feet asunder, and the Peas should be dropped in the drills about an inch distance, covering them about two inches deep with earth, being very careful that none of them lie uncovered, which will draw the mice, pigeons, or rooks, to attack the whole spot; and it often happens, by this neglect, that a whole plantation is devoured by these creatures; whereas, when there are none of the Peas left in sight, they do not so easily find them out.

About a fortnight after this, you should sow another spot, either of this sort, or any other large sort of Pea, to succeed those, and then continue to repeat sowing once a fortnight, till the middle or latter end of *May*, only observing to allow the Marrowfats, and other very large sorts of Peas, at least four feet and a half between row and row; and the Rose Pea should be allowed at least eight or ten inches distance plant from plant in the rows, for these grow very large, and if they have not room allowed them, they will spoil each other by drawing up very tall, and will produce no fruit.

When these plants come up, the earth should be drawn up to their shanks (as was before directed), and the ground kept entirely clear from weeds; and when the plants are grown eight or ten inches high, you should stick some Brushwood, into the ground close to the Peas, for them to ramp upon, which will support them from trailing upon the ground, which is very apt to rot the large growing sorts of Peas, especially in wet seasons; besides, by thus supporting them, the air can freely pass between them, which will preserve the blossoms from falling off before their time, and occasion them to bear much better, than if permitted to lie upon the ground, and there will be room to pass between the rows to gather the Peas when they are ripe.

The dwarf sorts of Peas may be sown much closer together than those before-mentioned, for these seldom rise above a foot high, and rarely spread above half a foot in width, so that these need not have more room than two feet row from row, and not above an inch asunder in the row. These will produce a good quantity of Peas, provided the season be not over-dry, but they seldom continue long in bearing, so that they are not so proper to sow for the main crop, when a quantity of Peas is expected for the table, their chief excellency being for hot-beds, where they will produce a greater quantity of Peas (provided they are well managed) than if exposed to the open air, where the heat of the sun soon dries them up.

The Sickle Pea is much more common in *Holland* than in *England*, it being the sort mostly cultivated in that country; but in *England* they are only propagated by curious gentlemen for their own table, and are rarely brought into the markets. This sort the birds are very fond of, and if they are not prevented, many times destroy the whole crop. This should be planted in rows about two feet and a half asunder, and be managed as hath been directed for the other sorts.

Although I have directed the sowing of the large sorts of Peas for the great crop, yet these are not so sweet as the early Hotspur Peas; therefore it will also be proper to continue a succession of those sorts through the season, in small quantities, to supply the best table, which may be done by sowing every fortnight; but all those, which are sown late in the season, should have a strong moist soil, for in hot light land they will burn up, and come to nothing.

The large growing sorts may be cultivated for the common use of the family, because these will produce in greater quantities than the other, and will endure the drought better, but the early kinds are by far the sweeter tasted Peas.

The best of all the large kinds is the Marrowfat, which, if gathered young, is a well-tasted Pea, and this will continue good through the month of *August*, if planted on a strong soil.

The gray and other large winter Peas are seldom cultivated in gardens, because they require a great deal of room, but are usually sown in fields in most parts of *England*. The best time for sowing of these is about the beginning of *March*, when the weather is pretty dry, for if they are put into the ground in a very wet season, they are apt to rot, especially if the ground be cold; these should be allowed at least three feet distance row from row, and must be sown very thin in the rows; for if they are sown too thick, the haulm will spread so as to fill the ground, and ramble over each other, which will cause the plants to rot, and prevent their bearing.

The common white Pea will do best on light sandy land, or on a rich loose soil. The usual method of sowing these Peas is with a broad cast, and so harrow them in; but it is a much better way to sow them in drills about three feet asunder, for half the quantity of seed will do for an acre, and being set regularly, the ground may be stirred with a

hoe to destroy the weeds, and earth up the Peas, which will greatly improve them, and the Peas may be much easier cut in autumn, when they are ripe. The usual time for sowing of these Peas is about the middle or latter end of *March*, on warm land, but on cold ground they should be sown a fortnight or three weeks later. In the common way of sowing, they allow three bushels or more to an acre, but if they are drilled, one bushel will be full enough.

The Green and Maple Rouncivals require a stronger soil than the white, and should be sown early in the spring; also the drills should be made at a greater distance from each other, for as these are apt to grow rank, especially in a wet season, they should be set in rows three feet and a half, or four feet asunder; and the ground between the rows should be stirred two or three times with a hoe, which will not only destroy the weeds, but, by earthing up the Peas, greatly improve them, and also render the ground better to receive whatever crop is put on it the following season.

The gray Peas thrive best on a strong clayey land; these are commonly sown under furrow, but by this method they are always too thick, and do not come up regular; therefore all these rank-growing plants should be sown in drills, where the seeds will be more equally scattered, and lodged at the same depth in the ground; whereas in the common way, some of the seeds lie twice as deep as others, and are not scattered at equal distances. These may be sown toward the end of *February*, as they are much hardier than either of the former sorts, but the culture for these should be the same.

The best method to sow these Peas is to draw a drill with a hoe by a line about two inches deep, and then scatter the seeds therein; after which, with a rake you may draw the earth over them, whereby they will be equally covered: this is a very quick method for gardens, but where they are sown in fields, they commonly make a shallow furrow with the plough, and scatter the seeds therein, and then with a harrow they cover them over again. After this, the great trouble is to keep them clear from weeds, and draw the earth up to the plants; this, in such countries where labour is dear, is a great expence to do it by the hand with a hoe; but this may be easily effected with a small plough, which may be drawn through between the rows, which will entirely eradicate the weeds, and by stirring the soil, render it mellow, and greatly promote the growth of the plants.

When any of these sorts are intended for seed, there should be as many rows of them left ungathered, as may be thought necessary to furnish a sufficient quantity of seed; and when the Peas are in flower, they should be carefully looked over to draw out all those plants which are not of the right sort, for there will always be some roguish plants (as the gardeners term them) in every sort, which, if left to mix, will degenerate the kind. These must remain until their pods are changed brown, and begin to split, when you should immediately gather them up, together with the haulm; and if you have not room to stack them till winter, you may thresh them out as soon as they are dry, and put them up in sacks for use; but you must be very careful not to let them remain too long abroad after they are ripe, for if wet should happen, it would rot them, and heat, after a shower of rain, would cause their pods to burst, and cast forth their seeds, so that the greatest part of them would be lost; but, as I said before, it is not advisable to continue sowing of the same seed longer than two years, for the reasons there laid down, but rather to exchange their seeds every year, or every two years at least, whereby you may always expect to have them prove right.

PISUM CORDATUM. See *Cardiospermum*.

PITTONIA. See *Tournefortia*.

PLANTA, a plant, is defined by the ingenious Mr. *John Martyn* to be an organical body, destitute of sense, and spontaneous motion, adhering to another body in such a manner, as to draw from it its nourishment, and having power of propagating itself by seed. As to the parts, of which a plant consists, they are the root, stalk, leaf, flower, and fruit.

PLANTAGO. *Tourn. Inst. R. H. 126. tab. 48.* Plantain.

To this genus Dr. *Linnaeus* has joined the *Coronopus* and *Psyllium* of *Tournefort*. The first of these is called Hartshorn, the latter Fleawort. Of these there are several distinct species, and some varieties, but as they are rarely cultivated in gardens, I shall not enumerate them here, and shall only mention such of them as grow naturally in *England*. Of the Plantain there are the following sorts; the common broad-leaved Plantain, called Weybread; the great hoary Plantain, or Lamb-tongue; the narrow-leaved Plantain, or Ribwort, and the following varieties have also been found in *England*, which are accidental; the Besom Plantain, and Rose Plantain. The Plantains grow naturally in pastures in most parts of *England*, and are frequently very troublesome weeds. The common Plantain, and Ribwort Plantain, are both used in medicine, and are so well known as to need no description.

Of the *Coronopus*, or Buckshorn Plantain, there are two varieties growing in *England*, viz. the common Buckshorn, which grows plentifully on heaths every where, and the narrow-leaved *Welsh* sort, which is found upon many of the *Welsh* mountains. The first of these was formerly cultivated as a salad herb in gardens, but has been long banished from thence for its rank disagreeable flavour; it is sometimes used in medicine. There has been one species of *Psyllium*, or Fleawort, found growing naturally in *England*, which is the sort used in medicine: this was found in the earth, thrown out of the bottom of the canals, which were dug for the *Chelsea* water-works, where it grew in great plenty. The seeds of this must have been buried there some ages, for no person remembers any of the plants growing in that neighbourhood before. The seeds of this are sometimes used, which are imported from the south of *France*.

PLANTAIN-TREE. See *Musa*.

PLANTING. Although the method of planting the various sorts of trees is fully set down under the several articles, where each kind is mentioned; yet it may not be amiss to say something in general upon that head in this place, which shall be set down as briefly as possible. And,

First, The first thing in the planting of trees is to prepare the ground (according to the different sorts of trees you intend to plant) before the trees are taken out of the earth; for you should suffer them to remain as little time out of the ground as possible.

In taking up the trees, you should carefully dig away the earth round their roots, so as to come at their several parts to cut them off; for if they are torn out of the ground without care, the roots will be broken and bruised very much to the great injury of the trees. When you have taken them up, the next thing is to prepare them for planting; in doing of which there are two things to be principally regarded; the one is to prepare the roots, and the other to prune their heads in such a manner as may be most serviceable in promoting the future growth of the trees.

And first as to the roots; all the small fibres are to be cut off as near to the place from whence they are produced as may be (excepting ever-greens, and such trees as are to be replanted immediately after they are taken up); otherwise the air will turn all the small roots and fibres black, which, if permitted to remain on when the tree is planted, will grow mouldy, and decay, and thereby greatly injure the new fibres which are produced, so that many times the trees

miscarry for want of duly observing this. After the fibres are cut off, you should prune off all the bruised or broken roots smooth, otherwise they are apt to rot, and distemper the trees; you should also cut out all irregular roots which cross each other, and all downright roots (especially in fruit trees) must be cut off; so that when the roots are regularly pruned, they may in some measure resemble the fingers of a hand when spread open; then you should shorten the larger roots in proportion to the age and strength of the tree, as also the particular sorts of trees are to be considered; for the Walnut, Mulberry, and some other tender-rooted kinds, should not be pruned so close, as the more hardy sorts of fruit or forest trees, which in young fruit trees, such as Pears, Apples, Plums, Peaches, &c. that are one year old from budding or grafting, may be left about eight or nine inches long, but in older trees they must be left of a much greater length; but this is to be understood of the larger roots only, for the small ones must be cut quite out, or pruned very short. Their extreme parts, which are generally very weak, commonly decay after moving, so that it is the better way entirely to displace them.

The next thing is the pruning of their heads, which must be differently performed in different trees, and the design of the trees must also be considered; for if they are fruit trees, and intended for walls or espaliers, it is the better way to plant them with the greatest part of their heads, which should remain on until the spring, just before the trees begin to shoot; when they must be cut down to five or six eyes (as is fully set down in the several articles of the various kinds of fruit), being very careful, in doing of this, not to disturb the new roots.

But if the trees are designed for standards, you should prune off all the small branches close to the places where they are produced, as also irregular branches which cross each other; and by their motion, when agitated by the wind, rub and bruise their bark, so as to occasion many times great wounds in those places; besides, it makes a disagreeable appearance to the sight, and adds to the closeness of its head, which should be always avoided in fruit trees, whose branches should be preserved as far distant from each other, as they are usually produced when in a regular way of growth (which is in all sorts of trees proportionable to the size of their leaves, and magnitude of their fruit). But to return: After having displaced these branches, you should also cut off all such parts of branches as have by any accident been broken or wounded; for these will remain a disagreeable sight, and often occasion a disease in the tree. But you should by no means cut off the main leading shoots, as is by too many practised, for those are necessary to attract the sap from the root, and thereby promote the growth of the tree.

Having thus prepared the trees for planting, we must now proceed to the placing them into the ground; but before this, I would advise, if the trees have been long out of the ground, so that the roots are dried, to place them in water eight or ten hours before they are planted, observing to put them in such manner, that their heads may remain erect, and their roots only immersed therein, which will swell the dried vessels of the roots, and prepare them to imbibe nourishment from the earth. In fixing of them, great regard should be had to the nature of the soil, which, if cold and moist, the trees should be planted very shallow; as also, if it be a hard rock or gravel, it will be much the better way to raise a hill of earth where each tree is to be planted, than to dig into the rock or gravel, and fill it up with earth (as is too often practised), whereby the trees are planted, as it were in a tub, there being but little room for their roots to extend; so that after two or three years growth, when their roots have extended to the sides of the

hole, they are stopped by the rock or gravel, can get no farther, and the trees will decline, and in a few years die. But when they are raised above the surface of the ground, their roots will extend, and find nourishment, though the earth upon the rock or gravel be not three inches thick, as may be frequently observed, where trees are growing upon such soils.

Having thus planted the trees, you should provide a parcel of stakes, which should be driven down by the sides of the trees, and fastened thereto to support them from being blown down, or displaced by the wind, and then lay some mulch upon the surface of the ground, about their roots, to prevent the earth from drying.

This is to be understood of standard trees, which cast their leaves, for such as are planted against walls, should have their branches fastened to the wall to prevent the trees being displaced by the wind, and place their roots about five inches from the wall, inclining their heads thereto; and the spring following, just before they shoot, their heads should be cut down to five or six buds, as is fully directed under the several articles of the different kinds of fruit.

As to the watering of all new-planted trees, I should advise it to be done with great moderation, nothing being more injurious to them than over-watering. Examples enough of this kind may have been seen in many parts of *England*; and by an experiment made by the late Rev. Dr. *Hales*, in placing the roots of a dwarf Pear-tree in water, the quantity of moisture imbibed decreased very much daily, because the sap-vessels of the roots, like those of the cut-off boughs in the same experiment, were so saturated and clogged with moisture, by standing in water, that more of it could not be drawn up. And this experiment was tried upon a tree, which was full of leaves, and thereby more capable to discharge a large quantity of moisture than such trees as are entirely destitute of leaves; so that it is impossible such trees can thrive, where the moisture is too great about their roots.

The distance which trees should be planted at, must be proportioned to their several kinds, and the several purposes for which they are intended, all which is explained under their several heads; but fruit-trees, planted either against walls, or for espaliers, should be allowed the following distances: for most sorts of vigorous-shooting Pear-trees, thirty-six or forty feet; for Apricots, sixteen or eighteen feet; Apples, twenty-five or thirty feet; Peaches and Nectarines, twelve feet; Cherries and Plums, twenty-five feet, according to the goodness of the soil, or the height of the wall. But as these things are mentioned in their several articles, it will be needless to repeat any more in this place.

It is common to hear persons remarking, that from the present spirit of planting, great advantages will accrue to the publick by the increase of timber; but whoever is the least skilled in the growth of timber must know, that little is to be expected from most of the plantations which have lately been made; for there are few persons who have had this in their view when they commenced planters, and of those few scarce any of them have set out right, for there never was any valuable timber produced from trees which were transplanted of any considerable size, nor is any of the timber of the trees which are transplanted young, equal in goodness to that which has grown from the seeds unremoved. Beside, if we consider the sorts of trees which are usually planted, it will be found, that they are not designed for timber; so that upon the whole, it is much to be doubted, whether the late method of planting has not rather been prejudicial to the growth and increase of timber, than otherwise.

Before I quit this subject of planting, I must beg leave to observe, that most people are so much in a hurry about planting, as not to take time to prepare their ground for the

reception of trees, but frequently make holes and stick in the trees, amongst all sorts of rubbish which is growing upon the land: and I have frequently observed, that there has not been any care afterward taken to dig the ground, or root out the noxious plants; but the trees have been left to struggle with these bad neighbours, which have had long possession of the ground, and have established themselves so strongly, as not to be easily overcome; therefore what can be expected from such plantations? This is to be understood of deciduous trees, for the Pines and Firs, if once well rooted in the ground, will soon get the better of the plants and destroy them.

Therefore I would advise every person who proposes to plant, to prepare the ground well before-hand, by trenching or deep ploughing it, and clearing of it from the roots of all bad weeds; for by so doing there will be a foundation laid for the future success of the plantation. Also I advise no person to undertake more of this work than he can afterward keep clean, for all plantations of deciduous trees will require this care, at least for seven years after they are made, if they hope to see the trees thrive well. Therefore all small plantations should have the ground annually dug between the trees; and as to those which are large, it should be ploughed between them. This will encourage the roots of the trees to extend themselves, whereby they will find a much greater share of nourishment, and by loosening of the ground, the moisture and air will more easily penetrate to the roots, to the no small advantage of the trees. But besides this operation, it will be absolutely necessary to hoe the ground three or four times in summer, either by hand or the hoe-plough. This I am aware will be objected to by many, on account of the expence; but if the first hoeing is performed early in the spring, before the weeds have gotten strength, a great quantity of ground may be gone over in a short time; and if the season is dry when it is performed, the weeds will presently die after they are cut; and if this is repeated before the weeds come up again to any size, it will be found the cheapest and very best husbandry, for if the weeds are suffered to grow till they are large, it will be a much greater expence to root them out, and make the ground clean; beside, the weeds will rob the trees of great part of their nourishment. I have sometimes been told, that it is necessary to let the weeds grow among trees in summer, in order to shade their roots, and keep the ground moist; but this has come from persons of no skill; but as others may have been deceived by such advice, I imagine it may not be improper to give some answer to this. And here I must observe, that if weeds are permitted to grow, they will draw away all moisture from the roots of the trees, for their own nourishment, so that the trees will be thereby deprived of the kindly dews and gentle showers of rain, which are of great service to young plantations; and these will be entirely drawn away by the weeds, which will prevent their penetrating of the ground, so that it is only the great rains which can descend to the roots of the trees. And whoever has the least doubt of this matter, if they will but try the experiment, by keeping one part of the plantation clean, and suffer the weeds to grow on another, they will soon be convinced of the truth by the growth of the trees. And though this cleaning is attended with an expence, yet the success will overpay this, beside the additional pleasure of seeing the ground always clean.

PLATANUS. *Tourn. Inst. R. H. 590. tab. 363.* The Plane-tree.

The Characters are,

It hath male and female flowers growing separate on the same tree. The male flowers are collected in a round ball; they have no petals, but have oblong coloured stamina, which are terminated

by four-cornered summits. The female flowers have small scaly empalements, and several small concave petals, with several awl-shaped germen sitting upon the styles, crowned by recurved stigmas; these are collected in large balls. The germen afterward turns to a roundish seed sitting upon the bristly style, and surrounded with downy hairs.

The Species are,

1. *PLATANUS foliis palmatis*. Hort. Cliff. 447. Plane-tree with hand-shaped leaves; or Eastern Plane-tree.

2. *PLATANUS foliis lobatis*. Hort. Cliff. 447. Plane-tree with lobated leaves; Occidental, or *Virginian* Plane-tree.

These two are undoubtedly distinct species, but there are two others in the *English* gardens, which I suppose to be varieties that have accidentally risen from seed; one is titled the *Maple-leaved* Plane-tree, and the other is called the *Spanish* Plane-tree.

The first sort grows naturally in *Asia*. This rises to a very great height; the stem is tall, erect, and covered with a smooth bark, which annually falls off; it sends out many side branches, which are generally a little crooked at their joints; the bark of the young branches is of a dark brown, inclining to a purple colour, which are garnished with leaves placed alternate; their foot-stalks are long; the leaves are broad, deeply cut into five segments, and the two outer are slightly cut again into two more; these segments have many acute indentures on their borders; the upper side of the leaves are of a deep green, and the under side pale. The flowers come out upon long foot-stalks or ropes hanging downward, each sustaining five or six round balls of flowers; the upper, which are the largest, are more than four inches in circumference; these sit very close to the foot-stalks. The flowers are so small, as scarce to be distinguished without glasses; they come out at the same time as the leaves, which is in *June*, and in warm summers the seeds will ripen late in autumn, and if left upon the trees, will remain till spring, when the balls fall to pieces, and the bristly down which surrounds the seeds, help to transport them to a great distance with the wind.

The second sort grows naturally in most parts of *North America*. This tree also grows to a large size; the stem very strait, and of equal girt most part of the length; the bark is smooth, and annually falls off like that of the other; the foot-stalks of the leaves are long; the leaves are broad, and are cut into angles, having several acute indentures on their borders, with three longitudinal midribs. They are of a light green on their upper side, and paler on their under. The flowers grow in round balls like the former, but are smaller. The leaves and flowers come out at the same time with the former, and the seeds ripen in autumn.

That which is called the *Maple-leaved* Plane, is certainly a femal variety of the Eastern Plane, for the seeds which scattered from a large tree of this kind in the *Chelsea* garden, have produced plants of that sort several times. This differs from the two sorts before mentioned, in having its leaves not so deeply cut as those of the Eastern Plane, but they are much deeper cut than those of the Occidental Plane. The foot-stalks of the leaves are much longer than those of either of the former, and the upper surface of the leaves is rougher, so that any person might take them for different species, who had not seen them rise from the same seeds.

The *Spanish* Plane-tree has larger leaves than either of the other sorts, which are more divided than those of the Occidental Plane tree, but not so much as the Eastern. Some of the leaves are cut into five, and others but three lobes; these are sharply indented on their edges, and are of a light green. This is by some called the middle Plane-tree, from its leaves being shaped between those of the two other sorts. It grows rather faster than either of the other sorts, but I have not seen any very large trees of this kind.

The first sort was brought out of the *Levant* to *Rome*, where it was cultivated with much cost and industry: the greatest orators and statesmen among the *Romans* took great pleasure in their villas, which were surrounded with *Platani*; and their fondness for this tree became so great, that we frequently read of their irrigating them with wine instead of water. *Pliny* affirms, that there is no tree whatsoever which so well defends us from the heat of the sun in summer, nor that admits it more kindly in winter, the branches being produced at a proportionable distance to the largeness of their leaves; so that when the leaves are fallen in winter, the branches growing at a great distance, easily admit the rays of the sun.

It is generally supposed, that the introduction of this tree into *England*, is owing to the great Lord Chancellor *Bacon*, who planted a noble parcel of them at *Verulam*, which were there very flourishing some years since, but have lately been destroyed.

However, notwithstanding the Plane-tree is backward in coming out in the spring, and the leaves decaying soon in autumn, yet for the goodly appearance and great magnitude to which it will grow, it deserves a place in large plantations, or shady recesses near habitations, especially if the plantation be designed on a moist soil, or near rivulets of water, in which places this tree will arrive to a prodigious magnitude.

The Eastern Plane-tree is propagated either from seeds, or by layers, the latter of which is generally practised in *England*; though the plants thus raised seldom make so large strait trees, as those which are produced from seeds; but it has been generally thought, that the seeds of this tree were not productive, because they have not been sown at a proper season, nor managed in a right manner; for I have had thousands of the young plants spring up from the seeds of a large tree, which scattered upon the ground in a moist place; and I since find, that if these seeds are sown soon after they are ripe, in a moist shady situation, they will rise extremely well; and the plants thus obtained, will make a considerable progress after the second year, being much hardier and less liable to lose their tops in winter, than those which are propagated by layers. And since the seeds of this tree ripen well in *England*, they may be propagated in as great plenty as any other forest tree.

The *Virginian* Plane-tree will grow extremely well from cuttings, if they are planted the beginning of *October* upon a moist soil, and if they are watered in dry weather, will make a prodigious progress; so that in a few years from the planting, they will afford noble trees for planting of avenues, and other shady walks; and their trunks are perfectly strait, growing nearly of the same size to a considerable height, there being the least difference in the girt of this tree, for several yards upwards, of any other sort of tree whatsoever.

They are all propagated very easily by layers, every twig of them will take root, if they are but covered with earth; these layers will be well rooted in one year, when they should be cut off from the old trees or stools, and planted in a nursery, where they may remain two or three years to get strength, and then transplanted where they are to remain, for the younger these trees are planted, the better they will thrive. An experiment of this I made in 1731, when I planted one of these trees, whose stem was eight inches in girt, and near it, in the same soil and situation, I planted another, whose girt was not three inches, and the latter is now much larger than the former, and gains more in one year than the other does in three.

PLOWING OF LAND.

There is not a greater improvement of arable land than that of well ploughing it, by which the soil is pulverized,

verized, and rendered fit to receive the fibres of plants; the oftener this is repeated, and the better it is performed, the greater improvement is made. But there are not many of the practitioners of the art of husbandry, who attend enough to this part of it, most of them contenting themselves with going on in the old beaten road of their predecessors; so that the only persons, who have made any considerable improvement in this part of agriculture, are the great gardeners, who cultivate most of their land with the plough, in which they have imitated, as near as possible, the use of the spade in labouring of their ground.

The difference between digging of land with the spade, and that of ploughing, consists in the parts of the earth being much more divided by the former than the latter method; therefore those gardeners, who are curious in the working of their land, oblige their labourers to spit the ground as thin as possible, that there may remain no large clods unbroken; so, when land is ploughed, the same regard should be had to break and pulverize the parts as much as possible; for when there are great clods left unbroken, the fibres of plants never penetrate farther than the surface of them; so that all the salts, included in these lumps of earth, are locked up, that the plants can receive no benefit from them. And these clods, in proportion to their size, make such interstices, that the air often penetrates through, and greatly injures the tender fibres of the roots. Therefore the oftener the land is ploughed, and the more the parts are separated and pulverized, by the plough and harrow, the better will the plants be nourished and fed; but, particularly in all strong land, this part of husbandry will be the most beneficial, but this cannot be effected under four or five ploughings, and by using such ploughs as have either two or four colters, which will cut and separate the clods much better than it can be performed by the common plough; and in the operation, great care should be had to the breadth of the furrow, for when these are made too broad, it will be impossible to break and separate the parts sufficiently. In some counties, where the husbandmen are not very expert in the use of the plough, I have seen gentlemen oblige them to plough by a line, and they have set out the exact width of each furrow. This not only adds a neatness to the ground, but likewise by keeping the furrows strait, and at equal distances, the land will be more equally worked; but many of the good ploughmen, in the counties near *London*, will direct the plough as strait by their eye, as if they were to use a line.

Another thing to be observed in ploughing of land is, that of going to a proper depth; for if the surface only be broken up and pulverized, the roots of whatever plants are sown or planted in it, will in a very short time reach the bottom, and meeting with the hard unbroken soil, they are stopped from getting farther, and of consequence the plants will stint in their growth; for there are few persons who have attended enough to the downright growth of the roots of plants; they only have had regard to the roots of those plants, which are of a strong fleshy substance, and are called Tap-roots, being in form of Carrots. These they suppose will require to have the land wrought to a greater depth, that the roots may run down, and be the longer; for in that particular their goodness consists. But they do not think that the small fibrous rooted plants ever require so much depth to run into the ground, and in this they are greatly mistaken; for I have traced the small fibres of Grass and Corn above three feet deep in the ground. And if any person is curious to observe the length of the fibres of plants, if they will but plant one of each sort into a small pot of earth, and keep them duly watered, till the plants are advanced to flower, and then turn them out of the pots carefully, so as not to break any of the fibres of the roots, and

after separating the earth from them, measure the length of their roots, they will be found much greater than most people imagine. I have myself frequently traced the roots of plants, which have surrounded the pots upward of twelve times, and the roots of some strong-growing plants, which have gotten through the holes in the bottom of flower-pots, have in three months time extended themselves ten or eleven feet from the plant; therefore the deeper the ground is laboured, the greater benefit the plants will receive from it; but it must be understood only of such land as the staple is deep enough to admit of this, for if the soil is shallow, and either gravel, chalk, or stone lie beneath, it will be very imprudent to turn up either of these; therefore the depth of the furrows in such lands must be determined by the staple of the land. By the word Staple must be understood all that depth of soil next the surface, which is proper for the growth of vegetables. Where clay is next the staple, provided it is not of the blue or ironmould sort, there will not be the same danger of going a little deeper than the staple, as in either of the before mentioned sorts of land; for if the clay be of a fat nature, when it hath been well exposed to air, and often laboured, it will be capable of affording a large share of nourishment to the crops.

If between each ploughing of the land a harrow with long teeth is made use of to tear and break the clods, it will be of great service to the land, especially if it is strong, for the more it is stirred by different instruments, the better will the parts be separated and pulverized; so that the common method, as practised by the farmers when they fallow their land, is far from answering their intention, for they plough up the ground, leaving it in great clods for some months, and frequently, during this time, Thistles and all bad weeds are suffered to grow upon the land, and exhaust the goodness of it, and perhaps, just before the seeds are sown, they give it two more ploughings. This is what the farmers call good husbandry, but if instead of this method they would labour the ground often with the plough, a harrow, and heavy roller, to break and separate the parts, and never suffer any weeds to grow upon the land, during its lying fallow, I am sure they would find their account in it; first, by the growth and increase of their crops, and afterward by a saving in the weeding; for if no weeds are suffered to grow to shed their seeds, during the time of fallowing the land, there will but few come up when the ground is sown, in comparison with what would otherwise, in the common husbandry.

PLUMBAGO. *Journ. Inst. R. H.* 140. *tab.* 58. *Lin. Gen. Plant.* 196. Leadwort.

The Characters are,

The flower has a tubulous permanent empalement, which is indented at the top in five parts; it hath one funnel-shaped petal, with a cylindrical tube, narrow at the top. The brim is cut into five oval parts; it has five awl-shaped stamina, situated in the tube, sitting upon the valves of the nectarium, which includes the germen. The small oval germen sustains a single style, the length of the tube, crowned by a slender five-pointed stigma. The germen afterward becomes a single oval seed, included in the empalement.

The Species are,

1. PLUMBAGO *foliis amplexicaulibus.* *Hort. Cliff.* 53. Leadwort with leaves embracing the stalks; common Leadwort or Toothwort.

2. PLUMBAGO *foliis petiolatis.* *Hort. Cliff.* 53. Leadwort with leaves having foot-stalks.

The first sort grows naturally in the south of *France*, in *Italy*, and *Spain*. This hath a perennial root, which strikes deep into the ground, from which arise many slender channelled stalks three feet high, garnished with oval spear-shaped leaves, whose base embraces the stalks; they are smooth,

smooth, entire, and of a grayish colour. The upper part of the stalks sends out many slender branches, garnished with small leaves. These, and also the principal stalks, are terminated by tufts of blue flowers, which are small, funnel-shaped, and have pretty long tubes; these are succeeded by oblong, rough, hairy seeds. This plant seldom flowers till *October* in *England*, so never produces ripe seeds here. There is a variety of this with white flowers and pale stalks, which is supposed to have risen from the seeds of the former.

The stalks of these decay in the winter, and new ones come up the following spring; they are propagated here by parting of their roots, which send out heads in plenty. These may be divided at any time, when the weather is mild, from the time the stalks decay, till the roots begin to shoot in the spring; it should have a light soil and a warm situation, otherwise it will not flower here. The roots should be allowed room to spread, and the stalks require support; and if the plants are kept clean from weeds, and the ground between them dug every winter, it is all the culture they require.

The second sort grows naturally in both *Indies*. This is a perennial plant, with a strong fibrous root, from which arise many slender stalks, which grow near four feet high, garnished with smooth, oval, spear-shaped leaves, ending in acute points, placed alternate, standing upon short foot-stalks. The upper part of the stalks divides into small branches, which are garnished with small oval leaves, and terminate in spikes of white flowers, which have long slender tubes, cut into five segments at the brim; these are succeeded by oblong seeds, covered with the prickly empalement. The upper part of the stalk, and the empalements of the flowers, are very glutinous, sticking to the fingers if touched, and the small flies which settle upon them, are fastened, so cannot get off again. This plant is too tender to thrive in the open air in *England*, so requires to be kept in a moderate stove, where they will continue flowering great part of the year, and those flowers, which appear early in the summer, will be succeeded by ripe seeds in autumn.

This is propagated by seeds, which should be sown on a good hot-bed in the spring, where the plants will come up in about five or six weeks. When these are fit to remove, they should be each planted into a separate small pot, and plunged into a hot bed of tan, observing to screen them from the sun, till they have taken new root; afterward they must be treated like other plants from the same country. In the summer they should have a large share of fresh air admitted to them in warm weather, and require water every other day. In winter they should be kept in a moderate temperature of warmth, and must be more sparingly watered. With this management the roots will abide several years, and produce plenty of flowers and seeds.

PLUM-TREE. See *Prunus*.

PLUMERIA. *Tourn. Inst. R. H. 659. tab. 439.* Red Jasmine.

The Characters are,

The flower has a small empalement, divided into five parts; it hath one funnel-shaped petal, with a long tube, cut into five oblong oval segments at the top, which spread open; it hath five awl-shaped stamina, situated in the center of the tube, terminated by summits which close together, and an oblong bifid germen, with scarce any style, crowned by a double acute stigma. The germen afterward becomes a long, swelling, acute-pointed capsule, with one cell, filled with winged seeds, placed over each other like scales of fish.

The Species are,

1. PLUMERIA *foliis ovato-oblongis. Hort. Cliff. 76.* Plumeria with oblong oval leaves; commonly called in the *West-Indies* Red Jasmine.

2. PLUMERIA *foliis ovato-oblongis, ramis patulis, floribus corymbosis.* Plumeria with oblong oval leaves, spreading branches, and flowers growing in a corymbus; called in the *West-Indies* the Japan-tree.

3. PLUMERIA *foliis lanceolatis revolutis, pedunculis supernè tuberosis. Lin. Sp. Plant. 210.* Plumeria with spear-shaped leaves, which turn backward, and the foot-stalks having swellings on the upper side.

4. PLUMERIA *foliis lanceolatis petiolatis obtusis. Lin. Sp. Plant. 210.* Plumeria with spear-shaped obtuse leaves, having foot-stalks.

5. PLUMERIA *foliis lineari-lanceolatis longissimis.* Plumeria with very long, narrow, spear-shaped leaves.

The first sort grows naturally in the *Spanish West-Indies*, from whence it was transplanted into most of the islands, where it is cultivated in the gardens for ornament. It rises to the height of eighteen or twenty feet; the stalk is covered with a dark green bark, having marks where the leaves have fallen off. The stalks are succulent, and abound with a milky juice, but within they are somewhat ligneous. Toward the top they put out a few thick succulent branches, which are garnished at their ends with oval oblong leaves, of a light green colour, having a large midrib, and many transverse veins; these are full of a milky juice. At the ends of the branches come out the flowers in pretty large clusters; they are shaped like those of the Oleander or Rose Bay, having one petal, which is tubulous, and cut into five oval obtuse segments, which spread open; they are of a pale red colour, and have an agreeable odour. When the flowers are past, the germen becomes a long swelling pod, filled with flat winged seeds, lying over each other like the scales of fish. It usually flowers here in *July* and *August*, but is never succeeded by pods in *England*.

The second sort I received from the island of *St. Christopher* by the name of Japan-tree. This sort is very rare in the *English* settlements at present, having been but lately introduced from the *Spanish West-Indies*. It is in leaf and stem very like the first, but the stalks do not rise so high; they divide into strong spreading branches, which are filled with a milky juice; the leaves are of a thicker consistence than those of the first, and their veins are larger; the flowers of this are of a deeper colour, and are produced in much larger clusters. It is very common to have upward of twenty of these flowers open in one bunch, and a number to succeed these as they decay, so as that the clusters have continued in beauty upward of two months, during which time they make a most beautiful appearance in the stove, and have a very agreeable scent.

The third sort grows plentifully at *Campeachy*. This is not near so beautiful as the two former sorts, the flowers being smaller, and produced in less bunches, and are moreover of short duration. But for the beauty of their stems and leaves, and for the sake of variety, they deserve room in every curious collection of plants.

The fourth sort was discovered by *Dr. Houstoun*, growing in great plenty near *Carthage*. This sort produces small white flowers, resembling those of the third, so is less valuable than the two first.

The seeds of the fifth sort were sent me by *Mr. Richard*, gardener to the king of *France* at *Versailles*, but I had no account of the country from whence it was sent. This hath a stalk very like the first sort, but the leaves are nine or ten inches long, and not more than one inch broad; they are thick, succulent, and full of a milky juice, a little roundish at their points. The flowers of this sort are said to be yellow, but as the plants have not yet flowered here, I can give no farther account of them.

All these plants may be propagated by seeds; these should be sown in pots filled with light earth, and plunged into

into a hot-bed of tanners bark; and when the plants are come up about two inches high, they should be transplanted into separate small pots filled with light sandy earth, and plunged into the hot-bed again. They must not have much water, for as all the sorts are very succulent, being full of a milky juice, somewhat like the Euphorbiums, moisture will cause them to rot. In hot weather the plants should have a pretty large share of fresh air admitted to them, by raising the glasses every day, in proportion to the warmth of the season, to prevent their drawing up weak. Toward *Michaelmas*, when the nights begin to be cold, the plants should be removed into the stove, and plunged into the bark-bed, where they must remain during the winter. As these plants all cast their leaves in the middle of winter, and continue destitute of them till about the beginning of *May*, so, during that time, they should be watered very sparingly, because they are in more danger of rotting, while they are in a less active state, by too much moisture, than when they are furnished with leaves, through which the moisture is more freely perspired.

All these sorts are too tender to thrive in the open air of this country in the summer season, therefore should be constantly preserved in the stove, where, in warm weather, they must have a large share of free air, but in cold weather they must be kept very warm. While they are young, it will be proper to continue them in the bark bed, but when they have obtained strength, they may be placed in a dry stove, where they will thrive well, provided they are kept in a moderate temperature of heat, and have not too much water.

These plants may also be propagated by cuttings, which should be taken from the old plants a month or six weeks before they are planted, during which time they should be laid on the flues in the stove, that the part which joined to the old plant may be healed over before they are planted, otherwise they will rot. These cuttings should be planted in small pots filled with light sandy earth, and plunged into a moderate hot-bed of tanners bark. If the cuttings succeed, they will have taken root in about two months, when they should have a larger share of air to harden them by degrees to bear the sun and air, and afterward may be treated as the old plants.

PODOPHYLLUM. *Lin. Gen. Plant.* 571. Ducksfoot, or May Apple.

The Characters are,

The bud of the flower is inclosed in a large three-leaved empalement, in form of a spatha or sheath. It has nine roundish concave petals, plaited on their borders, and smaller than the empalement; it has a roundish germen without a style, crowned by a plaited obtuse stigma. The germen afterward turns to an oval capsule of one cell, crowned by the stigma, filled with roundish seeds.

We have but one Species of this genus in the English gardens, viz.

PODOPHYLLUM foliis peltatis lobatis. *Lin. Sp. Plant.* 505. Ducks-foot with target-shaped leaves having lobes.

This plant grows naturally in many parts of *North America*. The root is composed of many thick tubers, which are fastened together by fleshy fibres, and propagate greatly under ground, sending out many smaller branches, which strike downward. In the spring arise several foot-stalks about six inches high, which divide into two smaller, each sustaining one leaf composed of five, six, or seven lobes, the five middle being deeply indented at the top; these join together at their base, where the foot-stalk meets, which is fastened to the under side of the leaf like the handle of a target; the leaves are smooth, and of a light green. At the division of the foot-stalk comes out the flower with a large empalement, covering it like a sheath; the flower hath

nine pretty large concave white petals, which are roundish at the top, and plaited on their borders. In the center is situated a large, roundish, oval germen, crowned by a plaited obtuse stigma, surrounded by a great number of short stamina, terminated by oblong, erect, yellow summits.

This plant propagates so fast by its creeping roots, as that few persons are at the trouble of sowing the seeds. Every part of the root will grow, so they may be annually parted, either in autumn when their leaves decay, or in the spring just before the roots begin to shoot; they require no other culture but to keep them clean from weeds. It loves a light loamy soil, and a shady situation, and is so hardy as seldom to be injured by frost.

POINCIANA. *Tourn. Inst. R. H.* 619. *tab.* 391. *Barbadoes* Flower fence, or Spanish Carnations.

The Characters are,

The empalement of the flower is composed of five oblong concave leaves, which fall off. The flower has five unequal petals; four of them are nearly equal and roundish, but the fifth is larger, deformed, and indented. It hath ten long, bristly, rising stigmas, terminated by oblong summits, and an awl-shaped declining germen, which sits upon the style, and is crowned by an acute stigma. The germen afterward becomes an oblong compressed pod, with several transverse partitions; in each of these is lodged a single flattish seed.

We have but one Species of this genus in the English gardens, viz.

POINCIANA aculeis geminis. *Hort. Upsal.* 101. Flower-fence with double spines.

There are two varieties of this, which were discovered by the late Dr. *Houftoun* in the *Spanish West-Indies*. One of these hath a red, and the other a yellow flower, but as there appears to be no other difference in the plants from the common sort, they must be supposed only accidental variations, which have risen from seeds.

This plant grows naturally in both *Indies*. It is planted in hedges, to divide the lands in *Barbadoes*, from whence it had the title of Flower-fence; it is also called *Spanish Carnations* by some of the inhabitants of the *British* islands. It rises with a strait stalk from ten to fifteen feet high, covered with a smooth gray bark, and is sometimes as thick as the small of a man's leg, dividing into several spreading branches at the top, which are armed at each joint with two short, strong, crooked spines, and are garnished with decompound winged leaves, each leaf being composed of six or eight pair of simple winged leaves, the lower pair being composed of four or five pair of lobes, the others gradually increasing in their number toward the top, where they decrease again, and are smaller. The lobes are of a light green colour, and, when bruised, emit a strong odour.

The branches are terminated by loose spikes of flowers, which are sometimes formed into a kind of pyramid, and at others they are disposed more in form of an umbel. The foot-stalk of each flower is near three inches long; the flower is composed of five petals, which are roundish at the top, but are contracted to narrow tails at their base; they spread open, and are beautifully variegated with a deep red or Orange colour, yellow, and some spots of green; they have a very agreeable odour. In the center of the flower is situated a slender style above three inches long, upon which the germen sits, and is accompanied by ten stamina, nearly of the same length with the style, terminated by oblong summits. After the flower is past, the germen becomes a broad flat pod, about three inches long, divided into three or four cells by transverse partitions, each including one flattish irregular seed. The leaves of this plant are used instead of *Sena* in the *West-Indies* to purge, and from thence the plant is by some persons titled *Sena*.

Ligon says the seeds of this plant were first carried to *Barbadoes* from *Cape Verd Islands*, and the beauty of the flowers was such, that the inhabitants soon spread it over that island, and afterward it was transported into most of the neighbouring islands. This may have been so, but it is very certain that the plant grows naturally in *Jamaica*, where the late *Dr. Houffoun* found it in the woods at a great distance from any settlements. He also found it growing naturally at *La Vera Cruz*, and at *Campeachy*, where he also found the two varieties with red and yellow flowers.

The seeds of this plant are annually brought over in plenty from the *West-Indies*, which, if sown upon a hot-bed, will rise easily. When the plants are come up, they should be transplanted each into a small pot, and plunged into a hot-bed of tanners bark, observing to shade them from the sun, till they have taken root; after which they must have air in proportion to the warmth of the season, and be frequently refreshed with water. When the plants have filled the pots with their roots, they should be shaken out, and placed into larger ones, that they may have room to grow. If care be taken to water and shift them as often as is necessary, they will grow to be three feet high the first season. At *Michaelmas* the pots should be plunged into a fresh hot-bed of tanners bark in the stove, which should be kept to the *Ananas* heat, marked on the botanical thermometers, and frequently refreshed with water, but they should not have too much water in winter. The earth, which these plants should be planted in, must be fresh, light, and sandy (but not over-rich), in which they will stand the winter better than if planted in a stronger soil.

These plants must constantly remain in the bark-stove, where in warm weather they should have a large share of air, but they must not be exposed to cold; if damp seizes their top, it very often kills the plants, or at least occasions the loss of their heads. With proper management they will grow much taller here than they usually do in *Barbadoes*, but their stems will not be larger than a man's finger, which is occasioned by their being drawn up by the glasses of the stove. I have had some of these plants more than eighteen feet high in the *Chelsea* garden, which have produced their beautiful flowers some years. These flowers have always appeared in *December*, but in the *West-Indies* I am informed they flower twice a year, at which times they make a most beautiful appearance.

POKE VIRGINIAN. See *Phytolacca*.

POLEMONIUM. *Tourn. Inst. R. H. 146. tab. 61.* Greek *Valerian*, or *Jacob's Ladder*.

The Characters are,

The flower has a permanent empalement, which is cut into five segments; it has one wheel-shaped petal. The tube is very short; the upper part is divided, and spreads open. It hath five slender stamina, inserted in the valves of the tube, which are shorter than the petal, and are terminated by roundish summits. In the bottom of the tube is situated an acute oval germen, supporting a slender style, equal with the petal, crowned by a revolving trifid stigma. The germen afterward turns to a three-cornered oval capsule, having three cells, filled with irregular acute-pointed seeds.

The Species are,

1. POLEMONIUM *calycibus corollæ tubo longioribus.* *Lin. Sp. Plant. 162.* Greek *Valerian* with an empalement longer than the tube of the flower.

2. POLEMONIUM *foliis pinnatis, radicibus reptatricibus.* *Flor. Virg. 22.* Greek *Valerian* with winged leaves, and a creeping root.

The first sort grows naturally in many parts of *Europe*. It has been discovered growing wild in *Carleton Beck*, and about *Malham Cove* near *Craven*, in *Yorkshire*. Of this there are three varieties, one with a white, another with a blue, and one with a variegated flower, also another with variegated leaves.

This plant has winged leaves, which are composed of several pair of lobes placed alternately. The stalks rise near a foot and a half high; they are hollow, channelled, and are garnished with winged leaves, of the same form with the lower, but decrease upward in their size; they are terminated by bunches of flowers, which sit very close; they have one petal, which has a short tube, cut into five roundish segments at the top; they are of a beautiful blue colour, and have each five stamina, which are terminated by yellow summits. These flowers appear the latter end of *May*, and are succeeded by oval acute-pointed capsules, with three cells, filled with irregular seeds, which ripen in *August*.

These plants are easily propagated by sowing their seeds in the spring upon a bed of light earth, and when they are come up pretty strong, they should be pricked out into another bed, about four or five inches asunder, observing to shade and water them, until they have taken root; after which they will require no farther care, but to keep them clear from weeds until *Michaelmas*, at which time they must be transplanted into the borders of the flower-garden, where, being intermixed with different sorts of flowers, they will make a beautiful appearance.

This plant is not naturally of long duration, but by taking them up in autumn, and parting of them, they may be continued several years, but as the seedling plants always flower much stronger than the offsets, few persons ever propagate them by slips.

The sort with white flowers will frequently arise from the seeds of the blue, as will also that with variegated flowers, but these may be continued by parting of their roots.

The sort with variegated leaves is preserved by parting of their roots, because the plants raised from seeds would be subject to degenerate, and become plain. The best time to part them is about *Michaelmas*, that they may take good root before the cold weather prevents them. These should have a fresh light soil, but if it be too rich, their roots will rot in winter, or the stripes will go off in the summer.

The second sort grows naturally in *Virginia* and other parts of *North America*. This hath creeping roots, by which it multiplies very fast. The leaves have seldom more than three or four pair of lobes, which stand at a much greater distance from each other than those of the common sort; they are of a darker green. The lobes are narrow, and are placed alternately; the stalks rise nine or ten inches high, sending out branches their whole length. The flowers are produced in loose bunches, standing upon pretty long foot-stalks; they are smaller than those of the common sort, and are of a lighter blue colour.

This sort may be propagated by seeds in the same manner as the common sort, or by parting of their roots in autumn, and is equally hardy with the common sort.

POLIANTHES. *Lin. Gen. Plant. 384.* The *Tuberose*.

The Characters are,

The flower has no empalement; it has one funnel-shaped petal. The tube is oblong and incurved; the brim is cut into six oval segments, which spread open. It hath six thick stamina, situated in the chaps of the petal, terminated by linear summits, which are longer than the stamina. In the bottom of the tube is situated a roundish germen, supporting a slender style, crowned by a thick trifid honey-bearing stigma. The germen afterward turns to an obtuse, roundish, three-cornered capsule, having three cells, which are filled with plain half-round seeds, disposed in a double range.

We have but one Species of this genus, viz.

POLIANTHES *floribus alternis.* *Hort. Cliff. 127.* *Polianthes* with flowers placed alternately; commonly called *Tuberose*.

The varieties of this are the *Tuberose*, with a double flower, the striped-leaved *Tuberose*, and the *Tuberose* with

a smaller flower; the last is mentioned by several authors as a distinct species, but is certainly a variety.

This sort is frequent in the south of *France*, from whence the roots have been often brought to *England* early in the spring, before those roots have arrived from *Italy*, which are annually imported; the stalks of this are weaker, and do not rise so high, and the flowers are smaller than those of the common *Tuberose*, but in other respects is the same.

The *Tuberose* grows naturally in *India*, from whence it was first brought to *Europe*, where it now thrives in the the warmer parts, as well as in its native soil. The *Genoese* are the people who cultivate this plant, to furnish all the other countries where the roots cannot be propagated without great trouble and care, and from thence the roots are annually sent to *England*, *Holland*, and *Germany*. In most parts of *Italy*, *Sicily*, and *Spain*, the roots thrive and propagate without care, where they are once planted.

This plant has been long cultivated in the *English* gardens, for the exceeding beauty and fragrancy of its flowers; the roots of this are annually brought from *Genoa*, by the persons who import *Orange* trees; for as these roots are too tender to thrive in the full ground in *England*, so there are few persons who care to take the trouble of nursing up their offsets, till they become blowing roots, because it will be two or three years before they arrive to a proper size for producing flowers; and as they must be protected from the frost in winter, the trouble and expence of covers is greater than the roots are worth, for they are generally sold pretty reasonable, by those who import them from *Italy*.

The double flowering is a variety of the first, which was obtained from seed by *Monf Le Cour*, of *Leyden* in *Holland*, who for many years was so tenacious of parting with any of the roots, even after he had propagated them in such plenty, as to have more than he could plant, caused them to be cut in pieces, that he might have the vanity to boast of being the only person in *Europe* who was possessed of this flower; but of late years the roots have been spread into many parts, and as there is no method to propagate this but by the offsets, most people who have had of this sort, are careful to multiply and increase it, which is done by planting the offsets upon a moderate hot-bed early in *March*, and covering the bed in cold weather with mats or straw; in summer they must have plenty of water in dry weather. In this bed the roots may remain till the leaves decay in autumn, but if there should happen any frost before that time, the bed should be covered to guard the roots from the frost, because if the frost enters so low as to reach the roots, it will kill them; and if the leaves are injured by the frost, it will weaken the roots. Where there is due care taken to screen them from frost, and too much wet, it will be the best way to let the roots remain in the bed till the end of *November*, or the beginning of *December*, provided hard frosts do not set in sooner, for the less time the roots are out of the ground, the stronger they will be, and the sooner they will flower; when the roots are taken up, they should be cleaned from the earth, and laid up in dry sand, where they may be secure from frost and wet; here they should remain until the season for planting them again; this same method should be practised by those who are desirous to cultivate the single sort in *England*, and also that with striped leaves must be propagated the same way.

I shall next give directions for the management of those roots, which are annually brought from *Italy*. And first, in the choice of the roots, those which are the largest and plumpest, if they are perfectly firm and round, are the best, and the fewer offsets they have, the stronger they will flower, but the under part of the roots should be particularly examined, because it is there that they first decay; after the roots are chosen, before they are planted, the offsets should

be taken off; for if these are left upon the roots, they will draw away part of the nourishment from the old root, whereby the flower-stems will be greatly weakened.

As these roots commonly arrive in *England* in the month of *February* or *March*, those who are desirous to have these early in flower, should make a moderate hot-bed soon after the roots arrive, which should have good rich earth laid upon the dung, about seven or eight inches deep; this bed should be covered with a frame, and when the bed is in a proper temperature for warmth, the roots should be planted at about six inches distance from each other every way. The upper part of the root should not be buried more than one inch in the ground; when the roots are planted, there should be but little water given them, until they shoot above ground, for too much wet will rot them, when they are in an inactive state, but afterward they will require plenty of water, especially when the season is warm. When the flower-stems begin to appear, the bed should have a large share of air given to it, otherwise the stalks will draw up weak, and produce but few flowers; for the more air these plants enjoy in good weather, the stronger they will grow, and produce a great number of flowers; therefore, toward the beginning of *May*, the frame may be quite taken off the bed, and hoops fastened over it, to support a covering of mats, which need not be laid over but in the night, or in very cold weather, so that by enjoying the free open air, their stems will be large; and if they are well watered in dry weather, their flowers will be large, and a great number on each stem.

This first planting will require more care than those which are designed to come after them; for in order to have a succession of these flowers, the roots should be planted at three different times, *viz.* the first the beginning of *March*, the second the beginning of *April*, and the third at the end of that month, or the beginning of *May*, but the latter beds will require a much less quantity of dung than the first, especially that bed which is the last made, for if there is but warmth enough to put the roots in motion, it is as much as will be required; and this last bed will need no covering, for many times those roots which are planted in the full ground at this season, will produce strong flowers in autumn; but in order to secure their flowering, it is always the best way to plant them on a gentle hot-bed. As to the second bed, that should be arched over with hoops, and covered with mats every night, and in bad weather, otherwise the late frosts which frequently happen in *May*, will pinch them.

These plants may remain in the beds until the flowers are near expanding, at which time they may be carefully taken up, preserving the earth to their roots, and planted in pots, and then placed in the shade for about a week to recover their removal; after which time the pots may be removed into halls, or other apartments, where they will continue in beauty a long time, and their fragrant odour will perfume the air of the rooms where they are placed, and by having a succession of them, they may be continued from *Midsummer* to the end of *October*, or middle of *November*; but as the stems of these plants advance, there should be some sticks put down by each root, to which the stems should be fastened, to prevent their being broken by the wind.

It is a common practice with many people, to plant these roots in pots, and plunge the pots into a hot-bed; but there is much more trouble in raising them in this method, than in that before directed; for if the roots are not planted in very small pots, there will be a necessity of making the beds much larger, in order to contain a quantity of the roots; and if they are first planted in small pots, they should be shaken out of these into pots of a larger size, when they begin

begin to shoot out their flower-stems, otherwise the stalks will be weak, and produce but few flowers; therefore I prefer the other method, as there is no danger in removing the roots, if it is done with care.

When the roots are strong and properly managed, the stems will rise three or four feet high, and each stem will produce twenty flowers or more; and in this the great beauty of these flowers consists, for when there are but a few flowers upon the stalks, they will soon fade away, and must be frequently renewed; for the flowers are produced in spikes coming out alternately upon the stalk, the lower flowers opening first, and as these decay, those above them open, so that in proportion to the number of flowers upon each stalk, they continue in beauty a longer or shorter time.

The sort with double flowers will require a little more care, in order to have the flowers fair; but this care is chiefly at the time of blowing, for the flowers of this sort will not open, if they are exposed to the open air; therefore when the flowers are fully formed and near opening, the pots should be placed in an airy glass-case, or a shelter of glasses should be prepared for them, that the dews and rains may not fall upon them, for that will cause the flowers to rot away before they open, and the heat of the sun drawn through the glasses, will cause their flowers to expand very fair. With this management, I have had this sort with very double flowers extremely fair, and upward of twenty upon one stem, so that they have made a beautiful appearance; but where this has not been practised, I have rarely seen one of them in any beauty.

POLIUM. *Tourn. Inst. R. H. 206. tab. 97.* Mountain Poley.

The Characters are,

The empalement of the flower is cut into five acute segments. The flower is of the lip kind; it hath one petal, with a short tube. The stamina occupy the place of the upper lip, and the lower lip is cut into five segments. It hath four awl-shaped stamina, which are terminated by small summits, and a germen divided into four parts, supporting a slender style, crowned by two narrow stigmas; the germen afterward become four naked seeds, inclosed in the empalement.

The Species are,

1. POLIUM *foliis lanceolatis integerrimis, caulibus procumbentibus, floribus corymbosis terminalibus.* Mountain Poley with entire spear-shaped leaves, trailing stalks, and flowers growing in a corymbus at the end of the branches.

2. POLIUM *spicis oblongis foliis obtusis crenatis tomentosis.* Mountain Poley with oblong spikes of flowers, and obtuse, crenated, woolly leaves; yellow Mountain Poley.

3. POLIUM *spicis subrotundis, caulibus suffruticosis incanis, foliis linearibus tomentosis.* Mountain Poley with roundish spikes of flowers, hoary shrubby stalks, and very narrow woolly leaves.

4. POLIUM *caule ramoso procumbente, foliis lineari-lanceolatis dentatis, floribus corymbosis terminalibus.* Poley with a branching trailing stalk, narrow, spear-shaped, woolly, indented leaves, and flowers growing in a corymbus, terminating the branches.

5. POLIUM *caule erecto diffuso, foliis lineari-lanceolatis crenatis, corymbis terminalibus lateralibusque.* Poley with an erect diffused stalk, narrow, spear-shaped, crenated leaves, and flowers growing in a corymbus, terminating and proceeding out of the sides of the branches.

6. POLIUM *caulibus procumbentibus hirsutissimis, foliis cuneiformi orbiculatis crenatis.* Poley with very hairy trailing stalks, and orbicular wedge-shaped leaves, which are crenated.

7. POLIUM *caule erecto ramoso, foliis lanceolatis dentatis subtus tomentosis, floribus confertis terminalibus.* Poley with an upright branching stalk, spear-shaped indented leaves, which

are woolly on their under side, and flowers growing in clusters, terminating the branches.

8. POLIUM *caule erecto corymboso, foliis linearibus reflexis, floribus terminalibus.* Poley with an upright stalk, branching out in form of a corymbus, narrow reflexed leaves, and flowers terminating the stalks.

9. POLIUM *caule ramoso, procumbente, foliis lineari-lanceolatis supernè dentatis, spicis oblongis terminalibus.* Poley with a trailing branching stalk, narrow spear-shaped leaves, which are indented toward the top, and oblong spikes of flowers terminating the stalks.

10. POLIUM *caule erecto suffruticoso, foliis linearibus confertis, spicis cylindricis fastigiatis terminalibus.* Poley with an upright under-shrub stalk, narrow leaves growing in clusters, and cylindrical spikes of flowers growing in bunches, which terminate the stalks.

11. POLIUM *caule erecto fruticoso, foliis lanceolatis tomentosis integerrimis, corymbis terminalibus.* Poley with an upright shrubby stalk, spear-shaped woolly leaves, which are entire, and flowers growing in a corymbus, terminating the stalks.

12. POLIUM *caule procumbente, foliis linearibus serratis, corymbis confertis terminalibus.* Poley with a trailing stalk, narrow sawed leaves, and clustered flowers growing in a corymbus, at the ends of the stalks.

13. POLIUM *caule diffuso procumbente, foliis linearibus dentatis tomentosis, spicis subrotundis.* Poley with a trailing diffused stalk, narrow indented woolly leaves, and roundish spikes of flowers.

14. POLIUM *caule erecto suffruticoso, foliis lanceolatis integerrimis, corymbis confertis terminalibus.* Poley with an erect shrubby stalk, spear-shaped entire leaves, and clustered flowers growing in a corymbus at the ends of the branches.

15. POLIUM *caule diffuso, foliis linearibus pinnato-dentatis, spicis subrotundis lateralibus.* Poley with a diffused stalk, linear, winged, indented leaves, and roundish spikes of flowers proceeding from the sides of the stalks.

The first sort grows naturally on the mountains about *Basil* and *Geneva*, as also in *France*. The root of this plant is composed of many ligneous fibres, from which arise several weak, trailing, ligneous stalks, eight or nine inches long, sending out many weak branches, garnished with small spear-shaped leaves, of a deep green, and entire, placed by pairs. The flowers are produced in a corymbus at the end of the branches; they are white, and shaped like those of the other species. These appear in *June* and *July*, but are seldom succeeded by seeds in *England*.

The second sort grows naturally in *Spain*. The stalks of this are rather herbaceous, and trail upon the ground; they are about six inches long, hoary, and garnished with woolly leaves; some of them are wedge-shaped, others are oblong, ending in obtuse points, and are crenated toward their ends. The flowers are collected in oblong thick spikes at the end of the branches; they are of a deep yellow colour, and appear the beginning of *June*, but are seldom succeeded by seeds in this country.

The third sort grows naturally in *Spain* and *Portugal*. The stalks of this are ligneous, erect, and branching, covered with a hoary down; they rise six or eight inches high, garnished with linear woolly leaves about half an inch long, having sometimes two or three slight indentures on their edges. The flowers are collected in roundish spikes at the end of the branches; they are of a bright yellow, and have woolly empalements. These appear in *June* and *July*.

The fourth sort grows naturally in the south of *France*, and in *Italy*. This hath a trailing branching stalk, which at the bottom is ligneous, but the branches are herbaceous and woolly; they are garnished with linear, spear-shaped, woolly leaves, indented on their edges. The flowers are produced in a corymbus at the end of the branches, which

are small, white, and shaped like those of the other species. This flowers in *June* and *July*.

The fifth sort grows naturally near the sea, in the south of *France* and in *Italy*. This hath an erect branching stalk, which rises a foot high; the lower part becomes ligneous, but the upper is herbaceous; the leaves are linear, spear-shaped, and crenated on their edges, of a pretty thick consistence, and a little woolly. The flowers are collected in a corymbus at the end of the branches; they are white, and like those of the other species. This flowers in *July* and *August*.

The sixth sort grows naturally on the *Pyrenean* mountains. This hath slender shrubby stalks, which trail close upon the ground, and put out roots; the leaves are round at the top, but at their base are contracted in form of a wedge, and are crenated on their edges, so as to resemble at first sight the leaves of *Ground-ivy*; but they are hairy, and of a thicker consistence. The flowers are collected in round bunches at the end of the branches; one half of their petals are purple, and the other half white; they are larger than those of the other species, but are of the same form. It flowers great part of summer, but seldom produces seeds here.

The seventh sort grows naturally in *Italy* and *Spain*. This hath a ligneous, erect, branching stalk, which rises near a foot high; it is very hoary, and branches out toward the top; the leaves are spear-shaped, indented on their edges, and woolly on their under side. The flowers are white, small, and grow in clusters at the end of the branches. It flowers in *June* and *July*.

The eighth sort grows naturally in *Spain* and *Italy*. This rises with a shrubby stalk nine or ten inches high, branching out toward the top in form of a corymbus; the leaves are linear, and their edges are reflexed. The flowers are collected in roundish woolly heads at the end of the branches; they are white, and smaller than most of the other species. This flowers in *June* and *July*.

The ninth sort grows naturally in *Spain*. It hath a trailing branching stalk about six or eight inches long, which is ligneous at bottom, but upward is herbaceous and hoary; the leaves are linear, spear-shaped, and indented toward the ends. The flowers are collected in oblong spikes at the end of the branches; they are of a pale yellow colour, and shaped like those of the other species. This flowers great part of summer.

The tenth sort grows naturally in *Sicily*. This hath slender shrubby stalks, which rise a foot and a half high; they are smooth and white, sending out a few short branches toward the top, garnished with small linear leaves growing in clusters. The flowers are collected in long cylindrical spikes, which stand in bunches at the top of the stalks, and sometimes come out on the sides; these are small and white. It flowers in *July* and *August*.

The eleventh sort grows naturally in *Valencia*. This hath slender, ligneous, hoary stalks near two feet high, garnished with small, spear-shaped, entire, woolly leaves at intervals, standing in clusters, and sit close to the stalk; the upper part of the stalk divides into several slender foot-stalks, each sustaining a small corymbus of white flowers. The whole plant has a strong aromack odour. It flowers late in summer.

The twelfth sort grows naturally in the south of *France* and in *Italy*. This hath trailing ligneous stalks about a foot long, garnished with linear, sawed, hoary leaves. The flowers are collected in a corymbus at the end of the branches; they are small and white. This flowers in *June* and *July*.

The thirteenth sort grows naturally in *Spain* and *Italy*. This hath diffused trailing stalks, which are very woolly,

garnished with narrow indented leaves, which are covered with a woolly down, and are terminated by roundish heads of flowers, which are yellow; the whole plant is very hoary. It flowers in *July*.

The fourteenth sort grows naturally in *Spain*. This hath erect branching stalks about six or eight inches high; the branches come out opposite the whole length of the stalk; they are garnished with small spear-shaped leaves, of a dark green colour on their upper side, but hoary on their under; the stalks and branches are terminated by clusters of blue flowers, which are collected in roundish heads. This sort flowers in *July* and *August*.

The fifteenth sort grows naturally about *Smyrna*. This hath diffused white stalks, which rise about a foot high, closely garnished with linear leaves, indented regularly on their edges like those of *Spleenwort*, but the indentures are not deep; they are of a dark green on their upper side, but hoary on their under. The flowers are collected in roundish spikes, which terminate the branches, and also come out from their side; they are white, and shaped like those of the other species. It flowers in *July* and *August*.

There are several other species of this genus, which grow naturally in the warmer parts of *Europe*; but those which are here mentioned, are all that I have yet seen growing in the *English* gardens, therefore I have omitted the other, as I have had no opportunity to examine them myself.

All the sorts, except the first, are abiding plants; they may be propagated by seeds. These should be sown upon a bed of fresh light earth in the spring, and when the plants come up, they must be carefully kept clean from weeds; about the middle of *July* the plants will be fit to remove, when they may be carefully taken up, and part of them planted on a warm border of dry rubbishy soil, observing to shade them from the sun, and water them till they have taken new root; after which they will require no other culture, but to keep them clean from weeds. My advising these, and many other aromack plants, which are natives of the warmer parts of *Europe*, to be planted in rubbish, is founded upon long experience of their abiding much longer, and resisting the cold of our winters much better than when they are growing in better ground, where they grow much freer, are fuller of moisture, and therefore more liable to be killed by frost.

The other part of the plants may be planted in small pots, filled with fresh, light, undunged earth, and placed in the shade till they have taken new root; then they may be removed into an open situation, where they may remain till the beginning of *November*, when they should be placed under a common frame, to secure them from the frost in winter, which sometimes destroys these plants in the open air; by this method the species may be preserved.

These plants may be disposed in a garden, so as to afford pleasure, by mixing them with *Marum*, *Mastich*, and several other aromack plants, upon the sloping sides of banks, which are exposed to the sun, or upon little hillocks raised in a sheltered situation, where, by the diversity of their hoary branches, being of various shapes, they will make a pretty appearance, and in such places they will resist the cold much better than when they are planted in a good soil.

They may also be propagated by cuttings or slips, which should be planted the beginning of *April*, just before they shoot, upon a border exposed to the east; and if the season proves dry, they must be watered and shaded until they have taken root; afterward they will require no other care but to keep them clean from weeds, and at *Michaelmas* the plants should be removed where they are designed to remain; but it will be proper to put a plant of each sort in pots, that they may be sheltered in winter, to preserve the kinds.

The fourth and fifth sorts are sometimes used in medicine.
POLYANTHOS. See Primula.

POLYGALA. Tourn. Inst. R. H. 174. tab. 79. Milk-wort.

The Characters are,

The flower has a small permanent-empalement. The flower is shaped like those of the butterfly kind; the number of petals is indeterminate. The wings are large, plain, and extend beyond the other petals; the standard is tubulous, short, and reflexed at the brim, where it is bifid. The keel is concave, compressed, and bellied toward the top. It hath eight stamina in two bodies, included in the keel, terminated by single summits, and an oblong germen, supporting an erect style, terminated by a thick bifid stigma. The germen after-ward becomes a heart-shaped capsule, having two cells, each containing one seed.

The Species are,

1. POLYGALA floribus cristatis racemosis, caulibus herbaceis simplicibus procumbentibus, foliis linearilanceolatis. Amœn. Acad. 2. p. 136. Milkwort with branching crested flowers, single, trailing, herbaceous stalks, and linear spear-shaped leaves; common Milkwort.

2. POLYGALA floribus cristatis racemosis, caule erecto, foliis lanceolato linearibus acutis. Sauv. Monsp. 53. Milkwort with branching crested flowers, an erect stalk, and acute, spear-shaped, linear leaves.

3. POLYGALA floribus cristatis, carinâ lunulatâ, caule fruticoso, foliis lævibus oblongis obtusis. Amœn. Acad. 2. p. 138. Milkwort with crested flowers, a moon-shaped keel, and a shrubby stalk bearing oblong leaves, which end in obtuse points.

4. POLYGALA floribus imberbibus sparsis, carinæ apice subrotundo, caule fruticoso, foliis lanceolatis. Amœn. Acad. 2. p. 140. Milkwort with flowers growing thinly and without beards, the point of the keel roundish, a shrubby stalk, and spear-shaped leaves.

5. POLYGALA floribus imberbibus spicatis, caule erecto herbaceo simplicissimo, foliis lato-lanceolatis. Amœn. Acad. 2. p. 139. Milkwort with spiked flowers, having no beards, an erect, single, herbaceous stalk, and broad spear-shaped leaves; commonly called Seneka Rattle Snakewort.

6. POLYGALA floribus imberbibus, oblongo-capitatis, caule erecto ramoso, foliis linearibus. Milkwort with beardless flowers growing in oblong heads, an erect branching stalk, and linear leaves.

7. POLYGALA floribus cristatis, racemo terminali, caule erecto ramoso, foliis lanceolatis tomentosis. Milkwort with crested flowers, an erect branching stalk, terminated by a loose spike of flowers, and woolly spear-shaped leaves.

There are several other species of this genus, some of which grow naturally in Europe, and others in America, but as they are seldom cultivated in gardens, so it would be to little purpose to enumerate them here.

The first sort grows naturally in pastures and upon heaths in many parts of England. Of this there are three varieties, one with a blue, another with a purple, and a third with white flowers, which are frequently found intermixed; and there is another which is larger, and supposed to be a distinct species; but I rather believe this difference is owing to the soil in which they grow, for the large one is generally found growing in moist pastures, and the small one upon dry heaths. This hath a perennial root, from which come out three or four slender, trailing, herbaceous stalks, garnished with linear spear-shaped leaves. The flowers are produced at the top of the stalks, branching out; they are small, and of a blue, purple, or white colour, having two wings, a keel and standard like the butterfly flowers. These appear in June, and are succeeded by flattish heart-shaped capsules, divided into two cells, each containing one seed.

The second sort grows naturally upon sterile ground about Montpelier. This sort is annual; it rises with an herbaceous stalk about six inches high, garnished with narrow leaves, placed opposite, ending in acute points. The flowers are small, of a worn-out purple colour; the keel is bearded like the common sort. This flowers in July, and has seed-vessels like the first sort, but smaller; the seeds ripen in autumn.

These sorts are very rarely admitted into gardens, nor do they thrive so well when sown or transplanted there, as in their natural situation. If these are cultivated, their seeds should be sown soon after they are ripe, otherwise they rarely grow.

The third sort grows naturally at the Cape of Good Hope. This hath a shrubby stalk, covered with a smooth brown bark, which rises five or six feet high, sending out several spreading branches toward the top, closely garnished with oblong, blunt-pointed, smooth leaves, of a lucid green, sitting close to the branches. The flowers are produced at the end of the branches; they are large, white on their outside, but of a bright purple within; the keel of the flower is hollowed like a half-moon, and is bearded; the wings are expanded wide, and the standard is incurved; this plant continueth flowering most part of summer. The flowers are succeeded by compressed heart-shaped seed-vessels, having two cells, each containing one hard, smooth, shining seed. This plant is propagated by seeds, which should be sown in small pots filled with light loamy earth soon after they are ripe. These pots may be placed where they may have the morning sun only till October, when they should be placed under a hot bed frame, and plunged into old tanners bark, which has lost its heat, where they may be defended from frost during the winter, and in the spring the pots should be plunged into a moderate hot-bed, which will bring up the plants. When these appear, they should not be too tenderly treated, but must have a large share of free air admitted to them; and when they are fit to transplant, they should be carefully shaken out of the pots, and separated, planting each into a small pot, filled with soft loamy earth, and plunged into a very moderate hot-bed, to forward their taking new root, observing to shade them from the sun, and gently refresh them with water, but they must not have too much wet. When they are rooted, they must be gradually inured to bear the open air; in June they may be placed abroad in a sheltered situation, where they may remain till the middle or latter end of October, according as the season proves favourable; then they must be removed into the green-house, and treated in the same way as Orange trees, being careful not to give them too much wet during the winter season. In the summer they must be placed abroad with other green-house plants, where, by their long continuance in flower, they will make a fine appearance. The management of this plant is nearly the same as for the Orange-tree.

The fourth sort grows naturally on the Alps, and also upon the mountains in Austria and Hungary. This rises with a slender, branching, ligneous stalk about a foot high, when it grows upon good ground, but on a rocky soil, seldom more than half that height. The branches are closely garnished with stiff, smooth, spear-shaped leaves, of a lucid green. From between the leaves, toward the top of the branches, the flowers come out upon very short foot-stalks; they are white on their outside, but within are of a purplish colour mixed with yellow, and have a grateful odour. These appear in May, and are succeeded by seed-vessels, shaped like those of the former sort.

This plant is very difficult to cultivate in gardens, for it commonly grows out of the fissures of rocks, so cannot be easily transplanted, and the seeds are with difficulty obtained from

from abroad; nor do these vegetate till they have been a whole year in the ground; and when the plants come up, they make very little progress here, and are as difficult to transplant as almost any plant at present known, which occasions its present scarcity in *England*.

The best method of cultivating this is by seeds, which should be procured as fresh as possible from the places of its natural growth, and sown in pots as soon as it arrives; these pots may be plunged into the ground, where they may have only the morning sun. If these are sown before *Christmas*, there will be a chance of the plants coming up the following spring, but those, which are not sown till toward spring, will remain in the ground a year; therefore the pots should be plunged into the ground, where they may have but little sun the following summer, and in autumn they may be removed, and plunged into an old tan-bed under a hot-bed frame, where they may be protected from severe frost; for although this plant is a native of the *Alps* and other cold mountains, yet as the seeds will not be covered with snow here, as they are in their native situation; they are frequently spoiled by the inconstancy of the weather in *England*. When the plants come up, they should be placed in shade during summer, and in autumn they may be turned out of the pots, and planted in a border, where they may have only the morning sun, for this plant will not thrive long in pots. If the winter proves very severe, it will be proper to cover the surface of the ground about their roots with mulch to keep out the frost. If the plants take root in the border, they should remain there undisturbed, and be only kept clean from weeds, for the ground about their roots should not be dug or dunged.

The fifth sort grows naturally in most parts of *North America*. This hath a perennial root, composed of several fleshy fibres, from which arise three or four branching stalks, which grow erect, garnished with spear-shaped leaves, placed alternately. The flowers are produced in loose spikes at the end of the branches; they are small, white, and shaped like those of the common sort, but their keels have no beards. It flowers here in *July*, but the plants do not produce seeds.

The root of this sort hath been long used by the *Seneca Indians*, to cure the bite of the Rattle-snake, which, if taken in time, is an infallible remedy. And of late years it hath been used by the inhabitants of *Virginia* in many disorders, which are occasioned by a thick fizy blood; so that the root of this plant, when its virtues are fully known, may become one of the most useful medicines yet discovered. The *Seneca Indians* use this root, which they powder, and generally carry about them when they travel in the woods, lest they should be bit by the Rattle-snake; and whenever this happens, they take a quantity of the powder inwardly, and apply some of it to the part bitten, which is a sure remedy.

The sixth sort grows naturally in *Maryland*. This hath a perennial root, from which arise two or three stalks about eight inches high, which divide into several erect branches, garnished with small linear leaves, of a dark green colour. The flowers are collected into oblong heads at the end of the stalks; they are small, and of a purplish blue colour.

Both these sorts are difficult to obtain, for the seeds rarely succeed, so the best way is to procure their roots from *America*; and when they arrive, plant them in a bed of light earth, in a sheltered situation. In summer they must be kept clean from weeds, and if the surface of the ground about their roots is covered with old tanners bark, or any other kind of mulch in winter, to keep out the frost, it will be a secure method to preserve them.

The seventh sort was discovered by the late Dr. *Houssoun* growing naturally at *La Vera Cruz*. This hath a taper pe-

rennial root, which runs deep in the ground, from which arise several slender branching stalks about six or seven inches high, garnished with downy spear-shaped leaves. The flowers are produced in loose spikes at the end of the branches; they are larger than those of the common sort, and are of a bluish purple colour. The keel of the flower is bearded, as in the common sort.

This is too tender to live in the open air in *England*, and it is one of those plants which will not thrive in pots, so it is difficult to preserve here. It is propagated by seeds. The seeds, which I received from Dr. *Houssoun*, remained a year in the ground before the plants appeared, and the plants lived one year; but when their roots reached the bottom of the pots, they decayed, and those, which were transplanted into larger pots, did not survive their removal, though it was performed with great care.

POLYGONATUM. See *Convallaria*.

POLYPODIUM. *Tourn. Inst. R. H. 540. tab. 316.* Polypody.

The Characters are,

This is one of the Fern tribe, which is distinguished from the others, by the fructification being in roundish spots, distributed on the under surface of the leaf.

The Species are,

1. POLYPODIUM *frondibus pinnatifidis, pinnis oblongis subserratis obtusis, radice squamata. Lin. Sp. Plant. 1085.* Polypody with wing-pointed leaves, having oblong obtuse lobes, which are somewhat sawed, and a scaly root; common Polypody.

2. POLYPODIUM *frondibus pinnatifidis, pinnis lanceolatis lacero-pinnatifidis serratis. Lin. Sp. Plant. 1086.* Polypody with wing pointed leaves, whose lobes are spear-shaped, and the jags wing-pointed and sawed; *Wells* Polypody with jagged leaves.

There are several other species of this plant, which are natives of *America*, some of which are preserved in curious botannick gardens for variety; but as they are rarely cultivated in other gardens, it is not worth while to enumerate them in this place.

The first sort is that which is used in medicine, and is found growing upon old walls and shady banks in divers parts of *England*. The second sort was brought from *Wales*, where it grows in great plenty, and is the most beautiful of all the sorts. These plants may be propagated by parting of their roots in the spring before they shoot, and should be planted in a very poor moist soil under the shade of a wall, for if they are exposed to the sun, they will not thrive. They chiefly delight to grow out of the joints of walls and old buildings, but are commonly found exposed to the north.

POMGRANATE. See *Psidium*.

POMUM ADAMI. See *Aurantium*.

PONTERERIA. *Lin. Gen. Plant. 361.*

The Characters are,

The flowers are included in an oblong sheath, which opens on one side; it hath six petals, which are divided; the three upper are erect, and form a kind of lip; the three under are reflexed. It hath six stamina, which are inserted to the petals; the three, which are longest, are fastened to the mouth of the tube; the other are inserted in the base; they are terminated by prostrate summits. Under the petals is situated an oblong germen, supporting a single style, which declines, and is crowned by a single stigma. The germen afterward turns to a soft fruit, divided into six cells, each containing several small roundish seeds.

The Species are,

1. PONTERERIA *foliis hastato-cordatis, floribus spicatis.* Pontederia with spear-pointed heart-shaped leaves, and spiked flowers.

POIXGALIA, Virginiana foliis oblongis floribus in thyrsis candidis radice Alcyonopharmaca

Yuccagan, Rattle, Snake Root

W. Wood sculp.

2. *PONTEDERIA foliis hastatis, floribus umbellatis. Lin. Sp. Plant. 288.* Pontederia with spear-pointed leaves, and flowers growing in umbels.

The first sort grows naturally in marshy places in *Virginia*, and most parts of *North America*, and the late Dr. *Houssoun* found it growing plentifully at *La Vera Cruz*. This hath a perennial root, from which arise two or three herbaceous thick stalks a foot high, each having one arrow-pointed heart-shaped leaf, of a pretty thick consistence. The base is deeply indented, and the two ears are rounded; the foot-stalk of the leaf closely embraces the stalk like a spatha or sheath for near three inches in length; above this is another sheath, which incloses the spike of flowers; this opens on one side, and the stalk rises near two inches above it, where the spike of flowers begin. The spikes are about three inches long; the flowers are blue, sit very close together, and have the appearance of lip flowers. These appear in *June*, but are not succeeded by seeds in *England*.

As this plant grows naturally on moist boggy places, it is very difficult to be preserved in *England*; nor does the plant arise from seeds here, for I have sowed the seeds in various situations, and managed them different, but could never get up any of the plants; but I had three or four of the plants sent me, inclosed in large clods of earth from *New England*, which I planted in pots, covering them with moss, and constantly supplied them with water. With this management two of them flowered, but the following winter destroyed them, as they were not put under shelter; so that to preserve them, they should be placed under a hot-bed frame in winter, where they may be exposed to the open air at all times, when the weather is mild.

The second sort grows naturally about *Madras* in watery places. This rises with a single stalk eight or nine inches high, having one arrow-pointed leaf, whose base embraces the stalk like a sheath, and from the open side of the sheath comes out the flowers, which are at first inclosed in another smaller sheath; these grow in a small kind of umbel; they are composed of six acute-pointed petals, which spread open. Each flower stands upon a slender foot-stalk about an inch long; the foot-stalk of the leaf rises a considerable height above the flowers, so that they appear to come out from the middle of the stalk.

This sort is much more difficult to preserve in *England*, because it grows naturally in a hot country, and always in places flowed with water. There was formerly one of these plants brought over to *Charles Duboise, Esq;* at *Mitcham*, but it was not long lived here.

POPULAGO. See *Caltha*.

POPULUS. *Tourn. Inst. R. H. 592. tab. 365.* The Poplar tree.

The Characters are,

The male and female flowers grow upon separate trees. The male flowers or katkins have one oblong, loose, cylindrical empalement, which is imbricated. Under each scale is situated a single flower, without any petal, having a nectarium of one leaf, turbinated at the bottom, and tubulous at the top, and eight stamina terminated by large four-cornered junmits. The female flowers are in katkins like the male, but have no stamina; they have an oval acute-pointed germen, with scarce any style, crowned by a four pointed stigma. The germen afterward becomes an oval capsule, with two cells, including many oval seeds, having hairy down.

The Species are,

1. *POPULUS foliis lobatis dentatis subtus tomentosus.* Poplar-tree with lobated indented leaves, which are downy on their under side; commonly called the *Abele-tree*.

2. *POPULUS foliis subrotundis, dentato-angulatis subtus tomentosus. Hort. Cliff. 460.* Poplar-tree with roundish leaves, which are angularly indented, and downy on their under side; or white Poplar.

3. *POPULUS foliis ovato-cordatis acuminatis erenatis.* Poplar-tree with oval heart-shaped leaves, ending in acute points, which are crenated; the black Poplar.

4. *POPULUS foliis subrotundis dentato angulatis utrinque glabris. Hort. Cliff. 460.* Poplar-tree with roundish leaves, having angular indentures, and smooth on both sides; the *Aspen-tree*.

5. *POPULUS foliis cordatis obsoletè crenatis, utrinque glabris.* Poplar-tree with heart-shaped leaves, which are somewhat crenated, and smooth on both sides.

6. *POPULUS foliis subcordatis oblongis crenatis. Hort. Cliff. 460.* Poplar-tree with oblong leaves, which are crenated, and almost heart-shaped; the *Carolina Poplar-tree*.

7. *POPULUS foliis subcordatis, infernè incanis, supernè atroviridis.* Poplar with leaves which are almost heart-shaped, hoary on their under side, and of a dark green above, commonly called *Tacamahacca*.

The first sort grows naturally in the temperate parts of *Europe*. This and the second sort are frequently confounded together, but they are certainly different species; this is commonly called *Abele-tree* here, and the second white Poplar. The leaves of the first are large, and divided into three, four, or five lobes, which are indented on their edges, of a very dark colour on their upper side, but very white and downy on their under, standing upon foot-stalks, which are about an inch long. The young branches of this tree have a purple bark, and are covered with a white down, but the bark of the stem and older branches is gray. In the beginning of *April* the male flowers or katkins appear, which are cylindrical, scaly, and about three inches long; about a week after come out the female flowers on katkins, which have no stamina like those of the male. Soon after these come out, the male katkins fall off, and in five or six weeks after the female flowers will have ripe seeds inclosed in a hairy covering; then the katkins will drop, and the seeds will be wafted by the winds to a great distance.

The leaves of the second sort are rounder, and not much above half the size of those of the first; they are indented on their edges into angles, and are downy on their under side, but not so white as those of the former, nor are their upper surfaces of so deep green. The shoots of this are paler, the katkins are longer, and the down of the seeds is whiter and longer.

The leaves of the third sort are oval, heart-shaped, and slightly crenated on their edges; they are smooth on both sides, and of a light green colour. The katkins of this are shorter than those of the two former.

The leaves of the fourth sort are roundish, angularly indented; they are smooth on both sides, and stand upon long slender foot-stalks, so are shaken by the least wind, from whence it was titled the trembling Poplar or *Aspen-tree*. The katkins of this are much like those of the first sort, but the young shoots are of a dark brown colour.

The fifth sort I saw growing in the private garden of Dr. *Boerhaave* near *Leyden*; this the doctor told me he received from *Prussia*. The leaves of this are heart-shaped; they are six or seven inches long, and four broad, and are slightly indented on their edges, standing upon very short foot-stalks. The shoots of this tree were very strong, and the tree seemed as if it would grow to a great size, but it was young when I saw it.

The sixth sort grows naturally in *Carolina*, where it becomes a large tree. The shoots of this sort are very strong in *England*, and are generally angular; they have a light green bark, like some sorts of the *Willow*. The leaves upon young trees, and also those upon the lower shoots, are very large, almost heart-shaped and crenated, but those upon the older trees are smaller; as the trees advance, their bark becomes lighter, approaching to a grayish colour.

The

The katkins of this sort are like those of the black Poplar, and the summits of the stamina are purple.

The shoots of this tree, while young, are frequently killed down a considerable length by the frost in winter, but as the trees grow older, their shoots are not so vigorous, and become more ligneous, so are not liable to the same disaster; but the trees should be planted in a sheltered situation, for as their leaves are very large, the wind has great power over them, and the branches being tender, they are frequently broken or split down by the winds in the summer season, where they are much exposed.

The seventh sort grows naturally in *Canada*, and in other parts of *North America*. This seems to be a tree of middling growth, and does not spire upward, but sends out many short thick shoots on every side, which are covered with a light brown bark, garnished with leaves, differing from each other in shape and size, most of them almost heart-shaped, but some are oval, and others near to spear-shaped; they are whitish on their under side, but of a dark green on their upper. The katkins are like those of the black Poplar, but the number of stamina in the male flowers is uncertain from eighteen to twenty-two. The hermaphrodite flowers come out a month later than the male.

These trees may be propagated either by layers or cuttings, which will readily take root, as also from suckers, which the white Poplars send up from their roots in great plenty. The best time for transplanting these suckers is in *October*, when their leaves begin to decay. These may be placed in a nursery for two or three years to get strength, before they are planted out where they are designed to remain; but if they are propagated from cuttings, it is better to defer the doing of that until *February*, at which time truncheons of two or three feet long should be thrust about a foot and a half into the ground. These will readily take root, and if the soil be moist in which they are planted, will arrive to a considerable bulk in a few years.

The black Poplar is not so apt to take root from large truncheons, therefore it is the better method to plant cuttings about a foot and a half in length, thrusting them a foot deep into the ground; these will take root very freely, and may be afterward transplanted where they are to remain. This sort will grow upon almost any soil, but will thrive best in moist places.

The white sorts, as also the Aspen-tree, likewise cause a great litter in the spring, when their katkins and down fall off; and their roots being very apt to produce a large quantity of suckers, but especially those trees that came from suckers, which render them unfit to be planted near a house or garden; but when they are interspersed with other trees in large plantations, they afford an agreeable variety, their leaves being very white on their under sides, which, when blown with the wind, are turned to light.

A considerable advantage may be made by planting these trees upon moist boggy soils, where few other trees will thrive. Many such places there are in *England*, which do not at present bring in much money to their owners; whereas, if they were planted with these trees, they would, in a very few years, over-purchase the ground, clear of all expence; but there are many persons, who think nothing, except Corn, worth cultivating in *England*; or if they plant timber, it must be Oak, Ash, or Elm; and if their land be not proper for either of these, it is deemed little worth; whereas, if the nature of the soil was examined, and proper sorts of plants adapted to it, there might be very great advantage made of several large tracts of land, which at this time lie neglected.

The wood of these trees, especially of the Abele, is very good to lay for floors, where it will last many years, and for its exceeding whiteness, is by many persons preferred to

Oak; but being of a soft texture, is very subject to take the impression of nails, &c. which renders it less proper for this purpose: it is also very proper for wainscoting of rooms, being less subject to swell or shrink, than most other sorts of wood; but for turnery-ware, there is no wood equal to this for its exceeding whiteness, so that trays, bowls, and many other utensils, are made of it; and the bellows-makers prefer it for their use, as do also the shoemakers, not only for heels, but also for the soles of shoes; it is also very good to make light carts, and the poles are very proper to support Vines, Hops, &c. and the lopping will afford good fuel, which in many countries is much wanted.

The *Carolina Poplar* may also be propagated by cuttings or layers; the latter is generally practised by the nursery-gardeners, being the surest method; and these plants are not so full of moisture as those raised by cuttings, so are less liable to be cut down by the frost when young. There has been no trials made here of the wood of this tree, so I cannot give any account of its worth.

The *Tacamahacca* sends up a great number of suckers from the roots, by which it multiplies in plenty, and every cutting which is planted will take root; so that when a plant is once obtained, there may soon be plenty of the plants raised. The buds of this tree are covered with a glutinous resin, which smells very strong, which is the *Tacamahacca* used in the shops.

PORRUM. *Tourn. Inst. R. H. 382. tab. 204. Leek.*

The Characters are,

The flower hath six bell-shaped petals, collected into a spherical head, covered by a common roundish spathe or sheath, which withers. They have six stamina; three of these are alternately broader than the other, and have forked summits in their middle. They have a short, round, three-cornered germen, supporting a single style, crowned by an acute stigma. The germen afterward becomes a short broad capsule with three lobes, having three cells, filled with angular seeds.

The Species are,

1. PORRUM radice oblongâ tunicatâ, caule planifolio, floribus capitatis, staminibus tricuspидatis. Leek with an oblong coated root, a plain leaf on the stalk, flowers collected in heads, and three-pointed stamina; commonly called *London Leek*.

2. PORRUM caule planifolio umbellifero, umbellâ globosâ, staminibus corollâ longioribus. Leek with a plain leaf on the stalk, which supports a globular umbel of flowers, whose stamina are longer than the petals.

The first sort is commonly cultivated in the *English* gardens. Of this there has been generally supposed two sorts, but I have made trial of them both, by sowing their seeds several times, and find they are the same; the difference which has risen between them, has been occasioned by some persons having saved the seeds from old roots, and not from the seedling Leeks, whereby they have degenerated them, and rendered them smaller and narrower leaved, but by care this may be recovered again, as I have experienced.

The other sort grows naturally in *Siberia*. This hath narrower leaves than the common sort; the stalks are smaller, and do not rise near so high; the heads of flowers are also smaller, and of a purplish colour; the stamina stand out beyond the flower.

Leeks are cultivated by sowing their seeds in the spring, in the same manner as was directed for Onions, with which these are commonly sown, the two sorts of seeds being mixed according to the proportion which is desired of either sort, though the most common method is, to mix an equal quantity of both, for the Onions will greatly out-grow the Leeks in the spring; but these being drawn off in *July*, the Leeks will have time to grow large afterwards, so that there may be a moderate crop of both sorts. The manage-

management of Leeks being exactly the same with Onions, I shall not repeat it in this place, but shall only add, that many persons do sow their Leeks in beds in the spring; and in June, after some of their early crops are taken off, they dig up the ground, and plant their Leeks out thereon, in rows a foot apart, and six inches asunder in the rows, observing to water them until they have taken root; after which they will require no further culture, but to clear the ground from weeds. The Leeks thus planted will grow to a great size, provided the ground be good, and this method is very proper for such persons who have little room.

If you would save the seeds of this plant, you should make choice of some of the largest and best you have, which must remain in the place where they grow until February, when they should be transplanted in a row against a warm hedge, pale, or wall, at about eight inches asunder; and when their stems advance, they should be supported by a string, to prevent their being broken down, to which they are very liable, especially when in head, and the closer they are drawn to the fence in autumn, the better the seeds will ripen; for it sometimes happens in cold summers or autumns, that those which grow in the open garden, do not perfect their seeds in this country, especially if there should be sharp frosts early in autumn, which will entirely spoil the seed.

When it is ripe (which may be known by the heads changing brown) you should cut off their heads with about a foot or more of the stalk to each, and tie them in bundles, three or four heads in each, and hang them up in a dry place, where they may remain till Christmas or after, when you may thresh out the seeds for use. The husk of these seeds is very tough, which renders it very difficult to get out the seeds; therefore some persons, who have but a small quantity, rub it hard against a rough tile, which will break the husks, and get the seeds out better than most other methods I have known used.

PORTULACA. *Tourn. Inst. R. H. 236. tab. 118.* Purslane.

The Characters are;

The empalement of the flower is small, bifid, and permanent, sitting upon the germen. The flower has five plain, erect, obtuse petals, and many hair-like stamina, about half the length of the petals, terminated by single summits, and a roundish germen. Supporting a short style, crowned by five oblong stigmas. The germen afterward becomes an oval capsule with one cell, containing many small seeds.

The Species are,

1. PORTULACA foliis cuneiformibus, floribus sessilibus. *Prod. Leyd. 473.* Purslane with wedge-shaped leaves, and flowers growing close to the stalks; broad-leaved, or garden Purslane.
2. PORTULACA foliis subulatis alternis, axillis pilosis, floribus sessilibus. *Lin. Sp. Plant. 445.* Purslane with awl-shaped leaves placed alternately, hairy joints, and flowers sitting close to the stalks.
3. PORTULACA foliis ovatis gibbis, pedunculo multifloro, caule fruticoso. *Lin. Sp. Plant. 445.* Purslane with oval gibbous leaves, foot-stalks having many flowers, and a shrubby stalk.

The first sort grows naturally in America, and most of the hot parts of the globe. This is the common Purslane which is cultivated in the gardens, and is so generally known as to need no description. There are two varieties of this, one with deep green leaves, and the other hath yellow leaves, which is called Golden Purslane; but as both these arise from the same seeds, so they are only seminal variations. There is also a third variety, with smaller and less succulent leaves, which is called Wild Purslane, because where-ever it is once sown in a garden, and the plants permitted to scatter their seeds, the plants will come up as

weeds the following year; but this I am sure is a degeneracy from the Garden Purslane, for I have sown it several times, and let the plants shed their seeds, and it has come up from those seeds in two years, degenerated to the wild sort.

Purslane is propagated from seeds, which may be sown upon beds of light rich earth during any of the summer months, but if you intend to have it early in the season, it should be sown upon a hot-bed, for it is too tender to be sown in the open air before April, and then it must be in a warm situation. This seed is very small, so that a little of it will be sufficient to supply a family. There is no other culture which this plant requires, but to keep it clear from weeds, and in dry weather to water it two or three times a week. In warm weather this plant will be fit for use in six weeks after sowing; so that in order to continue a succession of it, you should sow it at three or four different seasons, allowing a fortnight or three weeks between each sowing, which will be sufficient to last the whole summer, while it is proper to be eaten, for being of a very cold nature, it is unsafe to be eaten, except in the heat of summer in England; for which reason it is not to any purpose to sow it upon a hot bed, since it will come early enough for use in the open air.

If the seeds are intended to be saved, a sufficient number of the earliest plants should be left for this purpose, drawing out all those which are weak, or have small leaves, from among them; and when the seeds are ripe, the plants should be cut up, and spread upon cloths in the sun to dry, and then the seeds may be easily beaten out and sifted, to clear it from the leaves and seed-vessels.

The second sort grows naturally in most of the islands of the West-Indies. This is annual; the stalks are very succulent, of a purple colour, and branches out greatly; the lower branches lie near the ground, but those above them are more erect; the leaves are narrow, awl-shaped, and of a lucid green; they are placed alternately on the branches. At the joints there come out tufts of white hairs, and between these come out the flowers sitting close to the branches; they are of a fine pink colour, but of short duration, seldom continuing open longer than five or six hours; these are succeeded by short roundish capsules, filled with small black seeds. It flowers from the middle of June till autumn.

The third sort grows naturally at the Cape of Good Hope. This is a perennial plant, with a shrubby stalk, which rises four or five inches high, garnished with thick, globular, succulent leaves; at the top of the stalk comes forth a slender foot stalk about two inches long, sustaining four or five Rose shaped flowers, of a reddish colour. These appear in July, but are not succeeded by seeds in England. This plant is too tender to live in the open air in winter, so it must be kept in pots, and treated in the same way as the most tender succulent kinds of Fig Marygolds. It is propagated by cuttings in the same manner as they are.

POTENTILLA. *Lin. Gen. Plant. 558.* Cinquefoil.

The Characters are,

The empalement of the flower is of one leaf, which is slightly cut into ten parts; the segments are alternately less and reflexed. The flower is composed of five petals, which are inserted into the empalement, and spread open. It hath twenty awl-shaped stamina inserted in the empalement, terminated by moon-shaped summits. In the center of the flower there are several germen collected into one head, with very slender styles inserted in the side of the germen, crowned by obtuse stigmas. After the flower is past, the germen becomes a head of roundish seeds, included in the empalement.

The Species are,

1. POTENTILLA foliis pinnatis serratis, caule repente. *Flor. Lapp. 210.* Potentilla with winged sawed leaves, and a creeping stalk.

2. *POTENTILLA foliis pinnatis alternis, foliolis quinis ovatis crenatis, caule erecto.* Hort. Cliff. 193. *Potentilla* with alternate winged leaves, having five oval crenated lobes, and an erect stalk.

3. *POTENTILLA foliis pinnatis, caule fruticoso.* Hort. Cliff. 193. *Potentilla* with winged leaves and a shrubby stalk; commonly called shrubby Cinquefoil.

4. *POTENTILLA foliis digitatis lanceolatis serratis utrinque subpilosis, caule erecto.* Lin. Sp. Plant. 497. *Potentilla* with finger-shaped leaves, which are spear-shaped, sawed, hairy on both sides, with an erect stalk.

5. *POTENTILLA foliis quinatis cuneiformibus incisus subtus tomentosus, caule erecto.* Lin. Sp. Plant. 497. *Potentilla* with five wedge-shaped lobes to the leaves, which are woolly on their under side, and an erect stalk.

6. *POTENTILLA foliis digitatis apice conniventi-serratis, caulibus filiformibus procumbentibus, receptaculis hirsutis.* Hort. Cliff. 194. *Potentilla* with finger-shaped leaves, whose points are sawed, very slender trailing stalks, and hairy receptacles.

7. *POTENTILLA foliis ternatis, caule ramoso erecto, pedunculis supra genicula enatis.* Hort. Upsal. 134. *Potentilla* with leaves growing by threes, an upright branching stalk, and foot-stalks rising above the joints; or Alpine barren Strawberry.

8. *POTENTILLA foliis ternatis, foliolis ovatis obtuse crenatis, caule ramoso, pedunculis longioribus.* *Potentilla* with leaves growing by threes, the lobes whereof are oval and obtusely crenated, a branching stalk, and longer foot-stalks.

9. *POTENTILLA foliis septenis quinatisque, foliolis pinnato-incisus pilosis, caule erecto ramoso.* *Potentilla* with seven and five leaves, whose lobes are cut, winged, hairy, and an upright branching stalk.

10. *POTENTILLA foliis septenis quinatisque, foliolis lanceolatis pinnato-dentatis utrinque pilosis, caule erecto corymboso, petalis cordatis.* *Potentilla* with five and seven leaves, whose lobes are spear-shaped, wing-indented, and hairy on both sides, and have an erect branching stalk, with heart-shaped petals to the flower.

There are many more species of this genus, which are preserved in botannick gardens for the sake of variety, but as they are not cultivated in other places either for use or beauty, I shall not enumerate them here.

The first sort here mentioned grows naturally upon cold stiff land in most parts of *England*, and is a sure mark of the sterility of the soil. It spreads its stalks upon the ground, which send out roots from their joints, fastening into the ground, and thereby propagates so fast, as in a little time to spread over and fill the ground to a great distance. It flowers great part of summer. The leaves of this plant are used in medicine, and are accounted restrigent and vulnerary. It is never cultivated in gardens, being a very common weed in *England*.

The second sort grows naturally on the *Alps*, and mountains in *Germany*. This hath a perennial root, which sends out several heads joined together; from these arise the foot-stalks of the leaves, which are long, and sustain three pair of roundish lobes, terminated by an odd one; these are crenated on their edges, and sit close to the midrib. Out of each head arises a hairy stalk about nine inches high, divided into small foot-stalks, each sustaining two or three white flowers, very like those of the Strawberry. It is easily propagated by seeds. The best time for sowing them is in the autumn; it loves a moist soil, and a shady situation.

The third sort grows naturally in the northern counties of *England*, and in many of the northern parts of *Europe*. This hath a shrubby stalk, which rises about four feet high, dividing into many branches, garnished by winged leaves, composed of two or three pair of narrow, acute-pointed,

entire, hairy lobes, pale on their under side. The flowers are produced at the end of the branches in clusters; they have five yellow petals, spreading open in form of a Rose, with many germen and stamina within. These appear in *July*, and are sometimes succeeded by seeds inclosed in the empalement. This plant is commonly cultivated in the nursery-gardens as a flowering shrub; it is commonly propagated by suckers, or laying down the tender branches, which will take root in one year, and may then be taken off from the old plants, and planted in a nursery for a year or two to get strength, before they are planted where they are designed to remain. It may also be propagated by cuttings, which may be planted in autumn in a moist shady border, where they will take root the next spring, and the *Michaelmas* following may be transplanted into the nursery.

The best season for transplanting of these plants is in *October*, that they may get new roots before the hard frost sets in, for as this plant grows naturally upon moist boggy land, so when it is removed in the spring, if due care is not taken to water it in dry weather, it is apt to miscarry; nor will this plant live in a hot dry soil, but in a shady situation and on a cool moist soil, it will thrive exceedingly.

The fourth sort grows naturally in the south of *France* and *Italy*. This hath hand-shaped leaves, composed of five or seven lobes, which join at their base, where they meet the foot-stalk; they are deeply crenated on their sides, and are hairy on both. The stalks rise nine or ten inches high, branching toward the top. The flowers are white, shaped like those of the former sort, terminating the stalks, and are succeeded by seeds like the other. This is a biennial plant, which dies soon after the seeds are ripe. It may be propagated as the second sort.

The fifth sort grows naturally on the *Alps*, and in other rough hilly parts of *Europe*. This hath a thick fleshy root, from which arise several purple branching stalks about a foot high, garnished with leaves, composed of five wedge-shaped lobes, deeply cut on their edges, which are very hoary on their under side. The flowers grow at the top of the stalk, which branches out into many foot-stalks; they are yellow, and shaped like those of the fourth sort, but smaller. The root is perennial, and the plant may be propagated as the second sort.

The sixth sort grows on the mountains in *Austria*. This hath a perennial root; the leaves stand upon long foot-stalks, which arise immediately from the root; they are composed of five oblong lobes, which are a little sawed at their ends, very hoary and silky on their under sides, but green on their upper. The flowers are produced upon long slender foot-stalks, which arise immediately from the root; they are white, and shaped like those of the other species, but are seldom succeeded by seeds in *England*. It may be easily propagated by runners in the same manner as the Strawberry; the best time to transplant them is in autumn. It loves a cool soil and a shady situation.

The seventh sort grows naturally on the *Alps*. This is a biennial plant; the stalks grow erect, about a foot high; they are very hairy, garnished with trifoliate oblong leaves, sawed on their edges. The flowers are produced upon foot-stalks, which come out above the joints of the stalk; they are white, and very like those of the Strawberry. This plant flowers in *June*, and the seeds ripen in autumn, which, if permitted to scatter, will produce plants in plenty the following spring, which will require no other culture, but to keep them clean from weeds.

The eighth sort is also a biennial plant, but differs from the other, in having taller and stronger stalks, which branch out more; the lobes of the leaves are oval, obtuse, and bluntly indented on their edges; the flowers are larger, and the whole plant is of a deeper green. It flowers in *July*, and

and the seeds ripen in autumn. It propagates itself like the former sort.

The ninth sort grows naturally in *Italy* and *Sicily*. This is a biennial plant; the stalks rise near two feet high; they are purple and very hairy, garnished with leaves, composed of five or seven narrow lobes, which are deeply cut on their sides, so as to resemble those of winged leaves; the stalks branch out greatly toward their top. The flowers are yellow, and shaped like those of the fourth sort. It flowers in *June*, and the seeds ripen in autumn. It may be propagated as the fourth sort.

The tenth sort grows naturally in the south of *France* and *Italy*. This is a biennial plant; the stalks are large, and rise near two feet high; they branch very much toward their top; the leaves stand upon very short foot-stalks; they are sometimes composed of five, and at other times of seven lobes, which are regularly indented like winged leaves, and are very hairy on both sides. The flowers are produced at the top of the stalk, each having a foot-stalk an inch and a half long; their empalements are deeply cut into nine segments, which end in acute points. The flowers have sometimes but five, but generally six heart-shaped petals, which are of a pale yellow, and expand like those of the former sorts. It flowers in *July*, and the seeds ripen in autumn, which, if permitted to scatter, will produce plenty of plants the following spring. This requires no other culture, than to keep it clean from weeds.

POTERIUM. *Lin. Gen. Plant.* 948. Burnet.

The Characters are,

It hath male and female flowers in the same spike. The male flowers have a three-leaved empalement; they have one petal, which is cut into four parts; these are oval, concave, and permanent; they have a great number of long hair-like stamina, terminated by roundish twin summits. The female flowers have one wheel shaped petal, with a short tube, cut at the brim into four parts; these have no stamina, but two oblong oval germen, with two hairy styles the length of the petal, crowned by coloured pencil-shaped stigmas. The germen afterward becomes two hard seeds, inclosed in the petal of the flower.

The Species are,

1. POTERIUM *inermis, caulibus subangulosis.* Hort. Cliff. 446. Smooth Poterium with angular stalks. Burnet.

2. POTERIUM *inermis, caulibus teretibus strictis.* Lin. Sp. Plant. 994. Smooth Poterium with a narrow taper stalk.

3. POTERIUM *spinis ramosis.* Hort. Cliff. 445. Poterium with branching spines; or Prickly ever-green Burnet.

The first sort is the common Burnet, which grows naturally upon chalky lands in many parts of *England*. Of this there are two or three varieties, one of them is much smoother than the other, and the third hath larger seeds than either of the former; but these differences are not constant, so they are only seminal variations. This is a perennial plant, from whose root arise a great number of leaves, standing on pretty long foot-stalks, composed of five or six pair of lobes, terminated by an odd one. The lobes are generally ranged a little alternate on the midrib, but sometimes stand by pairs; these are sawed on their edges, and are sometimes smooth, and at others hairy. The stalks rise a foot and a half high, branching out pretty much, and are terminated by long slender foot-stalks, each sustaining an oblong spike of flowers, in which there are some male and others female; they are of a purplish red colour, and appear in *June*. The female flowers are each succeeded by two hard seeds, which ripen in autumn.

This plant is propagated in gardens; the young tender leaves are put into sallads, and the leaves are used for cool tankards in hot weather. It is used in medicine, and is reckoned to be cordial and alexipharmick. The powder of the root is commended against spitting of blood.

This plant is easily propagated by seeds, which should be sown in autumn, for if it is sown in spring, the seeds frequently lie in the ground till the spring following. If the seeds are permitted to scatter, the plants will come up in plenty; if these are transplanted out in a bed of undunged earth, at about a foot distance every way, and kept clean from weeds, they will continue several years, especially if the soil is dry, and will require no other care. It may also be propagated by parting of the roots in the autumn, but as the plants arise so freely from scattered seeds, the latter method is seldom practised.

The second sort grows naturally in the south of *France* and *Italy*. This is a biennial plant, which decays soon after the seeds are ripe. The leaves of this are like those of Agrimony, and are composed of three or four pair of oblong lobes, placed a little alternate on the midrib, and terminated by an odd one; they are deeply sawed on their edges, and have an agreeable scent; the stalks rise two feet high, garnished at each joint with one of those winged leaves, which gradually diminish in their size to the top, and just above the leaf arises a long foot-stalk, which supports two or three small ones, each sustaining a small roundish spike of flowers. These appear in *July*, and are succeeded by seeds, which ripen in autumn. It is propagated by seeds, which, if sown in autumn, the plants will come up the following spring. These require no other culture than to thin them where they are too close, and keep them clean from weeds; the second year they will flower and ripen their seeds, and soon after decay.

The third sort grows naturally in *Crete*, and in many of the islands of the *Archipelago*. This hath a shrubby perennial stalk, which rises about three feet high, dividing into several slender branches, which are armed with branching sharp thorns; the leaves are very small; they are winged, and have six or seven pair of very small lobes, ranged opposite along the midrib, terminated by an odd one; they are of a lucid green, and continue all the year. The flowers are produced in small heads at the end of the branches, and are of an herbaceous colour.

This plant is too tender to live through the winter in the open air, but if it is sheltered under a common hot-bed frame in winter, where it may have the free air at all times when the weather is mild, and sheltered from hard frost, it will thrive better than when it is more tenderly treated. It may be propagated by slips or cuttings during any of the summer months, which, if planted in a bed of light earth, and covered down close with a hand or bell-glass, and shaded from the sun, will take root freely, and may then be taken up and planted each into a separate small pot, filled with fresh undunged earth, and placed in the shade till they have taken new root, and then removed to a sheltered situation, where they may stand till the frost comes on, when they should be placed under the hot-bed frame. It requires but little water, especially in cool weather, and wants no particular culture.

PRASIUM. *Lin. Gen. Plant.* 655. Shrubby Hedge-nettle.

The Characters are,

The flower hath a bell-shaped empalement of one leaf, divided into two lips; the upper lip ends in three acute points; the lower lip is cut into two parts. The flower is of the lip kind; it hath one petal; the upper lip is oval, erect, and indented at the end. The lower lip is reflexed, and ends in three points, the middle one being broadest. It has four awl-shaped stamina under the upper lip, two of which are shorter than the other, having oblong summits on their side, and a four-pointed germen, sustaining a slender style the length of the stamina, crowned by a bifid stigma. The germen afterward becomes four berries, each containing a single roundish seed.

The Species are,

1. PRASIUM *foliis ovato-oblongis serratis*. Lin. Hort. Cliff. 309. Shrubby stinking Hedge-nettle, with oblong, oval, sawed leaves.

2. PRASIUM *foliis ovatis, duplici utrinque crenâ notatis*. Lin. Hort. Cliff. 309. Shrubby stinking Hedge-nettle, with oval leaves, which are indented on every side.

The first sort grows naturally in *Spain* and *Italy*. This rises with a shrubby stalk near three feet high, covered with a whitish bark, divided into many branches, garnished with oblong oval leaves, which are sawed on their edges. The flowers come out from the bosom of the leaves in whorls round the stalks; they are white, and have large permanent empalements, cut into five points. The flowers are of the lip kind; they appear in *June* and *July*, and are succeeded by four small berries sitting in the empalement, which turn black when they are ripe, and have a single roundish seed in each.

The second sort grows naturally in *Sicily*. This hath a shrubby stalk like the former, but rises a little higher; the bark is whiter, the leaves are shorter and oval, and are doubly crenated on each side; they are of a lucid green. The flowers come out in small whorls from the bosom of the leaves, like the former; they are somewhat larger, and are frequently marked with a few purple spots; these are succeeded by small berries like the other sort, which ripens at the same time.

These plants may be propagated either by cuttings, or from the seeds: if they are propagated by cuttings, they should be planted on a shady border toward the end of *April*; but the cuttings should not be taken from such plants as have been drawn weak, but rather from those which have been exposed to the open air, whose shoots are short and strong; and if a joint of the former year's wood is cut to each of them, they will more certainly succeed. These cuttings may remain in the same border till they are well rooted, when they may be transplanted into the places where they are to remain, or into pots, that they may be sheltered in winter under a common frame, where they may have as much free air as possible in dry weather, but only require to be screened from hard frost.

If they are propagated by seeds (which the plants produce in plenty every year) they should be sown on a bed of light earth in *April*; and in *May* the plants will come up, when they require no other care but that of keeping them clean from weeds; and in the autumn following they may be transplanted in the same manner as before directed for those raised from cuttings, and may be afterward treated more hardily, as they acquire strength.

A plant or two of each of these species may be allowed to have a place where there are collections of the different sorts of ever-green shrubs, for the sake of variety, especially where the different sorts of *Cistus*, *Phlomis*, *Tree-wormwood*, and *Medicago*, are admitted, because these are equally hardy; and when a severe winter happens, which destroys the one, the others are sure of the same fate; but in mild winters they will live abroad, especially if they are planted in a dry rubbishy soil, and have a sheltered situation, but on wet ground the plants will grow very vigorous in summer, so are liable to injury from the early frosts in autumn.

PRENANTHES. Lin. Gen. Plant. 816. Vaill. Mem. Ann. 1721. Wild Lettuce.

The Characters are,

It hath a smooth cylindrical empalement, having many scales, which are equal, but have three at the base unequal. This common empalement includes from five to eight hermaphrodite florets, disposed in a single round order; they have one petal, which is stretched out like a tongue, and indented in four parts at the end; they have five short hair-like stamina, terminated by cylindrical

summits. The germen is situated under the petal, supporting a slender style longer than the stamina, crowned by a bifid reflexed stigma. The germen afterward becomes a single heart-shaped seed, crowned with hairy down.

The Species are,

1. PRENANTHES *flosculis quinis, foliis lyrato-hastatis*. Hort. Cliff. 383. Prenanthes with five florets, and lyre-spear-shaped leaves.

2. PRENANTHES *flosculis quinis, foliis lanceolatis denticulatis*. Hort. Cliff. 383. Prenanthes with five florets, and spear-shaped indented leaves.

3. PRENANTHES *erecta, flosculis quinis foliis trilobis*. Lin. Sp. Plant. 797. Upright Prenanthes with five florets, and leaves having three lobes.

4. PRENANTHES *flosculis quinis, caule ramoso, foliis ovato-lanceolatis semiamplexicaulibus*. Prenanthes with five florets, a branching stalk, and oval spear-shaped leaves half embracing the stalk.

The first sort grows naturally upon walls and dry shady banks in many parts of *England*, so is never cultivated in gardens.

The second sort grows naturally upon the *Helvetian* mountains. This hath a creeping root, which spreads far in the ground, so becomes a troublesome weed, if admitted into gardens. The stalks of this rise four feet high; the leaves are spear-shaped, and a little indented toward their ends; the flowers are of a purple blue colour, and are produced in panicles from the sides, and at the top of the stalks. These appear in *July*, and are succeeded by seeds which ripen in autumn.

The third sort grows naturally in most parts of *North America*, where it is called Dr. Witt's Rattlesnake root. This seldom lives longer than two years. The lower leaves are four or five inches long, and three broad; they are sometimes divided into five lobes, but generally into three; they are indented a little on their edges, smooth, of a dark green on their upper side, but pale on their under. The stalks rise three feet high, and are garnished with a few small leaves, which are entire; the flowers come out from the side of the stalk in small bunches; these are of a pale yellow colour, and appear in *July*. They are succeeded by seeds, crowned with hairy down, which ripen in autumn. There is a variety of this with pale purple flowers, which arises from the same seeds. The roots of these plants are said to be an antidote to expel the venom of the Rattlesnake, which induced me to mention these plants.

The fourth sort grows naturally on the mountains in *Germany*. This hath a perennial root. The stalks rise a foot high, and branch out on each side; the leaves are spear-shaped and oval; their base is broad, and half surrounds the stalk; the flowers grow loosely upon slender foot stalks, which come out from the side, and at the end of the branches. These appear in *June*, and the seeds ripen in autumn.

These plants are seldom admitted into gardens, but if any person is desirous to cultivate them, if they sow the seeds soon after they are ripe in a shady situation, the plants will come up, and require no other care but to keep them clear from weeds.

PRIMULA. Lin. Gen. Plant. 180. The Primrose.

The Characters are,

The flower hath a tubulous empalement of one leaf, ending in five acute points; it hath one petal, with a cylindrical tube, but spreads open above, where it is cut into five heart-shaped segments. It has five short stamina, situated in the neck of the petal, terminated by erect acute-pointed summits, and a globular germen, supporting a slender style, crowned by a globular stigma. The germen afterward turns to an oblong capsule, with one cell opening at the top, filled with small angular seeds.

The

The Species are,

1. PRIMULA *foliis dentatis rugosis, pedunculis unifloris.* Primrose with rough indented leaves, and foot-stalks bearing one flower; or common Primrose.

2. PRIMULA *foliis dentatis rugosis, floribus fastigiatis.* Primrose with rough indented leaves, and flowers growing in bunches; called Cowslip.

3. PRIMULA *foliis cuneiformibus glabris, segmentis corollarum bifidis.* Primrose with smooth wedge-shaped leaves, and bifid segments to the empalement; called Birds-eyen.

4. PRIMULA *foliis petiolatis subcordatis crenatis, floribus fastigiatis pedunculis longissimis.* Primrose or Cowslip with heart-shaped crenated leaves, having foot-stalks, and flowers growing in bunches on very long foot-stalks.

The first sort of Primrose grows wild in woods, and other shady places in most parts of *England*, from whence their roots may be easily transplanted into the garden, where, if they are placed under hedges, and in shady walks, they make a beautiful appearance early in the spring, when few other plants are in flower.

This plant is so well known as to need no description; the flowers and roots of this are used in medicine.

There are several varieties of this, which have been accidentally obtained, as the common Primrose with double flowers; the red Primrose with single and double flowers; these have but one flower upon a foot-stalk, but the Paper-white Primrose is certainly a distinct species.

The second sort is the Cowslip, or Paigle, or Paralysis of the shops. This grows naturally in meadows and moist pastures in many parts of *England*. The flowers of this sort grow in bunches on the top of the foot-stalk, so are easily distinguished from the former; the flowers are much used in medicine, and sometimes the leaves. As these grow wild, their roots may be taken up, and transplanted into gardens.

The best time to transplant them is at *Michaelmas*, that their roots may have strength to produce their flowers early in the spring. These delight in a strong rich soil, but will grow in almost any sort of earth, provided they have a shady situation.

There are a great variety of this at present in the gardens, as the Hose in Hose, the double Cowslip, and all the sorts of Polyanthus, which have been so much improved within the last fifty years, as to almost equal the variety of the Auriculas; and in some parts of *England* they are so much esteemed as to sell for a guinea a root, so that there may be still a much greater variety raised, as there are so many persons engaged in the culture of this flower.

The several varieties of Polyanthus are produced by sowing of seeds, which should be saved from such flowers as have large upright stems, producing many flowers upon a stalk, which are large, beautifully striped, open flat, and not Pin-eyed. From the seeds of such flowers there is room to hope for a great variety of good sorts, but there should be no ordinary flowers stand near them, lest, by the mixture of their farina, the seeds should be degenerated.

These seeds should be sown in boxes filled with light rich earth in *December*, being very careful not to bury the seed too deep, for if it be only slightly covered with light earth, it will be sufficient. These boxes should be placed where they may have the benefit of the morning sun until ten of the clock, but must by no means be exposed to the heat of the day, especially when the plants begin to appear, for at that time one whole day's sun will entirely destroy them. In the spring, if the season should prove dry, you must often refresh them with water, and, as the heat increases, you should remove the boxes more in the shade, for the heat is very injurious to them.

By the end of *May* these plants will be strong enough to

plant out, at which time you should prepare some shady borders, which should be made rich with neats dung, upon which you must set the plants about four inches asunder every way, observing to water them until they have taken root; after which they will require no farther care but to keep them clear from weeds, until the latter end of *August* following, when you should prepare some borders, which are exposed to the east, with good light rich earth, into which you must transplant your Polyanthus, placing them six inches asunder equally in rows, observing, if the season proves dry, to water them until they have taken root. In these borders your plants will flower the succeeding spring, at which time you must observe to mark such of them as are fine to preserve, and the rest may be transplanted into wildernesses, and other shady places in the garden, where, although they are not very valuable flowers, they will afford an agreeable variety.

Those which you intend to preserve, may be removed soon after they have done flowering (provided you do not intend to save seeds from them), and may be then transplanted into a fresh border of the like rich earth, allowing them the same distance as before, observing also to water them until they have taken root; after which they will require no farther care, but only to keep them clean from weeds, and the following spring they will produce strong flowers, as their roots will be then in full vigour; so that, if the kinds are good, they will be little inferior to a shew of Auriculas.

These roots should be constantly removed and parted every year, and the earth of the border changed, otherwise they will degenerate, and lose the greatest part of their beauty.

If you intend to save seeds, which is the method to obtain a great variety, you must mark such of them, which, as I said before, have good properties. These should be, if possible, separated from all ordinary flowers, for if they stand surrounded with plain-coloured flowers, they will impregnate each other, whereby the seeds of the valuable flowers will not be near so good, as if the plants had been in a separate border, where no ordinary flowers grew; therefore the best way is to take out the roots of such as you do not esteem as soon as the flowers open, and plant them in another place, that there may be none left in the border, but such as you would chuse for seeds.

The flowers of these should not be gathered, except such as are produced singly upon pedicles, leaving all such as grow in large bunches; and if the season should prove dry, you must now and then refresh them with water, which will cause their seeds to be larger, and in greater quantity, than if they were entirely neglected. In *June* the seed will be ripe, which may be easily known by the pods changing brown, and opening; so that you should at that time look over the plants three times a week, gathering each time such of the seed-vessels as are ripe, which should be laid upon a paper to dry, and may then be put up until the season of sowing.

As the plants, which arise from seeds, generally flower much better than offsets, those who would have these flowers in perfection, should annually sow their seeds.

PRIMROSE-TREE. See *Onagra*.

PRINOS. *Lin. Gen. Plant.* 398. Winterberry.

The Characters are,

The flower hath a permanent empalement of one leaf, which is cut into six small plain segments. It hath one wheel-shaped petal, with no tube, cut into six plain segments; it hath six awl shaped stamina, shorter than the petal, terminated by obtuse summits, and an oval germen, sitting upon the style, crowned by an obtuse stigma. The germen afterward turns to a round berry, opening in three parts, including one hard seed.

The Species are,

1. PRINOS foliis longitudinaliter serratis. Lin. Sp. Plant. 330. Prinos, or Winterberry, with leaves sawed lengthways.

2. PRINOS foliis apice serratis. Lin. Sp. Plant. 330. Prinos with leaves sawed at the points.

The first sort grows naturally in *Virginia*, and other parts of *North America*. This rises with a shrubby stalk to the height of eight or ten feet, sending out many branches, garnished with spear-shaped leaves, terminating in acute points, veined on their under side, and sawed on their edges, having slender foot stalks standing alternately on the branches. The flowers come out from the side of the branches, sometimes single, at others two or three at each joint; they have no tube, but are wheel-shaped, and cut into six parts; they have six awl-shaped erect stamina, terminated by obtuse summits, and an oval germen, sitting upon the style, crowned by an obtuse stigma; these are succeeded by berries about the size of those of *Holly*, which turn purple when ripe. It flowers in *July*, and the seeds ripen in the winter.

The second sort grows naturally in *Canada*. This is of lower growth than the former. The leaves are shorter, and sawed at their points, but the flowers of this I have not seen.

It is propagated by seeds, which should be sown soon after they are ripe upon a bed of light earth, covering them about one inch deep. The seeds, which are so soon put into the ground, will many of them come up the following spring, whereas those, which are kept longer out of the ground, will remain a whole year before the plants will appear, in the same manner as the *Holly*, *Hawthorn*, and some others; therefore the ground should not be disturbed, if the plants do not come up the first year. The young plants may be treated in the same manner as hath been directed for the *American Hawthorns*, and are full as hardy, but they delight in a moist soil and a shady situation, for in hot land they make but little progress, and rarely produce any fruit.

PRIVET. See *Ligustrum*.

PROTEA. Lin. Gen. Plant. 104. Silver-tree.

The Characters are,

The flowers are collected in an oval head; they have one common imbricated scaly perianthium. The flower is of one petal, having a tube the length of the empalement; the brim is cut into four parts, which spread open, and are equal. It has four bristly stamina the length of the petal, terminated by incumbent summits, and a roundish germen with an erect bristly style, crowned by an obtuse stigma. The germen afterward turns to a roundish naked seed, sitting in a distinct cell of the cone.

The Species are,

1. PROTEA foliis lineari-lanceolatis integerrimis, superioribus hirsutis nitidis. Prod. Leyd. 184. Protea with linear, spear-shaped, entire leaves; the upper of which shine, and are hairy.

2. PROTEA foliis lanceolatis integerrimis acutis hirsutis nitidis. Hort. Cliff. 29. Protea with entire, spear-shaped, acute, hairy, shining leaves; commonly called Silver-tree.

3. PROTEA foliis oblongo-ovatis hirsutis nitidis integerrimis. Protea with oblong, oval, hairy, shining leaves, which are entire; called Wageboom.

These plants are natives of the country near the *Cape of Good Hope* in *Africa*, where there is a great number of species. In the catalogue of the *Leyden* garden there are upward of twenty sorts enumerated; not that they have them growing there, but they have good drawings of them, which were made in the country, where they are natives. The three sorts here mentioned are what I have now growing in the *Chelsea* garden.

As these plants are natives of the *Cape of Good Hope*, they are too tender to live abroad through the winter in *England*, but the first sort is hardy enough to live in a good green-house. This sort will grow to the height of ten or twelve feet, and may be trained up with a regular straight stem; the branches naturally form a regular large head. The leaves are long and narrow, of a shining silver colour; and, as they remain the whole year, the plants make a fine appearance, when they are intermixed with others in the green-house. In the summer these may be placed in the open air in a sheltered situation, for, if they are exposed to winds, the plants will be torn, and rendered unsightly, nor will they make any progress in their growth. In warm weather they must be frequently but sparingly watered, and in cold weather this must not be too often repeated, lest it should rot their fibres.

The second sort hath a strong upright stalk, covered with a purplish bark, dividing into several branches, which grow erect, garnished with broad, shining, silvery, spear-shaped leaves, which make a fine appearance, when intermixed with other exoticks. This should be placed in an airy dry glass-case, where it may be protected from cold, and have as much light as possible, and in winter should have little water; it rises easily from seeds. The seeds will sometimes remain in the ground six or eight months, and at other times the plants will appear in six weeks; therefore the best way is to sow the seeds in small pots filled with soft sandy loam, and plunge them into a moderate hot-bed; and, if the plants should not come up so soon as expected, the pots should remain in shelter till the following spring, when, if the seeds remain sound, the plants will come up. The pots, in which the seeds are sown, should have but little wet, for moisture frequently causes them to rot. When the plants appear, they should not be too tenderly treated, for they must not be kept too warm, nor should they have much wet; but in warm weather they must be exposed to the open air in a sheltered situation, and in winter protected from frost.

The third sort I raised from seeds, which came from the *Cape of Good Hope*; these seeds were long and slender, very different in shape from those of the second sort, but the plants have great resemblance to them. The leaves are very silky and white; the stalks are purple, and grow erect, but have not as yet put out any branches.

The first sort may be propagated by cuttings, which should be cut off in *April*, just before the plants begin to shoot; they should be planted in small pots, filled with light earth, and plunged into a moderate hot-bed, shading them from the sun, and now and then gently refreshing them with water, but it must be sparingly given, for much wet will rot them. These cuttings will put out roots by *Midsummer*, when they may be gently shaken out of the pots, and parted, planting each in a separate small pot filled with light earth, and place them in a frame, where they may be shaded till they have taken new root; then they should be gradually inured to the open air, into which they should be removed, and treated in the same way as the old plants.

PRUNELLA. Lin. Sp. Plant. 600. Self-heal.

The Characters are,

The flower has a permanent empalement, divided into two lips; it is of the ringent kind, having one petal with a short tube, and oblong chaps; the upper lip is entire and concave; the under lip is trifid; the middle segment is broad, and indented at the point; it has four awl-shaped stamina, two long and two shorter, and four germen, supporting a slender style, crowned by an indented stigma. The germen becomes four seeds inclosed in the empalement.

The Species are,

1. PRUNELLA foliis oblongo-ovatis petiolatis. Lin. Sp. Plant. 600. Greater Self-heal with oblong oval leaves.

2. PRUNELLA

2. PRUNELLA *foliis oblongo-ovatis laciniatis*. Self-heal with oblong, oval, jagged leaves.

3. PRUNELLA *foliis lanceolato-linearibus ciliatis subsessilibus*. Sauv. Monsp. 141. Self-heal with Hyssop leaves.

4. PRUNELLA *foliis lanceolato-linearibus, internodiis longissimis spicis interruptis*. Canada Self-heal with narrow leaves, and the joints of the stalk very distant.

5. PRUNELLA *foliis oblongis pinnato-sinuatis villosis infimis petiolatis summis sessilibus*. Self-heal with oblong, wing-pointed, hairy leaves.

6. PRUNELLA *foliis lineari-lanceolatis pinnato-incisis subsessilibus spicis interruptis*. Self-heal with vervain leaves, sitting close to the stalks, and interrupted spikes of flowers.

7. PRUNELLA *foliis lanceolatis integerrimis, infimis petiolatis, summis sessilibus, internodiis prælongis, spicis crassioribus*. Carolina Self-heal with entire leaves, and thick spikes of flowers.

8. PRUNELLA *bracteis pinnato-dentatis ciliatis*. Læfl. desc. 31. Portugal Self-heal with sweet flowers.

The first sort, which is used in medicine, grows naturally in pastures every where. The leaves are in shape a long oval; the stalks are square, rise about eight inches high, and are terminated by a close spike of flowers, which are for the most part blue, but sometimes are white. It flowers in June and July, and the seeds ripen in August and September. The second sort differs from the first, in having jagged leaves.

The third sort has very narrow leaves, which are covered with small hairs, and sit close to the stalks.

The fourth sort, which came originally from Canada, has very narrow leaves; the joints of the flower-stalk are far asunder, and the spikes of flowers are separated.

The fifth sort has hairy cut leaves, and sulphur-coloured flowers.

The seventh sort was brought from Carolina. The leaves of this are spear-shaped and entire; the flower-stalk is tall, the joints very distant, and is terminated by a thick spike of pale blue flowers.

The eighth sort grows naturally in Portugal and Spain. The leaves of this are finely cut, and are set with fine soft hairs; the stalk rises higher than most of the other sorts, and is terminated by spikes of blue flowers, which have an agreeable scent.

All these plants are hardy, so will thrive in the open air. They are easily propagated by seeds, which, if sown in the autumn, will more certainly succeed than those sown in the spring; or if their seeds are permitted to scatter, the plants will rise without any trouble, but if the sorts stand near each other, there will be some difficulty to keep them distinct, when their seeds fall to the ground. The plants want no other care but to be thinned to proper distances, and kept clean from weeds. They are not of long duration, so that whoever would keep the sorts, should sow their seeds annually, but as they are not very ornamental, so they are seldom preserved in gardens, unless by such as are curious in botany.

PRUNING OF TREES. There is not any part of gardening which is of more general use than that of pruning, and yet it is very rare to see fruit-trees skilfully managed. Almost every gardener will pretend to be a master of this business, though there are but few who rightly understand it, nor is it to be learned by rote, but requires a strict observation of the different manners of growth of the several sorts of fruit-trees, some requiring to be managed one way, and others must be treated in a quite different method, which is only to be known from carefully observing how each kind is naturally disposed to produce its fruit, for some sorts produce their fruit on the same year's wood, as Vines; others produce their fruit, for the most part, upon

the former year's wood, as Peaches, Nectarines, &c. and others upon cursons or spurs, which are produced upon wood of three, four, or five, to fifteen or twenty years old, as Pears, Plums, Cherries, &c. therefore, in order to the right management of fruit-trees, there should always be provision made to have a sufficient quantity of bearing wood in every part of the trees, and at the same time there should not be a superfluity of useless branches, which would exhaust the strength of the trees, and cause them to decay in a few years.

The reasons which have been laid down for pruning of fruit-trees are as follow: first, To preserve trees longer in a vigorous bearing state; the second is, To render the trees more beautiful to the eye; and thirdly, To cause the fruit to be larger and better tasted.

1. It preserves a tree longer in a healthy bearing state; for by pruning off all superfluous branches, so that there are no more left upon the tree than are necessary, or than can be properly nourished, the root is not exhausted in supplying useless branches, which must afterwards be cut out, whereby much of the sap will be uselessly expended.

2. By skilful pruning of a tree it is rendered much more pleasing to the eye; but here I would not be understood to be an advocate for a sort of pruning, which I have seen too much practised of late, viz. the drawing a regular line against the wall, according to the shape or figure they would reduce the tree to, and cutting all the branches, strong or weak, exactly to the chalked line; the absurdity of which practice will soon appear to every one who will be at the pains of observing the difference of those branches shooting the succeeding spring. All therefore that I mean by rendering a tree beautiful is, that the branches are all pruned according to their several strengths, and are nailed at equal distances, in proportion to the different sizes of their leaves and fruit, and that no part of the wall (so far as the trees are advanced) be left unfurnished with bearing wood. A tree well managed, though it does not represent any regular figure, yet will appear very beautiful to the sight, when it is thus dressed, and nailed to the wall.

3. It is of great advantage to the fruit; for the cutting away all useless branches, and shortening all the bearing shoots according to the strength of the tree, will render the tree more capable to nourish those which are left remaining, so that the fruit will be much larger, and better tasted. And this is the advantage which those trees against walls or espaliers have to such as are standards, which are permitted to grow as they are naturally inclined; for it is not their being trained either to a wall or espalier, which renders their fruit so much better than standards, but because the roots have a less quantity of branches and fruit to nourish, and consequently their fruit will be larger and better tasted.

The reasons for pruning being thus exhibited, the next thing is the method of performing it; but this being fully handled under the several articles of the different kinds of fruit, I shall not repeat it again in this place, and therefore shall only add some few general instructions, which are necessary to be understood, in order to the right management of fruit-trees.

There are many persons who suppose that, if their fruit-trees are but kept up to the wall or espalier, during the summer season, so as not to hang in very great disorder, and in winter to get a gardener to prune them, it is sufficient, but this is a mistake; for the greatest care ought to be employed about them in the spring, when the trees are in vigorous growth, which is the only proper season to procure a quantity of good wood in the different parts of the tree, and to displace all useless branches as soon as they are produced, whereby the vigour of the tree will be entirely

tirely distributed to such branches only as are designed to remain, which will render them strong, and more capable to produce good fruit; whereas, if all the branches are permitted to remain which are produced, some of the more vigorous will attract the greatest share of the sap from the tree, whereby they will be too luxuriant for producing fruit, and the greatest part of the other shoots will be starved, and rendered so weak, as not to be able to produce any thing else but blossoms and leaves (as hath been before mentioned); so that it is impossible for a person, let him be ever so well skilled in fruit trees, to reduce them into any tolerable order by winter-pruning only, if they are wholly neglected in the spring.

There are others who do not entirely neglect their trees during the summer season, as those before mentioned, but yet do little more good to them by what they call summer-pruning; for these persons neglect their trees at the proper season, which is in *April* and *May*, when their shoots are produced, and only about *Midsummer* go over them, nailing in all their branches, except such as are produced fore-right from the wall, which they cut out, and at the same time often shorten most of the other branches, which is almost as bad as the other; for those branches, which are intended for bearing the succeeding year, should not be shortened during the time of their growth, which will cause them to produce one or two lateral shoots from the eyes below the place where they were stopped, which shoots will draw much of the strength from the buds of the first shoot, whereby they are often flat, and do not produce their blossoms; and, if those two lateral shoots are not entirely cut away at the winter-pruning, they will prove as injurious to the tree; for the shoots, which these produce, will be what the *French* call water-shoots; and in suffering those luxuriant shoots to remain upon the tree until *Midsummer* before they are displaced, they will exhaust a great share of the nourishment from the other branches (as was before observed); and, by shading the fruit all the spring, when these are cut away, and the other branches fastened to the wall, the fruit, by being so suddenly exposed, will receive a very great check, which will cause their skins to grow tough, and thereby render them less delicate. This is to be chiefly understood of stone-fruit and Grapes, but Pears and Apples, being much hardier, suffer not so much, though it is a great disadvantage to those also to be thus managed.

It must also be remarked, that Peaches, Nectarines, Apricots, Cherries, and Plums, are always in the greatest vigour, when they are the least maimed by the knife, for where these trees have large amputations, they are very subject to gum and decay; so that it is certainly the most prudent method carefully to rub off all useless buds when they are first produced, and pinch others, where new shoots are wanted to supply the vacancies of the wall; by which management trees may be so ordered, as to want but little of the knife in winter-pruning, which is the surest way to preserve these trees healthful, and is performed with less trouble than the common method.

The management of Pears and Apples is much the same with these trees in summer, but in winter they must be very differently pruned; for as Peaches and Nectarines for the most part produce their fruit upon the former year's wood, therefore they must have their branches shortened, according to their strength, in order to produce new shoots for the succeeding year; so Pears, Apples, Plums, and Cherries, on the contrary, producing their fruit upon cufsons or spurs, which come out of the wood of five, six, or seven years old, should not be shortened, because thereby those buds, which were naturally disposed to form these cufsons or spurs, would produce wood branches, whereby the trees would be filled with wood, but never produce much

fruit; and, as it often happens that the blossom-buds are first produced at the extremity of the last year's shoot, by shortening the branches, the blossoms are cut away, which should always be carefully avoided.

There are several authors who have written on the subject of pruning in such a prolix manner, that it is impossible for a learner to understand their meaning. These have described the several sorts of branches, which are produced on fruit-trees, as wood branches, fruit branches, irregular branches, false branches, and luxuriant branches, all which they assert every person, who pretends to pruning, should distinguish well; whereas, there is nothing more in all this but a parcel of words to amuse the reader, without any real meaning, for all these are comprehended under the description already given of luxuriant or useless branches, and such as are termed useful or fruit bearing branches; and, where due care is taken in the spring of the year to displace these useless branches (as was before directed), there will be no such thing as irregular, false, or luxuriant branches at the winter-pruning, therefore it is to no purpose to amuse people with a cant of words, which, when fully understood, signify just nothing at all.

In pruning of standard-trees you should never shorten their branches, unless it be where they are very luxuriant, and grow irregular on one side of the tree, attracting the greatest part of the sap of the tree, whereby the other parts are unfurnished with branches, or rendered very weak, in which case the branch should be shortened down as low as is necessary, to obtain more branches, to fill up the hollow of the trees; but this is only to be understood of Pears and Apples, which will produce shoots from wood of three, four, or more years old, whereas most sorts of stone-fruit will gum and decay after such amputations.

But from hence I would not have it understood, that I would direct the reducing of these trees into an exact spherical figure, since there is nothing more detestable than to see a tree (which should be permitted to grow as it is naturally disposed, with its branches produced at proportionable distances, according to the size of the fruit), by endeavouring to make the head exactly regular, so crowded with small weak branches as to prevent the air from passing between them, which will render it incapable to produce fruit. All that I intend by this stopping of luxuriant branches, is only when one or two such happen on a young tree, where they entirely draw all the sap from the weaker branches, and starve them; then it is proper to use this method, which should be done in time, before they have exhausted the roots too much.

Whenever this happens to stone-fruit, which suffer much more by cutting than the former sorts, it should be remedied by stopping or pinching those shoots in the spring, before they have obtained too much vigour, which will cause them to push out side branches, whereby the sap will be diverted from ascending too fast to the leading branch (as hath been directed for wall trees), but this must be done with caution.

You must also cut out all dead or decaying branches, which cause their heads to look very ragged, especially at the time when the leaves are upon the tree, these, being destitute of them, have but a despicable appearance. In doing of this, you should observe to cut them close down to the place where they were produced, otherwise that part of the branch left will decay, and prove equally hurtful to the tree; for it seldom happens, when a branch begins to decay, that it does not die quite down to the place where it was produced, and, if permitted to remain long uncut, does often infect some of the other parts of the tree. If the branches are large which you cut off, it will be very proper, after having smoothed the cut part exactly even with

with a knife, chissel, or hatchet, to put on a plaster of grafting clay, which will prevent the wet from soaking into the tree at the wounded part.

All such branches as run cross each other, should also be cut out, for these not only occasion a confusion in the head of the tree, but, by lying over each other, rub off their bark by their motion, and very often occasion them to canker to the great injury of the tree, and on old trees (especially Apples) there are often young vigorous shoots from the old branches near the trunk, which grow upright into the head of the trees. These therefore should carefully be cut out every year, lest, by being permitted to grow, they fill the tree too full of wood, which should always be guarded against, since it is impossible for such trees to produce so much, or so good fruit as those, whose branches grow at a farther distance, whereby the sun and air freely pass between them in every part of the tree.

These are all the general directions which are proper to be given in this place, since not only the particular methods, but also the proper seasons for pruning all the different kinds of fruit, are fully exhibited under their several articles.

PRUNUS. *Tourn. Inst. R. H. 622. tab. 398.* The Plum-tree.

The Characters are,

The flower hath a bell-shaped empalement, cut into five points; it hath five large roundish petals, which are inserted in the empalement, and from twenty to thirty stamina, which are near as long as the petals, and are also inserted in the empalement, terminated by twin summits. It has a roundish germen, supporting a slender style, crowned by an orbicular stigma. The germen afterward turns to a roundish fruit, inclosing a nut of the same form.

The Species are,

1. PRUNUS *fructu parvo præcoci. Tourn.* The Jehanâtive, or white Primordian. This is a small longish Plum, of a clear yellowish colour, covered over with a white fiew, which easily wipes off; it is a pretty good bearer, and, for its coming very early, may have a place in a large garden of fruit, but it is meally, and has little flavour. This ripens the middle of July.

2. PRUNUS *fructu magno crasso subacido. Tourn.* Damas noir hâtive, *i. e.* the early black Damask, commonly called the Morocco Plum. This is a middle sized Plum, of a round shape, divided with a furrow (like Peaches). The outside is of a dark black colour, covered with a light Violet bloom; the flesh is yellow, and parts from the stone. It ripens the beginning of August, and is esteemed for its goodness.

3. PRUNUS *fructu parvo dulci atro-cæruleo. Tourn.* The little black Damask Plum. This is a small black Plum, covered with a light Violet bloom. The juice is sugared; the flesh parts from the stone; it is a good bearer, and ripens the middle of August.

4. PRUNUS *fructu magno dulci atro-cæruleo. Tourn.* Gros Damas Violet de Tours, *i. e.* great Damask Violet of Tours. This is a pretty large Plum, inclining to an oval shape. The outside is of a dark blue, covered with a Violet bloom; the juice is richly sugared; the flesh is yellow, and parts from the stone. It ripens the middle of August.

5. PRUNUS *fructu rotundo atro-rubente. Tourn.* The Orleans Plum. The fruit is so well known, that it is needless to describe it; it is a very plentiful bearer, which has occasioned its being so generally planted by those persons who supply the markets with fruit, but it is an indifferent Plum. It ripens the middle of August.

6. PRUNUS *fructu oblongo atro-rubente. Tourn.* The Fotheringham Plum. This fruit is somewhat long, deeply furrowed in the middle. The flesh is firm, and parts from the stone; the juice is very rich. This ripens in the middle of August.

7. PRUNUS *fructu nigro, carne durâ. Tourn.* The Perdigran Plum. This is a middle-sized Plum, of an oval shape. The outside is of a very dark colour, covered over with a Violet bloom; the flesh is firm, and full of an excellent rich juice. This is greatly esteemed by the curious. It ripens the end of August.

8. PRUNUS *fructu magno è violaceo rubente suavissimo saccharato. Tourn.* The Violet Perdigran Plum. This is a large fruit, rather round than long, of a bluish red colour on the outside. The flesh is of a yellowish colour, pretty firm, and closely adheres to the stone; the juice is of an exquisite rich flavour. This ripens the end of August.

9. PRUNUS *fructu ovato ex albo flavescente. Tourn.* The white Perdigran Plum. This is a middling Plum, of an oblong figure. The outside is yellow, covered with a white bloom; the flesh is firm, and tolerably well tasted. It is much esteemed for sweat-meats, having an agreeable sweetness, mixed with an acidity. It ripens the end of August.

10. PRUNUS *fructu ovato magno rubente. Tourn.* The red imperial Plum, sometimes called the red Bonum Magnum. This is a large oval-shaped fruit, of a deep red colour, covered with a fine bloom. The flesh is very dry, and very indifferent to be eaten raw, but is excellent for making sweatmeats: this is a great bearer. It ripens the beginning of September.

11. PRUNUS *fructu ovato magno flavescente. Tourn.* White imperial, Bonum Magnum, white Holland, or Mogul Plum. This is a large oval-shaped fruit, of a yellowish colour, powdered over with a white bloom. The flesh is firm, and adheres closely to the stone; the juice is of an acid taste, which renders it unpleasant to be eaten raw, but it is very good for baking or sweatmeats. It is a great bearer, and is ripe the middle of September.

12. PRUNUS *fructu ovato cæruleo. Tourn.* The Cheston Plum. This is a middle-sized fruit, of an oval figure. The outside is of a dark blue, powdered over with a Violet bloom; the juice is rich, and it is a great bearer. Ripe the middle of September.

13. PRUNUS *fructu maximo rotundo flavo & dulci. Tourn.* Prune d'Abricot, *i. e.* the Apricot Plum. This is a large round fruit, of a yellow colour on the outside, powdered over with a white bloom. The flesh is firm and dry, of a sweet taste, and comes clean from the stone. This ripens the end of September.

14. PRUNUS *fructu subrotundo, ex rubro & flavo mixto. Tourn.* The Maître Claude. Although this name is applied to this fruit, yet it is not what the French so call. This is a middle-sized fruit, rather round than long, of a fine mixed colour, between red and yellow. The flesh is firm, parts from the stone, and has a delicate flavour. Ripe the middle of September.

15. PRUNUS *fructu rubente dulcissimo. Tourn.* La Rochecourbon, or Diaprée rouge, *i. e.* the red Diaper Plum. This is a large round fruit, of a reddish colour, powdered over with a Violet bloom; the flesh adheres closely to the stone, and is of a very high flavour. Ripe the middle of September.

16. PRUNUS *fructu rotundo flavescente. Tourn.* La petite Reine Claude, *i. e.* the little Queen Claudia. This is a small round fruit, of a whitish yellowish colour, powdered over with a pearl-coloured bloom; the flesh is firm and thick, quits the stone, and its juice is richly sugared. Ripe the middle of September.

17. PRUNUS *fructu rotundo nigro-purpureo majori dulci. Tourn.* Myrobalan Plum. This is a middle-sized fruit, of a round shape; the outside is a dark purple, powdered over with a Violet bloom; the juice is very sweet. It is ripe the beginning of September.

18. PRUNUS *fructu rotundo è viridi flavescente, carne durâ suavissima. Tourn.* La grosse Reine Claude, *i. e.* the large Queen Claudia

Claudia, by some the Dauphiny. At *Tours* it is called the *Abricot verd*, *i. e.* green Apricot; at *Rouen*, *Le verte bonne*, *i. e.* the good Green; and in other places, *Damas verd*, *i. e.* green Damask, or *Trompvalet*, the Servants Cheat. This is one of the best Plums in *England*; it is of a middle size, round, and of a yellowish green colour on the outside; the flesh is firm, of a deep green colour, and parts from the stone; the juice has an exceeding rich flavour, and it is a great bearer. Ripe the middle of *September*. This Plum is confounded by most people in *England*, by the name of *Green Gage*; but this is the sort which should be chosen, although there are three or four different sorts of Plums generally sold for it, one of which is small, round, and dry; this quits the stone, and is sooner ripe, so not worth planting.

19. *PRUNUS fructu amygdalino. Tourn.* *Rognon de Coq*, *i. e.* Cock's Testicles. This is an oblong fruit, deeply furrowed in the middle, so as to resemble the testicles; it is of a whitish colour on the outside, streaked with red; the flesh of it adheres firmly to the stone, and it is late ripe.

20. *PRUNUS fructu rotundo flavo dulcissimo. Drap d'Or*, *i. e.* the Cloth of Gold Plum. This is a middle-sized fruit, of a bright yellow colour, spotted or streaked with red on the outside; the flesh is yellow, and full of an excellent juice. It is a plentiful bearer, and ripens about the middle of *September*.

21. *PRUNUS fructu cerei coloris. Tourn.* *Prune de Sainte Catharine*, *i. e.* St. Catharine Plum. This is an oval-shaped fruit, somewhat flat; the outside is of an Amber colour, powdered over with a whitish bloom, but the flesh is of a bright yellow colour, is dry and firm, adheres closely to the stone, and has a very agreeable sweet taste. This ripens at the end of *September*, and is very subject to dry upon the tree, when the autumn proves warm and dry. This makes fine sweatmeats, and is a plentiful bearer.

22. *PRUNUS fructu ovato rubente dulci.* The Royal Plum. This is a large fruit, of an oval shape, drawing to a point next the stalk; the outside is of a light red colour, powdered over with a whitish bloom; the flesh adheres to the stone, and has a fine sugary juice. This ripens the middle of *September*.

23. *PRUNUS fructu parvo ex viridi flavescente. Tourn.* *La Mirabelle*. This is a small round fruit, yellow on the outside; the flesh parts from the stone, is of a bright yellow colour, and has a fine sugary juice. This is a great bearer, ripens the end of *August*, and is excellent for sweatmeats.

24. *PRUNUS Brignoniensis, fructu suavissimo. Tourn.* *Prune de Brignole*, *i. e.* the Brignole Plum. This is a large oval-shaped fruit, of a yellowish colour, mixed with red on the outside; the flesh is of a bright yellow colour, is dry, and of an excellent rich flavour. This ripens the middle of *September*, and is esteemed the best Plum for sweatmeats yet known.

25. *PRUNUS fructu magno è violaceo rubente serotino. Tourn.* *Imperatrice*, *i. e.* the Empress. This is a middle-sized oval fruit, of a Violet colour, very much powdered with a whitish bloom; the flesh is yellow, cleaves to the stone, and is of an agreeable flavour. This ripens about the beginning of *October*.

26. *PRUNUS fructu ovato maximo flavo. Tourn.* *Prune de Monsieur*, *i. e.* Monsieur's Plum. This is sometimes called the *Wentworth Plum*. It is a large oval-shaped fruit, of a yellow colour, both within and without, very much resembling the *Bonum Magnum*, but the flesh of this parts from the stone, which the other doth not. This ripens towards the latter end of *September*, and is very good to preserve, but the juice is too sharp to be eaten raw. It is a great bearer.

27. *PRUNUS fructu majori rotundo rubro. Tourn.* *Prune*

Cerizette, *i. e.* the Cherry Plum. This fruit is commonly about the size of the Ox-heart Cherry, is round, and of a red colour; the stalk is long, like that of a Cherry, which this fruit so much resembles, as not to be distinguished therefrom at some distance. The blossoms of this tree come out very early in the spring, and being tender, are very often destroyed by cold, but it affords a very agreeable prospect in the spring; for as these trees are generally covered with flowers, which open about the same time as the Almonds, so when they are intermixed therewith, they make a beautiful appearance before many other sorts put out, but by blossoming so early, there are few years that they have much fruit.

28. *PRUNUS fructu albo oblongiusculo acido. Tourn.* The white Pear Plum. This is a good fruit for preserving, but is very unpleasant if eaten raw; it is very late ripe, and seldom planted in gardens, unless for stocks to bud some tender sorts of Peaches upon, for which purpose it is esteemed the best amongst all the sorts of Plums.

29. *PRUNUS Mytellinum. Park.* The Muscle Plum. This is an oblong flat Plum, of a blue colour; the stone is large, and the flesh but very thin, and not well tasted, so that its chief use is for stocks, as the former.

30. *PRUNUS fructu parvo violaceo.* The St. Julian Plum. This is a small fruit, of a dark Violet colour, powdered over with a mealy bloom; the flesh adheres closely to the stone, and in a fine autumn will dry upon the tree. The chief use of this Plum is for stocks, to bud the more generous kinds of Plums and Peaches upon, as also for the *Bruxelles* Apricot, which will not thrive so well upon any other stock.

31. *PRUNUS sylvestris major. J. B.* The black Bullace-tree. This grows wild in the hedges in divers parts of *England*, and is rarely cultivated in gardens.

32. *PRUNUS sylvestris, fructu majore albo. Raii Syn.* The white Bullace-tree. This grows wild as the former, and is seldom cultivated in gardens.

33. *PRUNUS sylvestris. Ger. Emac.* The Black-thorn, or Sloe-tree. This is very common in the hedges almost every where. The chief use of this tree is to plant for hedges, as White-thorn, &c. and being of quick growth, is very proper for that purpose.

All the varieties of Plums are propagated by budding or grafting them upon stocks of the Muscle, white Pear, St. Julian, *Bonum Magnum*, or any other sorts of free-shooting Plums. The manner of raising these stocks hath been already exhibited under the article of *NURSERIES*, therefore need not be repeated again in this place; but I would observe, that budding is much preferable to grafting for these sorts of fruit-trees, because they are very apt to gum, wherever there are large wounds made on them.

The trees should not be more than one year's growth from the bud when they are transplanted, for if they are older, they seldom succeed so well, being very subject to canker; or if they take well to the ground, commonly produce only two or three luxuriant branches, therefore it is much more advisable to choose young plants.

The manner of preparing the ground (if for walls) is the same as for Peaches; as is also the pruning the roots and planting, therefore I shall forbear repeating it again. The distance which these trees should be planted at, must not be less than twenty-four feet against high walls, and if the wall is low, they should be placed thirty feet asunder.

Plums should have a middling soil, neither too wet and heavy, nor over-light and dry, in either of which extremes they seldom do so well; those sorts which are planted against walls, should be placed to an east or south-east aspect, which is more kindly to these fruits than a full south aspect, on which they are subject to shrivel, and be very dry;

dry; and many sorts will be extreme mealy, if exposed too much to the heat of the sun, and most of the sorts will ripen extremely well on espaliers, if rightly managed.

There are some persons who plant Plums for standards, in which method several of the ordinary sorts will bear very well; but the fruit will not be near so fair as those produced on espaliers, and will be more in danger of being bruised or blown down by strong winds. The distance of placing them for espaliers, must be the same as against walls, as must also their pruning and management; so that whatever may be hereafter mentioned for one, should be likewise understood for both.

Plums do not only produce their fruit upon the last year's wood; but also upon cursons or spurs, which come out of wood that is many years old; so that there is not a necessity of shortening the branches, in order to obtain new shoots annually, in every part of the tree (as in Peaches, Nectarines, &c. hath been directed), since the more these trees are pruned, the more luxuriant they grow, until the strength of them is exhausted, and then they gum and spoil; therefore the safest method to manage these trees is, to lay in their shoots horizontally, annually, as they are produced, at equal distances, in proportion to the length of their leaves; and where there is not a sufficient quantity of branches to fill up the vacancies of the tree, there the shoots may be pinched the beginning of *May* (in the manner as hath been directed for Peaches, &c.) which will cause them to produce some lateral branches to supply those places; and during the growing season, all fore-right shoots should be displaced, and such as are to remain must be regularly trained to the wall or espalier, which will not only render them beautiful, but also give to each an equal advantage of sun and air; and hereby the fruit will be always kept in a growing state, which they seldom are, when overshaded with shoots some part of the season, and then suddenly exposed to the air, by the taking off or training those branches in their proper position.

With thus carefully going over these trees in the growing season, there will be but little occasion for cutting them in winter, which (as I before have said) is of ill consequence to all sorts of stone-fruit; for when the branches are shortened, the fruit is cut away, and the number of shoots increased, because whenever a branch is shortened, there are commonly two or more shoots produced from the eyes immediately below the cut; so that by thus unskillfully pruning, many persons crowd their trees with branches, and thereby render the trees unfruitful, and what little fruit the trees produce, are small and ill tasted.

The few rules here laid down will be sufficient, if due observation be joined therewith, to instruct any person in the right management of these sorts of fruit-trees; therefore I shall not say more on that subject, lest by multiplying instructions, it may render it more obscure to a learner.

PSEUDOACACIA. See Robinia.

PSEUDODICTAMNUS. See Marrubium.

PSIDIUM. *Lin. Gen. Plant.* 541. The Guava.

The Characters are,

The flower has a bell-shaped empalement, divided into five oval points at the top. It hath five oval, concave, spreading petals, indented in the empalement, with a great number of stamina, which are shorter than the petals, and are inserted in the empalement, terminated by small summits. It has a roundish germen, situated under the flower, supporting a long awl-shaped style, crowned by a simple stigma. The germen afterward becomes a large oval fruit, crowned by the empalement, inclosing a great number of small seeds.

The Species are,

1. PSIDIUM ramis angulosis, foliis ovatis venosis, fructu

majori. Psidium with angular branches, oval veined leaves, and a larger fruit; the red Guava.

2. PSIDIUM foliis oblongo-ovatis venosis, fructu parvo odorato. Psidium with oblong oval leaves, which are veined, and a small sweet-scented fruit.

Both these sorts grow naturally in the *East* and *West-Indies*, and there is also a third with a large white fruit, but I do not know whether this is a variety of the common Guava, or of that with the small white fruit; though I am inclined to believe it is the former, because I have raised many plants from the seeds of the small white Guava, which have produced fruit in the *Chelsea* garden, and have not varied from their parent plant.

The common red Guava hath a pretty thick trunk, which rises twenty feet high, covered with a smooth bark; the branches are angular, garnished with oval leaves, having a strong midrib, and many veins running toward the sides, of a light green colour, standing opposite upon very short foot-stalks. From the wings of the leaves the flowers come out upon foot-stalks, about an inch and a half long; they are composed of five large, roundish, concave petals, which are inserted in the empalement, and within these are a great number of stamina, which are shorter than the petals, terminated by small summits; these stamina are also inserted in the empalement. Under the flower is situated a roundish germen, supporting a very long awl-shaped style, crowned by a simple stigma. After the flower is past, the germen becomes a large oval fruit, shaped like a Pomgranate, having one cell, crowned by the empalement of the flower, and filled with small seeds; the fruit, when ripe, has an agreeable odour. They are much eaten in the *West-Indies*, both by men and beasts; and the seeds, which pass whole through the body, and are voided with the excrement in hot countries, grow, whereby the trees are spread over the ground, where they are permitted to grow. This fruit is very astringent, and nearly of the same quality with Pomgranate, so should be avoided by those persons who are subject to be costive.

The large white sort grows naturally in the islands of the *West-Indies*, and is often found intermixed with the former, so is supposed to be only an accidental variety arising from the same seeds. This differs from the former, in the colour of the midrib of the leaves, which in this are pale, but those of the former are red. The flowers and fruit of of this are larger, and the inside of the fruit is white.

The leaves of the small white Guava, are like those of the larger, but the branches of the tree are not so angular; the flowers are much smaller, and the fruit is no larger than a middling Gooseberry, but when ripe has a very strong aromack flavour. This flowers in *June*, and the fruit ripens in autumn.

These plants are propagated by seeds, which when brought over in the entire fruit, gathered full ripe, they will more certainly succeed; these should be sown in pots filled with kitchen-garden earth, and plunged into a hot-bed of tanners bark; in about six weeks the plants will appear (if the seeds are good) when they must have free air admitted to them, in proportion to the warmth of the season; when the plants have obtained strength enough to remove, they should be each planted in a small pot, filled with the like earth, and plunged into a fresh hot-bed, shading them from the sun, until they have taken new root; then they should have a large share of free air admitted to them every day in warm weather, to prevent their drawing up weak; they must also be frequently refreshed with water in summer. In the autumn they must be plunged into the tan-bed in the stove; during the winter they should be kept in a moderate warmth, and not have too much water; in summer they will require plenty of wet, and in hot weather a great

share of air. With this management the plants will produce flowers and fruit the third year, and may be continued a long time.

PSORALEA. *Lin. Gen. Plant.* 801. Barba Jovis.

The Characters are,

The empalement of the flower is cut into five parts, the lower segments being twice the length of the other. The flower is of the butterfly kind; it hath five petals; the standard is roundish, and indented at the top. The wings are small, obtuse, and moon-shaped; the keel is moon-shaped, and composed of two petals. It hath nine stamina joined together, and one bristly stamina standing separate, terminated by roundish summits, with a linear germen, supporting an awl-shaped rising style, crowned by an obtuse stigma. The germen afterward turns to a slender compressed pod, inclosing one kidney-shaped seed.

The Species are,

1. PSORALEA *foliis pinnatis, floribus axillaribus.* *Hort. Upsal.* 225. Pforalea with winged leaves, and flowers proceeding from the sides of the stalks.

2. PSORALEA *foliis simplicibus ovatis.* *Hort. Upsal.* 225. Pforalea with single oval leaves.

3. PSORALEA *foliis ternatis, foliis ovatis, caule fruticoso hirsuto, floribus spicatis terminalibus.* Pforalea with trifoliate oval leaves, a hairy shrubby stalk, and flowers growing in spikes terminating the branches.

4. PSORALEA *foliis pinnatis argenteis, caulibus procumbentibus, floribus axillaribus.* Pforalea with silvery winged leaves, trailing stalks, and flowers proceeding from the sides of the stalks.

5. PSORALEA *foliis pinnatis, caule ramofo scandente, floribus alaribus sessilibus.* Pforalea with winged leaves, a climbing branching stalk, and flowers sitting close at the wings of the stalk.

6. PSORALEA *foliis ternatis, caule fruticoso ramofissimo, floribus capitatis pedunculatis alaribus.* Pforalea with trifoliate leaves, a very branching shrubby stalk, and flowers growing in heads, which have foot-stalks, proceeding from the wings of the leaves.

7. PSORALEA *foliis pinnatis, spicis terminalibus.* *Lin. Sp. Plant.* 764. Pforalea with winged leaves, and flowers growing in spikes terminating the branches.

8. PSORALEA *foliis pinnatis, foliolis rotundioribus villosis, floribus capitatis alaribus terminalibusque, caule fruticoso.* Pforalea with winged leaves, having hairy round lobes, flowers growing in heads from the wings of the leaves, and at the end of the branches, and a shrubby stalk.

9. PSORALEA *foliis ternatis, foliolis ovatis, floribus capitatis, pedunculis longissimis.* Pforalea with trifoliate leaves, having oval lobes, and flowers growing in heads on very long foot-stalks.

10. PSORALEA *foliis ternatis, foliolis ovato-lanceolatis, floribus capitatis pedunculis longioribus.* Pforalea with trifoliate leaves, having oval spear-shaped lobes, and flowers growing in heads upon long foot-stalks.

The first sort grows naturally at the *Cape of Good-Hope*; it rises with a soft shrubby stalk four or five feet high, garnished with deep green winged leaves, composed of three or four pair of very narrow linear lobes, terminated by an odd one, standing upon short foot-stalks. The flowers sit very close to the branches, coming out from the wings of the leaves; they are often in clusters. The standard, which is erect and reflexed at the top, is of a fine blue; the wings are pale, and the keel white; these flowers are succeeded by short pods the length of the empalement, each containing one kidney-shaped seed. It flowers great part of summer, and the seeds ripen in autumn. This is easily propagated by seeds, which should be sown upon a moderate hot-bed; and when the plants come up, they must

not be drawn weak, so they should have air and but little heat. When they are fit to remove, they should be planted in separate small pots, filled with light earth, and plunged again into the bed, shading them from the sun till they have taken new root; then they should be gradually inured to the open air, into which they should be removed about the end of *May*, and kept abroad till *October*; then they must be placed in the green-house, and treated in the same way as other plants from the same country.

The second sort grows naturally in *India*. This is an annual plant; the stalks rise a foot and a half high, and are garnished at each joint by one oval leaf. The flowers stand upon long slender foot-stalks, which come out at the wings of the leaves, collected into small round heads, and are of a pale flesh colour. It flowers in *July*, and the seeds ripen in autumn. This is propagated by seeds, which must be sown upon a hot-bed in the spring; and when the plants are fit to remove, they should be planted into separate small pots filled with light earth, and plunged into a moderate hot-bed, shading them from the sun till they have taken new root; after which they must have free air admitted to them in warm weather. When the plants have filled the pots with their roots, they should be removed into larger, and the beginning of *July* they may be removed into an airy glass-case, where they may be defended from cold, but should have free air in warm weather; with this care the plants will flower and ripen their seeds.

The third sort was discovered by the late *Dr. Houstoun at La Vera Cruz*. This rises with a shrubby stalk three or four feet high, sending out a few side branches, garnished with oval, trifoliate, hairy leaves, standing upon slender foot-stalks. The flowers are collected in spikes at the end of the branches; they are of a purple colour, and are succeeded by short pods, each containing one kidney-shaped seed. It is propagated by seeds, which must be sown upon a hot-bed, and the plants afterward treated in the same way as the second sort; but as this is an abiding plant, so they must be removed into the stove in autumn, and kept in a moderate warmth in winter; and in summer they must have a large share of air, but should constantly remain in the stove; the second year they will produce flowers, and sometimes their seeds will ripen in *England*.

The seeds of the fourth sort came from *Malabar*. This is an annual plant, with trailing stalks, garnished with silvery leaves, composed of three or four pair of narrow lobes, terminated by an odd one. The flowers grow in small clusters at the wings of the leaves; they are small; and of a purple colour; the seed-pods are short, and have one small kidney-shaped seed in each. This is propagated by seeds, in the same manner as the second sort.

The fifth sort was discovered by the late *Dr. Houstoun at Campeachy*, where it grows naturally. This hath slender, shrubby, climbing stalks, which twine about any neighbouring support; and rise to the height of six or seven feet, garnished with winged leaves, composed of three pair of small, oval, obtuse lobes, terminated by an odd one. The flowers come out in small clusters from the wings of the leaves; they are small, of a bright blue colour, and are succeeded by short pods, including one kidney-shaped seed.

The sixth sort was discovered by the same gentleman, growing naturally at *Campeachy*. This rises with a shrubby stalk seven or eight feet high, sending out many long slender branches on every side, garnished with trifoliate leaves, whose lobes are small and wedge-shaped. The flowers are produced from the wings of the leaves in close small heads, standing upon pretty long foot-stalks; they are blue, and are succeeded by short pods, each containing a single kidney-shaped seed.

These two sorts are propagated by seeds, which must be sown upon a hot-bed, and when the plants come up, they must be treated in the same way as the third sort.

The seventh sort was discovered by the late Dr. *Houfoun* at *La Vera Cruz*. This is an annual plant, with a very branching herbaceous stalk, rising a foot and a half high, garnished with winged leaves, composed of five or six pair of narrow wedge-shaped lobes, terminated by an odd one. The flowers are collected in close oblong spikes, terminating the branches; they are small, of a bright blue colour, and are succeeded by short pods, each containing a single kidney-shaped seed. This is propagated by seeds, and requires the same treatment as the second sort.

The eighth sort grows naturally at *La Vera Cruz*, from whence the late Dr. *Houfoun* sent the seeds. This hath an upright shrubby stalk, which rises five or six feet high, having a few side branches, closely garnished with winged leaves, composed of three or four pair of small roundish hairy lobes, terminated by an odd one. The flowers are collected in small heads, coming out from the wings of the leaves, and at the end of the branches; they are yellow and red intermixed, and are succeeded by short pods, containing one kidney-shaped seed. This sort requires the same treatment as the third.

The ninth sort grows naturally in the south of *France* and *Italy*. The root of this is perennial, but the stalk is not of long duration, seldom lasting more than two years; it rises about two feet high, sending out two or three slender branches, garnished with trifoliolate leaves, whose lobes are oval, standing upon long foot-stalks; these, if handled, emit a strong scent of bitumen. The flowers are collected in heads, and have foot-stalks seven or eight inches long; they are blue, and are succeeded by short pods, containing one seed.

The tenth sort grows naturally in *Sicily*, and also in *Jamaica*, from both which countries I have received the seeds. This hath been supposed to be the same with the former, but I have many years propagated both by seeds, and have never found either of them vary. The leaves of this are much longer and narrower than those of the former sort, and are rounded at their base; the stalks are shrubby, and of long duration; the heads of flowers are smaller, and the leaves have not so strong an odour. These are propagated by seeds, which should be sown on a bed of light earth in *April*, and in *May* the plants will come up, when they should be kept clean from weeds, and as soon as they are fit to remove, they should be transplanted. Those of the ninth sort will live through the winter in the open air, if they are planted in a warm dry border; but the tenth sort requires some shelter in winter, so these should be planted in pots, and put into a common frame in winter, where they may be screened from hard frost. These plants flower from *June* to autumn, and perfect their seeds annually.

PSYLLIUM. See *Plantago*.

PTARMICA. See *Achillea*.

PTELEA. *Lin. Gen. Plant.* 141. Shrub Trefoil.

The Characters are,

The empalement of the flower is cut in four acute parts. The flower has four oval spear-shaped petals; it hath four awl-shaped stamina, terminated by roundish summits, and an orbicular compressed germen, supporting a short style, crowned by two obtuse stigmas. The germen afterward becomes a roundish membranaceous capsule with two cells, each containing one obtuse seed.

The Species are,

1. PTELEA *foliis ternatis*. *Lin. Sp. Plant.* 118. Ptelea with trifoliolate leaves; commonly called *Carolina Shrub Trefoil*.

2. PTELEA *foliis simplicibus*. *Lin. Sp. Plant.* 118. Ptelea with single leaves.

The first sort grows naturally in *North America*. It was first discovered in *Virginia* by Mr. *Banister*, who sent the seeds to *England*, from which some plants were raised at *Fulham*, and other curious gardens, but being planted in the open air, they were destroyed by a severe winter, so that there were scarce any of the plants left in *England*; but in 1724, Mr. *Catesby* sent over a good quantity of the seeds from *Carolina*, which succeeded so well, as to furnish many gardens with the plants. This rises with an upright woody stem twelve or fourteen feet high, dividing into many branches, covered with a smooth grayish bark, garnished with trifoliolate leaves, standing upon long foot-stalks. The lobes are oval, spear-shaped, smooth, and of a bright green on their upper side, but pale on their under; these come out late in the spring, and at the same time the bunches of flower-buds appear, which is generally in the beginning of *June*, the leaves being then but small, and afterward increase in their size, but are not fully grown till the flowers decay. The flowers are produced in large bunches at the end of the branches; they are of an herbaceous white colour, composed of four or five short petals, ending in acute points, fastened at their base to a short empalement, cut into four segments almost to the bottom. In the center is situated an orbicular compressed germen, supporting a short style, which is attended by four awl-shaped stamina; the germen afterward turns to a capsule, surrounded by a leafy border, having two cells, each containing one seed.

These shrubs may be propagated by cuttings, which should be planted in pots, and plunged into a moderate hot-bed. The best time for planting them is in the beginning of *March*; but they must be carefully managed, so as not to have too much heat, and shaded from the sun in the middle of the day, otherwise they will not succeed. They may also be propagated by layers, but these are often two years before they take root; but if good seeds can be procured either here or from abroad, the plants raised from those will be much stronger, than those which are propagated by either of the former methods.

The seeds may be sown in the beginning of *April*, on a bed of light earth, in a warm sheltered situation, where, if the ground is moistened in dry weather, the plants will come up in two months; but if the seeds are sown in pots, and placed on a very moderate hot-bed, the plants will come up sooner, and make greater progress the first year, but they must not be forced or drawn, for that will make them very tender; therefore in *June* the plants should be exposed to the open air, in a sheltered situation, where they may remain till the frost comes on; when those in the pots should be either placed under a common frame, to shelter them from severe frost, or the pots plunged into the ground, near a hedge, that the frost may be prevented from penetrating through the sides of the pots to the roots of the plants. The following spring the plants may be planted into a nursery-bed, at about one foot distance, where they may grow two years, by which time they will be fit to transplant where they are designed to remain.

These plants are a little tender while they are young, therefore will require some protection the first and second years, but particularly from the early frosts in autumn, which frequently kill the tops of the tender shoots before they are hardened; and the more vigorous the plants have grown the preceding summer, the greater danger there is of their being killed, therefore they should be screened either with mats, or some other covering; but as they advance in strength, they become more hardy, and are rarely injured by frost.

The second sort grows naturally in both *Indies*. It is very common in most of the islands in the *West-Indies*. This sends up several stalks from the root, about the size of a man's

man's arm, sending out several upright branches, covered with a light brown bark, which frequently separates from the wood, and hangs loose; they are garnished with stiff leaves, which vary greatly in their shape and size; they are spear-shaped, entire, and of a light green, growing with their points upward, and have very short foot-stalks. The flowers are produced at the end of the branches in a sort of racemus, each standing upon a slender foot-stalk; they have four solid channelled petals, of an herbaceous colour, having four stamina, which spread open, and in the center is situated a roundish compressed germen, which afterward turns to a compressed capsule with three cells, surrounded by a broad leafy border, each cell containing one or two roundish seeds.

This plant is propagated by seeds, which, if obtained fresh from abroad, will rise easily upon a hot-bed; when the plants are fit to remove, they should be each planted in a separate small pot, filled with light loamy earth, and plunged into a hot-bed of tanners bark, shading them from the sun till they have taken new root; then they should have free air admitted to them every day, in proportion to the warmth of the season, for they must not be drawn up weak, nor should they have too much water. In the autumn, the plants must be removed into the stove, where they should have a temperate warmth in winter, but during that season little water should be given them; nor should they have too much heat, for either of these will soon destroy them: as the plants obtain strength, so they will become more hardy, and may be set abroad in the open air for two or three months in the heat of summer, but it should be in a sheltered situation; in the winter they must be placed in a stove, kept to a moderate temperature of warmth, for the plants will not live in a green-house here.

This was formerly shewn for the Tea-tree in many of the European gardens, where it many years passed for it among those who knew no better.

PULEGIUM. *Raii Meth. Plant.* 61. Pennyroyal, or Pudden-grafs.

The Characters are,

The empalement of the flower is permanent, cut into five parts. The flower is of the lip kind; it hath one petal, with a short tube, divided at the brim into four parts; the helmet or upper lip of the flower, is entire; the lower is cut into three equal segments. It hath four stamina, two being longer than the other, terminated by roundish summits, and a four-pointed germen, supporting an erect style, crowned by a bifid stigma. The germen afterward becomes four small seeds, sitting in the empalement of the flower.

The Species are,

1. **PULEGIUM** *foliis ovatis obtusis, staminibus corollam æquantibus, caule repente.* Pennyroyal with oval obtuse leaves, stamina equalling the petal, and a creeping stalk; common or broad-leaved Pennyroyal.

2. **PULEGIUM** *foliis lanceolatis, staminibus corollâ longioribus, caule erecto.* Pennyroyal with spear-shaped leaves, stamina longer than the petal, and an upright stalk.

3. **PULEGIUM** *foliis linearibus, floribus verticillatis terminalibusque.* Pennyroyal with linear leaves, and flowers growing in whorls at the ends of the stalks; narrow-leaved Pennyroyal.

The first sort grows naturally upon moist commons, where the water stands in winter, in many parts of England. The root is fibrous and perennial; the stalks are smooth, and trail upon the ground, putting out roots at every joint, whereby it spreads and propagates very fast; the stalks are garnished at each joint by two oval leaves, which are for the most part entire. The flowers grow toward the upper part of the branches, coming out just above the leaves at each joint in whorls; they are of a pale pur-

ple colour, small and galeated, the helmet being entire; whereas in the Mint, this is indented at the point. The stamina of the flowers are of the same length with the petal, but the style is somewhat longer; the whole plant has a very strong smell, and a hot aromack taste. There is a distilled water of this plant, and also an oil, which is kept in the shops for medicinal use. There is a variety of this with a white flower, which is sometimes found growing naturally in England.

The seeds of the second sort were sent me from Gibraltar, which succeeded in the Chelsea garden, but had been before introduced into several gardens, where it had been cultivated to supply the markets. The stalks of this grow erect, and near a foot high; the leaves are longer and narrower than those of the common sort; the whorls of flowers are much larger, and their stamina are longer than the petals. This sort hath almost superseded the first in the markets, for as the stalks grow erect, so it is much easier to cut and tie in bunches than the common sort; it also comes earlier to flower, and has a brighter appearance, but whether it is as good for use, I shall leave to be determined by those whose province it belongs to.

The third sort grows naturally in the south of France and Italy; it is called Hart's Pennyroyal. This is by some preferred to the common sort for medicinal use; the stalks of this grow erect, near two feet high, sending out side branches all their length; the leaves are very narrow, and of a thicker substance than those of the common sort; the whorls of flowers are rather larger; the scent is not quite so strong as that of the first sort, and the stalks are frequently terminated by whorls of flowers. This is cultivated in gardens here, and flowers about the same time as the common sort. There is a variety of this with white flowers, which grows taller than that with purple flowers, but I do not believe it is a different sort.

All these plants propagate themselves very fast by their branches trailing upon the ground, which emit roots at every joint, and fasten themselves into the earth, and send forth new branches; so that no more is required in their culture, than to cut off any of these rooted branches, and plant them out in fresh beds, allowing them at least a foot from plant to plant every way, that they may have room to grow; or the young shoots of these planted in the spring, will take root like Mint.

The best time for this work is in September, that the plants may be rooted before winter; for if the old roots are permitted to remain so close together, as they generally grow in the compass of a year, they are subject to rot in winter; besides, the young plants will be much stronger, and produce a larger crop the succeeding summer, than if they were removed in the spring. These plants all love a moist strong soil, in which they will flourish exceedingly.

PULMONARIA. *Tourn. Inst. R. H.* 136. tab. 55. Lungwort.

The Characters are,

The flower hath a cylindrical permanent empalement, cut into five parts at the top. The flower is of one petal, having a cylindrical tube, cut at the top into five parts, which spread open, but the chaps are pervious. It hath five short stamina, terminated by erect summits, which close together, and four germen, supporting a short style, crowned by an obtuse indented stigma. The germen afterward turns to four roundish seeds, sitting in the bottom of the empalement.

The Species are,

1. **PULMONARIA** *foliis radicalibus ovato-cordatis scabris.* Hort. Cliff. 44. Lungwort, whose lower leaves are oval, heart-shaped, and rough; common spotted Lungwort, or Jerusalem Cowslip.

2. *PULMONARIA foliis caulinis ovatis glabris, floribus patulis, segmentis obtusifusculis.* Lungwort with oval smooth leaves to the stalks, spreading flowers, and obtuse segments.

3. *PULMONARIA foliis lanceolatis basi semiamplexicaulibus, calycibus abbreviatis.* Lungwort with spear-shaped leaves, whose base half embraces the stalk, and the empalement shorter than the tube of the flower.

4. *PULMONARIA foliis radicalibus lanceolatis.* Hort. Cliff. 44. Lungwort with the lower leaves spear-shaped.

5. *PULMONARIA caulibus procumbentibus, floribus singularibus alaribus, calycibus inflatis corollâ longioribus.* Lungwort with trailing stalks, flowers growing singly from the sides, and swollen empalements, which are longer than the petal.

6. *PULMONARIA calycibus abbreviatis, foliis lanceolatis obtusifusculis.* Lin. Sp. Plant. 135. Lungwort with short empalements to the flowers, and spear-shaped obtuse leaves.

The first sort grows naturally in woods and shady places, in *Italy* and *Germany*, and is cultivated in the *English* gardens chiefly for medicinal use. It hath a perennial fibrous root; the lower leaves are rough, of an oval heart-shape, of a dark green on their upper side, marked with many broad whitish spots, but pale and unspotted on their under; the stalks rise almost a foot high, having several smaller leaves on them, standing alternately. The flowers are produced in small bunches on the top of the stalks, each having a tubulous hairy empalement, as long as the tube of the flower; the brims of the petal are spread open above them, which are shaped like a cup; these are red, purple, and blue, in the same bunch, and are succeeded by four naked seeds, which ripen in the empalement. It is accounted a pectoral balsamick plant, and good for coughs and consumptions, spitting of blood, and the like disorders of the lungs; it is likewise put into wound-drinks.

The second sort grows naturally on the *Alps*. This hath a perennial fibrous root; the leaves are large, smooth, and spotted on their upper side; the stalks rise nine inches high, garnished with oval leaves, whose base join the stalks. The flowers grow in small bunches on the top of the stalk; they are purple, and spread open wider than those of the common sort.

The third sort grows naturally upon the *Helvetian* mountains. It is a perennial plant, whose leaves are large, spear-shaped, and rough. The foot-stalks of the lower leaves are broad; the stalks rise a foot high, garnished with spear-shaped leaves, whose base half embrace the stalks; they are greatly spotted with white, appearing as if they were incrustated with sugar-candy; the flowers grow in large bunches on the top of the stalk; their tubes are longer than the empalement, and their brims are spread more than those of the common sort. They are of a bright blue.

The fourth sort grows naturally in *Austria* and *Hungary*. This hath leaves much narrower than those of the common sort, covered with soft hairs. The stalks rise a foot high, garnished with narrow leaves, of the same shape with those below, but smaller; these almost embrace the stalk with their base. The flowers are produced in bunches on the top of the stalks like the others; they are of a red colour before they expand, but, when they are fully blown, of a most beautiful blue colour.

The fifth sort was discovered in the *Archipelago* by Dr. *Tournefort*. This is an annual plant. The lower leaves are oblong and hairy; the stalks trail upon the ground, and are garnished with oblong hairy leaves, sitting close to the stalks; just above each leaf comes a single flower of a sullen purple colour, funnel shaped, the brims not spreading; the empalement is swollen like an inflated bladder, and covers the petal of the flower, so as not to be seen without a near inspection; after the flowers are past, the four seeds ripen in the empalement.

The sixth sort grows naturally upon mountains in most parts of *North America*. The seeds of this plant were sent many years since by Mr. *Banister* from *Virginia*, and some of the plants were raised in the gardens of the bishop of *London* at *Fulham*, where for several years it was growing. This hath a thick, fleshy, perennial root, sending out many small fibres. The stalks rise a foot and a half high; the leaves, which are near the root, are long, smooth, obtuse, and of a light green, having short foot-stalks; those upon the stalk diminish in their size upward, but are of the same shape, and sit close to the stalk. Each of the small branches is terminated by a cluster of flowers, whose empalements are very short, and are cut into five segments almost to the bottom; the tube of the flower is long, and at the top spreads open in shape of a funnel, the brim being entire, but appears five-cornered from the folding of the petal. The most common colour of these flowers is blue, but there are some purple, others red, and some white. The leaves and stalks entirely decay in *August*, and the roots remain naked till the following spring.

There are some other species of this genus, which are preserved in botannick gardens for the sake of variety, but, having little beauty, they are seldom cultivated in other places.

The first, second, third, fifth, and sixth sorts have perennial roots, so may be cultivated by parting of their roots, which is best done in the autumn, that the plants may be well rooted before the dry weather comes on in the spring, which will cause them to flower much stronger.

The soil in which they are planted should not be rich, but rather a fresh light sandy ground, in which they will thrive much better. They should have a shady situation, and the first and third sorts thrive best in a moist soil, for in a hot dry soil they burn and decay in summer, unless they are duly watered in dry weather. The sixth sort should not have a soil too moist, for as the roots run deep in the ground, they will be in danger of rotting by much wet.

The other sort is annual, so is propagated by seeds. The best time to sow these is in autumn, soon after they are ripe, for the plants will resist the cold of our winters very well, and will flower early the following summer, so good seeds may be obtained; whereas, those which are sown in the spring sometimes miscarry, or lie a year in the ground. These seeds should be sown where they are designed to remain, for the plants do not succeed very well, when they are transplanted. When the plants come up, they require no other culture, but to keep them clear from weeds, and, where they are too close, to thin them. If these plants are permitted to scatter their seeds, they will come up better than when they are sown.

PULSATILLA. Tourn. Inst. R. H. 234. tab. 148. Pasque-flower.

The Characters are,

The flower hath a leafy involucre, ending in many points; it hath two orders of petals, three in each, and a great number of slender stamina, about half the length of the petals, terminated by erect twin summits, and a great number of germen collected in a head. The germen afterward becomes so many seeds, having long hairy tales sitting upon the oblong receptacle.

The Species are,

1. *PULSATILLA foliis decompositis pinnatis, flore nutante, limbo erecto.* Hort. Cliff. 223. Pasque flower with decomposed winged leaves, and a nodding flower, having an erect rim.

2. *PULSATILLA foliis decompositis pinnatis, flore pendulo, limbo reflexo.* Hort. Cliff. 223. Pasque flower with decomposed winged leaves, and a pendulous flower, whose border is reflexed.

3. *PULSATILLA foliis simpliciter pinnatis, foliolis lobatis, flore erecto.* Flor. Suec. 448. Pasque-flower with simple winged leaves, whose wings have lobes, and an erect flower.

4. *PULSATILLA foliis digitatis multifidis, flore erecto patente.* Pasque-flower with hand-shaped leaves, having many points, and an erect spreading flower.

The first of these plants is common in divers parts of *England*; it grows in great plenty on *Gogmagog* hills on the left-hand of the highway leading from *Cambridge* to *Haveril*, just on the top of the hill; also about *Hildersham*, six miles from *Cambridge*, and on *Bernack Heath* not far from *Stamford*, and an *Southrop Common* adjoining thereto; also on mountains and dry pastures just by *Leadstone Hall* near *Pentefract* in *Yorkshire*.

This hath a fleshy taper root, which runs deep in the ground; the leaves are hairy, and finely cut, like those of the wild Carrot; the stalk rises a foot high, is pretty thick, hairy, and naked to the top, where there is a leafy involucre to the flower, which is hairy, ending in many points; it is terminated by one flower, composed of six petals, ranged in two orders, three without, and three within; they are oblong, thick, and of a purple colour, bell-shaped, nodding on one side, and their points turn upward. Within the petals are a great number of slender yellowish stamina, terminated by erect summits, and in the center a great number of germen are collected in a head, which afterward become seeds, each having a long tail, by which they are distinguished from *Anemone*.

There is a variety of this with double flowers, and another with white, but these have been obtained from seeds of the other.

The second sort hath shorter leaves than the first; the stalks do not rise so high; the flowers do not expand so wide, and hang downward, but their brims are reflexed; they are of a very dark purple colour. This grows naturally in the meadows in *Germany*.

The third sort grows naturally on the *Alps* and *Helvetian* mountains; this hath a perennial root. The leaves are like those of *Smallage*, and are simply winged; the stalk rises near a foot high, is naked almost to the top, where comes out a neat hairy involucre, and above that one yellow flower, shaped like the perennial yellow *Adonis* standing erect.

The fourth sort grows in *Siberia*; it hath a thick fleshy root, which sends out many strong fibres. The leaves are hand-shaped, composed of several roundish lobes, like some of the sorts of *Ranunculi*; they are downy, and cut into several segments. The stalk rises nine or ten inches high, having a hairy involucre a considerable distance below the flower; it is terminated by one flower, which is large, spreading, and of a whitish yellow colour, with deep yellow stamina.

There are some other species of this plant, but those here mentioned are all the sorts which I have seen growing in *England*, and therefore I have not enumerated more, as it would be to little purpose, since it is difficult to procure them from the countries where they naturally grow.

These plants may be propagated by seeds, which should be sown in boxes or pots filled with very light sandy earth, observing not to cover the seeds too deep with mould, which will prevent their rising, for they require no more than just to be covered. These boxes should be placed where they may have the morning sun until ten of the clock, but must be screened from it in the heat of the day, and, if the season proves dry, the earth should be often refreshed with water. The best time for sowing of these seeds is in *July*, soon after they are ripe, for if they are kept till spring, they seldom grow.

The boxes or pots, in which the seeds are sown, should remain in this shady situation until the beginning of *October*, when they should be moved where they may enjoy the full sun during the winter season. About the beginning of *March* the plants will begin to appear, at which time the boxes should be again removed, where they may have only the forenoon sun; for if they are too much exposed to the heat, the young plants will die away. They should also be refreshed with water in dry weather, which will greatly promote their growth, and they must be carefully kept clean from weeds, which, if suffered to grow among them, will in a short time destroy them.

When the leaves of these plants are entirely decayed (which is commonly in *July*), you should then take up the roots, which, being nearly of the colour of the ground, will be difficult to find while small; therefore you should pass the earth through a fine wire-sieve, which is the best method to separate the roots from the earth (but notwithstanding all possible care taken, yet there will be many small roots left; so that the earth should either be put into the boxes again, or spread upon a bed of light earth, to see what plants will arise out of it the succeeding year). The roots, being taken up, should be immediately planted again in beds of fresh loamy earth, about three or four inches asunder, covering them about three inches thick with the same earth. The spring following most of these plants will produce flowers, but they will not be so large and fair as in the succeeding years, when the roots are larger.

The roots of these plants generally run down deep in the ground, and are of a fleshy substance, somewhat like Carrots, so will not bear to be kept long out of the ground; therefore, when they are removed, it should be done in autumn, that they may take fresh root before the frost comes on, for if they are transplanted in the spring, they will not produce strong flowers. These plants thrive best in a loamy soil, for in very light dry ground they are apt to decay in summer.

PUMPKION. See Pepo.

PUNICA. Tourn. Inst. R. H. 633. tab. 407. The Pomgranate-tree.

The Characters are,

The empalement of the flower is bell-shaped, coloured, and cut into six parts at the top. The flower has five roundish, erect, spreading petals, which are inserted in the empalement, and a great number of slender stamina, which are also inserted in the empalement, terminated by oblong summits. The germen is situated under the flower, supporting a single style, crowned by a beaded stigma; it afterward becomes a large almost globular fruit, crowned by the empalement. The fruit is divided into several cells by membranous partitions, which are filled with roundish succulent seeds.

The Species are,

1. *PUNICA foliis linearilanceolatis, caule arborecente, flore majore.* Pomgranate with linear spear-shaped leaves, a tree-like stalk, and a larger flower.

2. *PUNICA foliis linearibus, caule frutescente, flore minore.* Pomgranate with linear leaves, a shrubby stalk, and a smaller flower; dwarf Pomgranate.

There are the following varieties of the first sort, which are supposed to be accidentally obtained by culture from the seeds, therefore I have not enumerated them as species; but as many curious persons will expect to find them inserted here, I shall just mention them.

The wild Pomgranate, with single and double flowers.

The sweet Pomgranate.

The small flowering Pomgranate, with single and double flowers.

The Pomgranate with striped flowers.

These plants grow naturally in *Spain, Portugal, Italy, and Mauritania*. There are also many of them in the *West-Indies*, but they are supposed to have been transplanted there from *Europe*. They are so much improved there, as to be much preferable to any in *Europe*, the fruit being larger and finer flavoured.

This tree rises with a woody stem eighteen or twenty feet high, garnished with narrow spear-shaped leaves, of a light lucid green, and stand opposite. The flowers come out at the end of the branches sometimes singly, and at others three or four together; one of the largest terminating the branch, and immediately under that are two or three smaller buds, which, after the flower is past, swell larger, and expand, whereby there is a continued succession of flowers for some months. The empalement of the flower is very thick, fleshy, and of one piece cut at the top into five segments; it is of a fine red colour, and within are included five (in the single flowers, but in the double a great number) of scarlet petals, which are inserted in the empalement. In the center is situated the style, arising from the germen, encompassed by many slender stamina, which are terminated by oblong yellowish summits. After the flower decays, the germen swells to a roundish fruit, crowned by the empalement, having a hard shell, including a pulp, filled with angular seeds.

The Balautia of the shops is the empalement of the flower of the double flowering Pomgranate.

The first of these trees is now pretty common in the *English* gardens, where formerly it was nursed up in cases, and preserved in green-houses with great care (as was also the double-flowering kind); but they are both hardy enough to resist the severest cold of our climate in the open air, and, if planted against warm walls in a good situation, the first sort will often produce fruit, which in warm seasons will ripen tolerably well; but as these fruits do not ripen till late in the autumn, they are seldom well tasted in *England*, for which reason the sort with double flowers is commonly preferred to it. The sort with sweet fruit, as also the wild sort, are less common in the *English* gardens than the former two.

These plants may be easily propagated by laying down their branches in the spring, which in one year's time will take good root, and may then be transplanted where they are designed to remain. The best season for transplanting of these trees is in spring, just before they begin to shoot; they should have a strong rich soil, in which they flower much better, and produce more fruit, than if planted on dry poor ground; but in order to obtain the flowers in plenty, there should be care taken in the pruning of these trees, for want of which we often see these trees very full of small shoots, but do not find many flowers produced upon them; therefore I shall set down directions for pruning of these trees, so as to obtain a great quantity of flowers and fruit.

The flowers of this tree always proceed from the extremity of the branches, which are produced the same year. This therefore directs, that all weak branches of the former year should be cut out, and that the stronger should be shortened, in proportion to their strength, in order to obtain new shoots in every part of the tree. The branches may be laid in against the wall about four or five inches asunder; for, as their leaves are small, there is not a necessity of allowing them a greater distance. The best time for this work is about *Michaelmas*, or a little later, according to the mildness of the season, for if they are left until spring before they are pruned, they seldom put out their shoots so early, and the earlier they come out, the sooner the flowers will appear, which is of great consequence where fruit is desired. In summer they will require no other dressing, but to cut off very vigorous shoots, which grow from the wall, and

never produce flowers (for it is the middling shoots only which are fruitful); and when the fruit is formed, the branches on which they grow should be fastened to the wall to support them, otherwise the weight of the fruit, when grown large, will be apt to break them down.

Though, as I said before, the fruit of this tree seldom arrives to any perfection in this country, so as to render it valuable; yet, for the beauty of its scarlet-coloured flowers, together with the variety of its fruit, there should be one tree planted in every good garden, since the culture is not great which they require; the chief care is to plant them upon a rich strong soil, and in a warm situation. Upon some trees which had these advantages, I have obtained a great quantity of fruit, which have arrived to their full magnitude, but I cannot say they were well-flavoured; however, they made a very handsome appearance upon the trees.

The double flowering kind is much more esteemed than the other in this country, for the sake of its large, fine, double flowers, which are of a most beautiful scarlet colour, and, if the trees are supplied with nourishment, will continue to produce flowers for near three months successively. This must be pruned and managed in the same manner as hath been already directed for the fruit-bearing kind, but this sort may be rendered more productive of its beautiful flowers, by grafting it upon stocks of the single kind, which will check the luxuriance of the trees, and cause them to produce flowers upon almost every shoot; by which method I have had a low tree, which was planted in the open air, extremely full of flowers, which made a very fine appearance.

The second sort grows naturally in the *West-Indies*, where the inhabitants plant it in their gardens to form hedges. It seldom rises more than five or six feet high in those countries, so may be kept within compass, and there the plants continue flowering great part of the year. The flowers of this kind are much smaller than those of the common sort; the leaves are shorter and narrower, and the fruit is not larger than a Nutmeg, and has little flavour, so it is chiefly propagated for the beauty of its flowers. This is undoubtedly a distinct species from the common sort, and is much tenderer.

This plant may be propagated by layers in the same manner as the former sorts, but must be planted in pots filled with rich earth, and preserved in a green-house, otherwise it is too tender to endure the cold of our winters, for though it may live abroad in a warm situation, yet it will make little progress in the summer, when the flowers begin to appear; if the plants are exposed to the open air, the buds often fall off, and never open, so that they should not be exposed to the open air, but placed in an airy glass-case, giving them a large share of air every day in mild weather. As they will be covered at the top by the glasses, the flowers will expand, and the fruit will grow to the full size in *England* with this management, though they are not very desirable; but hereby the plants may be continued in flower upward of three months, and will make a fine appearance.

PURSLAIN. See *Portulaca*.

PYRACANTHA. See *Mespilus*.

PYROLA. *Tourn. Inst. R. H. 256. tab. 132. Lin. Gen. Plant. 490. Winter-green.*

The Characters are,

The flower hath a permanent empalement cut into five parts; it hath five roundish, concave, spreading petals, and ten awl-shaped stamina, terminated by large nodding summits, with two rising horns, and a roundish germen, supporting a slender style, which is longer than the stamina, crowned by a thick stigma. The germen afterward becomes a roundish, depressed, five-cornered

capsule, with five cells opening at the angles, filled with seeds.

The Species are,

1. PYROLA *flaminibus adscendentibus, pistillo declinato*. Flor. Suec. 330. Winter-green with rising stamina, and a declining pointal.

2. PYROLA *racemo unilaterali*. Flor. Suec. 332. Winter-green with a bunch of flowers ranged on one side the foot-stalk.

3. PYROLA *scapo uniflora*. Flor. Lapp. 167. Winter-green with one flower on the stalk.

4. PYROLA *pedunculis bifloris*. Lin. Sp. Plant. 396. Winter-green with two flowers on a foot-stalk.

The first sort grows wild in many places in the north of England, particularly near *Hallifax* in *Yorkshire*, on rocky hills and heaths, as also in shady woods, so it is very difficult to preserve in gardens in the southern parts.

This hath a perennial root, from which spring out five or six roundish leaves about an inch and a half long, and almost as broad, of a thick consistence, of a deep lucid green, and entire, standing upon pretty long foot-stalks. Between these arise a slender upright stalk near a foot high, naked great part of the length, ending in a loose spike of flowers, which are composed of five large concave white petals, spreading open like a Rose, but the two upper leaves are formed into a kind of helmet. In the center is situated a crooked pointal, bending downward, attended by ten slender stamina, terminated by saffron-coloured summits.

The second sort grows naturally upon mountains in *Italy*, particularly near *Verona* and *Genoa*, and I have found it growing in *Westmoreland*. This hath a slender creeping perennial root, from which arise two or three very slender ligneous stalks about five inches high, sustaining at the top four or five oval acute-pointed leaves an inch and a half long, and one broad, of a thinner consistence, and a brighter green than those of the former, each standing upon a short foot-stalk; and between these, on the side of the stalk, comes out the foot-stalk of the flowers, upon which they are ranged along one side; they are shaped like the other, but are smaller, as are also the capsules.

The third sort grows naturally in shady woods in the northern parts of *Europe*. This hath a perennial creeping root, from which come forth four or five roundish leaves, of a pretty thick consistence, and between these arises a foot-stalk about four inches high, sustaining one large white flower on the top, of the same shape as the others.

The fourth sort grows naturally in *North America*. This hath a ligneous perennial root, from which arise two or three ligneous stalks a foot and a half high, garnished with stiff leaves two or three inches long, ending in acute points, having some sharp indentures on their borders; the midrib is remarkably broad, and very white, as are also the veins which run from it. The flowers are produced at the end of the stalk on slender foot-stalks about three inches long, each sustaining two small pale-coloured flowers at the top.

These are all of them very difficult to cultivate in gardens, for as they grow on very cold hills, and in mossy moorish soil, when they are removed to a better soil, and a warmer situation, they seldom continue long. The best time to transplant these plants into gardens is about *Michaelmas*, provided the roots can then be found, when they should be taken up with balls of earth to their roots, and planted in a shady situation, and on a moist undunged soil, where they should be frequently watered in dry weather, otherwise they will not thrive. Some of these plants may be planted in pots, which should be filled with earth as nearly resembling that, in which they naturally grow, as possible, and place them in a shady situation, where, if they are constantly watered in dry weather, they will thrive very well.

The first sort is ordered by the College of Physicians to be used in medicine, and is generally brought over from *Switzerland* amongst other vulnerary plants, in which class this plant is ranged, and by some hath been greatly commended.

PYRUS. *Tourn. Inst. R. H. 628. tab. 404.* The Pear-tree.

The Characters are,

The flower hath a permanent empalement of one leaf, which is divided into five parts at the top; it hath five roundish concave petals, which are inserted in the empalement, and about twenty awl-shaped stamina shorter than the petals inserted in the empalement, and terminated by single summits. The germen is situated under the flower, supporting three or four styles, crowned by single summits; it afterward becomes a pyramidal fleshy fruit, indented at the top, but produced at the base, having five membranaceous cells, each containing one smooth oblong seed pointed at the base.

The Pear and Quince may be joined together with more propriety than the Apple with either, for the fruit of the two former are produced at their base, whereas the Apple is indented, nor will the Apple grow upon either of the other two, or those upon the Apple, when grafted or budded, but the Quince or Pear will grow upon each other; so there is a boundary set by nature between those and the Apple.

The several varieties of Pears, which are now cultivated in the curious fruit gardens, have been accidentally obtained by seeds, so must not be deemed distinct species; but, as they are generally distinguished in the fruit-gardens and nursery by the shape, size, and flavour of their fruit; I shall continue those distinctions, that the work may not appear imperfect to such as delight in the cultivation of these fruits.

The Varieties are,

1. PYRUS *sativa, fructu aestivo parvo racemoso odoratissimo*. *Tourn.* Petit Muscat, *i. e.* Little Musk Pear, commonly called the Supreme. This fruit is generally produced in large clusters; it is rather round than long; the stalk short; and, when ripe, the skin is of a yellow colour; the juice is somewhat musky, and, if gathered before it is too ripe, is a good Pear. This ripens the beginning of *July*, and will continue good but for a few days.

2. PYRUS *sativa, fructu aestivo minimo odoratissimo*. *Tourn.* Poire de Chio, *i. e.* The Chio Pear, commonly called the little Bastard Musk Pear; this is smaller than the former; but is in shape pretty much like that. The skin, when ripe, has a few streaks of red on the side next the sun, and the fruit seldom hangs in clusters as the former, but in other respects is nearly like that.

3. PYRUS *sativa, fructu aestivo parvo, è virido albido*. *Tourn.* Poire Hâtiveau, *i. e.* the Hasting Pear: Poire Madeleine, ou Citron des Carmes. This is a larger Pear than either of the former, and is produced more toward the pedicle. The skin is thin, and of a whitish green colour when ripe; the flesh is melting, and, if not too ripe, of a sugary flavour, but is apt to be meally. This ripens in the middle of *July*.

4. PYRUS *sativa, fructu aestivo partim saturatè rubente, partim flavescente*. *Tourn.* Muscadelles Rouges, *i. e.* the red Muscadelle. It is also called La Bellissime. This is a large early Pear, of great beauty; the skin is of a fine yellow colour, when ripe, beautifully striped with red; the flesh is half melting, and has a rich flavour, if gathered before it be too ripe, but it is apt to be meally.

5. PYRUS *sativa, fructu aestivo parvo flavescente moscato*. *Tourn.* Petit Muscat, *i. e.* the little Muscat. This is a small Pear, rather round than long; the skin is very thin, and, when ripe, of a yellowish colour; the flesh is melting,

of a musky flavour, but will not keep long when ripe. This comes the end of July.

6. *PYRUS sativa, fructu aestivo oblongo ferrugineo, carne tenerâ moschatâ. Tourn.* Cuisse Madame, Lady's Thigh, in England commonly called Jargonelle. This is a very long Pear, of a pyramidal shape, having a long foot-stalk; the skin is pretty thick, of a russet green colour from the sun, but towards the sun it is inclined to an iron colour; the flesh is breaking, and has a rich musky flavour. Ripe the beginning of August. This is one of the best early summer Pears yet known, and is certainly what all the French gardeners call the Cuisse Madame, as may be easily observed by their description of this Pear; but I suppose that the titles of this and the Jargonelle, were changed in coming to England, and have been continued by the same names.

7. *PYRUS sativa, fructu oblongo, è viridi flavescente.* The Windsor Pear. This is an oblong fruit, which swells toward the crown, but near the stalk is drawn toward a point; the skin is smooth, and, when ripe, of a yellowish green colour; the flesh is very soft, and, if permitted to hang but two or three days after it is ripe, grows meally, and is good for nothing.

8. *PYRUS sativa, fructu aestivo oblongo, è viridi albo.* The Jargonelle, now commonly called Cuisse Madame. This is certainly what the French gardeners call the Jargonelle, which, as I before observed, is now in England given to another fruit much preferable to this, so that the two names are changed; for the Jargonelle is always placed amongst those which the French call bad fruit, and the Cuisse Madame is set down amongst their best fruit, which is certainly the reverse with us, as they are now named. This Pear is somewhat like the Windsor, but is not so swelling toward the crown, and is smaller toward the stalk; the skin is smooth, of a pale green colour; the flesh is apt to be meally, if it stands to be ripe, but, being a plentiful bearer, is much propagated for the London markets.

9. *PYRUS sativa, fructu aestivo globoso sessili moscato, maculis nigris conferso. Tourn.* Orange Mosquée, *i. e.* the Orange Musk. This is a middle-sized Pear, of a short globular form; the skin is of a yellowish colour, spotted with black; the flesh is musky, but is very apt to be a little dry and choaky. It ripens the beginning of August.

10. *PYRUS sativa, fructu aestivo albido majori. Tourn.* Gros Blanquet, *i. e.* Great Blanket. This is also called La Muffette d'Anjou, *i. e.* the Bagpipe of Anjou. This is a large Pear approaching to a round form; the skin is smooth, of a pale green colour; the flesh is soft, and full of juice, which hath a rich flavour; the stalk is short, thick, and spotted; the wood is slender, and the leaf is very much like that of the tree called the Jargonelle. This ripens the beginning of August.

11. *PYRUS sativa, fructu aestivo albido saccharato odoratissimo. Tourn.* The Blanquette, or Musk Blanquette; the little Blanket Pear. This Pear is much less than the former, and more pinched in near the stalk, which is also short, but slenderer than that of the former; the skin is soft, of a pale green colour; the flesh is tender, and full of a rich musky juice; the wood of this tree is much stronger than is that of the former, and the shoots are commonly shorter. This ripens the middle of August.

12. *PYRUS sativa, fructu aestivo albido, pediculo longo donato. Tourn.* Blanquette à longue queue, *i. e.* Long-stalked Blanket Pear. This Pear is in shape somewhat like the former, but the eye is larger, and more hollowed at the crown; toward the stalk it is somewhat plumper, and a little crooked; the skin is very smooth, white, and sometimes toward the sun is a little coloured; the flesh is between melting and breaking, and is full of a rich sugary juice. This ripens the middle of August.

13. *PYRUS sativa, fructu aestivo oblongo rufescente saccharato. Tourn.* Poire sans Peau, *i. e.* the Skinless Pear. It is also called Fleur de Guigne, *i. e.* Flower of Guigne, and by some Rouffelet hâtif, *i. e.* the early Russelet. This is a middle-sized fruit, of a long shape, and a reddish colour, somewhat like the Russelet; the skin is extremely thin; the flesh is melting, and full of a rich sugary juice; the shoots are long and strait. This ripens the middle of August.

14. *PYRUS sativa, fructu aestivo turbinato, carne tenerâ saccharatâ. Muscat Robine, i. e. the Musk Robine Pear.* This is also called Poire à la Reine, *i. e.* the Queen's Pear; Poire d'Ambre, *i. e.* the Amber Pear; and Pucelle de Xaintonge, *i. e.* the Virgin of Xaintonge. This is a small round Pear, of a yellowish colour when ripe; the flesh is between melting and breaking. It hath a rich musky flavour, and is a great bearer. It ripens the middle of August.

15. *PYRUS sativa, fructu aestivo turbinato moscato. La Bourdon Mosque, i. e. the Musk Drone Pear.* This is a middle-sized round fruit, whose skin is of a yellowish colour when ripe; the flesh is melting, and full of a high musky juice, but it must not hang too long on the tree, for it is subject to grow meally in a short time. This ripens the end of August.

16. *PYRUS sativa, fructu aestivo globoso sessili, è viridi purpurascete saccharato odorato. Tourn.* Orange Rouge, *i. e.* the red Orange Pear. This Pear hath been the most common of all the sorts in France, which was occasioned by the general esteem it was in some years since. It is a middle-sized round fruit, of a greenish colour, but the side next the sun changes to a purple colour when ripe; the flesh is melting, and the juice is sugared with a little perfume; the eye is very hollow, and the stalk is short. This ripens the end of August.

17. *PYRUS sativa, fructu aestivo oblongo minori cinereo odorato. Tourn.* Cassolette Friolet, Muscat Verd Lechefrion; this is so called from its being shaped like a perfuming pot. It is a long fruit, in shape like the Jargonelle, of an Ash-colour; its flesh is melting, and full of a perfumed juice, but it is very apt to rot in the middle as soon as ripe, otherwise it would be esteemed an excellent Pear. It is ripe the end of August.

18. *PYRUS sativa, fructu aestivo turbinato, è viridi albido. Orange Musquée, i. e. the Musk Orange Pear.* This is a large round Pear, in shape like a Bergamot; the skin is green, and the flesh is melting, but it is very subject to rot upon the tree, which renders it not near so valuable as some others. It ripens the end of August.

19. *PYRUS sativa, fructu aestivo globoso è viridi purpurascete. Tourn.* Gros Oignonnet, *i. e.* the great Onion Pear. It is also called Amiré-roux, *i. e.* Brown Admired; and Roy d'Été, *i. e.* King of Summer; Archiduc d'Été, *i. e.* the Summer Archduke. This is a middle-sized round Pear, of a brownish colour next the sun; the flesh is melting, and the juice is passably good. This ripens the end of August.

20. *PYRUS sativa, fructu aestivo globoso sessili ex albido flavescete saccharato odorato. Tourn. Robine.* It is also called Muscat d'August, *i. e.* the August Muscat; Poire d'Averat, *i. e.* the Averat Pear; and Poire Royale, *i. e.* the Royal Pear. This is a roundish flat Pear, in shape very like a Bergamot; the stalk is long, strait, and a little spotted, and the eye is a little hollowed; the skin is smooth, of a whitish yellow colour; the flesh is breaking, but not hard, and its juice is richly sugared and perfumed. It is a great bearer, and is esteemed one of the best summer Pears yet known. It ripens the end of August.

21. *PYRUS sativa, fructu aestivo globoso sessili odorato. Tourn.* Poire-rose, *i. e.* the Rose Pear; and L'Épinerose, *i. e.* the Thorny Rose. This is a short round fruit, shaped like the great Onion Pear, but much larger, of a yellowish

green colour, but a little inclining to red on the side next the sun; the stalk is very long and slender; the flesh is breaking, and the juice is musky. This ripens the end of August. The shoots and the leaves of this tree are large.

22. *PYRUS sativa, fructu aestivo globoso albido saccharato.* Tourn. Poire du Pouchet. This is a large round whitish Pear, shaped somewhat like the Besidéri; the flesh is soft and tender, and the juice is sugary. This ripens the end of August.

23. *PYRUS sativa, fructu aestivo turbinato sessili saturatius rubente punctato.* Tourn. Poire de Parfum, *i. e.* the perfumed Pear. This is a middle-sized round fruit, whose skin is somewhat thick and tough, and of a deep red colour spotted with brown; the flesh is melting, but dry, and has a perfumed flavour. This ripens the end of August.

24. *PYRUS sativa, fructu aestivo oblongo magno, partim rubro, partim albido, odorato.* Tourn. Boncrétien d'Été, *i. e.* the Summer Boncrétien, or Good Christian. This is a large oblong fruit, whose skin is smooth and thin; the side next the sun is of a beautiful red colour, but the other side is of a whitish green; the flesh is between breaking and tender, and is very full of juice, which is of a rich perfumed flavour. It ripens the beginning of September.

25. *PYRUS sativa, fructu aestivo globoso, ex rubro albidoque rubente saccharato odorato.* Tourn. Sab-viati. This Pear is large, round, and flat, very much like the Besidéri in shape, but not in colour; the stalk is very long and slender, and the fruit is a little hollowed both at the eye and stalk; the colour is red and yellow next the sun, but on the other side is whitish; the skin is rough; the flesh is tender, but a little soft, and has no core; the juice is sugary and perfumed, somewhat like the Robine, but is not near so moist. This ripens the beginning of September.

26. *PYRUS sativa, fructu aestivo globoso sessili rufescente odorato.* Tourn. Caillot-rosat, *i. e.* Rose-water Pear. This is a large round Pear, somewhat like the Messire-Jean, but rounder; the stalk is very short, and the fruit is hollowed like an Apple, where the stalk is produced; the skin is rough, and of a brown colour; the flesh is breaking, and the juice is very sweet. This ripens the middle of September.

27. *PYRUS sativa, fructu aestivo longo, acerbitate strangulationem minitante.* Tourn. Poire d'Etrangillon, *i. e.* the Choaky Pear; the flesh is red. This is seldom preserved in gardens, so there needs no description of it.

28. *PYRUS sativa, fructu aestivo oblongo à ferrugineo rubente, nonnunquam maculato.* Poire du Rousselet, *i. e.* the Rousselet Pear. This is a large oblong Pear; the skin is brown, and of a dark red colour next the sun; the flesh is soft and tender, without much core; the juice is agreeably perfumed, if gathered before it be too ripe. This produces larger fruit on an espalier than on standard-trees. It ripens the middle of September.

29. *PYRUS sativa, fructu aestivo subrotundo, partim rubro, partim flavescente, odorato.* Poire de Prince, *i. e.* the Prince's Pear. This is a small roundish Pear, of a bright red colour next the sun, but of a yellowish colour on the opposite side; the flesh is between breaking and melting: the juice is very high-flavoured. It is a great bearer. It ripens the middle of September, but will keep a fortnight good, which is what few summer fruits will do.

30. *PYRUS sativa, fructu aestivo globoso viridi, in ore liquescente.* Gros Mouille-bouche, *i. e.* the great Mouthwater Pear. This is a large round Pear, with a smooth green skin; the stalk is short and thick; the flesh is melting, and full of juice, if gathered before it be too ripe, otherwise it is apt to grow mealy. This ripens the middle of September.

31. *PYRUS sativa, fructu aestivo rotundo sessili saccharato, à viridi flavescente.* Bergamotte d'Été, *i. e.* Summer Berga-

mot; this is by some called the *Hamden's* Bergamot. It is a pretty large round flat Pear, of a greenish yellow colour, and hollowed a little at both ends like an Apple; the flesh is melting, and the juice is highly perfumed. This ripens the middle of September.

32. *PYRUS sativa, fructu autumnali sessili saccharato odorato, à viridi flavescente, in ore liquescente.* Tourn. Bergamotte d'Automne, *i. e.* the Autumn Bergamot. This is a smaller Pear than the former, but is nearly of the same shape; the skin is of a yellowish green, but changes to a faint red on the side next the sun; the flesh is melting, and its juice is richly perfumed. It is a great bearer, ripens the end of September, and is one of the best Pears of the season.

33. *PYRUS sativa, fructu autumnali turbinato viridi, striis sanguineis distincta.* Tourn. Bergamotte de Suisse, *i. e.* the Swiss Bergamot. This Pear is somewhat rounder than either of the former; the skin is tough, of a greenish colour, striped with red; the flesh is melting, and full of juice, but is not so richly perfumed as either of the former. This ripens the end of September.

34. *PYRUS sativa, fructu autumnali suavissimo, in ore liquescente.* Tourn. Beurré rouge, *i. e.* the red Butter Pear. It is called l'Amboise, and in Normandy Isambert; as also Beurré gris, *i. e.* the gray Butter; and Beurré vert, *i. e.* the green Butter Pear. All these different names of Beurrés have been occasioned by the difference of the colours of the same sort of Pear, which is either owing to the different exposure where they grew, or from the stock, those upon free stocks being commonly of a browner colour than those which are upon Quince-stocks; whence some persons have supposed them to be different fruits, though in reality they are the same. This is a large long fruit, for the most part of a brown colour. The flesh is very melting, and full of a rich sugary juice. It ripens the beginning of October, and, when gathered from the tree, is one of the very best sort of Pears we have.

35. *PYRUS sativa, fructu autumnali turbinato sessili flavescente, & in ore liquescente.* Tourn. Le Doyenne, *i. e.* the Dean's Pear. It is also called by all the following names; Saint Michel; Beurré blanc d'Automne, *i. e.* the white autumn Butter Pear; Poire de Neige, *i. e.* the Snow Pear; Bonne Ente, *i. e.* a good Graft; the Carlisle and Valencia. It is a large fair fruit, in shape somewhat like the grey Beurré, but shorter and rounder; the skin is smooth, and, when ripe, changes to a yellowish colour; the flesh is melting, and full of juice, which is very cold, but it will not keep good a week after it is gathered, being very subject to grow mealy; it is a very indifferent fruit, but a great bearer, and ripens the beginning of October.

36. *PYRUS sativa, fructu autumnali longo viridique odorato, in ore liquescente.* Tourn. La Verte-longue, *i. e.* the long green Pear. It is also called Mouille-bouche d'Automne, *i. e.* the Autumn Mouth-water Pear. This is a long fruit, which is very green when ripe; the flesh is melting, and full of juice, which, if it grows upon a dry warm soil, and a free stock, is very sugary, otherwise it is but a very indifferent Pear. It ripens the middle of October, but some years they will keep till December.

37. *PYRUS sativa, fructu autumnali tuberoso sessili saccharato, carne durâ.* Tourn. Messire Jean blanc & gris, *i. e.* the white and gray Monsieur John. These, although made two sorts of fruit by many persons, are indubitably the same; the difference of their colour proceeding from the different soils and situations where they grow, or the stocks on which they are grafted. This Pear, when grafted on a free stock, and planted on a middling soil, neither too wet nor over-dry; is one of the best autumn Pears yet known; but when it is grafted on a Quince-stock, it is very apt to be stony, or if planted on a very dry soil, is very apt to be small

small and good for little, unless the trees are watered in dry seasons, which has rendered it less esteemed by some persons, who have not considered the cause of their hardness; for when it is rightly managed, there are not many Pears in the same season to be compared with it. This is a large roundish fruit; the skin is rough, and commonly of a brown colour; the flesh is breaking, and very full of a rich sugared juice. It ripens the end of *October*, and will continue good near a month.

38. *PYRUS sativa, fructu autumnali globofo ferrugineo, carne tenerâ sapidissimâ. Tourn.* Muscat fleurî, *i. e.* the flowered Muscat. It is also called *Muscat à longue queue d'Automne, i. e.* the long stalked Muscat of the Autumn. This is an excellent Pear, of a middling size, round; the skin is of a dark red colour; the flesh is very tender, and of a delicate flavour. It ripens the end of *October*.

39. *PYRUS sativa, fructu autumnali globofo ferrugineo, carne viscidâ. Tourn.* Poire de Vigne, *i. e.* the Vine Pear. This is a round fruit, of a middling size; the skin of a dark red colour; the flesh is very melting, and full of a clammy juice; the stalk is very long and slender. The fruit should be gathered before it be full ripe, otherwise it grows meally and soon rots. It ripens the end of *October*.

40. *PYRUS sativa, fructu autumnali oblongo, dilutè rufescente, saccharato, odoratissimo. Tourn.* Poire Rouffeline, *i. e.* the Rouffeline Pear. It is also called in *Touraine*, *Le Muscat à longue queue de la fin d'Automne, i. e.* the long stalked Muscat of the End of Autumn. This is by some *English* gardeners called the Brute-bonne, but that is a very different fruit from this. It is shaped somewhat like the Russet, but the skin of this is smooth, and of a greenish yellow from the sun, but the side next the sun is of a deep red colour, with some spots of gray; the flesh is very tender and delicate; the juice is very sweet, with an agreeable perfume. It ripens the middle of *October*, but must not be long kept, lest it rot in the middle.

41. *PYRUS sativa, fructu autumnali oblongo majori cinerco. Tourn.* Poire Pendart, *i. e.* the Knave's Pear. This is very like the Cassolette Pear, but is somewhat larger; the flesh is fine and tender; the juice is very much sugared. It ripens the end of *October*.

42. *PYRUS sativa, fructu autumnali turbinato tuberoso viridi saccharato, in ore liquescente. Tourn.* Sucré vert, *i. e.* the green Sugar Pear. This Pear is shaped like the Winter-Thorn, but is smaller; the skin is very smooth and green; the flesh is very buttery; the juice is sugared, and of an agreeable flavour; but it is sometimes subject to be stony in the middle, especially if grafted on a Quince-stock.

43. *PYRUS sativa, fructu autumnali tuberosa sessili, è viridi flavescente, maculis nigris consperso, carne tenerâ saccharatâ. Tourn.* La Marquise, *i. e.* the Marquis's Pear. This is often of two different shapes, according to the nature of the soil where they are planted, for when the soil is dry, the fruit very much resembles a fine Blanquet; but when the soil is very rich and moist, it grows much larger. It is a well-shaped Pear, flat at the top; the eye is small and hollowed; the skin is of a greenish yellow, a little inclining to red on the side next the sun. If this Pear does not change yellow in ripening, it is seldom good; but if it does, the flesh will be tender and delicate, very full of juice, which is sugared. It ripens the beginning of *November*.

44. *PYRUS sativa, fructu autumnali oblongo, partim albido, partim rufescente. Tourn.* The Chat-brulé, *i. e.* the Burnt Cat. This is a small oblong Pear, shaped much like the Martin Sec, but differs from it in colour; this being of a pale colour on one side, but of a dark brown on the other; the skin is smooth; the flesh is tender, but dry, and, if kept a short time, is apt to grow meally. It is in eating the beginning of *November*.

45. *PYRUS sativa, fructu autumnali globofo sessili, ex albido flavescente. Le Besidéri.* It is so called from *Héri*, which is a forest in *Bretagne*, between *Reunes* and *Nantes*, where this Pear was found. This is a middle-sized round Pear, of a pale green, inclining to a yellowish colour; the stalk is very long and slender; the flesh is dry, and but very indifferent for eating, but it bakes well. It ripens the middle of *November*.

46. *PYRUS sativa, fructu brumali sessili, è viridi flavescente, maculato, utrinque umbilicato, in ore liquescente. Tourn.* The Crasane, or Bergamot Crasane. It is also called *Beurré Plat, i. e.* the flat Butter Pear. This is a middle-sized Pear, hollowed at the crown like an Apple; the stalk is very long and crooked; the skin is of a greenish yellow colour when ripe, covered over with a russet coat; the flesh is extremely tender and buttery, and is full of a rich sugared juice, and is the very best Pear of the season. This is in eating the beginning of *November*.

47. *PYRUS sativa, fructu brumali turbinato sessili flavescente saccharato odorato, in ore liquescente. Tourn.* Lansac ou la Dauphine, *i. e.* the Lansac or Dauphine Pear. This Pear is commonly about the size of a Bergamot, of a roundish figure, flat towards the head, but a little produced towards the stalk; the skin is smooth, and of a yellowish green colour; the flesh is yellow, tender, and melting; the juice is sugared, and a little perfumed; the eye is very large, as is also the flower; the stalk is long and strait. When this Pear is upon a free stock, and planted on a good soil, it is one of the best fruits of the season; but when it is on a Quince-stock, or upon a very dry soil, the fruit will be small, stony, and worth little. It ripens the end of *November*.

48. *PYRUS sativa, fructu brumali oblongo, partim intense, partim dilutè ferrugineo, saccharato, odorato. Tourn.* Martin Sec, *i. e.* the Dry Martin. This is sometimes called the Dry Martin of *Champagne*, to distinguish it from another Dry Martin of *Burgundy*. This Pear is almost like the Russet in shape and colour, which has occasioned some persons to give it the name of Winter Russet. It is an oblong Pear, whose skin is of a deep russet colour on one side, but the other side is inclining to a red; the flesh is breaking and fine; the juice is sugared, with a little perfume, and if grafted on a free-stock, is an excellent Pear, but if it be on a Quince-stock, it is very apt to be stony. It is in eating the end of *November*, but if they were permitted to hang their full time on the tree, will keep good two months.

49. *PYRUS sativa, fructu brumali magno sessili, è cinerco flavescente. Tourn.* La Villaine d'Arjou, *i. e.* the Villain of Anjou. It is also called *Poire Tulipée, i. e.* the Tulip Pear, and *Bigarrade, i. e.* the Great Orange. This is a large round Pear, with a very long slender stalk; the skin is of a pale yellow colour; the flesh is breaking, but not very full of juice. This is in eating the end of *November*.

50. *PYRUS sativa, fructu brumali flavescente odoratissimo, pediculo crassiori. Tourn.* Poire de gros queue, *i. e.* the large stalked Pear. This is a large roundish Pear, with a yellow skin; the stalk is very thick, from whence it had the name; the flesh is breaking, dry, and has a very musky flavour; but it is apt to be stony, especially if it be planted in a dry soil, or grafted on a Quince-stock, as are most of the perfumed Pears.

51. *PYRUS sativa, fructu brumali turbinato rufescente odorato. L'Amadote, i. e.* the Amadot Pear. This is a middle-sized Pear, somewhat long, but flat at the top; the skin is generally rough, and of a russet colour; the flesh is dry, and high flavoured, if grafted on a free-stock. The wood of this tree is generally thorny, and is esteemed the best sort of Pears for stocks to graft the melting Pears upon, because it gives them some of its fine musky flavour. It is in eating the beginning of *December*, but will keep good six weeks.

52. *PYRUS sativa, fructu brumali, globoso, dilute virente, tuberoso, punctato, in ore liquescente. Tourn.* Petit Oin, *i. e.* Little Lard Pear. It is also called Bouvar and Roussette d'Anjou, *i. e.* the Ruffet of Anjou; and Amadont, and Marveille d'Hyver, *i. e.* the Wonder of the Winter. This Pear is of the size and shape of the Ambret or L'Eschafferie, but the skin is of a clear green colour, and a little spotted; the stalk is pretty long and slender; the eye is large, and deeply hollowed; the flesh is extremely fine, and melting; the juice is much sugared, and has an agreeable musky flavour. It is in eating the middle of *December*, and is esteemed one of the best fruits in that season. This is better on a free-stock than upon the Quince.

53. *PYRUS sativa, fructu brumali longo è viridi albicante, in ore liquescente. Tourn.* Louisebonne, *i. e.* the Good Lewis Pear. This Pear is shaped somewhat like the St. Germain, or the Autumn Verte-longue, but is not quite so much pointed; the stalk is very short, fleshy, and somewhat bent; the eye and the flower are small; the skin is very smooth; the colour is green, inclining to a white when ripe; the flesh is extremely tender and full of juice, which is very sweet, especially when it grows upon a dry soil, otherwise it is apt to be very large and ill tasted. It is in eating the beginning of *December*.

54. *PYRUS sativa, fructu brumali, tuberoso, è viridi flavescente, punctato, saccharato. Tourn.* Poire de Colmar, *i. e.* the Colmar Pear. It is also called Poire Manne, the Manna Pear, and Bergamotte tardive, the late Bergamot. This Pear is somewhat like a Boncrétien in shape, but the head is flat; the eye is large, and deeply hollowed: the middle is larger than the head, and is sloped toward the stalk, which is short, large, and a little bent; the skin is green, with a few yellowish spots, but is sometimes a little coloured on the side next the sun; the flesh is very tender, and the juice is greatly sugared. It is in eating the latter end of *December*, but will often keep good till the end of *January*, and is esteemed one of the best fruits of that season.

55. *PYRUS sativa, fructu brumali, globoso, citrifermi, flavescente, punctato, in ore liquescente, saccharato, odoratissimo. Tourn.* L'Eschafferie. It is also called Verte-longue d'Hyver, *i. e.* the Winter long green Pear, and Besidéri, Landri, *i. e.* the Landry Wilding. This Pear is shaped like a Citron; the skin is smooth, and of a green colour, with some spots while it hangs on the tree, but as it ripens it becomes of a yellowish colour; the stalk is strait and long; the eye is small, and not hollowed; the flesh is melting and buttery; the juice is sugared, with a little perfume. It is in eating the latter end of *December*.

56. *PYRUS sativa, fructu brumali longo, è viridi flavescente, in ore liquescente, saccharato. Tourn.* Le Virgoulé, or La Virgouleuse. It is also called Bujaleuf, and Chambrette; and Poire de Glasse, *i. e.* the Ice Pear in *Gascoigne*; but it is called *Virgoulé*, from a village of that name in the neighbourhood of *St. Leonard* in *Limousin*, where it was raised and sent to *Paris* by the Marquis of *Chambert*. This Pear is large, long, and of a green colour, inclining to yellow as it ripens; the stalk is short, fleshy, and a little bent; the eye is of a middling size, a little hollowed; the skin is very smooth, and sometimes a little coloured towards the sun; the flesh is melting, and full of a rich juice. It is in eating the latter end of *December*, and will continue good till the end of *January*, and is esteemed one of the best fruits of the season; but the tree is very apt to produce vigorous shoots, and the blossoms being generally produced at the extreme part of the shoot, where they are shortened, the fruit will be entirely cut away, which is the reason it is condemned as a bad bearer; but when it is grafted on a free-stock, it ought to be allowed at least forty feet to spread; and if upon a Quince-stock, it should be allowed upwards

of thirty feet, and the branches trained in against the espalier or wall, at full length, in a horizontal position, as they are produced. Where this tree is thus treated, it will bear very plentifully, and the fruit will be good.

57. *PYRUS sativa, spinosa, fructu globoso, sessili, ferrugineo, in ore liquescente, saccharato, odoratissimo. Tourn.* Poire d'Ambrette. This is so called from its musky flavour, which resembles the smell of the Sweet Sultan-flower, which is called Ambrette in *France*. This Pear is like the L'Eschafferie in shape, but is of a ruffet colour; the eye is larger, and more hollowed; the flesh is melting; the juice is richly sugared and perfumed; the seeds are large, black, and the cells in which they are lodged are very large; the wood is very thorny, especially when grafted on free-stocks. The fruit is in eating the latter end of *December*, and continues good till the latter end of *January*, and is esteemed a very good fruit by most people.

58. *PYRUS sativa, fructu brumali, magno, pyramidato, albedo, in ore liquescente, saccharato, odorato. Tourn.* Epine d'Hyver, *i. e.* Winter-thorn Pear. This is a large fine Pear, nearly of a pyramidal figure; the skin is smooth, of a pale green colour, inclining to yellow as it ripens; the stalk is short and slender; the flesh is melting and buttery; the juice is very sweet, and in a dry season is highly perfumed; but when it is planted on a moist soil, or the season proves wet, it is very insipid, so that it should never be planted on a strong soil. It ripens the end of *December*, and will continue good two months.

59. *PYRUS sativa, fructu brumali longo, è viridi flavescente, in ore liquescente. Tourn.* La Saint Germain, *i. e.* the St. Germain Pear. It is also called L'Inconnue de la Fare, *i. e.* the Unknown of *La Fare*; it being first discovered upon the banks of a river which is called by that name, in the parish of *St. Germain*. This is a large long Pear, of a yellowish green colour when ripe; the flesh is melting, and very full of juice, which in a dry season, or if planted on a warm dry soil, is very sweet; but when it is planted on a moist soil, the juice is very apt to be harsh and austere, which renders it less esteemed by some persons, though in general it is greatly valued. This is in eating from the end of *December* till *February*.

60. *PYRUS sativa, fructu brumali tuberoso subacido flavescente punctato. Tourn.* Saint Austin. This is about the size of a middling Virgoulé Pear, but is somewhat shorter and slenderer near the stalk; the skin is of a fine Citron colour, spotted with red on the side next the sun; the flesh is tender, but not buttery, and is pretty full of juice, which is often a little sharp, which to some persons is disagreeable, but others value it on that account. This is in eating in *December*, and will continue good two months.

61. *PYRUS sativa, fructu brumali pyramidato, partim purpureo, punctis nigris consperso, flavescente. Tourn.* Boncrétien d'Espagne, *i. e.* the Spanish Boncrétien. This is a large Pear, of a pyramidal form, of a fine red or purple colour on the side next the sun, and full of small black spots; the other side is of a pale yellow colour; the flesh is breaking, and when it is on a light rich soil, and grafted on a free-stock, its juice is very sweet. It ripens in the end of *December*, and will continue good a month or six weeks. If this be grafted on a Quince-stock, it is very apt to be dry and stony. This is a very good fruit for baking.

62. *PYRUS sativa, fructu brumali, magno, oblongo, turbinato, ferrugineo, utrinque umbilicato. Tourn.* Poire de Livre, *i. e.* the Pound Pear. It is also called Gros Ratteau Gris, *i. e.* the gray raked Pear; and Poire d'Amour, *i. e.* the Lovely Pear. In *England* this is called *Parkinson's Warden*, or the Black Pear of *Worcester*. This is a very large Pear, each of which commonly weighs a pound or more; the skin is rough, and of an obscure red colour on the side next

next the sun, but somewhat paler on the other; the stalk is very short, and the eye is greatly hollowed. This is not fit for eating, but bakes or stews exceeding well, and is in season from *December* to *March*.

63. *PYRUS sativa, fructu brumali parvo flavescente, maculis rubris consperso. Tourn.* Besi de Cassoy, *i. e.* the Wilding of Cassoy, a forest in *Bretagne*, where it was discovered, and passes under the name of Rouffet d'Anjou. It is also called Petit Beurré d'Hyver, *i. e.* the small Winter Butter Pear. This is a small oblong Pear, of a yellowish colour, spotted with red; the flesh is melting, and the juice is very rich. It is in eating in *December* and *January*. This is a prodigious bearer, and commonly produces its fruit in large clusters, provided it be not too much pruned; for it generally produces its blossom-buds at the extremity of its shoots, which, if shortened, the fruit would be cut away. There was a tree of this kind in the gardens of *Camden-house* near *Kenington*, which generally produced a great quantity of fruit.

64. *PYRUS sativa, fructu brumali turbinato inæquali, ventre tumido, partim purpureo, partim flavescente. Tourn.* Ronville. It is also called Hocrenaille and Martin sire, *i. e.* the Lord Martin Pear. This Pear is about the size and shape of a large Rufflet; the eye is of a middling size, and hollowed a little; the middle of the Pear is generally swelled more on one side than on the other, but is equally extended towards the stalk; the skin is very smooth, soft, and is of a lively red colour next the sun, but on the other side it changes yellow as it ripens. The flesh is breaking, and full of juice, which is very sweet, and a little perfumed; but if grafted on a Quince-stock, is very apt to be small and stony.

65. *PYRUS sativa, fructu brumali citriformi flavescente duro moschato odoratissimo. Tourn.* Citron d'Hyver, *i. e.* the Winter Citron Pear. It is also called the Musk Orange Pear, in some places. This is a pretty large Pear, in shape and colour very like an Orange or Citron, from whence it had its name. The flesh is hard, dry, and very subject to be stony; for which reasons it is not valued as an eating Pear, but will bake very well. It is in season from *December* to *March*.

66. *PYRUS sativa, fructu brumali oblongo, è viridi flavescente, saccharato, saporis austeri. Tourn.* Rufflet d'Hyver, *i. e.* the Winter Rufflet. This is by some supposed to be the same Pear as is called the Dry Martin, but it is very different from that in several particulars. The colour of this is a greenish yellow, inclining to brown; the stalk is long and slender; the flesh is buttery, melting, and generally full of juice, which is very sweet, but the skin is apt to contain an austere juice, so that if it be not pared, it is apt to be disagreeable to many persons palates. It is in eating in *January* and *February*.

67. *PYRUS sativa Pictaviensis, fructu brumali globoso sessili saccharato odorato. Tourn.* Poire Portail, *i. e.* the Gate Pear. This Pear was discovered in the Province of *Poitou*, where it was so much esteemed, that they preferred it to most other fruit, though in the opinion of the most curious judges, it does not deserve the great character which is given to it; for it rarely happens that it proves good for eating, being generally dry, stony, and hard, unless in extraordinary seasons, and upon a very good soil. This must always be grafted on a free-stock, and should be planted on a light rich soil; and in very dry seasons the trees should be watered, otherwise the fruit will be stony. It is in season from *January* to *March*, and bakes well.

68. *PYRUS sativa, fructu brumali magno globoso flavescente, punctis rufis consperso. Tourn.* Franc real. It is also called Fin-or d'Hyver, *i. e.* the Golden End of Winter. This is a very large Pear, almost of a globular figure; the skin is yellow, spotted with red; the stalk is short, and the wood

of the tree mealy. The flesh of this Pear is dry, and very apt to be stony, but it bakes exceeding well, and continues good from *January* till *March*.

69. *PYRUS sativa, fructu brumali turbinato sessili subacido flavescente, punctis asperioribus consperso. Tourn.* Bergamotte Bugi. It is also called Bergamotte de Pasque, *i. e.* the Easter Bergamot. It is a large Pear, almost round, but is a little produced in length towards the stalk; the eye is flat, and the skin is green, having many rough protuberances like spots dispersed all over, but, as it ripens, becomes yellowish; the flesh is breaking, and in a good season the juice is sweet; but it must have a free-stock, a south east wall, and a good soil, otherwise it is apt to be stony and austere. It is in eating from *February* till *April*.

70. *LE MUSCAT D'ALLEMAN, i. e.* the German Muscat. This is an excellent Pear, more long than round, of the shape of the Winter-royal, but is less toward the eye, is more rufflet, and of a red colour next the sun; it is buttery, melting, and a little musky. This is in eating in *March* and *April*.

71. *LE BERGAMOTTE D'HOLLANDE, i. e.* the Holland Bergamot; it is large and round, of the shape of the ordinary Bergamot. The colour is greenish; the flesh is half buttery and tender; the juice is highly flavoured. This is a very good Pear, and will keep till *March*.

72. *LE POIRE DE NAPLES, i. e.* the Pear of Naples. This is a pretty large, long, greenish Pear; the flesh is half breaking; the juice is sweet, and a little vinous. It is in eating in *March*. I am in doubt whether this Pear is not in some places taken for a Saint Germain, for there is a Pear in some gardens very like the Saint Germain, which will keep till *April*, and this Pear agrees with the characters of that. It is called in *England* the Easter St. Germain.

73. *PYRUS sativa, fructu brumali magno pyramidato, è flavo nonnihil rubente. Tourn.* Boncrétien d'Hyver, *i. e.* the Winter Boncrétien Pear. This Pear is very large and long, of a pyramidal figure; the skin is of a yellowish colour, but the side next the sun inclines to a soft red; the flesh is breaking, and is very full of rich sugared juice. This is esteemed in *France* one of the best winter Pears, but in *England* it is seldom so good; though I am fully satisfied, if it were grafted on a free-stock, and planted in a good soil, against a wall exposed to the south east, and the branches trained at full length, it might be rendered more acceptable than it is at present in *England*.

74. *PYRUS sativa, fructu brumali magno, cydoniæ facie, partim flavo, partim purpureo. Tourn.* Catillac or Cadillac. This is a large Pear, shaped somewhat like a Quince; the skin is for the most part of a yellow colour, but changes to a deep red on the side next the sun; the flesh is hard, and the juice austere, but it is a very good fruit for baking, and being a plentiful bearer, deserves a place in every good collection of fruit. It will be good from *Christmas* to *April*, or longer.

75. *PYRUS sativa, fructu brumali oblongo flavescente, punctis rubris consperso. La Pastorelle.* This Pear is of the size and shape of a fine Rufflet; the stalk is short and crooked; the skin is somewhat rough, of a yellowish colour, spotted with red; the flesh is tender, buttery, and when it grows on a dry soil, the juice is very sweet; but on a wet soil, or in moist years, it is subject to have an austere taste. This Pear is in eating in *February* and *March*.

76. *PYRUS sativa, fructu brumali sessili, partim flavescente, partim purpurascete. Tourn.* La Double Fleur, *i. e.* the double flowering Pear. This is so called, because the flowers have a double range of petals or leaves. It is a large short Pear; the stalk is long and strait; the skin is very smooth, of a yellowish colour, but the side next the sun is commonly of a fine red or purple colour. This is by some esteemed for

for eating, but it is generally too austere in this country for that purpose. It is the best Pear in the world for baking or composts. It is good from *February* to *May*.

77. *PYRUS sativa, fructu brumali oblongo, partim flavescente, partim purpurascente.* Saint Martial. It is also called in some places *Poire Angelique, i. e.* the Angelick Pear. This Pear is oblong, in shape like the Boncrézien, but not so large, a little flatter at the crown; it has a very long stalk; the skin is smooth and yellowish, but on the side next the sun it turns to a purplish colour; the flesh is tender, buttery, and the juice is very sweet. This is in eating in *February* and *March*, and will keep very long.

78. *PYRUS sativa, fructu brumali oblongo, partim albido, partim purpureo odorato, saccharato.* La Poire de Chaumontelle, or Besi de Chaumontelle, *i. e.* the Wilding of *Chaumontelle*. This Pear is in shape somewhat like the Autumn Beurré, but is flatter at the crown; the skin is a little rough, of a pale green colour, but turns to a purplish colour next the sun; the flesh is melting; the juice is very rich, and a little perfumed. It is in eating from *November* to *January*, and is esteemed by some the best late Pear yet known.

79. *PYRUS sativa, fructu brumali globoso sessili cinerco maculis amplis obscurioribus consperso.* Town. Carmelite. This is a middle-sized Pear, of a roundish form; the skin is of a gray colour on one side, but is inclined to a red on the other, having some broad spots of a dark colour all over; the flesh is commonly hard and dry, so that it is not very much esteemed. It is in season in *March*.

80. *PYRUS sativa, fructu brumali maximo pyramidato, dilute virente.* The Union Pear, otherwise called *Dr. Uvedale's St. Germain*. This is a very large long Pear, of a deep green colour, but the side next the sun doth sometimes change to a red as it ripens. This is not fit for eating, but bakes very well; and being a great bearer, and a very large fruit, deserves a place in every good collection. It is in season from *Christmas* to *April*.

The time of each fruit ripening, as here set down, is taken at a medium for seven years, and in the neighbourhood of *London*, where all sorts of fruit generally ripen a fortnight or three weeks earlier than in almost any part of *England*, it is very obvious to every person, who will attend to the culture of fruit-trees, that their time of ripening is accelerated by long cultivation; for many of the sorts of Pears, which some years past rarely became ripe in *England*, unless they grew against the best aspected walls, are now found to ripen extremely well on espaliers and dwarfs; and those Pears, which seldom were in eating till *January*, are ripe a month earlier. There is also a very great difference in their time of ripening in different seasons, for I have known the fruit of a Pear-tree in one year all ripe and gone by the middle of *October*, and the very next year the fruit of the same tree has not been fit to eat till the end of *December*, so that allowance should be made for these accidents. The Besi de Chaumontelle Pear, about forty years past, was seldom fit to eat before *February*, and has continued good till the middle of *April*; but now this Pear is commonly ripe in *November*, and when it is planted on a warm soil, and against a good aspected wall, it is in eating the middle of *October*. This forwarding of the several kinds of Pears, may be in some measure owing to the stocks upon which they are grafted; for if they are grafted upon early summer Pear-stocks, they will ripen much earlier than when they are upon hard Winter Pear-stocks; and if some of the very soft melting Pears were grafted upon such stocks as are raised from the most austere fruit, such as are never fit to eat, and of which the best Perry is made, it would improve those fruits, and continue them much longer good; or if the common free-stocks were first grafted with any of these hard Winter Pears, and when they have grown a year, then to

graft or bud these soft melting Pears upon them, it would have the same effect; but the Pears so raised, will require a year's more growth in the nursery, and consequently cannot be sold at the same price as those which are raised in the common method, these requiring to be twice budded or grafted, so that there is double labour, beside standing a full year longer; but this difference in the first expence of the trees, is not worth regarding by any person who is desirous to have good fruit; for the setting out in a right way is that which every one should be the most careful of, since by mistaking at first, much time is lost, and an after expence of new trees often attends it.

The ripening of these fruits may also be accelerated by the method of pruning and managing these trees, which are greatly improved within the space of a few years past; for if we look into the directions which are given by the best writers on this subject, we shall soon discover how little they knew sixty years ago, of the true method of pruning and managing all sorts of fruit-trees, scarce one of them making any difference in the management of the different kinds of fruit.

Pears are propagated by grafting or budding them upon stocks of their own kind, which are commonly called free-stocks, or upon Quince-stocks, or White-thorn, upon all which these fruits will take; but the latter sort of stock is now seldom used, because they never keep pace in their growth with the fruit budded or grafted upon them; as also because the fruit upon such stocks are commonly drier, and more apt to be stony, than when they are upon Pear-stocks. Quince-stocks are greatly used in the nurseries for all sorts of Pears which are designed for dwarfs or walls, in order to check the luxuriancy of their growth, so that they may be kept within compass better than upon free-stocks. But against the general use of these stocks, for all sorts of Pears indifferently, there are very great objections: 1st, Because some sorts of Pears will not thrive upon these stocks, but in two or three years decay, or at most will but just keep alive. 2dly, Most of the sorts of hard-breaking Pears, are rendered stony, and good for little; so that, whenever any of these sorts are thus injudiciously raised, the fruit, although the kind be ever so good, is condemned as good for nothing by such as are not well acquainted with it, when the fault is entirely owing to the stock, on which it was grafted. On the contrary, most melting buttery Pears are greatly improved by being upon Quince-stocks, provided they are planted on a strong soil; but, if the ground be very dry and gravelly, no sort of Pear will do well upon Quince-stocks in such places.

These general directions being given, there is no occasion to repeat any part of the method in which these stocks are raised, and the fruits budded or grafted thereon, which has been already mentioned under the article of *NURSERIES*.

The distance which these trees should be planted, either against walls or espaliers, must not be less than thirty feet, but, if they are planted forty feet, it will be better; for, if they have not room to spread on each side, it will be impossible to preserve them in good order, especially those on free-stocks, for the more these trees are pruned, the more they will shoot; and, as I said before, many sorts of Pears produce their blossom-buds first at the extremity of the former year's shoots; so that when they are shortened, the fruit will be cut away, and this cannot be avoided, where the trees have not room allowed in their first planting.

This distance, I doubt not, will be objected to by many who have not fully attended to the growth of these trees, especially as it hath been the general practice of most gardeners to plant these trees at less than half the distance which is here mentioned; but, whoever will be at the trouble to view any of these trees which have been some years

years standing, they will always find, if, by accident, one of these trees has been planted against a building, where the branches have had room to spread, that this tree has produced more fruit than twelve trees which have been crowded close, and have not room for their branches to extend. There are some Pear-trees now growing, which spread more than fifty feet in length, and are upward of twenty feet high, which produce a much greater quantity of fruit than three trees in the same room would have done, as there are examples enough to prove, where trees are planted against houses and the ends of buildings at about twelve feet, or much less distance, because there is height of walling for them to grow, which is the reason commonly given by those who plant these trees so close together. But one tree will bear more fruit, when the branches are trained horizontally, than three or four trees, whose branches are led upright; and there never can be any danger of the upper part of the wall being left naked or unfurnished, for I have seen a Pear-tree which has spread more than fifty feet in width, and covered the wall upward of thirty-six feet in height: this was a Summer Boncrétien Pear, and was extremely fruitful, which rarely happens to this sort when they are not allowed a large share of room. The finest tree of this sort of Pear, which I ever have seen, was a large standard-tree in my own possession, whose stem was not more than ten feet high, where the branches came out regularly, and extended near thirty feet on every side from the trunk, many of which were, by the weight of the fruit in summer, brought down to the ground, so were obliged to be supported with props toward the extremity of the branches, to prevent their lying upon the ground; and this tree had its branches so disposed, as to form a natural parabola of forty feet in height, bearing from the lowest to the highest branches; so that in a kindly season, when the blossoms escaped the frost, it hath produced upward of two thousand Pears, which were much better flavoured than any of the same sort which I have yet tasted. This instance I mention only to shew how much one of these trees will spread, if proper room be allowed it, and also to observe that, as the branches of this tree had never been shortened, they were fruitful to their extremities. This shews the absurdity of the *French* gardeners, who do not allow more than ten or twelve feet distance to these trees; and some of their most improved writers on this subject have advised the planting an Apple-tree between the Pear-trees, where they are allowed twelve feet, and yet these authors afterward say, that a good Pear-tree will shoot three feet each way in one year; therefore, according to their own observation, the trees so planted will have their branches meet together in two or three years at most; and what must be the case with such trees in five or six years, is not difficult to know. But this method of planting has not been peculiar to the *French*, for most of the gardens in *England* have been little better planted. Indeed, those persons who were intrusted with the making and planting most of the *English* gardens, had little skill of their own, so were obliged to follow the directions of the *French* gardeners, of whom they had so great an opinion, as to get their books translated, and to these have added some trifling notes, which rather betray their weakness; for, where they have objected to the little room which their authors had allowed to these trees, they have, at the most, allowed them but three feet more, from which it is plain, they had not considered the natural growth of the trees, and whoever departs from nature, may be justly pronounced an unskilful gardener.

As most of the *English* gardens have been made and planted by persons of little judgment, it is very rare to find any of them which produce much fruit, for although many of these gardens have been totally altered, and new-planted, yet

they have seldom been much altered for the better, and the possessors have been put to the expence of removing the old trees, also the earth of their borders, and to purchase new trees, which have been planted perhaps a foot or two farther asunder than the old trees, which were removed; so that, when the young trees have grown a few years, they were in the same condition as the old, and it will be the loss of so many years to the owner; but this will constantly be the case, when it is the interest of the persons employed, who can sell so many young trees, and the planting of three times the number of trees in a garden, more than is proper, may in some measure be ascribed to the same, though in many instances I should be inclinable to think it has proceeded from ignorance, rather than design.

But where fruit-trees have been thus injudiciously planted, if the stocks are healthy and good, the best way to recover this loss is to dig up two or three, and leave every third or fourth tree, according to the distance which they were planted, and spread down the branches of those which are left horizontally, I mean, all such as are capable of being so brought down; but those, which are too stubborn for this, should be cut off near the stem, where there will be new shoots enough produced to furnish the wall or espalier; and, if the sort of fruit is not the same as desired, the young branches may be budded the same summer, or grafted the following spring with any other sort of Pear, and hereby many years may be saved; for one of these old trees will spread to a much greater length, and produce more fruit, when thus managed, in three years, than a new tree will in ten or twelve, especially if the ground is mended. This is a method which I have practised with great success, where I have been employed to amend the blunders of these great gardeners, as they are stiled, and hereby the walls and espaliers have been well furnished in a few years.

But the next thing to be done, after being furnished with proper trees, is the preparing of the ground to receive them; in the doing of which, there should be great regard had to the nature of the soil, where the trees are to grow; for, if it is a strong stiff land, and subject to wet in the winter, the borders should be raised as much above the level of the ground as you conveniently can. And if under the good soil there is a sufficient quantity of lime rubbish, or stones laid to prevent the roots of the trees from running downward, it will be of great service to them. The borders for these should not be less than eight feet broad, but, if they are twelve, it will be still better. And as these borders may be planted with such sorts of esculent plants as do not grow large, or whose roots do not run deep, or mat together on the surface, these will do no harm to the Pear-trees, for these are not so nice in their culture as Peach and Nectarine-trees; so the turning of the ground, and mending it for these crops, will rather improve than injure the trees, provided the plants do not shade the trees, or are not suffered to stand too long upon the borders. But all the Cabbage kind, as also Beans, should be excluded from these borders, because they root deep in the ground, and draw much nourishment from the trees.

But if the soil is shallow, and the bottom is either gravel or chalk, there must be a sufficient depth of good earth laid upon the borders, so as to make them two feet and a half deep; for, if the ground is not of this depth, the trees will not thrive well. And, in doing of this, I must caution every person not to dig out the gravel in a trench (as is by some practised), and fill this trench with good earth, for by so doing, when the roots of the trees are extended to the width of the trench, they will meet with the gravel which will stop them so, that they will be confined, as if they were in tubs of earth, whereby the trees will be soon spoiled; therefore, when the gravel or chalk is removed, it

should be entirely taken away over the whole garden, otherwise it will be better to raise the whole border above it.

If the garden is to be new-made from a field, then all the good earth on the surface should be carefully preserved, and, if the good ground is taken out where the walks are designed to be made, and laid upon the borders, or in the quarters, it will add to the depth of the soil, and save expence in bringing in of new earth. If the ground can be prepared one year before it is planted, the trees will thrive the better, for by laying the ground in ridges, and turning it over two or three times, it will loosen the soil, and render it much better for planting; but in trenching, or ploughing of the ground, there should be great care taken not to go deeper than the ground is good, otherwise all the good soil will be buried below the roots, and the bad ground will be turned on the top, which is what I have known done at a great expence by persons, who have been at the top of their profession, and have thereby entirely ruined the gardens.

Where there is a necessity of bringing in any fresh earth for the borders, it will be proper to do it as soon as possible, and to mix this with the surface of the earth of the borders, that it may be turned over two or three times, that the parts may be well mixed and incorporated before the trees are planted; and, if some very rotten dung is added to this, it will greatly improve it. In choosing of the earth, which is to be brought into the garden, there should be this care, *viz.* That if the natural soil of the garden is light and dry, then the new earth should be loamy and stiff; but where the natural soil is strong or loamy, then the new earth should be light and sandy, which will loosen the parts of the natural soil, and greatly mend it.

There are some persons who recommend the laying the whole depth of the borders with what they call Virgin-earth, that is, such as is taken from a pasture where the land has not been ploughed; but if this is not brought into the garden at least one year before the trees are planted, that by turning it over often it may be sweetened, it will not be so good as that which is taken from a kitchen-garden, where the land is good, and has been well wrought, for by often turning and breaking of the soil, it will be the better prepared to receive the trees.

Others recommend the mixing a great quantity of rotten dung with the earth of the borders; but this is not so proper, for, by making of the ground too rich, it will only encourage the luxuriant growth of the trees; therefore it is always better to mend the borders from time to time as they may require, and not to add so much dung in the first making them.

Another care is required in the making of the borders on wet ground, which is to contrive some covered drains to convey off the water in winter, otherwise, by this being detained about the roots of the trees, it will greatly prejudice them; and in the building of the walls round a kitchen-garden, where the ground is inclinable to be wet, there should be some arches turned in the foundations of those walls, which are in the lowest part of the garden, to let off the wet.

The manner of preparing these trees for planting is the same as hath been directed for other fruit-trees, *viz.* to cut off all the small fibres from the roots, and to shorten some of the longest roots, and cut off all the bruised ones, or such as shoot downright: this being done, you should plant them in the places intended at the before-mentioned distance. The best time to plant these trees (if upon a middling or dry soil) is in *October* or *November*, leaving their heads on till spring, which should be fastened to the walls or stakes, to prevent the wind from disturbing their roots; and in the beginning of *March* their heads should be cut off in the

manner already directed for Peaches and other fruit-trees, observing also to lay some mulch upon the surface of the ground about their roots when they are planted, as hath been several times already directed for other trees, but in wet ground the trees may be planted in *February*, or the beginning of *March*, at any time before the buds are much swelled, but these may be cut down when they are planted.

The first summer after planting, the branches should be trained to a wall or espalier (against which they are planted) in a horizontal position, as they are produced, without shortening of them, and the *Michaels* following some of these shoots should be shortened down to five or six eyes, in order to obtain a sufficient quantity of branches, to furnish the lower part of the wall or espalier; but the shoots ought not to be shortened, unless where there is a want of branches to fill a vacancy, therefore the less the knife is used to these trees, the better they will succeed; for, whenever the shoots are stopped, it occasions the buds immediately below the cut to send forth two or more shoots, whereby there will be a confusion of branches, and rarely any fruit is produced with this management.

The distance which the branches of Pears should be trained, must be proportioned to the size of their fruit. Such sorts whose fruit are small, may be allowed five or six inches, but the larger sorts must not be less than seven or eight inches asunder. If this be duly observed, and the branches carefully trained horizontally as they are produced, there will be no occasion for much cutting these trees, which, instead of checking their growth, does, on the contrary, cause them to shoot the stronger.

It is very surprising to read the tedious methods which most of the writers on fruit-trees have directed for pruning of these trees, for, by their prolix and perplexed methods, one would imagine they had endeavoured to render themselves as unintelligible as possible; and this, I am sure, may be affirmed, that it is next to impossible for a learner ever to arrive at any tolerable skill in pruning by the tedious and perplexed directions which are published by *Monf. Quintiny*, and those who have copied from him; for, as these have all set out wrong in the beginning, by allowing their trees less than a third of the distance which they should be planted, they have prescribed rules to keep them within that compass, which are the most absurd, and contrary to all reason.

I shall therefore only lay down a few necessary directions for the pruning and managing of these trees, which shall be done in as few words as possible, that a learner may the more easily understand it, and which (together with proper observations) will be sufficient to any person in the right management of them.

Pear-trees generally produce their blossom-buds first at the extremity of the last year's shoots, so that, if these are shortened, the blossoms are cut off; but this is not all the damage, for (as I before said) this occasions the buds immediately below the cut to put forth two or more shoots, whereby the number of branches will be increased, and the tree crowded too much with wood; besides, those buds, which by this management produce shoots, would have only produced cufsons and spurs, upon which the blossom-buds are produced, if the leading branch had not been shortened; therefore these should never be stopped, unless to furnish wood to fill a vacancy.

It is not necessary to provide a new supply of wood in Pear-trees, as must be done for Peaches, Nectarines, &c. which only produce their fruit upon young wood, for Pears produce their fruit upon cufsons or spurs, which continue fruitful many years; so that, where these trees have been skilfully managed, I have seen branches which have been trained horizontally upwards of twenty feet from the trunk of

of the tree, and have been fruitful their whole length. And if we do but carefully observe the branches of a healthy standard-tree, which has been permitted to grow without pruning, we shall find many of these spurs that are ten or twelve years old or more, which are very full of blossom-buds, and produce a good number of fruit annually.

During the summer season these trees should be often looked over to train the shoots, as they are produced, regularly to the wall or espalier, and to displace fore-right and luxuriant branches as they shoot out, whereby the fruit will be equally exposed to the air and sun; which will render them more beautiful and better tasted than when they are shaded by the branches; and by thus managing the trees in summer, they will always appear beautiful, and in winter they will want but little pruning.

Where Pear-trees are thus regularly trained without stopping of their shoots, and have full room for their branches to extend on each side, there will never be any occasion for disbarking of the branches, or cutting off the roots (as hath been directed by several writers on gardening); which methods, however they may answer the intention for the present, yet will certainly greatly injure the trees, as must all violent amputations, which should be ever avoided, as much as possible, on fruit-trees; and this, I am sure, can never be wanted, where trees have been rightly planted, and regularly trained, while young.

The season for pruning of these trees is any time after the fruits are gathered, until the beginning of *March*, but the sooner it is done after the fruit is gathered, the better, for reasons already given for pruning of Peach-trees; though indeed the deferring of these until spring, where there are large quantities of trees to prune, is not so injurious to them, as to some tender fruits; but, if the branches are regularly trained in the summer, and the luxuriant shoots rubbed off, there will be little left to do to them in winter.

All the sorts of summer Pears will ripen very well either on standards, dwarfs, or espaliers, as will all autumn Pears upon dwarfs or espaliers; but, where a person is very curious in his fruit, I would always advise the planting them against espaliers, in which method they take up less room in a garden, and, if they are well managed, appear very beautiful, the fruit larger and better tasted than those produced on dwarfs, as hath been already observed; but some of the winter Pears must be planted against east, south-east, or south-west walls, otherwise they will not ripen well in *England* in bad seasons.

But although this may be the case with some of the late winter Pears in very bad seasons, yet, in general, most sorts of them will ripen extremely well in all warm situations, when they are planted in espalier, and the fruit will be better flavoured than that which grows against walls, and will keep much longer good; for, as the heat against walls, which are exposed to the sun, will be very great at some times, and at others there will be little warmth, all fruit, which grow near them, will be hastened unequally, and therefore is never so well flavoured as the same sorts are which ripen well in the open air; and all the fruit, which is ripened thus unequally, will decay much sooner than those which ripen gradually in the open air; therefore those winter Pears, which grow in espalier, may be kept six weeks longer than those which grow against walls, which is a very desirable thing; for to have plenty of these fruit, at a season when it is very rare to find any other fruit to supply the table but Apples, is what all lovers of fruit must be greatly pleased to enjoy, which is what may be effected by planting many of the late sorts in espalier, where, although the fruit will not be so well coloured as those from the walls, yet they will be found exceeding good. When the *Besi de Chaumontelle* came first to *England*, the trees

were planted in espalier, and some of them not on a very good soil, or in a warm situation, and yet from these trees I have eaten this Pear in great perfection in *April*, and sometimes it has kept till *May*; whereas, all those which have been since planted against walls ripen their fruit by the beginning of *November*, and are generally gone by the middle of *December*, nor are the latter so well tasted as those off the espaliers.

The *Virguleuse*, and *St. Germain*, as also the *Colmar*, are esteemed the most difficult sorts to ripen their fruit, yet these I have eaten in great perfection from espaliers, and often from standard-trees, where they grew upon a warm soil, but the fruit was much smaller on the standard-trees than those of the same sorts which grew against walls or espaliers, but they were full as well flavoured; and some of these sorts I have eaten good in *April*, which is two months later than they usually keep; but yet I would not advise the planting of these late Pears in standard-trees, because they should hang very late on the trees in autumn, at which season the winds are generally very high; and these standard-trees being much exposed, the fruit is often blown off the trees before they are ripe, and those of them, which may hang on the trees, are frequently bruised by being forced against the branches by the winds, so that they seldom keep well. What I mentioned this for, is to prove that these Pears will ripen very well without the assistance of a wall; so that, if they are planted in espaliers, where the trees are kept low, the fruit will not be so much exposed to the strong winds in autumn as those on the standards, therefore can be in no danger of the fruit coming to perfection; and, as the trees in espaliers will be constantly pruned, and managed in the same manner as those against walls, the fruit will be as large on those trees; therefore, where a person has a warm situation, and a kindly soil, I would not advise the being at an expence to build walls on purpose for Pears, but to plant them against espaliers, and, where there is any one who is very curious to have plenty of these fruit, and will be at the expence to procure them, I should advise the having a sufficient quantity of Reed-mats made to fix up against the back of the espalier in the spring, when the trees are in blossom, which will screen them from cold winds, and preserve the tender fruit until they are past danger, when the Reeds may be taken down, and put under a shed to preserve them from the weather; and, if the autumn should prove bad, these Reeds may be fixed up again, which will forward the ripening of the fruit, and also prevent the winds from blowing down, and bruising of it. These Reeds may be purchased for one Shilling per yard, running measure, at six feet and a half high, and, if they are carefully laid up, and kept from the weather, these Reeds will last seven or eight years, so that the expence will not be very great, and, when the advantages which these are of to the fruit are considered, I believe no person will object to the use of them.

But after the fruit is set and growing, there will be farther care necessary in order to have the fruit good, for it is not enough to have preserved a good crop of fruit on the trees, and then leave them entirely to nature during the season of their growth, but there will require some skill and attendance on the trees to help nature, or supply the deficiency of the seasons; for beside the pruning and training of the trees in the manner before directed, there will also be wanting some management of their roots according to the nature of the soil, and the difference of seasons. In all strong land, where the ground is apt to bind very hard in dry weather, the surface of the borders should be now and then forked over to loosen the earth, which will admit the showers and large dews to penetrate and moisten the ground, and be of great service to the trees and fruit, and also pre-

vent the growth of weeds. And if the soil is light and dry, and the season should prove hot and dry, there should be large hollows made round the stems of the trees to hold water; into each of these there should be poured eight or nine pots of water, which should be repeated once in a week, or ten days, during the months of *June* and *July*, if the season should continue dry. There should also be some mulch laid over the surface of these hollows to prevent the sun and air from drying the ground. Where this is practised, the fruit will be kept constantly growing, and prove large and plump; whereas, if this is omitted, the fruit will often be small, grow crooked, crack, and fall off from the trees. For if the fruit is once stunted in their growth, and rain should fall plentifully after, it will occasion a great quantity of the fruit to fall off the trees; and those which remain to ripen, will not keep so long as those which never receive any check in their growth; it is from this cause, that some years the fruit in general decays before the usual time. For after it has been for some time stunted in its growth, and then the season proves favourable, whereby it receives a sudden growth, it becomes so replete with juice, as to distend the vessels too suddenly, so that they will not be firm, which occasions their decay; therefore it is always best to keep the fruit constantly in a growing state, whereby it will acquire a proper size, and be rendered better flavoured.

There will also be required some dressing to the ground near the fruit-trees, but this should be laid on in autumn, after the trees are pruned. This dressing should be different, according to the nature of the soil; if the land is warm and dry, then the dressing should be of very rotten dung, mixed with loam; and if this is mixed six or eight months before it is laid upon the borders, and three or four times turned over, it will be the better; as will also the mixture, if it is made with neats or hogs-dung, both which are colder than horse-dung, so more proper for hot land. But in cold stiff land, rotten horse-dung, mixed with light sandy earth, or sea-coal ashes, will be the most proper, as this will loosen the ground, and add a warmth to it.

These dressings should be repeated every other year, otherwise the trees will not thrive so well, nor will the fruit be so good. For, notwithstanding what many persons have advanced to the contrary, yet experience is against them, for the finest fruit in *England*, both as to size and flavour, is produced on land which is the most dunged and worked. Therefore I would advise the trenching of the ground about the fruit-trees very well every winter, for I am sure it will be found to answer their expectations, who will practise this method. And where the ground in the quarters is well dressed and trenched, the fruit-trees will partake of the benefit, for as the trees advance in their growth, so their roots are extended to a great distance from their stems; and it is chiefly from the distant roots that the trees are supplied with their nourishment, therefore the dressing of the borders only, will not be sufficient for fruit-trees which are old.

In the gathering of Pears, great regard should be had to the bud which is formed at the bottom of the foot-stalk, for the next year's blossoms, which, by forcing off the Pear before it be mature, is many times spoiled; for while the fruit is growing, there is always a bud formed by the side of the foot-stalk upon the same spur, for the next year's fruit; so that when the Pears are ripe, if they are gently turned upward, the foot-stalk will readily part from the spur, without injuring of the bud.

The season for gathering all-summer Pears is just as they

ripen, for none of these will remain good above a day or two after they are taken from the tree; nor will many of the autumn Pears keep good above ten days or a fortnight, after they are gathered. But the winter fruits should hang as long upon the trees as the season will permit, for they must not receive the frost, which will cause them to rot, and render their juices flat and ill tasted; but if the weather continue mild until the end of *October*, it will then be a good season for gathering them in, which must always be done in dry weather, and when the trees are perfectly dry.

In the doing of this, you ought carefully to avoid bruising them, therefore you should have a broad flat basket to lay them in as they are gathered; and when they are carried into the store-room, they should be taken out singly, and each sort laid up in a close heap on a dry place, in order to sweat, where they may remain for ten days or a fortnight, during which time the windows should be open to admit the air, in order to carry off all the moisture which is perspired from the fruit; after this, the Pears should be taken singly, and wiped dry with a woollen cloth, and then packed up in close baskets, observing to put some Wheat-straw in the bottoms, and round the sides of the baskets, to prevent their bruising against the baskets. And if some thick soft paper is laid double or treble all round the basket, between the Straw and the Pears, this will prevent the Pears from imbibing the musty taste which is communicated to them by the Straw, when they are contiguous; which taste often penetrates through the skin so strongly, that when the fruit is pared, the taste will remain. You should also observe to put but one sort of fruit into a basket, lest by their different fermentations they should rot each other; but if you have enough of one sort to fill a basket which holds two or three bushels, it will be still better. After you have filled the baskets, you must cover them over with Wheat-straw very close, first laying a covering of paper two or three times double over the fruit, and fasten them down; then place these baskets in a close room, where they may be kept dry and from frost; but the less air is let into the room, the better the fruit will keep. It will be very necessary to fix a label to each basket, denoting the sort of fruit therein contained, which will save the trouble of opening them, whenever you want to know the sorts of fruit; besides, they ought not to be opened before their season to be eaten; for the oftener they are opened, and exposed to the air, the worse they will keep. I don't doubt but this will be objected to by many, who imagine fruit cannot be laid too thin; for which reason, they make shelves to dispose them singly upon, and are very fond of admitting fresh air, whenever the weather is mild, supposing it very necessary to preserve the fruit; but the contrary of this is found true, by those persons who have large stocks of fruit laid up in their storehouses in *London*, which remain closely shut up for several months, in the manner before related; and when these are opened, the fruit is always found plumper and sounder than any of those fruits which were preserved singly upon shelves, whose skins are always shrivelled and dry. For (as *Mr. Boyle* observes) the air is the cause of putrefaction; and, in order to prove this, that honourable gentleman put fruits of several kinds into glasses where the air was exhausted, in which places they remained sound for several months, but, upon being exposed to the air, rotted in a very short time, which plainly shews the absurdity of the common method now used, to preserve fruit.

QUERCUS. Tourn. Inst. R. H. 582. tab. 349.
 The Oak-tree.

The Characters are,

It hath male and female flowers on the same tree; the male flowers are disposed in a loose catkin. The female flowers, which sit close to the buds, have a hemispherical thick empalement of one leaf, which is rough and entire, almost hiding the flower, which has no petal, but a small oval germen, supporting a single five-pointed style, crowned by single permanent stigmas. The germen after-ward becomes an oval Nut (or Acorn) with a thick cover, having one cell, whose base is fixed into the empalement or cup.

The Species are,

1. *QUERCUS foliis deciduis oblongis, supernè latioribus sinibus acutioribus, angulis obtusis petiolatis glandibus sessilibus.* Oak with oblong deciduous leaves, broader toward the top, having acute indentures, with obtuse angles, which have foot-stalks, and acorns sitting close to the branches; or common Oak.

2. *QUERCUS foliis deciduis oblongis obtusis, pinnato-sinuatis petiolis brevissimis, pedunculis glandorum longissimis.* Oak with oblong, obtuse, deciduous leaves, which are winged-sinuuated, very short foot-stalks, with a fruit growing upon long foot-stalks.

3. *QUERCUS foliis oblongis sinuatis obtusis perennantibus, pedunculis glandorum longissimis.* Oak with oblong, obtuse, indented leaves, which are ever-green, having very long foot-stalks to the Acorns; or broad-leaved ever-green Oak.

4. *QUERCUS foliis oblongis obtusè-sinuatis, setaceo mucronatis sessilibus, glandibus majoribus.* Oak with oblong, obtusely indented leaves, which have bristly points, and sit close to the stalks, with larger Acorns.

5. *QUERCUS foliis oblongis pinnato-sinuatis, subtus tomentosis, glandibus sessilibus calycibus tomentosis.* Oak with oblong wing-indented leaves, which are downy on their under side, and Acorns having woolly cups sitting close to the branches.

6. *QUERCUS humilis, foliis oblongis obtusè dentatis, fructibus sessilibus conglomeratis.* Dwarf Oak with oblong, obtusely indented leaves, and fruit growing in clusters, sitting close to the branches; or dwarf Oak.

7. *QUERCUS foliis oblongis lyrato pinnatifidis, laciniis transversis acutis, subtus subtomentosis.* Lin. Sp. Plant. 997. Oak with oblong leaves, which are lyre-shaped, wing-pointed and have transverse acute jags, which are somewhat downy on their under side.

8. *QUERCUS foliis pinnato-sinuatis lævibus, fructibus sessilibus.* Prod. Leyd. 80. Oak with smooth wing-indented leaves, and fruit sitting close to the branches; commonly called the cut-leaved Italian Oak.

9. *QUERCUS foliis ovato-oblongis glabris, serrato repandis.* Lin. Sp. Plant. 996. Oak with oblong, oval, smooth, sawed leaves, and reflexed indentures.

10. *QUERCUS foliis obtusè-sinuatis setaceo-mucronatis.* Lin. Sp. Plant. 996. Oak with obtuse sinuated leaves, terminated by bristly points.

Q U E

11. *QUERCUS foliis obovatis utrinque acuminatis sinuato-serratis, denticulatis rotundatis uniformibus.* Hort. Cliff. 448. Oak with oblong oval leaves, which are pointed on both sides, and have sawed sinuses with uniform roundish indentures; the American Chestnut-leaved Oak.

12. *QUERCUS foliis cuneiformibus obsoletè trilobis.* Flor. Virg. 117. Oak with wedge-shaped leaves, having three worn-out lobes; the Black Oak.

13. *QUERCUS foliorum sinibus obtusis, angulis acutis setâ-terminatis, intermediis vix tridentatis margine integerrimo.* Hort. Cliff. 448. Oak with obtuse sinuses to the leaves, and acute angles terminated by bristles, and an entire border; the Scarlet Oak of Virginia.

14. *QUERCUS foliis obliquè pinnatifidis, sinibus angulisque obtusis.* Lin. Sp. Plant. 996. Oak with oblique many-pointed leaves, having obtuse sinuses and angles; the White Oak of Virginia.

15. *QUERCUS foliis lineari-lanceolatis integerrimis glabris.* Oak with linear, spear-shaped, entire, smooth leaves; the Willow-leaved Oak.

16. *QUERCUS foliis oblongo-ovatis subtus tomentosis integerrimis.* Prod. Leyd. 81. Oak with oblong, oval, entire leaves, which are downy on their under side; the narrow-leaved ever-green Oak.

17. *QUERCUS foliis oblongo-ovatis sinuato-spinosis subtus tomentosis, glandibus pedunculatis.* Sauv. Monsp. 96. Ever-green Oak with oblong, oval, prickly, indented leaves, which are woolly on their under side, and bears Acorns with foot-stalks; or the Holly-leaved ever-green Oak.

18. *QUERCUS foliis ovatis indivisis spinoso-dentatis glabris.* Prod. Leyd. 80. Oak with oval, undivided, smooth leaves, which are prickly and indented; or the Kermes Oak.

19. *QUERCUS foliis lanceolato-ovatis integerrimis petiolatis sempervirentibus.* Oak with spear-shaped, oval, entire leaves, which are ever-green, and have foot-stalks; commonly called Live Oak in America.

20. *QUERCUS foliis ovato-oblongis indivisis serratis subtus tomentosis, cortice rimoso fungoso.* Hort. Cliff. 448. Oak with oval, oblong, undivided leaves, which are sawed and woolly on their under side, and have a fungous cleft bark; or Cork-tree.

The first sort here mentioned, is the most common Oak of this country, which is so well known as to need no description; the leaves of this, have pretty long foot stalks, and the Acorns have none, but sit close to the branches.

The second sort, is not so common here as the first, but in the wilds of Kent and Sussex I have seen many large trees of this kind. The leaves of this are not so deeply sinuated as those of the first, nor are they so irregular, but the indentures are opposite, like the lobes of winged leaves; these have scarce any foot-stalks, but sit close to the branches; the Acorns stand upon very long foot stalks, in which they differ from the common sort. The timber of this sort is accounted better than that of the first, and the trees when growing have a better appearance. These have been generally supposed to be seminal varieties, which have accidentally

tally come from Acorns of the same tree; I was long of this opinion myself, but having lately seen some young trees with Acorns upon them, which were raised from Acorns of the second sort, and finding they retain their difference, I am inclined to believe they are different.

The third sort grows upon the *Apennines*, and also in *Savabia* and *Portugal*. The leaves of this are broader and not so deeply sinuated as those of the common Oak; they are of a lighter green on their upper side, but pale on their under; they have very short foot-stalks, their points are obtuse, and the Acorns have very long foot-stalks, which frequently sustain three or four growing in a cluster.

The fourth sort grows common in some parts of *France*, where it rises to be a tall stately tree. The leaves are oblong and obtusely sinuated, each sinus being terminated by a bristly point; the Acorns are larger than those of the common Oak.

The fifth sort grows in the south of *France* and in *Italy*. The leaves of this are shorter and broader than those of the common Oak, and are regularly indented on their sides, the indentures being opposite, but not deep; they are of a light green on their upper side, and are covered with a soft down on their under, standing upon short foot-stalks; the Acorns grow in clusters, sitting close to the branches; their cups are covered with a white down.

The sixth sort grows in the south of *France* and in *Italy*. This is a low bushy Oak, which rises but six or seven feet high, sending out many slender branches, garnished with oblong leaves, which are obtusely indented, standing upon slender foot-stalks; the Acorns are small, and grow in clusters, and the galls grow three or four together.

The seventh sort grows in *Burgundy*. The leaves of this are oblong and pointed, and are frequently indented in the middle like a lyre; they are jagged and acute-pointed, a little hoary on their under side, standing upon slender foot-stalks. The Acorns are small, and have rough prickly cups.

The eighth sort grows naturally in *Spain* and *Italy*. The leaves of this tree are smooth; they are deeply sinuated like winged leaves; some of the sinuses are obtuse, and others end in acute points; they have very short foot-stalks; the branches are covered with a purplish bark when young; the Acorns are long and slender, the cups rough and a little prickly, sitting close to the branches. The Acorns of this sort are sweet, and are frequently eaten by the poor in the south of *France*, who in times of scarcity grind them and make bread with the flour.

The ninth sort grows naturally in the *Levant*, from whence the Acorns are annually brought to *Europe*, where they are used for dyeing; these are called *Velani*, and the tree *Velanida* by the *Greeks*. It is one of the fairest species of Oak in the world; the trunk of this rises as high as the common Oak; the branches extend very wide on every side, and are covered with a grayish bark, intermixed with brown spots; they are closely garnished with oblong oval leaves, which are deeply sawed on their edges; most of the saws or teeth turn backward, and terminate in acute points. The leaves are stiff, of a pale green on their upper side, and on their under side are a little downy; the Acorns have very large scaly cups, which almost cover them; the scales are ligneous and acute-pointed, standing out a quarter of an inch; some of the cups are as large as middling Apples.

The tenth sort grows naturally in *Virginia*, and in other parts of *North America*. This is a large tree in the countries where it naturally grows; the bark is smooth, of a grayish colour, but that of the younger branches is darker; the leaves are long and broad; they are obtusely sinuated, each sinus ending with a bristly point, of a bright green, standing upon short foot-stalks. The leaves continue their verdure very late in autumn, so that unless hard frost comes

on early, they do not fall till near *Christmas*, nor do they change their colour long before. The Acorns of this sort are a little longer, but not so thick as those of the common Oak.

The eleventh sort grows naturally in *North America*. Of this there seems to be two kinds, one of which grows to a much larger size than the other, though this may be occasioned by the soil in which they grow; for the largest sort grows in the rich low lands, where it becomes the largest tree of any of the Oaks in those countries. The wood is not of a fine grain, but is very serviceable; the bark is gray and scaly; the leaves are long and broad, indented on the edges, and have many transverse veins running from the midrib to the borders; they are of a bright green, and so nearly resemble those of the Chestnut-tree, as scarcely to be distinguished from it. The Acorns of this sort are very large, and their cups are short. The leaves of the other variety are not so large, nor so strongly veined, and the Acorns are smaller and a little longer, which may arise from the soil.

The twelfth sort grows naturally on poor land in most parts of *North America*; this never grows to a large size, and the wood is of no value. The bark is of a dark brown colour; the leaves are very broad at the top, where they have two waved indentures, which divide them almost into three lobes; they diminish gradually to their base, where they are narrow; they are smooth, of a lucid green, and have short foot-stalks. The Acorns are smaller than those of the common Oak, and have short cups.

The thirteenth sort grows naturally in *North America*, where it is called the Red Oak, from the leaves changing to a deep red or purple before they fall off. There has been supposed two sorts of this Oak, but I believe they are only feminal varieties; for from the Acorns of the same tree, I have seen plants raised, whose leaves have been of very different shapes and sizes, and have varied greatly in their colour in autumn, some changing to a bright red or scarlet, and others to a deep purple colour. The wood is soft, spongy, and not durable. The Acorns of this sort also vary in size and shape; some of them are smaller, and others shorter and larger than those of the common Oak.

The fourteenth sort grows naturally in *North America*, where the wood is esteemed preferable to any of their other sorts for building, being much more durable than any of them. The bark of this tree is grayish; the leaves are long and broad, and are regularly indented almost to the midrib; the indentures are obtuse; they are of a light green, and have short foot-stalks. The Acorns of this greatly resemble those of the common Oak.

The fifteenth sort grows naturally in *North America*, where they distinguish two sorts; one of them is called the *Highland Willow Oak*, which grows upon poor dry land; the leaves are of a pale green and entire, shaped like those of the Willow-tree. The Acorns are very small, but have pretty large cups.

The other grows in low moist land, and rises to a much greater height; the leaves are longer and narrower, and the Acorns are of the same size and shape, so that I suspect their difference is owing to the soil in which they grow.

The sixteenth sort is generally known by the title of *Ilex*, or ever-green Oak. Of this there are several varieties, which differ greatly in the size and shape of their leaves; but these will all arise from Acorns of the same tree, as I have several times experienced; nay, the lower and upper branches of the same tree are frequently garnished with leaves, very different in size and shape from each other. The leaves are entire, of a lucid green on their upper side, but whitish and downy on their under, standing upon pretty long foot-stalks; these remain green all the year, and do not fall till they are thrust off by young leaves in the spring.

The Acorns are smaller than those of the common Oak, but of the same shape.

The seventeenth sort is supposed to be a different sort. The leaves are shorter and broader than the other, approaching in shape to those of the Holly-tree, and are set with prickles on their edges.

The eighteenth sort is the Oak, from which the Kermes, or what is called Scarlet Grain, is collected, which is an insect that harbours on this tree. It grows naturally in *Provence* and *Languedoc*, where it is known by the title d'Avaux. This is of small growth, seldom rising above twelve or fourteen feet high, sending out branches on every side, so as to form a bushy shrub; the leaves are oval and undivided; they are smooth on their surface, but indented on their edges, which are armed with prickles like those of the Holly-tree. The Acorns are smaller than those of the common Oak.

The nineteenth sort grows naturally in *Carolina* and *Virginia*, where it rises to the height of forty feet. The Grain of the wood is hard, tough, and coarse; the bark is grayish; the leaves are entire, ovally spear-shaped, and of a dark green, of a thick consistence, and continue green all the year. The Acorns are small, oblong, and have short cups; they are very sweet, so are eaten by the *Indians*, who lay them up in store for the winter; they also draw a very sweet oil from them, little inferior to that of sweet Almonds. This is called the Live Oak in *America*.

The twentieth sort is the tree whose bark is the cork. Of this there are two or three varieties, *viz.* one with a broad, another with a narrow leaf, which are ever-green; and there is one or two which cast their leaves in autumn, but the broad-leaved ever-green is the most common; the other may probably be only a variety, arising by accident. The leaves of this are oblong, oval, undivided, sawed on their edges, and have a little down on their under sides; their foot-stalks are very short; the leaves continue green through the winter till the middle of *May*, when they generally fall off just before the new leaves come out, so that the trees are very often almost bare for a short time. The Acorns are very like those of the common Oak.

The exterior bark of this tree is the cork; this is taken off from the trees every eight or ten years, but there is an interior bark which nourishes the trees, so that the stripping off the outer, is so far from injuring them, that it is necessary to continue the trees, for those whose bark are not taken off, seldom last longer than fifty or sixty years in health; whereas the trees, which are barked every eight or ten years, will live a hundred and fifty years or more. The bark of the young trees is porous and good for little, however it is necessary to take it off when the trees are twelve or fifteen years old, without which the bark will not be good, and after eight or ten years the bark will be fit to take off again; but this second peeling is of little use, but the third peeling the bark will be in perfection, and will continue so many years, for the best cork is taken from the old trees. The time of year for stripping off this bark is in *July*, when the second sap flows plentifully. This is performed with an instrument, like that used for disbarking Oaks.

All the sorts of Oaks are propagated by sowing their Acorns; the sooner they are put into the ground after they are ripe, the better they will succeed; for they are very apt to sprout where they are spread thin, and if they are laid in heaps, they ferment and rot in a little time; therefore the best season for sowing them is in *October*, by which time they will be fallen from the trees.

Where Oak trees are cultivated with a view to profit, the Acorns should be sown where the trees are designed to grow, for those which are transplanted, will never arrive to the size of those which stand where they are sown, nor

will they last near so long sound. For in some places, where these trees have been transplanted with the greatest care, and have grown very fast for several years after, yet are now decaying, when those which remain in the place where they came up from the Acorns, are still very thriving, and have not the least sign of decay. Therefore, whoever designs to cultivate these trees for timber, should never think of transplanting them, but sow the Acorns on the same ground where they are to grow; for the timber of all those trees which are transplanted, is not near so valuable as that of the trees from Acorns. I shall give some plain directions for the sowing of Acorns, and managing of the young trees during their minority, until they are out of danger, and require no farther care.

The first thing to be done is, that of fencing the ground very well, to keep out cattle, hares, and rabbits; for if either of these can get into the ground, they will soon destroy all the young trees. Indeed they will in a few years grow to be out of danger from the hares and rabbits, but it will be many years before they will be past injury from cattle, if they are permitted to get into the plantation, therefore durable fences should be put round the ground: if in the beginning a pale fence is made about the land, which may be close at the bottom and open above, and within the pale a quick hedge planted; this will become a good fence by the time the pale decays, against all sorts of cattle, and then the trees will have got above the reach of hares and rabbits, so that they cannot injure them, for the bark of the trees will be too hard for them to gnaw.

After the ground is well fenced, it should be prepared, by ploughing of it three or four times, and after each ploughing to harrow it well, to break the clods, and cleanse the ground from couch, and the roots of all bad weeds. Indeed if the ground is green sward, it will be better to have one crop of Beans, Peas, or Turneps, off the ground, before the Acorns are sown, provided these crops are well hoed, to stir the surface and destroy the weeds; for if this is observed, the crop will mend and improve the land for sowing; but in this case the ground should be ploughed as soon as possible, when the crop is taken off, to prepare it for the Acorns, which should be sown as soon as may be after they are ripe; for although they may be preserved in sand for some time, yet they will be apt to sprout; and if so, the shoots are in danger of being broken and spoiled; therefore I should advise the sowing early, which is certainly the best method.

In making choice of the Acorns, all those should be preferred, which are taken from the largest and most thriving trees; and those of Pollard-trees should always be rejected, though the latter are generally the most productive of Acorns, but those of the large trees commonly produce the strongest and most thriving plants.

The season for sowing of the Acorns being come, and the ground having been ploughed and harrowed smooth, the next work is to sow the Acorns, which must be done by drawing of drills across the ground, at about four feet asunder, and two inches deep, into which the Acorns should be scattered at two inches distance. These drills may be drawn either with a drill-plough, or by hand with a hoe; but the former is the most expeditious method, therefore in large plantations should be preferred. In the drawing of the drills, if the land has any slope to one side, these should be made the same way as the ground slopes, that there may be no stoppage of the wet by the rows of plants crossing the hanging of the land. This should be particularly observed in all wet ground, or where the wet is subject to lie in winter, but in dry land it is not of much consequence. When the Acorns are sown, the drills should be carefully filled in, so as to cover the Acorns securely;

for if any of them are exposed, they will entice the birds and mice, and if either of these once attack them, they will make great havock with them.

The reason of my directing the drills to be made at this distance, is for the more convenient stirring of the ground between the rows, to keep the young plants clear from weeds; for if this is not carefully done, it cannot be expected that the young plants should make much progress; and yet this is generally neglected by many who pretend to be great planters, and are often at a large expence to plant, but seldom regard them after; so that the young plants have the difficulty to encounter the weeds, which frequently are four or five times the height of the plants, and not only shade and draw them, but also exhaust all the goodness of the ground, and consequently starve the plants. Therefore, whoever hopes to have success in their plantations, should determine to be at the expence of keeping them clean for eight or ten years after sowing, by which time the plants will have obtained strength enough to keep down the weeds; the neglecting of this has occasioned so many young plantations to miscarry, as are frequently to be met with in divers parts of *England*.

About the middle of *April*, the young plants will appear above ground; but before this, if the ground should produce many young weeds, it will be good husbandry to scuffle the surface over with *Dutch* hoes, in a dry time, either the latter end of *March* or the beginning of *April*, to destroy the weeds, whereby the ground will be kept clean, until all the plants are come up, so as to be plainly discerned, by which time it may be proper to hoe the ground over again; for by doing it early, while the weeds are small, a man will perform more of this work in one day, than he can in three or four when the weeds are grown large; besides, there will be great hazard of cutting off or injuring the young plants, when they are hid by the weeds, and small weeds being cut, are soon dried up by the sun; but large weeds often take fresh root and grow again, especially if rain should fall soon after, and then the weeds will grow the faster for being stirred; therefore it is not only the best method, but also the cheapest husbandry, to begin cleaning early in the spring, and to repeat it as often as the weeds are produced.

The first summer, while the plants are young, it will be the best way to perform these hoeings by hand, but afterward it may be done with the hoe-plough; for as the rows are four feet asunder, there will be room enough for this plough to work; and as this will stir and loosen the ground, it will be of great service to the plants; but there will require a little land labour where the plough is used, in order to destroy the weeds, which will come up in the rows between the plants; for these will be out of the reach of the plough, and if they are not destroyed, they will soon overgrow and bear down the young plants.

After the plants have grown two years, it will be proper to draw out some of them, where they grow too close; but in the doing of this, great care should be had not to injure the roots of those left, for as the plants, which are drawn out, are only fit for plantations designed for pleasure, so these should not be so much regarded in their being removed, as to sacrifice any of those which are designed to remain. In the thinning of these plantations, the plants may at the first time be left about one foot asunder, which will give them room enough to grow two or three years longer, by which time it may be easy to judge which are likely to make the best trees. Therefore these may be then fixed on as standards to remain, though it will be proper to have a greater number at this time marked than can be permitted to grow, because some of them may not answer the expectation; and as it will be improper to thin

these trees too much at one time, so the leaving double the number intended at the second thinning, will not be amiss. Therefore, if they are then left at about four feet distance in the rows, they will have room enough to grow three or four years longer; by which time, if the plants have made good progress, their roots will have spread over the ground, therefore it will be proper to take up every other tree in the rows. But by this I do not mean to be exact in the removing, but to make choice of the best plants to stand, whichever rows they may be in, or if they should not be exactly at the distance here assigned. All that is designed here, is to lay down general rules, which should be as nearly complied with as the plants will permit; therefore every person should be guided by the growth of the trees in the performance of this work.

When the plants have been reduced to the distance of about eight feet, they will not require any more thinning. But in two or three years time, those which are not to remain will be fit to cut down, to make stools for under-wood; and those which are to remain, will have made such progress as to become a shelter to each other, for this is what should be principally attended to whenever the trees are thinned; therefore in all such places as are much exposed to the wind, the trees should be thinned with great caution, and by slow degrees, for if the air is let too much at once in the plantation, it will give a sudden check to the trees, and greatly retard their growth; but in sheltered situations, there need not be so great caution used as in those places, for the plants will not be in so much danger of suffering.

The distance which I should choose to allow to those trees which are designed to remain for timber is, from twenty-five to about thirty feet, which will not be too near, where the trees thrive well; in which case their heads will spread, so as to meet in about thirty or thirty-five years; nor will this distance be too great, so as to impede the upright growth of the trees. This distance is intended, that the trees should enjoy the whole benefit of the soil; therefore, after one crop of the under-wood, or at the most two crops are cut, I would advise the stubbing up the stools, that the ground may be entirely clear, for the advantage of the growing timber, which is what should be principally regarded; but in general most people have more regard to the immediate profit of the under-wood than the future good of the timber, and frequently by so doing spoil both; for if the under-wood is left after the trees have spread so far as that their heads meet, it will not be of much worth, and yet, by their stools being left, they will draw away a great share of nourishment from the timber-trees, and retard them in their progress.

The soil in which the Oak makes the greatest progress, is a deep rich loam, in which the trees grow to the largest size; and the timber of those trees which grow upon this land, is generally more pliable than that which grows on a shallow or drier ground, but the wood of the latter is much more compact and hard. Indeed there are few soils in *England* in which the Oak will not grow, provided there is proper care taken in their cultivation, though this tree will not thrive equally in all soils; but yet it might be cultivated to a national advantage upon many large wastes in several parts of *England*, as also to the great profit of the estates where these tracts of land now lie uncultivated, and produce nothing to the owner. And should the present temper of destroying the timber of *England* continue in practice some years longer, in the same degree which it has for some years past, and as little care taken to raise a supply, this country, which has been so long esteemed for its naval strength, may be obliged to seek for timber abroad, or be content with such a naval strength as the poor remains

of some frugal estates may have left growing; for as to the large forests, from whence the navy has been so long supplied, a few years will put an end to the timber there; and how can it be otherwise, when the persons to whose care these are committed, reap an advantage from the destruction of the timber?

Before I quit this subject, I must beg leave to take notice of another great evil, which is of so much consequence to the publick, as to deserve their utmost attention; which is, that of cutting down the Oaks in the spring of the year, at the time when the sap is flowing. This is done for the sake of the bark, which will then easily peel off; and for the sake of this, I think, there is a law, whereby people are obliged to cut down their timber at this season. But by so doing, the timber is not half so durable as that which is fallen in the winter; so that those ships which have been built of this spring-cut timber, have decayed more in seven or eight years, than others which were built with timber cut in winter, have done in twenty or thirty. And this our neighbours the *French* have experienced, and therefore have wisely ordered, that the bark should be taken off the trees standing, at the proper time, but the trees are left till the next, and sometimes until the second winter, before they are cut down; the timber of these are found to be more durable and better for use, than that of any trees which have not been peeled. Therefore, I wish we were wise enough to copy after them in those things which are for the publick good, rather than to imitate them in their follies, which has been too much the fashion of late years.

The other sorts of Oak, which are only planted for pleasure, either in parks or gardens, may be raised from Acorns sown in beds, and the plants may be trained in a nursery three or four years; then they should be planted where they are to remain, for although they are not cultivated for their wood, yet the younger they are planted out, the better they will succeed, provided they are kept clean from weeds, and secured from animals.

QUICK. By the word quick are generally understood all live hedges, of whatever sort of plants they are composed, to distinguish them from dead hedges; but, in the more strict sense of this word, it is applied to the Hawthorn, or *Mespilus Sylvestris*; under which name, the young plants or sets are commonly sold by the nursery-gardeners, who raise them for sale.

In the choice of these sets, those which are raised in the nursery are to be preferred to such as are drawn out of the woods, because the latter have seldom good roots, though as they are larger plants than are commonly to be had in

the nursery, many people prefer them on that account; but from long experience I have found, that those hedges which have been planted with young plants from the nursery, have always made the best hedges. Indeed, if persons would have patience to wait for these from seed, and to sow the laws in the place where the hedge is designed, these unremoved plants will make a much stronger and more durable fence, than those which are transplanted; but I am aware that most people will be for condemning this practice, as being tedious in raising; but if the laws are buried one year in the ground, to prepare them for vegetation before they are sown, it will not be so long before this will become a good fence, as is generally imagined. Nay, from some trials of this kind which I have made, I have found that those plants which have remained where they came up from seed, have made such progress as to overtake, in six years, plants of two or three years growth, which were transplanted at the time when these seeds were sown.

And if the hedges are raised from seed, it will not be amiss to mix Holly-berries with the Haws; the Berries and Haws should be buried one year, to prepare them, so that then both will come up together the following spring; and this mixture of Holly, with the quick, will not only have a beautiful appearance in the winter, but will also thicken the hedge at the bottom, and make it a better fence.

But where the hedge is to be planted, the sets should not be more than three years old from the Haws, for when they are older, their roots will be hard and woody; and as they are commonly trimmed off before the sets are planted, so they very often miscarry, and such of them as do live, will not make so good progress as younger plants, nor are they so durable; for these plants will not bear transplanting so well as many others, especially when they have stood long in the seed-bed unremoved.

The method of planting, as also of plashing and pruning of these hedges, having been fully explained under the article **HEDGES**, I shall not repeat it here.

QUICK-BEAM. See *Sorbus Sylvestris*.

QUINCE-TREE. See *Cydonia*.

QUINCUNX ORDER is a plantation of trees, disposed originally in a square, consisting of five trees, one at each corner, and a fifth in the middle, which disposition, repeated again and again, forms a regular grove, wood, or wilderness, and, when viewed by an angle of the square or parallelogram, presents equal or parallel alleys.

QUINQUEFOLIUM. See *Potentilla*.

RAMSONS. See Allium.
RANDIA. *Houft. Gen. Nov. 28. Lin. Gen. Plant. 114.*

The Characters are,

The empalement of the flower is of one leaf cut into five short segments at the brim. The flower is funnel-shaped, cut into five parts at the top; it hath five short stamina, terminated by oblong erect summits, and an oval germen, supporting a cylindrical style, crowned by two obtuse unequal stigmas. The germen afterward becomes an oval capsule, with one cell, having a hard cover, including many compressed cartilaginous seeds, surrounded with pulp.

We have but one Species of this genus at present in the English gardens, viz.

RANDIA *foliis ovatis emarginatis, spinis geminatis, caule fruticoso.* Randia with oval leaves, which are indented at the top, spines growing by pairs, and a shrubby stalk.

This plant grows naturally at *La Vera Cruz*, where the late Dr. *Houftoun* found it in plenty, and sent the seeds to Europe; he gave this title to the genus in honour of Mr. *Isaac Rand*, who was a curious botanist. It was discovered by Sir *Hans Sloane* in the island of *Barbadoes*.

It rises with a shrubby stalk to the height of ten or twelve feet, covered with a whitish bark. The branches come out opposite from the side of the stalk, each pair crossing the other; the leaves are of a thick consistence, roundish, and a little indented at the top, placed by pairs, standing upon short foot-stalks. At the joints immediately under the leaves are two short spines standing opposite. The flowers are produced from the side of the branches; they are small, white, tubulous, and divided at the brim slightly into five parts. These are succeeded by oval berries about the size of a marble, having a brittle shell under a thin skin, with one cell, inclosing many compressed seeds, surrounded with black pulp. It is propagated by seeds, which should be sown early in the spring in pots, and plunged into a hot-bed of tanners bark. When the plants come up, they must have fresh air admitted to them every day, when the weather is warm. In about a month's time after the plants come up, they will be fit to transplant, when they should be carefully shaken out of the pots, and each planted into a separate small pot, and then plunged into the hot-bed again, where they must be screened from the sun, until they have taken new root; after which time they must have air and moisture, in proportion to the warmth of the season. The plants may remain in the hot-bed till toward *Michaelmas*, when the nights begin to be cold; at which time they should be removed into the stove, and, if they are plunged into the bark-bed, it will greatly forward their growth, though they will live in the dry stove, if they are kept in a moderate temperature of heat. During the two first seasons, while the plants are young, it will be proper to keep them constantly in the stove, but then their leaves must be washed, whenever they contract filth; this will bring them forward; but, after the plants have obtained

R A N

strength, they may be exposed every summer to the open air, in the warmest part of the year, for two or three months, provided they are placed in a warm situation, but in winter they must be constantly placed in a stove, and kept in a moderate warmth, otherwise they will not live in this country.

The leaves of this plant continue green throughout the year, which renders the plant valuable, because it makes an agreeable variety in the winter season, when mixed with other tender plants.

RANUNCULUS. *Tourn. Inst. R. H. 285. tab. 149.* Crowfoot.

The Characters are,

The empalement of the flower is composed of five oval concave leaves; the flower has five obtuse petals, which have a narrow base; each of these have an open nectarium upon their tails. It hath many stamina, terminated by oblong, erect, twin summits, and numerous germen collected in a head, having no styles, but are crowned by small reflexed stigmas. The germen afterward become seeds of uncertain irregular figures, fastened to the receptacle by very short foot-stalks.

I shall not here enumerate all the species of this genus, many of which are common weeds in most parts of England, and others are so in several parts of Europe, so are rarely admitted into gardens, therefore I shall only mention those sorts which are cultivated in gardens.

1. **R**ANUNCULUS *calycibus patulis, pedunculis teretibus, foliis tripartito-multifidis, summis linearibus.* *Lin. Flor. Suec. 466. flore pleno.* Ranunculus with a spreading empalement, a taper foot-stalk, many-pointed leaves, divided by threes, and those at the top linear, bearing a double flower; upright Garden Ranunculus with a double flower.

2. **R**ANUNCULUS *calycibus patulis, pedunculis sulcatis, stolonibus repentibus, foliis compositis.* *Flor. Suec. 468. flore pleno.* Ranunculus with a spreading empalement, furrowed foot-stalks, creeping shoots, and compound leaves, with a double flower; or Garden Ranunculus.

3. **R**ANUNCULUS *foliis radicalibus reniformibus crenatis sublobatis, caulinis tripartitis lanceolatis integerrimis, caule multifloro.* *Lin. Sp. Plant. 550.* Ranunculus with kidney-shaped lower leaves, which are crenated and almost divided into lobes, but those upon the stalks divided into three spear-shaped lobes, which are entire, bearing many flowers on a stalk.

4. **R**ANUNCULUS *foliis omnibus quinatis lanceolatis incisoferratis.* *Hort. Cliff. 229. flore pleno.* Ranunculus with all the leaves divided into five spear-shaped segments, which are sawed, and bear a double flower; commonly called Mountain Ranunculus.

5. **R**ANUNCULUS *foliis linearibus sessilibus, caule erecto sulcato, pedunculis longissimis.* Ranunculus with linear leaves fitting close to the stalk, which is erect, furrowed, having very long foot-stalks to the flowers.

6. **R**ANUNCULUS *foliis supra decompositis, caule simplicissimo unifolio, radice tuberosâ.* *Hort. Cliff. 230. flore pleno.* Ranunculus with leaves, which are decomposed above, a single stalk bearing one leaf, and a tuberous root with a double flower.

7. *RANUNCULUS foliis radicalibus reniformibus crenatis incis, caulinis digitatis linearibus, caule multiflora.* Hort. Cliff. 229. *flora pleno.* Ranunculus with kidney-shaped, crenated, lower leaves, those on the stalks hand-shaped, linear, and stalks bearing many flowers.

8. *RANUNCULUS foliis ovatis acuminatis amplexicaulis, caule subuniflora, radice fasciculata.* Hort. Cliff. 229. Ranunculus with oval acute-pointed leaves, which embrace the stalks, one flower upon a stalk, and roots growing in bunches.

9. *RANUNCULUS caule erecto bifolio, foliis multifidis, caulinis alternis sessilibus.* Flor. Leyd. Prod. 492. Ranunculus with an erect stalk bearing two leaves, which are many-pointed, those upon the stalks alternate and sitting close.

10. *RANUNCULUS foliis ternatis biternatisque, foliolis trifidis obtusis, caule simplici.* Ranunculus with leaves placed by threes, which are divided again into twice trifoliate leaves, ending in three obtuse points, and a simple stalk.

11. *RANUNCULUS foliis ternatis biternatisque, foliolis trifidis incis, caule inferno ramoso.* Lin. Sp. Plant. 552. Ranunculus with trifoliate and twice trifoliate leaves, whose lobes are trifid and cut, and a stalk branching at the bottom.

The first sort is a variety of the common upright Meadow Ranunculus, which grows naturally in almost every pasture; but as this hath double flowers, so it is cultivated in gardens. The stalks of this are erect, and rise more than a foot high; the lower leaves have very long foot-stalks; they are divided into several segments, resembling those of the Aconite, or Monkshood; the leaves toward the top of the stalks are cut into linear segments to the bottom; the stalk branches at the top into several foot-stalks, which are terminated by double yellow flowers. This is propagated by parting of the roots in autumn, and should be planted in a moist soil and a shady situation.

The second sort is a variety of the common creeping Crowfoot, which grows naturally in cultivated fields in most parts of *England*. The shoots from the root of this sort trail upon the ground, and put out roots from every joint in the manner of the Strawberry, so that when it is once introduced into a garden, it will multiply fast enough; the leaves and stalks are hairy; the flowers are yellow and double, but small.

The third sort grows naturally in *Crete*. This hath an Asphodel root; the lower leaves are large, kidney-shaped, and a little hairy, deeply crenated on their borders, and are divided almost into five lobes, having long hairy foot-stalks. The stalks rise about nine or ten inches high, garnished with two or three leaves, which are cut into three entire segments; the top of the stalk divides into several foot-stalks, each sustaining one large pale yellow flower. It is propagated by offsets from the roots, in the same way as the Garden Ranunculus, and should be planted in a warm border, otherwise the frost will destroy the roots.

The fourth sort grows naturally upon the *Alps*, with a single flower, but the double has been obtained by seeds, and is preserved in many curious gardens for the beauty of its flowers. This is by some gardeners called the Fair Maid of *France*; it hath a perennial root, composed of many strong fibres; the leaves are divided into five spear-shaped lobes; they are deeply sawed on their edges, and have several longitudinal veins. The stalks rise a foot and a half high, and branch out at the top into three or four divisions; at each of which there is one leaf, of the same shape with the lower, but smaller. The flowers are pure white and very double, each standing upon a short foot-stalk. This is propagated by parting the roots in autumn, as soon as the leaves decay, and should be planted in an east border, and a loamy soil, not too stiff.

The fifth sort grows naturally on the *Alps*. This has a

perennial root; the leaves are long and narrow, like those of Grass, sitting close to the stalks, which rise a little more than a foot high; these divide at the top into three or four slender foot-stalks, which are terminated by single yellow flowers, like those of the common Butterflower. There is a double flower of this kind in the *Paris* garden, but we have not yet got it in *England*.

The sixth sort grows naturally in *Austria*, and also in the *Levant*. This hath a tuberous root; the leaves decomposed and smooth; the stalks rise near a foot high, and have one leaf of the same shape with the lower, but smaller; the stalk is terminated by one double flower, about the size of the common Butterflower, but of a fine bright yellow colour. It is propagated by offsets from the roots in the same way as the Garden Ranunculus, and must be planted in a warm border, otherwise the frost will destroy the roots in winter.

The seventh sort is a variety of the common sweet Wood Ranunculus, which hath a double flower. This is a very hardy plant; it may be easily propagated by the root, and should have a loamy soil and a shady situation.

The eighth sort grows naturally upon the *Alps* and *Apennine* mountains, where it seldom rises more than six inches high; the leaves are narrow, and but one flower upon a stalk; but when it is planted in a garden, the stalks rise a foot and a half high, and are garnished with oval acute-pointed leaves, smooth, of a grayish colour, and embrace the stalks with their base; the stalks branch out at the top into several foot-stalks, each sustaining one white flower. It is propagated by parting of the roots in autumn, soon after the leaves decay, and may be planted on a shady border, where it will thrive exceedingly.

The ninth sort was discovered by Dr. *Tournefort* in the *Levant*. This hath a perennial root, from which arise several leaves, cut into many points, like those of Wolf-bane; the stalk rises a foot high, is garnished with two leaves, which sit close, and are alternate. The stalk is terminated by one single yellow flower, much larger than that of the Butterflower. It is propagated by parting of the roots in autumn, and should be planted in a light loamy soil.

The tenth sort is common in the *English* gardens, and was some years past more so than at present; for since the *Persian* Ranunculus has been introduced here, and so many fine varieties have been obtained from seeds, they have almost banished this sort out of the gardens. This hath a grumous root, like the *Persian* sort; the leaves are divided by threes, and those are twice again divided by threes; they are obtuse pointed; the stalk rises about nine inches high, terminated by one large double red flower.

The eleventh sort was originally brought from *Persia*, but since it has been in *Europe* has been greatly improved by culture, many new flowers have been obtained from seeds, amongst which are many with semidouble flowers, which produce seeds; and from these there are such prodigious varieties of new flowers annually obtained, which are of beautiful colours, so as to exceed all other flowers of that season, and even vie with the most beautiful Carnations; these are many of them finely scented, and the roots, when strong, generally produce twenty or thirty flowers upon each; which, succeeding each other, continue in beauty a full month or longer, according to the heat of the season, or the care taken to defend them from the injuries of the weather; all which excellent qualities have rendered them so valuable, that the old sorts are almost disregarded, except in some few old gardens.

All the very double flowers of this sort never produce seeds, so that they are only multiplied by offsets from their roots, which they generally produce in great plenty, if planted in a good soil, and duly attended in winter. The season for planting

their roots is any time in *October*, for if they are planted sooner, they are apt to come up in a short time, and grow pretty rank before winter, whereby they will be in greater danger of suffering by frost, and if they are planted much later, they will be in danger of perishing under ground; so that you should not keep them out of the ground any longer than the beginning or middle of *October*.

The beds in which the *Persian Ranunculus* roots are planted, should be made with fresh light earth, at least three feet deep: the best soil for them may be composed in this manner, *viz.* Take a quantity of fresh earth from a rich upland pasture, about six inches deep, together with the green sward; this should be laid in a heap to rot for twelve months before it is mixed, observing to turn it over very often to sweeten it, and break the clods; to this you should add a fourth part of very rotten neats dung, and a proportionable quantity of sea or drift-sand, according as the earth is lighter or stiffer; if it be light, and inclining to a sand, there should be no sand added, but if it be a hazel loam, one load of sand will be sufficient for eight loads of earth; but if the earth is strong and heavy, the sand should be added in a greater proportion: this should be mixed eight months or a year before it is used, and should be often turned over, in order to unite their parts well together, before it is put into the beds.

The depth which this should be laid in the beds, must be about three feet; this should be sunk below the surface, in proportion to the dryness or moisture of the place where they are situated, which in dry ground should be two feet eight inches below the surface, and the beds raised four inches above; but in a moist place they should be two feet four inches below, and eight above the ground; and in this case, it will be very proper to lay some rubbish and stones in the bottom of each bed, to drain off the moisture; and if upon this, at the bottom of the beds, some very rotten neats dung is laid two or three inches thick, the roots will reach this in the spring, and the flowers will be fairer. This earth I would by no means advise to be screened very fine, only in turning it over each time, you should be careful to break the clods, and throw out all large stones, which will be sufficient; for if it is made very fine, when the great rains in winter come on, it will cause the earth to bind into one solid lump, whereby the moisture will be detained, and the roots, not being able to extend their tender fibres, will rot. Of this I have many examples, but one particularly to my cost: when I had procured a fine parcel of these roots from abroad, and being desirous of having them thrive very well, I took great pains to screen the earth of my beds very fine, which I laid above two feet deep, and planted a good part of my roots therein; but the season advancing, and having a great deal of other business upon my hands, I did not screen the earth of all my beds, but planted some of them without doing any thing more than raking them; and the success was, that the roots in those beds which were screened, did, great part of them, entirely rot, and the remaining part were so weak, as not to produce any good flowers; whereas those which were planted in the beds which were not screened, did thrive and flower very well, and scarce any of the roots failed, though the earth of all the beds was the same, and were in the same situation, both with regard to wind and sun; so that the damage which those roots sustained, was owing entirely to the fineness of the earth, and this I have several times since observed in other gardens.

I am aware, that this depth of three feet, which I have here directed to make the beds for these flowers, will be objected to by many persons, on account of the expence and trouble of preparing them, as also supposing it unnecessary to make the beds so deep, for flowers whose roots

are small; but if they will give themselves the trouble of making the experiment, by preparing one bed in this manner, and another in the common way, and plant them both with the same flowers, they will soon be convinced of their error, by the success of the flowers. For in the beds which have been prepared of this depth, I have seen one root produce upward of fifty flowers, each of which grew near a foot high, and were extremely large and fair; whereas, in the common method of culture, they are thought to do very well, when they produce eight or ten flowers on each root, and those grow six inches high; but if a person will trace the length of the small fibres of these roots, he will find them to extend three or four feet downwards. And as it is by these distant fibres that the nourishment is taken in, for the increase and strength of the flowers; so if these meet with a poor barren soil below, they shrink, and the flowers are starved for want of proper nourishment in the spring, when it is most required.

The beds being thus prepared, they should lie a fortnight or more to settle, before the roots are planted, that there may be no danger of the earth settling unequally after they are planted, which would prejudice them, by having hollow places in some parts of the bed, to which the water would run and lodge, and so rot the roots. Then having levelled the earth, laying the surface a little rounding, you should mark out the rows by a line, at about six inches distance each way, so that the roots may be planted every way in straight lines; then you should open the earth with your fingers at each cross, where the roots are to be planted about two inches deep, placing the roots exactly in the middle, with their crowns upright; then with the head of a rake you should draw the earth upon the surface of the bed level, whereby the top of the roots will be about an inch covered with earth, which will be sufficient at first. This work should be done in dry weather, because the earth will then work better than if it were wet; but the sooner after planting there happens to be rain, the better it will be for the roots, for if it should prove dry weather long after, and the earth of the beds be very dry, the roots will be subject to mould and decay; therefore in such a case it will be proper to give a little water to the beds, if there should no rain happen in a fortnight's time, which is very rare at that season of the year, so that they will seldom be in danger of suffering that way.

When the roots are thus planted, there will no more be required until toward the end of *November*, by which time they will begin to heave the ground and their buds appear, when you should lay a little of the same fresh earth, of which the beds were composed, about half an inch thick all over the beds, which will greatly defend the crown of the root from frost; and when you perceive the buds to break through this second covering, if it should prove very hard frost, it will be very proper to arch the beds over with hoops, and cover them with mats, especially in the spring, when the flower-buds will begin to appear, for if they are exposed to too much frost, or blighting winds at that season, their flowers seldom open fairly, and many times their roots are destroyed.

In the beginning of *March* the flower-stems will begin to rise, at which time you should carefully clear the beds from weeds, and stir the earth with your fingers between the roots, being very careful not to injure them; this will not only make the beds appear handsome, but also greatly strengthen their flowers. When the flowers are past, and the leaves are withered, you should take up the roots, and carefully clear them from the earth; then spread them upon a mat to dry, in a shady place; after which they may be put up in bags or boxes in a dry room, until the *October* following, which is the season for planting them again.

These *Persian* sorts are not only propagated by offsets from the old roots, but are also multiplied by seeds, which the semidouble kinds produce in plenty; therefore, whoever is desirous to have these in perfection, should annually sow their seeds, from which new varieties will be every year produced; but in order thereto, you should be careful in sowing your seed, or in procuring it from such persons as understand how to save it; that is, who will be careful not to leave any flowers for seeds, but such as have five or six rows of petals at least, and are well coloured, for since these flowers increase plentifully, it is not worth the trouble to sow any indifferent seeds, because there can be but little hopes of obtaining any good flowers from them.

Being prepared with seeds about the middle of *August*, which is the proper season for sowing of them, you should get some large pots, flat seed pans, or boxes. These should be filled with light rich earth, levelling the surface very even; then sow the seeds thereon pretty thick, and cover it about a quarter of an inch thick with the same light earth; after which you should remove these pots or boxes into a shady situation, where they may have the morning sun until ten of the clock; and if the season should prove dry, you must often refresh them with water, being very careful in doing of this, not to wash the seeds out of the ground. In this situation the pots should remain until the beginning of *October*, by which time the plants will begin to come up, though sometimes the seeds will remain in the earth until *November*; then you should remove the pots into a more open exposure, where they may have full sun, which at that time is necessary to exhale the moisture of the earth; but toward the middle or end of *November*, when you are apprehensive of frost, the pots should be removed under a common hot-bed frame, where they may be covered with the glasses in the night time, and in bad weather; but in the day, when the weather is mild, they should be entirely opened, otherwise the plants will draw up too weak. The only danger they are in, is from violent rains and frosts, the first often rotting the tender plants, and the frost will often turn them out of the ground, therefore they should be carefully guarded against both these.

In the spring, as the season grows warm, these pots should be exposed to the open air, placing them at first near the shelter of a hedge, to protect them from the cold winds; but towards the beginning or middle of *April*, they should be removed again into a more shady situation, according to the warmth of the season, and if it should prove dry, they must be sometimes refreshed with water; but you should be careful not to give it to them in great quantities, which is very apt to rot these tender roots; the latter end of *April* or beginning of *May*, they should be placed where they may have only the morning sun, in which place they may remain till their leaves decay, when they may be taken out of the earth, and the roots dried in a shady place; after which they may be put up in bags, and preserved in a dry place until the *October* following, when they must be planted in the manner before directed for the old roots.

The spring following these roots will flower, at which time you should carefully mark such of them as are worthy to be preserved, and the single, or bad coloured flowers, may be pulled up and thrown away, which is the surest method of removing them from the good sorts; for if they are permitted to remain together until their leaves decay, there may be some offsets of the bad sorts mixed with the good flowers. You should not suffer those flowers, which you intend to blow fine the succeeding year, to bear seeds, but cut off the flowers when they begin to decay, for those roots which have produced seeds, seldom flower well afterwards; nor will the principal old root, which has flowered

strong, ever blow so fair as will the offsets, which is what should be principally observed, when a person purchases any of these roots, for great part of the complaints made by those who have bought these roots at a dear rate, is principally owing to this. The persons who sold them, being apprized of this matter, have parted with their old roots to their purchasers, and reserved the offsets for their own use; which old roots have often so much degenerated from what they were the preceding year, as to cause a suspicion, whether the persons they were purchased from had not changed the roots: this degeneracy attends these flowers, after having flowered extremely large and fair, or that they have been permitted to seed; so that it is absolutely necessary to sow seeds every year, in order to preserve a succession of good flowers.

The manner of preparing the beds, and the distance and method of planting the roots, having been already directed, I shall not repeat it here, but will only observe, that these flowers being tender, must be protected from hard frosts, and cutting sharp winds, especially after *Christmas*, when their flower-buds are forming, for if they are neglected at that season, their flowers will rarely prove fair; nor should you suffer them to receive too much wet in winter or spring, which is equally as injurious to them as frost. In planting of these roots you should observe to place the semidouble kinds, from which you intend to save seeds, in separate beds by themselves, and not intermix them with the double flowers, because they will require to be treated in a different manner, for when the flowers of the semidouble kinds begin to fade, you should carefully guard them from wet, for if they are permitted to receive hard rains, or are watered at that season, the seeds rarely come to maturity, or are so weak, that scarce one in fifty of them will grow.

When the seed begins to ripen (which may be easily known, by their separating from the axis and falling) you should look over the beds every day, gathering it as it ripens, for there will be a considerable distance in the seeds of the same bed coming to maturity, at least a fortnight, three weeks, or a month. When you gather the seed, it should not be exposed to the sun, but spread to dry in a shady place; after which you must put it up where the vermin cannot come to it, until the time of sowing it.

By this method of sowing seeds every year, you will not only increase your stock of roots, but also raise new varieties, which may be greatly mended by changing the seeds into fresh ground; for if a person continually sows his seed in the same garden many years, they will not produce near so fine flowers, as if he procured his seeds at some distance, which is also the case with most other plants.

It will also be necessary to take away all the earth out of the beds in which the roots were blown the preceding year, and put in new, if you intend to plant *Ranunculuses* there again, otherwise they will not thrive near so well, notwithstanding you may add some new compost to the beds, and this is what all the curious florists continually observe.

RAPA. *Tourn. Inst. R. H. 228. tab. 112.* Turnep.

The Characters are,

The empalement of the flower is three leaved: The flower hath four plain spreading petals, which are narrow at their base. It has four oval honey glands, situated between the stamina and style, and six erect oval-shaped stamina; the two which are opposite are the length of the empalement, the other four are longer, terminated by erect acute-pointed summits. It hath a taper germen, supporting a short thick style, crowned by an entire beaded stigma. The germen afterward becomes a long taper pod, depressed on the sides, opening in two cells, which are filled with roundish seeds.

The Species are,

1. RAPA radice orbiculatâ depressâ carnosâ. Turnep with an orbicular, depressed, fleshy root.

2. RAPA

2. *RAPA radice oblongâ carnosâ*. Turnep with an oblong fleshy root.

3. *RAPA radice fusiformi*. Turnep with a spindle-shaped root; commonly called *French Turnep*.

The first is the Turnep which is commonly cultivated in the fields, of which there are the following varieties, *viz.* the round red or purple topped Turnep, the green topped Turnep, the yellow Turnep, the black rooted Turnep, and the early *Dutch Turnep*. The last sort is commonly sown early in the spring, for to supply the markets in *May* and *June*, but is never cultivated for a general crop. The red rooted Turnep was formerly more cultivated in *England* than at present, for since the large green topped Turnep has been introduced, all the skilful farmers prefer it to the other sorts; the roots of the green will grow to a large size, and continue good much longer than the other sorts. The next to this is the red or purple topped Turnep, which will also grow large, and is extremely good for some time, but the roots of this will become stringy much sooner than those of the green topped. The long rooted Turnep, the yellow Turnep, and the blackish rooted Turnep, are now rarely cultivated in *England*, neither of them being so good for the table or for feed, as the red and green topped Turnep, though there are some few persons who sow them for the sake of variety.

The *French Turnep* is not much cultivated in *England*, but in *France* and *Holland* they are in great esteem, especially for soups, their roots being small, and boiled whole in the soup, and so served up to the table; these must be used while they are young, otherwise they will become rank and stringy.

These are supposed to be only varieties, which have accidentally been obtained from seeds, therefore I have not enumerated them as distinct species; but yet I am certain they are constant, where care is taken in the saving of their seeds, not to suffer any mixture to stand for seeds: I have sown of three or four sorts several years, and have always found them retain their differences; however, it is not easy to determine if some of these were not by culture first obtained from seeds of the common white Turnep. The yellow Turnep seems most unlikely to have been an accidental variety, for I have never known this alter, and the roots are yellow within, whereas all the other have white flesh, notwithstanding their outsides are of very different colours.

The long rooted Turnep, is, I think, a distinct species, the form of the root, and its manner of growth being totally different from the other sorts. I have seen these roots as long as those of the Parsnep, and nearly of the same shape; these run deep into the ground, so are unfit for feeding of cattle; and unless they are used very young, become strong, so not proper for the table, which has occasioned their being rejected of late years.

The green topped Turnep grows above ground more than any of the other, which renders it preferable for feeding of cattle, and being the softest and sweetest root when grown large of any of the kinds, is most esteemed for the table; but in very severe winters they are in greater danger of suffering by frost, than those whose roots lie more in the ground, especially if they are not covered by snow; for when they are frequently hard frozen and thawed, it causes them to rot sooner than those whose flesh is less tender and sweet. I have seen the roots of this sort, which were more than a foot diameter boiled, and were as sweet and tender, as any of the smallest roots.

Turneps delight in a light, sandy, loamy soil, which must not be rich, for in a rich soil they grow rank and are sticky, but if it be moist they will thrive the better in summer, especially in fresh land, where they are always sweeter than upon an old worn-out or a rich soil.

The common season for sowing of Turneps, is any time from the beginning of *June* to the middle of *August*, or a little later; though it is not advisable to sow them much after, because, if the autumn should not prove very mild, they will not have time to apple before winter, nor will the roots of those which are sown after the middle of *July*, grow very large, unless the frost keeps off long in autumn. But, notwithstanding this is the general season in which the greatest part of Turneps are sown in the country, yet about *London* they are sown successively from *March* to *August*, by those who propagate them to supply the markets with their roots; but there is a great hazard of losing those which are sown early in the year, if the season should prove dry, by the fly, which will devour whole fields of this plant while young; so that where a small quantity for the supply of a family is wanted, it will be absolutely necessary to water them in dry weather; and where a person sows those seeds in *April* and *May*, it should always be upon a moist soil, otherwise they seldom come to good, the heat of the weather at that season being too great for them upon a dry soil; but those which are sown toward the middle or latter end of *June*, commonly receive some refreshing showers to bring them forward; without which, it is very common to have them all destroyed.

These seeds should always be sown upon an open spot of ground, for if they are near hedges, walls, buildings, or trees, they will draw up, and be very long topped, but their roots will not grow to any size.

They are sown in great plenty in the fields near *London*, not only for the use of the kitchen, but for food for cattle in winter, when there is a scarcity of other food; and this way is become a great improvement to barren sandy lands, particularly in *Norfolk*, where, by the culture of Turneps, many persons have doubled the yearly value of their ground.

The land upon which this seed is sown, should be ploughed in *April*, and twy-fallowed in *May*, that is, once more ploughed and twice well harrowed, and made very fine; then the seed should be sown pretty thin (for it being small, a little will sow a large piece of ground, one pound is the common allowance for an acre of land). The seed must be harrowed in as soon as it is sown, with a short tinned harrow, and the ground rolled with a wooden roll, to break the clods, and make the surface even. In ten days or a fortnight after sowing, the plants will come up; at which time, if the season should prove dry, they will be in great danger of being destroyed by the fly; but if it so happen, the ground must be sowed again, for the seed being cheap, the chief expence is the labour; but the ground should be first harrowed to loosen it, especially if it is stiff land.

When the plants have got four or five leaves, they should be hoed to destroy the weeds, and to cut up the plants where they are too thick, leaving the remaining ones about six or eight inches asunder each way, which will be room enough for the plants to stand for the first hoeing; the sooner this is performed, when the plants have four leaves, the better they will thrive; but in the second hoeing, which must be performed about a month after the first, they should be cut up, so as that the remaining plants may stand fourteen or sixteen inches distance, or more, especially if they are designed for feeding of cattle, for where the plants are allowed a good distance, the roots will be proportionably large; so that what is lost in number, will be over-gained by their bulk, which is what I have often observed. But in such places where they are sown for the use of the kitchen, they need not be left at a greater distance than ten inches or a foot, because large roots are not so generally esteemed for the table.

It is not many years since the practice of sowing Turneps for feeding of cattle, has been of general use; how it happened that this improvement should have been so long neglected in every part of *Europe*, is not easy to determine, since it is very plain, that this piece of husbandry was known to the ancients. For *Columella*, in treating of the several kinds of vegetables which are proper for the field, recommends the cultivating Rapa in plenty; because (says he) those roots which are not wanted for the table, will be eaten by the cattle: yet this plant was not much cultivated in the fields till within the last sixty or seventy years, nor is the true method of cultivating Turneps yet known, or at least not practised, in some of the distant counties of *England*, at this time. For in many places the seed is sown with Barley in the spring, and those plants which come up, and live till the Barley is cut, produce a little green for the sheep to pick up, but never have any roots. In other places, where the Turnep-seed is sown by itself, the method of hoeing them is not understood, so that weeds and Turneps are permitted to grow together; and where the Turneps come up thick in patches, they are never thinned, so that they draw up to have long leaves, but never can have good roots, which is the principal part of the plant, therefore should be chiefly attended to.

The general method now practised in *England*, for cultivating this plant in the fields, is the same as is practised by the farming gardeners, who supply the *London* markets with these roots, and is the same as before directed. But it is only within the compass of a few years, that the country-people have been acquainted with the method of hoeing them; so that the farmers formerly employed gardeners, who had been bred up in the kitchen-gardens, to perform this work. The usual price given *per acre*, for twice hoeing and leaving the crop clean, and the plants set out properly, was seven shillings; at which price the gardeners could get so much *per week*, as to make it worth their while to leave their habitations, and practise this in different counties, during the season for this work, which always happens, after the greatest hurry of business in the kitchen-gardens is over; so that they usually formed themselves in small gangs of six or seven persons, and set out on their different routs, each gang fixing at a distance from the rest, and undertaking the work of as many farmers in the neighbourhood, as they could manage in the season; but as this work is now performed by many country labourers, that practice is lost to the kitchen-gardeners, the labourers doing it much cheaper.

There has also been another method practised very lately, by some very curious farmers, in cultivating of Turneps, which is, by sowing the seed in rows, with the drill-plough. In some places the rows are sown three feet asunder, in others four, in some five, and some six. The latter has been recommended by some, as the most proper distance; and although the intervals are so large, yet the crop produced on an acre has been much greater than upon the same quantity of land, where the rows have been but half this distance; and upon all the fields which have been tilled, the crops have greatly exceeded those which have been hand-hoed. The late lord viscount *Townshend* was at the expence of making the trial of these two different methods of husbandry, with the greatest care, by equally dividing the same fields into different lands, which were alternately sown in drills, and the intermediate lands in broad cast. The latter were hoed by hand, in the common method, and the other cultivated by the hoeing-plough; and when the roots were fully grown, his lordship had an equal quantity of land, which had been sowed in the different methods, measured, and the roots drawn up and weighed; those roots which had been cultivated by the plough, were so much

larger than the other, that the crop of one acre weighed a ton and a half more than that of an acre in the other husbandry.

But when the Turneps are sown in drills, they will require to be hoed by hand, to separate and cut out the plants, where they are too near together in the rows; as also to cut up the weeds between the plants, where the plough cannot reach them. If this is carefully performed, the ploughing of the intervals will encourage the growth of the roots, by thus stirring of the ground, and make it much better prepared for the crop of Barley, or whatever else is sown the following spring. This method of culture may be supposed to be more expensive than that commonly practised, by those unacquainted with it, but those who have made trials of both, find the horse-hoeing to be much the cheapest, and by far the best. For the country people, who are employed in hand-hoeing of Turneps, are very apt to hurry over their work, so that half the weeds are left growing, and the plants are seldom singled out so well as they should be; nor are they curious enough to distinguish the Charlock (which is one of the most common weeds in arable land) from the Turneps; so that about the middle of *September*, it is very common to see the fields of Turneps full of the yellow flowers of the Charlock. Now, in the horse-hoeing, all the weeds in the intervals will be entirely destroyed; so that if a few plants in the rows of Turneps should be overlooked, they may be easily drawn when they appear visible, and by this method the land will be sooner and better cleaned from weeds.

The greatest evil which attends a crop of Turneps, is that of their being destroyed by the fly, which usually happens soon after the plants come above ground, or while they are in the seed-leaf, for, after they have put out their rough leaves pretty strong, they will be past this danger. This always happens in dry weather, so that, if there should be rain when the Turneps come up, they will grow so fast, as to be in a few days out of danger from the fly; and it hath been found, that those, which have been sown in drills, have escaped the fly much better than those sown in broad cast; but, if foot is sown along the surface of each drill, it will be of great service to keep off the fly, and a small quantity of it will be sufficient for a large field, where the drills only are to be covered.

Another danger of the crops being destroyed is from the caterpillars, which very often attack them, when they are grown so large as to have six or eight leaves on a plant. The surest method of destroying these insects, is to turn a large parcel of poultry into the field, which should be kept hungry, and turned early in the morning into the field; these fowls will soon devour the insects, and clear the Turneps. To this evil the Turneps, which are sown in drills, are not so much exposed, for as the ground between the rows will be kept stirred, the plants will be kept growing, so will not be in danger of suffering from these insects, for the parent insects never deposit their eggs upon any plants which are in health, but as soon as they are stunted, they are immediately covered with the eggs of these insects; and this holds in general with vegetables as with animals, who are seldom attacked by vermin when they are in perfect health; whereas, when they become unhealthy, they are soon overspread with them; so that it is the disease which occasions the vermin, and not the vermin the disease, as is commonly imagined.

When the Turneps are sown in drills, it will be the best way to plow between every other row at first, and some time after to plow the alternate intervals, by which method the plants will receive more benefit from the often stirring the ground than they would do, if all the intervals were hoed at one time, and the plants will be in less danger of suffering

suffering from the earth being thrown up too high on some rows, while others may be left too bare of earth; but, when the earth has been thrown up on one side of the drill, it may be turned down again soon after the next interval is plowed. This alternate moving of the earth will prepare the ground very well for the succeeding crop, and greatly improve the Turneps; but, as the plow cannot well be drawn nearer to the drills than two or three inches, the remaining ground should be forked to loosen the parts, and make way for the fibres of the roots to strike out into the intervals; otherwise, if the land is strong, it will become so hard in those places which are not stirred, as to stint the growth of the Turneps. This may be done at a small expence; a good hand will perform a great deal of this work in a day, and, whoever will make the trial, will find their account in practising it, especially on all strong land, where the Turneps are much more liable to suffer from the binding of the ground, than they will be on a loose soil; but yet, in all sorts of ground, it will be of great service to practise this.

When the ground is thus stirred in every part, one plowing will be sufficient, after the Turneps are eaten, for the sowing of Barley, or any other crop; so that there will be an advantage in this, when the Turneps are kept late on the ground, as will often be the case, especially when they are cultivated for feeding of ewes, because it is often the middle of April before the ground will be cleared; for late seed in the spring, before the natural grass comes up, is the most wanted, where numbers of sheep or ewes are maintained, and one acre of Turneps will afford more feed than fifty acres of the best pasture at that season.

In Norfolk and some other counties they cultivate great quantities of Turneps for feeding of black cattle, which turn to great advantage to their farms, for hereby they procure a good dressing for their land; so that they have extraordinary good crops of Barley upon those lands, which would not have been worth the plowing, if it had not been thus husbanded.

When the Turneps are fed off the ground, the cattle should not be suffered to run over too much of the ground, for, if they are not confined by hurdles to as much as is sufficient for them one day, the cattle will spoil three times the quantity of Turneps as they can eat, so that it is very bad husbandry to give them too much room; therefore the hurdles should be every day removed forward, and, if the Turneps are drawn out of the ground before the cattle or sheep are turned into the new inclosure, there will be less waste made, for they will then eat up the whole roots; whereas, if they are turned upon the Turneps growing, they will scoop the roots, and leave the rinds, which being hollow, the urine of the sheep will lodge in them; so that, when they are forked out of the ground, the sheep will not eat any of those roots which are thus tainted.

I cannot omit taking notice of a common mistake, which has generally prevailed with persons who have not been well informed to the contrary, which is, in relation to the mutton which is fatted with Turneps, most people believing it to be rank and ill-tasted, whereas it is a known fact, that the best mutton this country affords is all fatted on Turneps, and that rank mutton, whose fat is yellow, is what the low marshy lands of *Lincolnshire*, and other rank pastures, produce.

In order to save good Turnep seeds, you should transplant some of the fairest roots in *February*, placing them at least two feet asunder each way, observing to keep the ground clear from weeds, until the Turneps have spread so as to cover the ground, when they will prevent the weeds from growing; when the pods are formed, you should carefully guard them against the birds, otherwise they will de-

vour it, especially when it is near ripe; at which time you should either shoot the birds as they alight upon the seed, or lay some birdlimed twigs upon it, whereby some of them will be caught, and, if they are permitted to remain some time, and afterwards turned loose, they will prevent the birds from coming thither again for some time, as I have experienced. When the seed is ripe, it should be cut up, and spread to dry in the sun; after which it may be threshed out, and preserved for use.

There have been many receipts for preventing the fly taking Turneps, but few of them deserve notice, therefore I shall only mention two or three which I have seen tried with success. The first was steeping the seeds in water with flower of brimstone mixed, so as to make it strong of the brimstone: another was steeping it in water with a quantity of the juice of Horse-aloes mixed, both which have been found of use. The sowing of foot or tobacco-dust over the young plants, as soon as they appear above ground, has also been found very serviceable: in short, whatever will add vigour to the young plants, will prevent their being destroyed by the fly, for these never attack them, till they are stunted in their growth.

RAPHANUS. *Tourn. Inst. R. H. 229. tab. 114.* Radish.

The Characters are,

The empalement of the flower is erect. The flower has four heart-shaped petals, placed in form of a cross, which spread open, and are narrow at their base; it hath four honey glands, one on each side the short stamina between them and the style, and one between each of the long stamina and the empalement; it hath six erect stamina; two, which are opposite, are the length of the empalement; the other four are as long as the base of the petals, terminated by single summits, with an oblong swelling germen, crowned by a beaded stigma. The germen afterward becomes an oblong, smooth, spongy pod, having an acute point, swelling and almost jointed, having two cells, divided by an intermediate partition, filled with roundish seeds.

The Species are,

1. RAPHANUS *radice oblongâ*. Radish with an oblong root.
2. RAPHANUS *radice rotundâ*. Round-rooted Radish, or small, round, *Naples Radish*.
3. RAPHANUS *radice orbiculatâ depressâ*. Radish with an orbicular depressed root; commonly called Turnep-rooted, or white *Spanish Radish*.
4. RAPHANUS *radice fusiformi*. Radish with a spindle-shaped root; or the black *Spanish Radish*.
5. RAPHANUS *siliquis teretibus articulatis lævibus unilocularibus*. *Hort. Cliff. 340.* Radish with smooth, taper, jointed pods, having one cell; or white flowering Charlock with a jointed pod.

The last sort grows naturally on arable lands in most parts of *Europe*, so is seldom admitted into gardens.

The other four sorts are supposed to be only seminal variations, but from forty years experience I have never found either of these to vary from one to the other sort; and I am certain, whoever will make the trial, by saving the seeds of each carefully without mixture, will always find the plants prove the same as the seeds were saved from.

The first sort here mentioned is that which is commonly cultivated in kitchen-gardens for its roots, of which there are several varieties, as the small-topped, the deep red, the pale red or salmon, and the long-topped striped Radish; all which are varieties arising from culture. The small-topped sort is most commonly preferred by the gardeners near *London*, because they require much less room than those with large tops; for as the forward Radishes are what produce the greatest profit to the gardener, which are commonly sown upon borders near hedges, walls, or pales, if they are of the large-topped sort, will be apt to grow mostly to a top, and

and not swell so much in the root as the other, especially if they are left pretty close.

The seasons for sowing this seed are various, according to the time when they are desired for use; but the earliest season is commonly toward the latter end of *October*, that the gardeners near *London* sow them to supply the markets; and these, if they do not miscarry, will be fit for use in the beginning of *March* following, which is full as soon as most people care to eat them. These are commonly sown on warm borders near walls, pales, or hedges, where they may be defended from the cold winds; but there are some who sow Radish seeds among other crops in the middle of *September*, and, if these are not destroyed by frost, they will be fit for use soon after *Christmas*; but these must be eaten while they are young, for they soon grow sticky and strong.

The second sowing is commonly about *Christmas*, provided the season be mild, and the ground in a fit condition to work; these are also sowed near shelter, but not so near pales and hedges as the first sowing. If these are not destroyed by frost, they will be fit for use the end of *March* or the beginning of *April*; but, in order to have a succession of these roots for the table through the season, you should repeat the sowing of their seeds once a fortnight from the middle of *January* till the beginning of *April*, always observing to sow the latter crops upon a moist soil, and an open situation, otherwise they will run up, and grow sticky, before they are fit for use.

Many of the gardeners near *London* sow Carrot-seed with their early Radishes, so that when their Radishes are killed, which sometimes happens, the Carrots will remain, for the seeds of Carrots commonly lie in the ground five or six weeks before they come up, and the Radishes seldom lie above a fortnight under ground at that season, so that these are often up and killed, when the Carrot-seed remains safe in the ground; but, when both crops succeed, the Radishes must be drawn off very young, otherwise the Carrots will be drawn up so weak, as not to be able to support themselves, when the Radishes are gone.

It is also a constant practice with the kitchen-gardeners to mix Spinach-seed with their latter crops of Radishes, so that when the Radishes are drawn off, and the ground cleaned between the Spinach, it will grow prodigiously, and in a fortnight's time will as completely cover the ground as though there had been no other crop. And this Spinach, if it be of the broad-leaved kind, will be larger and fairer than it commonly is when sown by itself, because where people have no other crop mixed with them, they commonly sow them too thick, whereby they are drawn up weak; but here the roots standing pretty far apart, so after the Radishes are gone, they have full room to spread, and, if the soil be good, it is a prodigious size this Spinach will grow to, before it runs up for seed; but this husbandry is chiefly practised by such gardeners as pay very dear for their land, and are obliged to have as many crops in a year as possible, otherwise they could not afford to pay such large rents.

When the Radishes are come up, and have got five or six leaves, they must be pulled up where they are too close, otherwise they will draw up to a top, but the roots will not increase their bulk. In doing of this, some only draw them out by hand, but the best method is to hoe them with a small hoe, which will stir the ground, and destroy the young weeds, and also promote the growth of the plants. The distance which these should be left, if for drawing up small, may be three inches, but, if they are to stand until they are pretty large, six inches are full near enough, and a small spot of ground will afford as many Radishes at each sowing, as can be spent in a family while they are good.

If you intend to save seeds of your Radishes, you should, at the beginning of *May*, prepare a spot of ground in proportion to the quantity of seeds intended (but you should always make allowance for bad seasons, because it often happens, in a very dry season, that there will not be a fourth part of the quantity of seeds upon the same proportion of ground as there will be in a moist season). This ground should be well dug and levelled; then you should draw up some of the straight and best-coloured Radishes (throwing away all such as are short, and that branch out in their roots); these should be planted in rows three feet distance, and two feet asunder in the rows, observing, if the season be dry, to water them until they have taken root; after which they will require no farther care, but only to hoe down the weeds between them, until they are advanced so high, as to spread over the ground, when they will prevent the growth of weeds.

When the seed begins to ripen, you should carefully guard it against the birds, otherwise they will destroy it. When it is ripe (which you may know by the pods changing brown), you should cut it, and spread it in the sun to dry; after which you should thresh it out, and lay it up for use, where the mice cannot come to it, otherwise they will eat it up.

The small round-rooted Radish is not very common in *England*, but in many parts of *Italy* it is the only sort cultivated; the roots of this kind are very white, round, small, and very sweet. This may be propagated in the same manner as the common sort, with this difference, *viz.* that this must not be sown till the beginning of *March*, and the plants allowed a greater distance. The seeds of this kind are very subject to degenerate, when saved in *England*, unless they are at such distance from the common sort, as that the farina of one cannot mix with the other.

The other round-rooted Radishes are rarely cultivated in *England*, but those who have a mind to have them, may sow them in the same manner as the last.

The black and white *Spanish* Radishes are commonly cultivated for medicinal use, but there are some persons who are very fond of them for the table. These are commonly sown about the middle of *July*, or a little earlier, and they are fit for the table by the end of *August*, or the beginning of *September*, and will continue good till the frost spoils them. These must be thinned to a greater distance than the common sort, for the roots of these grow as large as Turneps, therefore should not be left nearer together than six inches.

Some persons, who are very curious to have these roots in winter, draw them out of the ground before the hard frost comes on, and lay them up in dry sand in the same manner as is practised for Carrots, being careful to guard them from wet and frost, and by this method they preserve them till the spring.

RAPISTRUM. See Sinapis.

RAPUNCULUS. *Tourn. Inst. R. II. 113. tab. 38.* Rampion.

The Characters are,

The empalement of the flower is of one leaf, divided into five acute parts, sitting upon the germen. The flower hath one petal, which is starry, cut into five linear segments, which are recurved; it hath five stamina, which are shorter than the petal, terminated by oblong summits. The germen, which is situated under the flower, supports a slender recurved style, crowned by an oblong, twisted, three-pointed stigma, which afterward becomes a roundish capsule, with three cells, filled with small roundish seeds.

The Species are,

1. RAPUNCULUS *spicâ oblongâ, capsulis bilocularibus, foliis radicalibus cordatis.* Rampion with an oblong spike of flowers, capsules containing two cells, and the lower leaves heart-shaped.

2. *RAPUNCULUS fasciculo terminali sessili, foliis dentatis, radicalibus cordatis.* Rampion with flowers growing in bunches, terminating the stalks, indented leaves, and those at the bottom heart-shaped.

3. *RAPUNCULUS capitulo subrotundo, foliis linearibus integerrimis.* Rampion with roundish heads, and linear entire leaves.

4. *RAPUNCULUS capitulo subfolioso, foliis omnibus lanceolatis.* Rampion with heads which are somewhat leafy, and all the leaves spear-shaped.

5. *RAPUNCULUS capitulo subrotundo, foliis serratis radicalibus cordatis.* Rampion with roundish heads, sawed leaves, the lower ones of which are heart-shaped.

6. *RAPUNCULUS foliis obtusis, spicâ pauciflorâ.* Hall. Helv. 497. Rampion with obtuse leaves, and a spike containing few flowers.

These are all of them hardy plants, which will thrive in the open air. They are propagated by seed, which should be sown in autumn, for if they are kept out of the ground till the spring, they frequently fail. The seeds should be sown on a bed of fresh undunged earth, where they are designed to remain, for they do not thrive so well when they are transplanted; therefore the best method is to make small drills cross the bed about eighteen inches asunder, and sow the seeds therein; then cover them lightly over with earth, for if they are buried too deep, they will rot in the ground. In the following spring the plants will come up, when they should be diligently weeded, which is all the care they will require, only they should be thinned where they are too close, so as to leave them six or seven inches apart in the rows, and afterward they require no farther attention, but to keep them clear from weeds.

As these plants do not continue above two or three years, they should be sown every other year to continue the sorts, for they are plants which require little trouble to cultivate, and their flowers make a pretty variety in large gardens, therefore they may be allowed a place amongst other hardy flowers.

RAPUNTIIUM. Tourn. Inst. R. H. 163. tab. 51. Rampions, or Cardinal Flower.

The Characters are,

The empalement of the flower is cut into five linear segments, the two upper being larger than the other. The flower is of one petal, with a long cylindrical tube, a little curved, and is divided at the brim into five segments, two of which compose the upper lip, and are smaller than the three lower which compose the under; it hath five awl-shaped stamina, terminated by oblong summits, which coalesce at the top in form of a cylinder, but open in five parts at their base; it has an acute germen, situated below the flower, supporting a cylindrical style, crowned by a hairy obtuse stigma. The germen afterward becomes an oval capsule, opening at the top, filled with small seeds.

The Species are,

1. *RAPUNTIIUM caule erecto, foliis lanceolatis serratis, spicâ terminali.* Cardinal-flower with an erect stalk, spear-shaped sawed leaves, and a spike of flowers terminating the stalk; commonly called scarlet Cardinal-flower.

2. *RAPUNTIIUM caule erecto, foliis linearilanceolatis integerrimis acuminatis spicâ terminali.* Cardinal-flower with an erect stalk, linear, spear-shaped, entire, acute-pointed leaves, and a spike of flowers terminating the stalks.

3. *RAPUNTIIUM caule erecto, foliis ovato-lanceolatis crenatis, calycum sinibus reflexis.* Cardinal-flower with an erect stalk, oval, spear-shaped, crenated leaves, and the sinuses of the empalements reflexed; commonly called the blue Cardinal-flower.

4. *RAPUNTIIUM caule erecto, foliis cordatis obsolete dentatis petiolatis, floribus sparsis thyrso longissimo.* Cardinal-flower with an erect stalk, heart-shaped leaves, which are some-

what indented, having foot-stalks, and the longest spike of flowers, which are placed thinly.

5. *RAPUNTIIUM caule erecto, foliis inferioribus subrotundis crenatis, superioribus lanceolatis serratis, spicâ terminali.* Rapuntium with an erect stalk, the lower leaves roundish and crenated, the upper spear-shaped, sawed, and a spike of flowers terminating the stalk.

6. *RAPUNTIIUM caule erecto, foliis ovatis subserratis, pedunculo longioribus, capsulis inflatis.* Cardinal-flower with an erect stalk, oval leaves, which are somewhat sawed, longer than the foot-stalks, and swelling seed-vessels.

7. *RAPUNTIIUM foliis ovalibus crenatis lanatis, floribus lateralibus solitariis.* Cardinal-flower with oval crenated leaves, which are downy, and flowers growing singly from the sides of the stalks.

8. *RAPUNTIIUM foliis lanceolatis dentatis, pedunculis brevissimis lateralibus tubo corollæ longissimo.* Cardinal-flower with spear-shaped indented leaves, very short foot-stalks to the flowers, which proceed from the sides of the stalks, and a very long tube to the petal.

9. *RAPUNTIIUM caule patulo ramoso foliis lanceolatis subdentatis, pedunculis longissimis.* Rapuntium with a spreading branching stalk, spear-shaped leaves, which are somewhat indented, and very long foot-stalks to the flowers.

10. *RAPUNTIIUM caulibus procumbentibus, foliis lanceolatis serratis, pedunculis lateralibus.* Cardinal-flower with trailing stalks, spear-shaped sawed leaves, and foot-stalks proceeding from their sides.

The first sort grows naturally by the side of rivers and ditches in great part of *North America*, but has been many years cultivated in the *European* gardens for the great beauty of its scarlet flowers. The root is composed of many white fleshy fibres; the lower leaves are oblong, a little sawed, and of a dark purplish colour on their upper side; the stalks are erect, and rise about a foot and a half high, garnished with spear-shaped leaves, sawed on their edges, having very short foot-stalks, and are placed alternately; the stalk is terminated by a spike of flowers of an exceeding beautiful scarlet colour; these have a pretty long tube, which is a little incurved, but at the top is cut longitudinally into five segments; three upper, which are the smallest, are greatly reflexed; the three under, which form the lower lip, are larger, and spread open.

This is propagated by seeds, which, when they ripen in *England*, should be sown in autumn in pots, and placed under a common hot-bed frame; or, if the seeds come from the country, where the plants grow naturally, they should be sown in the same way, so soon as they arrive, for if they are kept out of the ground till spring, they will lie a year in the ground before they vegetate. The pots, in which these seeds are sown, should be exposed to the open air at all times, when the weather is mild, but they must be screened from the frost, and very hard rain in winter. In the spring the plants will appear, when they should have as much free air as possible in mild weather, and, if the spring proves dry, they must be frequently refreshed with water. As soon as they are fit to remove, they should be each planted in a separate small pot, and placed in the shade, till they have taken new root; then they may be placed where they may have the morning sun, in which situation they may remain till autumn. During the summer they must be duly watered in dry weather, and, when the roots have filled the pots, they should be removed into larger. In autumn they must be placed under a common frame, to screen them from hard frost, but they should enjoy the open air at all times, when the weather is mild. The spring following they should be new-potted, and placed where they may have the morning sun, always observing to water them duly in dry weather, which will cause their stalks

to be stronger, and produce larger spikes of flowers, which will continue long in beauty, if they are not too much exposed to the sun, and, if the autumn proves warm, the seeds will ripen well in *England*. The roots of this plant will sometimes last two or three years, and produce offsets for increase, but those will not flower so strong as the seedling plants, therefore an annual supply of them should be raised. There are many who propagate this plant by cutting their stalks into proper lengths, and plant them in pots filled with good earth, or into an east border, covering them close with glasses. These frequently take root, so produce young plants, but they are not so good as the seedlings.

The plants of this sort will live in the full ground, if they are protected from hard frost in winter, and they will flower stronger than those in pots.

The second sort grows naturally at *Campeachy*, from whence the late Mr. *Robert Millar* sent the seeds; this hath a fibrous root like the first. The stalks are much larger, and rise a foot higher; they are closely garnished with leaves, which are long, smooth, and entire, ending in acute points, and are terminated by short spikes of flowers, which are larger than those of the first sort, but are of the same beautiful scarlet colour.

This is propagated by seeds in the same way as the first, but the plants are not so hardy, therefore require to be placed in a moderate stove in winter, and in summer they should be placed in a deep frame, where they may be covered with glasses in bad weather, but enjoy the free air at all times, when the weather is favourable. With this management the plants flowered very well in the *Chelsea* garden, but they did not perfect seeds.

The third sort grows naturally in *Virginia*, but has been long an inhabitant of the *English* gardens; this hath a perennial fibrous root. The leaves are smooth, oval, spear-shaped, and a little indented on their edges; the stalks rise a foot and a half high, garnished with leaves like those at the bottom, which are gradually smaller to the top, sitting close to the stalk. The flowers come out from the wings of the leaves; they are of a pale blue colour, and have large empalements, whose edges are reflexed. The seeds frequently ripen in *England*.

It is propagated in the same way as the first sort, and the plants require the same culture.

The fourth sort grows naturally in *Jamaica*, from whence the late Dr. *Houssoun* sent the seeds; this is an annual plant. The stalk rises a foot high, then divides into four or five smaller, which grow erect. The lower part is garnished with heart-shaped smooth leaves, having small indentures on their borders, and stand upon short foot-stalks. The upper slender stalks are thinly garnished with small purplish flowers to the top, and are succeeded by small seed-vessels, which ripen in autumn. When the seeds are permitted to scatter on the pots which stand near them, and those are sheltered from the frost, the plants will come up plentifully the following spring, or, if they are sown in pots in autumn, and sheltered in the winter, the plants will arise the following spring, and these should be transplanted into separate small pots, placing them under a frame, where they will flower in *June* and *July*, and their seeds will ripen in *September*, when the plants will decay.

The fifth sort grows naturally in the forests about *Blois* in *France*; this is an annual plant. The root is composed of many fleshy fibres; the stalk rises about two feet high, garnished with spear-shaped leaves, which are very thin, and sawed on their edges, sitting close to the stalk; the upper part of the stalk is garnished with very small leaves; from their base arise the flowers, which are of a bright blue colour. These appear in *July*, and are succeeded by roundish seed vessels, with holes at the top, which are filled with small red seeds.

The seeds of this plant should be sown in autumn in pots filled with loamy earth, and placed under a hot-bed frame in winter, and, when the plants come up in the spring, they should be transplanted either into a border of soft loamy earth, or into separate pots, shading them till they have taken new root; afterward they must be duly watered in dry weather, which will cause them to flower strong, and produce good seeds annually.

The sixth sort grows naturally in *North America*; this is a biennial plant in *England*, which rarely flowers the same year as the plants come up, but decays soon after the seeds are ripe. The stalks of this are channelled and hairy; they grow erect to the height of two feet, garnished with thin oval leaves, sitting close to the stalk, of a light green, and a little sawed on their edges. The flowers stand upon long slender foot-stalks, which come out from the wings of the leaves, forming a loose spike, which terminate the stalk; they are small, and of a light blue colour. This is propagated by seeds, which should be sown in autumn, in pots filled with rich earth, and treated in the same way as the first sort.

The seventh sort grows naturally at the *Cape of Good Hope*. This is a biennial plant; the stalks rise a foot and a half high, covered with a hairy down, and are purplish toward the bottom; the leaves are oval, of a deep green colour, a little hairy on their under side, and sit close to the stalks. The flowers stand upon long slender foot-stalks, which come out from the bosom of the leaves, sometimes one proceeding from a joint, and at others they come out opposite on each side the stalk, each foot-stalk sustaining one pale blue flower, which being small makes but little appearance. This may be propagated in the same way as the first.

The eighth sort grows naturally in moist places, on most of the islands of the *West-Indies*. This is also a biennial plant, whose root is composed of a few strong ligneous fibres; the stalk rises about eight or nine inches high, is closely garnished with leaves on every side, which are hairy, very deeply indented on their edges, of a deep green, and sit close to the stalks. The flowers are white, and come out at every joint from the wings of the leaves, standing upon very short foot-stalks; the tube of the flower is from three to four inches long, very slender, and deeply cut at the top into five segments, which spread open, and are succeeded by turgid seed-vessels, crowned by the five segments of the petal, having three holes at the top, filled with small grayish seeds. The seeds of this sort should be sown soon after it is ripe, in pots filled with rich earth, and plunged into the tan-bed in the stove. In the spring these pots may be removed, and plunged into a hot-bed, which will soon bring up the plants; when these are fit to remove, they should be each transplanted into a separate small pot, and plunged into a fresh hot-bed, shading them from the sun till they have taken new root; then they may be treated in the same way as other tender plants from the same country, giving them a large share of air in warm weather. In autumn the plants must be plunged into the tan-bed of the stove, where they will flower the following summer and produce ripe seeds, soon after which the plants will decay. If the seeds of this plant are brought from the *West-Indies*, they should be sown as soon as they arrive, in pots, and if it happens in the winter, the pots should be plunged into the tan-bed in the stove; but if it is in the spring or summer, they may be plunged into a hot-bed in the common frames. These seeds when sown in the spring, seldom grow the same year, therefore the following autumn the pots should be removed into the stove, and managed according to the above directions.

The ninth sort grows naturally at the *Cape of Good Hope*. This is an annual plant; the stalks are slender, branching,

and spread out on every side; they rise about a foot high, garnished with small spear-shaped leaves, which are indented on their edges, and sit close to the branches. The flowers are blue; they stand upon very slender long foot-stalks; and are succeeded by small roundish seed-vessels, filled with small seeds, which ripen in *September*. If the seeds of this sort are sown in autumn, they will succeed much better than when they are sown in spring; these may be sown in pots, and sheltered under a common hot-bed frame in winter, exposing them to the open air at all times in mild weather, but screening them from the frost; and in the spring, the pots should be plunged into a moderate hot-bed, which will soon bring up the plants; when these are fit to remove, they should be each planted in a separate small pot, and plunged into a moderate hot-bed again, shading them from the sun till they have taken new root; then they must have a large share of free air at all times when the weather is mild; and as the plants grow strong, they should be gradually hardened to bear the open air, into which they should be removed in *June*, placing them in a sheltered situation, where they will flower in *July*; and if the season proves favourable, the seeds will ripen in *September*, but if the season should prove cold, it will be proper to remove one or two plants into a glass-case, to obtain good seeds.

The tenth sort comes from the *Cape of Good Hope*. This hath trailing stalks; the leaves are sawed on their edges, and the foot-stalks come out from the side of the branches, in which it differs from the last. It may be propagated by seeds, and treated in the same manner as the last.

RAUVOLFIA. *Plum. Nov. Gen. 19. tab. 40.*

The Characters are,

The flower has a permanent empalement of one leaf, cut into five parts at the top. The petal is funnel-shaped, the tube is cylindrical, and is cut at the brim into five parts. It has five stamina, which are a little shorter than the tube, terminated by erect summits, and a roundish germen, supporting a short style, crowned by a headed stigma. The germen afterward becomes a globular berry, with two cells, inclosing one compressed seed in each.

The Species are,

1. RAUVOLFIA *foliis quaternis, ovato-lanceolatis subdentatis*. Rauwolfia with leaves placed by fours, which are oval, spear-shaped, and somewhat indented.

2. RAUVOLFIA *foliis quaternis lanceolatis integerrimis*. Rauwolfia with four spear-shaped entire leaves at each joint.

Both these sorts grow naturally in the warmest parts of *America*; Mr. Robert Millar sent the seeds of them from *Carthogena* in *New Spain*, where he observed the shrubs growing in great plenty. These rise with several ligneous stalks from the root, which grow ten or twelve feet high, sending out a few small side branches, covered with a smooth green bark when young, but as they are older, their bark changes to a gray. The leaves are placed by fours at each joint round the branches; those of the first sort are two inches and a half long, and an inch and a half broad in the middle; they are of a light green, and have a few slight indentures on their edges; the leaves of the other sort are full as long, but are a third part narrower, and of a thinner substance. These differences continue in the plants which are raised from seeds, for I have several times propagated them both from seeds, and have constantly found the seeds produce the same as the plants from which they were taken. The flowers are produced on slender foot stalks, which arise from the wings of the leaves; they are tubulous, globular at their base, and are succeeded by roundish berries about the size of those of the Privet, which turn black when ripe. These plants flower most part of summer, and the fruit ripens in autumn and winter; the leaves and stalks of these plants have a milky juice, which flows out if they are broken.

These plants are propagated by seeds, which should be sown in autumn soon after they are ripe, for if they are kept out of the ground till spring, the plants rarely come up the same year; and this is frequently the case with those seeds, which are brought to *England*.

The seeds should be sown in pots, and plunged into a hot bed of tanners bark, for as they are very hard, they frequently remain a long time in the ground; therefore when they are in pots, they may be shifted from one bed to another, as their heat decays. When the plants come up, they should have a large share of fresh air admitted to them in warm weather, and but little water. When they are about two inches high, they should be transplanted each into a separate small pot, and plunged into the hot-bed again, observing to shade them from the sun until they have taken new root; after which time they should have free air admitted to them every day, in proportion to the warmth of the season. In this hot-bed the plants may remain till toward *Michaelmas*, when they should be removed into the stove, and plunged into the tan-bed, where they must be kept warm, and not have too much moisture in cold weather.

As these plants are natives of very hot countries, they will not live in the open air in *England*, therefore they should constantly remain in the stove; and if they are continued in the bark-bed, they will thrive much faster than when they are placed on stands in a dry stove. But in the summer season they should have a large share of fresh air admitted to them, and the leaves of the plants must be now and then washed with a sponge, to clear them from the filth they are apt to contract, which, if suffered to remain, will retard the growth of the plants. Where due care is taken of them, they will thrive very fast; the second year they will produce flowers, and continue so to do for many years, and will perfect their seeds in *England*. They may also be propagated by cuttings, which should be laid to dry for two or three days before they are planted; and then should be plunged into a moderate hot-bed of tanners bark, observing to shade them until they have taken root, after which time they may be treated as the seedling plants.

RESEDA. *Tourn. Inst. R. H. 423. tab. 238.* Bastard-rocket. *Mignonette.* *Weld.*

The Characters are,

The empalement of the flower is cut into several parts almost to the bottom, and is permanent. The petals of the flower are unequal, generally trifid, and have a honey gland on their base, the length of the empalement. The honey glands are plain, erect, and produced from the upper side of the receptacle, between the stamina and the place of the upper petal, joining with the base of the petals, dilating from the sides. It hath fifteen or sixteen short stamina, terminated by erect obtuse summits, and a gibbous germen, sitting upon very short styles, crowned by a single stigma. The germen afterward becomes a gibbous angular capsule of one cell, with an aperture between the styles, filled with kidney-shaped seeds, fastened to the angles of the capsule.

The Species are,

1. RESEDA *foliis pinnatis, foliolis integris alternis floribus tetragynis*. Bastard-rocket with winged leaves, whose lobes are entire, placed alternate, and have four styles to the flower.

2. RESEDA *foliis omnibus trifidis, inferioribus pinnatis*. Hort. Cliff. 213. Bastard-rocket with all the leaves trifid, and the lower ones winged.

3. RESEDA *foliis integris trilobisque, calycibus maximis*. Hort. Cliff. 412. Bastard-rocket with entire trifid leaves, having the largest empalement.

4. RESEDA *foliis difformibus, dentatis floribus trigynis*. Bastard-rocket with difformed indented leaves, and flowers having three styles.

5. RESEDA

5. RESEDA *foliis pinnatis, floribus tetragynis*. Hort. Upsal. 149. Bastard-rocket with winged leaves, and flowers having four styles.

6. RESEDA *foliis integris trilobisque, floribus tetragynis*. Tab. 217. Bastard-rocket with entire and three-lobed leaves, and flowers having four styles; commonly called sweet Reseda, or *Mignonette d'Egypt*.

7. RESEDA *foliis subulatis sparsis*. Sauv. Monsp. 41. Bastard-rocket with awl-shaped leaves placed thinly.

8. RESEDA *foliis lanceolatis integris, calycibus quadrifidis*. Lin. Sp. Plant. 448. Bastard-rocket with spear-shaped entire leaves, and quadrifid empalements.

The first sort grows naturally in the south of *France, Italy, and Spain*. This is a biennial plant, which flowers and seeds the second year, and perishes soon after. The root is long, white, a little ligneous; the leaves are unequally winged and entire; the stalks are channelled, garnished with smaller winged leaves; they rise a foot and a half high, terminated by a long loose spike of pale yellow flowers, composed of several unequal petals; the two upper are the largest, the side ones less, and the lower are so small, as to be scarce conspicuous; they are all of a singular figure, and appear as if one leaf came out of two others. In the middle are situated many stamens, terminated by yellow summits; at the bottom a three-cornered germen, which afterward turns to a three-cornered seed-vessel, having three or four holes at the top, filled with black seeds.

The second sort grows naturally in chalky land, in many parts of *England*; the lower leaves of this are winged, and every lobe is cut into three smaller; they are curled on their edges, and have some small indentures. The stalks rise about the same height as the former, and are terminated by longer and looser spikes of flowers; the flowers are paler, and approach to a white.

The third sort grows naturally in the south of *France and Italy*. This is an annual plant, which has generally a single fleshy tap-root, running deep in the ground, sending out several trailing stalks near a foot long, which divide into smaller branches, garnished with small leaves, some of which are wedge-shaped and entire, others are cut into three obtuse parts. The end of the branches are terminated by loose spikes of flowers, standing upon pretty long foot-stalks. The empalement of the flower is large, divided into five segments almost to the bottom; the flowers are white, and shaped like those of the other sorts.

The fourth sort grows naturally in *Italy and Spain*. This is a biennial plant; the lower leaves are unequally winged, some of the intermediate lobes or segments being much less than the other, and of different shapes. The stalk rises a foot and a half high, garnished with smaller disformed winged leaves, indented on their edges. The flowers are produced in slender loose spikes at the top of the stalks; they are small and white, of the same shape with the others.

The fifth sort grows naturally in the south of *France*. It is a biennial plant; the lower leaves are large, winged, and composed of many narrow lobes or segments, placed alternate, which are of a grayish colour; the stalks rise two feet and a half high, garnished with the like leaves, which diminish in their size to the top; the stalks are terminated by shorter and thicker spikes of flowers than either of the former, which are white, and shaped like those of the other species.

The sixth sort is supposed to grow naturally in *Egypt*. The seeds of this were sent me by Dr. *Adrian Van Royen*, the late professor of botany at *Leyden*. The root of this plant is composed of many strong fibres, from which come out several stalks about a foot long, which divide into small branches, garnished with oblong leaves, some of which are entire, and others are divided into three parts, of a deep

green. The flowers are of an herbaceous white colour, produced in loose spikes at the end of the branches; they stand upon pretty long foot-stalks, and have large empalements, equal with the petals, and smell very like fresh Raspberries, which occasions its being much cultivated in the *English* gardens. This plant is so like the third sort, as to be taken for the same by some, but the flowers of the third have no scent; so that those who have been imposed on, by having the seeds of the third sort sent them for this, have supposed the plant was degenerated.

The seventh sort grows naturally upon the mountains in *Spain*. This hath a perennial root, from which arise a few slender ligneous stalks a foot and a half high, which are thinly garnished with linear obtuse leaves, of a grayish colour; the upper part of the stalk is garnished for a good length with small, whitish, purple flowers, ranged in a very loose spike, sitting close to the stalk.

The eighth sort grows naturally upon dry banks and old walls in many parts of *England*, but is cultivated in some places for the dyer's use. This is now generally believed to be the plant, with which the ancient inhabitants of this island painted themselves, and not the woad, as has been by some supposed; for the dyers weed is a native here, whereas the woad has been since introduced into this country. This is a biennial plant; the root is composed of a few ligneous fibres; the leaves are four inches long, and half an inch broad, entire, and ending in obtuse points; these the first year spread circularly near the ground, and have some gentle wavings on their edges; the stalks rise three feet high, garnished with leaves of the same shape with those at bottom. They are terminated by long loose spikes of yellowish flowers, which appear the latter end of *June*, and the seeds ripen in *September*.

The five sorts first mentioned, and also the seventh, are seldom cultivated in gardens, except for the sake of variety, having very little beauty to recommend them, and being of no use; but whoever has a mind to have them, need only sow their seeds in autumn, and when the plants come up, if they are thinned and kept clean from weeds, it is all the culture they require; or if their seeds are permitted to scatter, the plants will come up in plenty, and sometimes become troublesome weeds.

The seeds of the sixth sort should be sown on a moderate hot-bed in *March*, and when the plants are strong enough to transplant, they should be pricked out upon another moderate hot-bed to bring them forward; but the plants should have a large share of air in warm weather, otherwise they will draw up very weak. About the latter end of *May* the plants may be planted out, some into pots, to place near the apartments, and others into warm borders, where they may remain to flower and seed. For the plants which grow in the full ground, often produce more seeds than those which are in pots; but at the time when the seed-vessels begin to swell, the plants are frequently infested with green caterpillars, which, if they are not destroyed, will eat off all the seed-vessels.

If the seeds of this plant are sown on a bed of light earth in *April*, the plants will come up very well, and when they are not transplanted, will grow larger than those which are raised in the hot-bed, but they will not flower so early. The plants may be preserved through the winter in a green-house, where they will continue flowering most part of the year, but the second year they are not so vigorous as in the first.

The eighth sort is the weld, which is accounted a rich commodity for dyeing; where this is cultivated, the seeds are commonly sown with Barley in the spring, and after the Barley is taken off the ground, the weld begins to make some progress, and the next season is pulled up for use.

This has been long practised, and it will be difficult to prevail on the cultivators of this plant to depart from their old customs; but if any person will follow the directions hereafter given, I can from experience promise them much better success.

The weld will grow upon very poor soil, but the crop will be in proportion to the goodness of the land, for upon very poor ground the plants will not rise a foot high, whereas upon good ground I have measured them upward of three feet, and the stalks, leaves, &c. have been in proportion; so that the better the soil is upon which it is sown, the greater will be the produce.

The best way to cultivate this plant, is to sow it without any other crop; if the ground is ready by the beginning or middle of *August*, that will be a good season; the land should be well ploughed and harrowed fine, but unless it is very poor, it will not require dung; when the ground is well harrowed and made fine, the seeds should be sown; one gallon of the seeds is sufficient to sow an acre of land, for they are small. If rain falls in a little time after the seeds are sown, it will bring up the plants, and in two months time they will be so far advanced, as to be easily distinguished from the weeds; then they should be hoed in the like manner as Turneps, always observing to do it in dry weather, for then the weeds will soon die after they are cut up; at this time the plants may be left about six inches distance; if this is done in dry weather, and the work well performed, the plants will be clean from weeds till the spring; but as young weeds will come up in *March*, so if in dry weather the ground is hoed again, it may be performed at a small expence while the weeds are young, then they will soon decay; and if after this there should be many more weeds appear, it will be proper to hoe it a third time, about the beginning of *May*, which will preserve the ground clean till the weld is fit to pull. The best time to pull the weld for use, is as soon as it begins to flower, though most people stay till the seeds are ripe, being unwilling to lose the seeds; but it is much better to sow a small piece of land with this seed, to remain for a produce of new seeds, than to let the whole stand for seed, because the plants, which are permitted to stand so long, will be much less worth for use than the value of the seeds; besides, by drawing off the crop early, the ground may be sown with Wheat the same season; for the plants may be drawn up the latter end of *June*, when they will be in the greatest vigour, so will afford a greater quantity of the dye.

When the plants are pulled, they may be set up in small handfuls to dry in the field, and when it is dry enough, it may be tied up in bundles and housed dry, being careful to stack it loosely, that the air may pass between to prevent its fermenting.

That which is left for seeds should be pulled as soon as the seeds are ripe and set up to dry, then beat out for use, for if the plants are left too long, the seeds will scatter. The usual price of the seed is ten shillings a bushel.

RHABBARUM. See Rheum.

RHABBARUM MONACHORUM. See Rumex.

RHAGADIOLUS. See Lapsana.

RHAMNOIDES. See Hippophæ.

RHAMNUS. *Tourn. Inst. R. H. 593. tab. 366.* The Buckthorn.

The Characters are,

It hath male and female flowers on different plants; these have no empalements according to some, or petals according to others. The cover of the sexes is funnel-shaped, cut into four parts at the top, which spread open. The male flowers have four stamina the length of the tube, terminated by small summits. The female flowers have a roundish germen, supporting a short style, crowned by a quadrifid stigma. The ger-

men afterward becomes a roundish berry, inclosing four hard seeds.

The Species are,

1. RHAMNUS *floribus axillaribus, foliis ovato-lanceolatis serratis nervosis.* Buckthorn with flowers proceeding from the sides of the branches, and oval, spear-shaped, sawed, veined leaves; the purging, or common Buckthorn.

2. RHAMNUS *floribus axillaribus, foliis ovatis acuminatis nervosis integerrimis.* Buckthorn with flowers proceeding from the sides of the branches, and oval, acute-pointed, entire leaves, having veins.

3. RHAMNUS *foliis lanceolatis, floribus axillaribus.* Buckthorn with spear-shaped leaves, and flowers growing from the sides of the stalks.

4. RHAMNUS *foliis cuneiformibus confertis perennantibus, floribus corymbosis alaribus.* Buckthorn with wedge-shaped ever-green leaves, growing in clusters, and flowers growing in roundish bunches from the sides of the branches.

The first sort grows naturally in the hedges in many parts of *England*; it rises with a strong woody stalk to the height of twelve or fourteen feet, sending out many irregular branches; the young shoots have a smooth, grayish, brown bark, but the bark of the older branches is darker and rougher, armed with a few short thorns. The leaves stand upon pretty long slender foot-stalks, of the oval spear-shape, sawed on their edges, of a dark green on their upper side, but of a pale or light green on their under, having a pretty strong midrib, and several veins proceeding from it. The flowers come out in clusters from the side of the branches; those of the male have as many stamina as there are divisions in the petal; those of the female have a roundish germen, which afterward turns to a pulpy berry, of a roundish form, inclosing four hard seeds.

The berries of this are used in medicine. From the juice of these berries is made a very fine green colour, called by the *French Verd-de-vestie*, which is much esteemed by the painters in miniature.

The second sort grows naturally in the south of *France*. This is an humble shrub, seldom rising more than three or four feet high, sending out many irregular branches, covered with a dark brown bark, garnished with oval leaves, ending in acute points; they are of a yellowish green, and a thin consistence, having several veins diverging from the midrib toward the sides. The flowers come out upon small curfons or spurs on the side of the branches, each standing upon a separate short foot-stalk, of a yellowish herbaceous colour, having short swelling tubes, cut into five acute segments at the top, which spread open; they appear in *June*, but are not succeeded by berries here.

Mr. *Du Hamel de Monceaux*, of the Royal Academy of Sciences at *Paris*, says, that the fruit of this species gathered green is the *Graine d'Avignon*, or *Avignon Berries*, which are used in dyeing of yellow; but I have been assured by a gentleman of skill who resided long in the south of *France*, that the *Avignon Berries* were the fruit of the narrow-leaved *Alaternus*; and in order to be satisfied of the truth, I gathered a quantity of the berries of the narrow-leaved *Alaternus* before they were full ripe, and carried them to two eminent dealers in this commodity, and asked them if they knew what those berries were; they both assured me, after making trial of them, that they were *Avignon Berries*, and if I had a large quantity of them, they would purchase them all; therefore, as the *Alaternus* before mentioned is one of the most common shrubs in the south of *France*, from whence the *Avignon Berries* are brought, we may suppose Mr. *Du Hamel* has been ill informed.

The third sort grows naturally in *Spain* and *Italy*. This grows to a larger size than the second, but not so high as the first. The branches are stronger, and armed with a few long

long spines; the leaves are like those of the wild Plum, but a little longer and narrower; the flowers are small, of a yellowish colour, and are produced from the side of the branches.

The first sort is so common in the hedges in many parts of *England*, that it is seldom cultivated in gardens. This rises easily from seeds, if they are sown in autumn soon after the berries are ripe, but, if they are kept out of the ground till spring, the plants will not come up till the year after; these will require no particular treatment, but may be managed in the same way as young Crabs, or any other hardy deciduous tree; it may also be propagated by cuttings or layers. If the young shoots are layed in autumn, they will put out roots by the following autumn, when they may be taken off from the plants, and either planted in a nursery to remain there to get strength for a year or two, or they may be planted where they are designed to remain. This is not so proper for hedges as the Hawthorn or Crab, so those should be preferred to it.

The two other sorts are preserved in botannick gardens for the sake of variety, but, as they are not beautiful, few persons cultivate them here. As these do not produce fruit in *England*, they are propagated either by laying down of the young branches in autumn, or by planting the cuttings in the spring, before the buds begin to swell. These will put out roots in the same manner as the common sort, and may be treated in the same way, for they are both hardy plants, and will thrive in the open air.

The fourth sort grows naturally at the *Cape of Good Hope*, so is too tender to thrive in the open air in *England*, but, if it is placed in a common green-house with Myrtles, Olives, and the hardier kinds of exotick plants in winter, and removed to the open air in summer, it will thrive very well. This rises with a shrubby stalk to the height of four or five feet, sending out many side branches, which, when young, are covered with a green bark, but, as they advance, the bark changes to a dark brown, armed with a few long slender thorns, and garnished with wedge-shaped leaves, which come out in clusters at each joint, four, five, or six rising from the same point, which differ in size; they are of a deep green, and continue all the year; their points are rounded, growing narrower to their base, fitting close to the branches. The flowers are produced on the side of the branches at each joint; they are collected into roundish bunches, standing upon foot-stalks an inch long; they are white, and have short tubes; their upper part is cut into five acute segments, which spread open in form of a star. These appear in *June*, at which time the whole shrub seems covered with flowers, so as to make a fine appearance; and, as the leaves continue green all the year, it deserves a place where there is a conveniency to shelter them in winter.

This sort has not as yet produced seeds in *England*, but it may be easily propagated by cuttings, which should be planted in pots the beginning of *April*. The pots should be plunged into a moderate hot-bed, and the cuttings should be shaded from the sun in the heat of the day; but they must by no means have too much wet. These cuttings will put out roots in about six weeks; then they must have a large share of air admitted to them, and gradually inured to bear the open air, into which they should be soon after removed; when they are well hardened, they may be shaken out of the pots, and separated, being careful to preserve a ball of earth to each, and plant them into single pots, placing them in the shade till they have taken new root; then they may be removed into a sheltered situation, where they may remain till the frost comes on in autumn, at which time they must be housed, and treated in the same way as the other hardier kinds of green-house plants.

RHEUM. *Lin. Gen. Plant.* 454. The Rhubarb,

The Characters are,

The flower has no empalement; it hath one petal, which is narrow at the base, and impervious. The brim is cut into six parts, which are obtuse and alternately smaller; it hath nine hair-like stamina inserted in the petal, and is of the same length, terminated by oblong twin summits, which are obtuse, and a short three-cornered germen, with scarce any style, crowned by three-feathered stigmas, which are reflexed. The germen afterward becomes a large three-cornered seed, with acute membranaceous borders.

The Species are,

1. RHEUM *foliis cordatis glabris, spicis compactis obtusis.* Rhubarb with smooth heart-shaped leaves, and obtuse compact spikes of flowers.

2. RHEUM *foliis subvillosis, petiolis æqualibus.* *Lin. Diff.* 1. *tab. 1. Sp. Plant.* 372. Rhubarb with hairy leaves, having equal foot-stalks.

3. RHEUM *foliis cordatis glabris, marginibus sinuatis, spicis divisis nutantibus.* *Tab.* 218. Rhubarb with heart-shaped smooth leaves, which are sinuated on their borders, and divided spikes of flowers which nod.

4. RHEUM *foliis granulatis, petiolis æqualibus.* *Lin. Sp. Plant.* 372. Rhubarb with granulated leaves, having equal foot-stalks; called by the *Arabians* Ribes.

The first sort grows naturally near the *Pontick Sea*, but has been long an inhabitant of the *English* gardens. When the seeds were first brought to *Europe*, they were supposed to be of the true Rhubarb, but upon making trial of the roots, they were found to be greatly inferior to those of the true Rhubarb; and upon examination it was found to be the Rhapontick of *Prosper Alpinus*, commonly called *Pontick Rhubarb*. This hath a large thick root, which divides into many less running deep in the ground; the outside is of a reddish brown colour, and the inside yellow, from which arise several leaves in number according to the size of the root; these come up folded in the spring, and afterward expand themselves; they are of a roundish heart-shape, smooth, having very thick foot-stalks of a reddish colour, which are a little channelled on their lower side, but flat at the top. When the plant grows in rich land, the foot-stalks of the leaves are near two feet long, and thicker than a man's thumb; the leaves also are often two feet long, and as much in breadth, having several strong longitudinal veins running from the foot-stalk to the borders; they are of a deep green, a little waved on their edges, and have an acid taste, but particularly the foot-stalks, which are now frequently used for making of tarts. From between the leaves arise the flower-stem, which is of a purple colour, garnished with one leaf at each joint, of the same shape with those below, but smaller, and sit close to the stalk. The stalks grow from two to three feet high, according to the strength of the ground, and are terminated by thick close obtuse spikes of white flowers; these are succeeded by large triangular brown seeds, having a border or wing at each angle, which ripen in *August*.

The seeds of the second sort were sent me from *Leyden* by the late *Dr. Boerhaave*, by the title of *Rhabarbarum Chinense verum*, or true *China Rhubarb*, which succeeded in the *Chelsea* garden. The root of this sort divides into a greater number of thick fibres than those of the first, which run deeper into the ground, and are of a deeper yellow within. The leaves appear much earlier in the spring; the foot-stalks are not so much channelled on their under side, and are plain on their upper; they are not so red nor so thick. The leaves are longer, running more to a point, and are waved on their edges, are a little hairy on their upper side, and have many strong veins or ribs on their under. The flower-stem is of a pale brownish colour, rising about four feet high, dividing into several loose panicles

panicles or bunches of white flowers, which are succeeded by triangular seeds, like those of the first sort, which ripen earlier in the season.

The seeds of the third sort were sent me from *Petersburgh*, for the true *Tartarian* Rhubarb. The roots of this sort are large, and do not divide into so many parts as those of the second, and are yellower within; the leaves appear as early in the spring; the foot-stalks of these are of a pale green, almost as large as those of the first sort; they have scarce any channels, and are flat on their upper side; the leaves are heart-shaped, smooth; they do not run out to so great length in a point as the second, but are longer than those of the first; they are very broad toward their base, and have very large pale green ribs on their under side, a little waved on their edges, and have a sharp acid flavour. The flower-stalk is a pale green; it rises four feet high, as large as a common walking cane, garnished at each joint by one leaf, of the same shape with those below, but smaller, sitting close to the stalk; the upper part of the stalk divides into small branches, which are again divided into less, each sustaining a panicle or spike of white flowers, which are succeeded by large triangular bordered seeds, like those of the first sort.

The roots of this last approach nearer to those of the foreign Rhubarb, than either of the other, both in shape and quality; and as the seeds which were sent to *Petersburgh*, were gathered from the plants growing on the spot where the Rhubarb is taken up, so there is little reason to doubt of its being the true sort, though the roots which have grown in *England*, have not been equal in quality with those of the foreign; but this may have been occasioned for want of age, or by being taken out of the ground at an improper season; therefore farther trials may improve it, and as the plants produce great plenty of seeds here, so they may be propagated with great ease.

It has been learnedly controverted by the botanists, whether the Rhapontick of the ancients, and the Rhubarb of the moderns, is one and the same plant, some affirming, and others denying that there is any agreement; the reasonings on both sides may be seen in the appendix to the second volume of *John Bauhin's* History of Plants.

The fourth sort grows naturally on *Mount Libanus*, and other mountainous parts of *Syria*. This hath a thick fleshy root, which runs pretty deep in the ground, from which arise several leaves in the spring, which come up folded together, and afterward expand; they have very short foot-stalks, so spread near the ground, but during the spring their borders are erect, and form a sort of hood, having several folds, curled and waved on their edges; they are of a purplish green, and have purple veins and borders; their surface appears studded with rough protuberances; when the leaves are fully expanded in summer, they are a foot long, and above two feet broad; their under side is paler than the upper, and their borders appear fringed. I have not seen this plant in flower, but the seeds of it were brought from *Mount Libanus*, by the Right Rev. Dr. *Pococke*, the present bishop of *Ossory*; these were large, covered with a succulent pulp, of a deep red colour, and very astringent taste; this succulent covering may have occasioned its being taken for a berry, by many of the old writers; the shape of the seed is like that of the other species.

These plants are all propagated by seeds, which should be sown in autumn soon after they are ripe; then the plants will come up the following spring; but if they are kept out of the ground till spring, the plants will not come up till the next spring, so that a whole year will be lost. The seeds should be sown where the plants are designed to remain, for as their roots are large and fleshy, so when they are transplanted, they do not recover their removal in less

than two years; nor will the roots of those plants which are transplanted, ever grow so large and fair, as those which remain where they were sown. When the plants appear in the spring, the ground should be hoed over to cut up the weeds, and where the plants are too close, some should be cut up, to allow room for the others to grow, in the same manner as is practised for Carrots and Parsneps, leaving them at the first time of hoeing six or eight inches asunder, for fear of accidents, but at the second time of hoeing they may be separated to a foot and a half distance or more. After this the plants will require no other culture, but to keep them clean from weeds, so that as soon as the weeds appear, if the ground is scuffled over with a *Dutch* hoe in dry weather, it may be done for a small expence, and thereby the ground will be kept clean. If this is begun early in the spring before the weeds are large, they will soon die, and by repeating it two or three times at proper intervals, during the spring, the ground will be made clean; and when the plants spread out their leaves to cover the ground, they will prevent the growth of weeds.

In autumn the leaves of these plants decay; then the ground should be made clean, and in the spring before the plants begin to put up their new leaves, the ground should be hoed and made clean again; the second year after the plants come up, many of the strongest will produce flowers and seeds, but the third year most of them will flower. The seeds of these should be carefully gathered when ripe, and not permitted to scatter, lest they should grow to injure the old plants. The roots of these plants will remain many years without decaying, and I am informed, that the old roots of the true Rhubarb are much preferable to the young ones. They delight in a rich soil, not too dry nor over moist, and where there is a good depth for their roots to run down in such land, their leaves will be very large, and their roots will grow to a great size.

The first sort is now frequently cultivated in gardens for the foot-stalks of their leaves, which are peeled and made into tarts in the spring: it is also kept in gardens, to supply the shops with the roots, which are used in medicine.

The true Rhubarb is now sown in many gardens, and may probably succeed so well here in time, as that a sufficient quantity of that valuable drug may be raised, to supply our consumption.

RHEXIA. *Gron. Flor. Virg.* 41.

The Characters are,

The empalement of the flower is permanent, oblong, tubulous, and of one leaf, divided into four parts at the trim. The flower has four roundish petals inserted in the empalement. It hath eight slender stamina, which are inserted in the empalement, terminated by declining furrowed summits. It has a roundish germen, supporting a declining style the length of the stamina, crowned by a thick oblong stigma. The germen afterward becomes a roundish capsule, with four cells in the swollen empalement, opening with four valves, filled with roundish seeds.

The Species are,

1. RHEXIA *calycibus glabris. Flor. Virg.* 41. Rhexia with smooth empalements.

2. RHEXIA *foliis ciliatis. Lin. Sp. Plant.* 346. Rhexia with fine hairy leaves.

The first sort was discovered by Mr. *Banister* in *Virginia*, from whence he sent the seeds to *England*, which succeeded in several gardens. This rises with an erect stalk near a foot and a half high, is four-cornered and hairy, garnished with hairy spear-shaped leaves, placed opposite. The stalk has two foot-stalks coming out from the side opposite, at the upper joint, and is terminated by two other; these each sustain two or three red flowers with heart-shaped petals, which spread open in form of a cross.

The second sort grows naturally in *Maryland*, from whence I received the seeds. This sends up an erect stalk about ten inches high, garnished with spear-shaped leaves, set on by pairs; from every joint of the stalk comes out two short shoots opposite, garnished with small leaves of the same shape; the whole plant is covered with stinging iron-coloured hairs. The stalk divides at the top into two foot-stalks, spreading from each other, having one reddish flower on each; these have four heart-shaped petals, which spread open like the other. These plants are propagated by seeds, which must be procured from the places where they grow naturally. If the seeds arrive before the spring, and are sown soon after they arrive, in pots filled with good fresh earth, and placed under a garden-frame to guard them from frost, the plants will come up the following spring; but when the seeds are sown in the spring, the plants rarely come up the first year. When the plants come up and are fit to remove, part of them should be planted in an east border, where they may have only the morning sun, and the other may be planted into pots, that they may be sheltered under a frame in winter, for they are sometimes destroyed by severe frost, though they will live abroad in the common winters very well; the second year the plants will flower, and with care they may be continued three or four years.

RHINANTHUS. *Lin. Gen. Plant.* 658. Rattle, or Lousewort.

There are several species of this genus which grow naturally in moist meadows in many parts of *Europe*, one of which is very common in *England*, where it is one of the most troublesome weeds among the Grass, spreading itself over the whole ground, so that in many of the water meadows, there is more of this plant than Grass. It is an annual plant, which flowers the latter end of *May*, so that the seeds ripen by the time the Grass of these meadows is mowed, and the seeds scatter and fill the ground with young plants the following spring; therefore, in order to destroy it, the Grass should be cut as soon as the flowers of this plant appear.

These plants are with great difficulty kept in gardens; they are biennial, so are only propagated by seeds; these should be sown soon after they are ripe, otherwise they will not succeed, nor will the plants bear removing, therefore should be sown where they are to remain, which should be in a moist rich soil and a shady situation: when the plants come up, they must be thinned and kept clear from weeds, which is all the culture they require. If the seeds of these plants are permitted to scatter, the plants will come up better than those which are sown by hand.

RHIZOPHORA. *Lin. Gen. Plant.* 524. This is called Mangrove by the inhabitants of the *West-Indies*; there are several species of this genus which grow in salt water rivers, both in the *East* and *West-Indies*, but as they will not grow upon land, it is needless to enumerate them here.

RHODIOLA. *Lin. Gen. Plant.* 997. Rose-root.

The Characters are,

It hath male and female flowers in different plants; the male flowers have an empalement of one leaf, cut into four or five segments almost to the bottom; they have four obtuse petals, and four nectariums, which are erect and shorter than the empalement, with eight awl-shaped stamina, which are longer than the petals, terminated by obtuse summits. They have four oblong acute germen, without style or stigma, so are abortive. The female flowers have the same empalement as the male; they have four obtuse petals equal with the empalement, and have four nectariums like the male, with four oblong acute-pointed germen sitting upon an erect style, crowned by obtuse stigmas. The germen afterward become four horned capsules, compressed on their inner side, filled with roundish seeds.

The Species are,

1. **RHODIOLA** *staminibus corollâ duplo longioribus.* Rose-root with stamina twice as long as the petals.

2. **RHODIOLA** *staminibus corolla fere æquantibus.* Rose-root with stamina scarcely equalling the length of the petals.

The first sort grows naturally in the clefts of the rocks and rugged parts of the mountains of *Wales*, *Yorkshire*, and *Westmoreland*. This has a very thick fleshy root, which, when bruised or cut, sends out an odour like *Roses*; it has many heads, from whence in the spring come out thick succulent stalks like those of *Orpine*, about nine inches long, closely garnished with thick succulent leaves, of a gray colour, which are indented on their edges toward the top, and are placed alternately on every side the stalk. The stalk is terminated by a cluster of yellowish herbaceous flowers, which appear early in *May*; the male flowers have stamina twice the length of the petals. They have a very agreeable scent, but are not of long continuance.

The second sort grows naturally on the *Alps*; the roots of this are smaller than those of the other sort; the stalks are small, not above nine inches long; the leaves are small, but shaped like those of the other sort; the petals of the flowers are purplish, and the stamina are but little longer than the petals. This flowers later than the other sort.

These plants are preserved in the gardens of the curious, for the sake of variety; they are easily propagated by parting of the roots, which should be performed the beginning of *September*, at which time their stalks begin to decay; and if the fleshy parts of the roots are cut or broken, they should be laid to dry a few days before they are planted. These plants require a shady situation and a dry undunged soil, in which they will continue many years.

RHODODENDRON. *Lin. Gen. Plant.* 484. Dwarf Rose-bay.

The Characters are,

The flower has a permanent empalement cut into five parts; the flower hath one wheel funnel-shaped petal, spreading open at the brim; it has ten slender stamina which decline, and are the length of the petals, terminated by oval summits, and a five-cornered germen, supporting a slender style the length of the petal, crowned by an obtuse stigma. The germen afterward becomes an oval capsule with five cells, filled with small seeds.

The Species are,

1. **RHODODENDRON** *foliis ciliatis nudis, corollis infundibuliformibus.* *Lin. Sp. Plant.* 292. Rose-bay with naked hairy leaves, and funnel-shaped petals.

2. **RHODODENDRON** *foliis glabris, subtus leprosis, corollis infundibuliformibus.* *Lin. Sp. Plant.* 392. Rose-bay with smooth leaves, which are hoary on their under side, and have funnel-shaped petals.

3. **RHODODENDRON** *foliis nitidis ovalibus margine acuto reflexo.* *Lin. Sp.* Rose-bay with neat oval leaves, sharply reflexed on their border.

The first sort grows naturally on the *Alps*, and several mountains in *Italy*. This is a low shrub, which seldom rises two feet high, sending out many short ligneous branches, covered with a light brown bark, garnished closely with oval spear-shaped leaves, sitting pretty close to the branches; they are entire, have a great number of fine iron-coloured hairs on their edges and under side. The flowers are produced in bunches at the end of the branches, having one funnel-shaped petal; the tube is about half an inch long; the brim is cut into five obtuse segments, which spread half open; they are of a pale red colour, and have ten stamina in each, which are the length of the tube; after the flowers are past, the germen in the center turns to an oval capsule with five cells, filled with small seeds.

The second sort grows naturally on the *Alps* and *Apennines*. This rises with a shrubby stalk near three feet high,

sending out many irregular branches, covered with a purplish bark, closely garnished with smooth, spear-shaped, entire leaves, whose borders are reflexed backward; the upper side is of a light lucid green, their under side of an iron colour; they are placed all round the branches, without any order. The flowers are produced in round bunches at the end of the branches; they are funnel-shaped, having short tubes cut into five obtuse segments at the brim, which spread a little open; they are of a pale Rose colour, and make a good appearance.

The third sort is a very beautiful shrub, especially where it thrives well, and produces many flowers; but there are few soils and situations in this country which agrees well with it, so the shrubs are of short duration. This grows naturally in many parts of *North America*, where there are usually several stems arising from one root, which grow ten or twelve feet high; the leaves are as large as those of the Laurel, and of as thick consistence, continuing green the whole year. The flowers are produced in roundish bunches at the extremity of the former year's shoots; they are of a pale Rose colour, studded with spots of a deeper red. The tube of the flower is bent, somewhat like those of ringent flowers, in which it chiefly differs from the *Kalmia*; the stamina also incline to one side of the tube, with the style situated between them. When these shrubs are adorned with several bunches of flowers, there are very few flowering-shrubs can be compared with these for beauty.

There are some other species of this genus, which grow naturally in the eastern countries, and others are natives of *America*; but the sorts here mentioned are all I have seen in the *English* gardens; these are difficult to propagate and preserve in gardens, for they grow naturally upon barren rocky soils and in cold situations, where they are covered with snow great part of the winter; so that when they are planted in better ground, they do not thrive, and for want of their usual covering of snow in winter, they are frequently killed by frost; but could these plants be tamed, and propagated in plenty, they would be great ornaments to the gardens.

They are propagated by seeds, but these are so very small, that if they are covered deep, they will not grow. The seeds should be sown as soon as possible, after they are ripe, in pots filled with fresh gentle loamy earth, and very lightly covered with a little fine earth; then the pots should be plunged up to their rims in a shady border, and in hard frost they should be covered with bell or hand-glasses, taking them off in mild weather. If these seeds are sown early in autumn, the plants will come up the following spring; these must be kept shaded from the sun, especially the first summer, and duly refreshed with water; in autumn following they may be transplanted to a shady situation, on a loamy soil, covering the ground about their roots with Moss, which will guard them from frost in winter, and keep the ground moist in summer.

Plants of the third sort are frequently brought to *England* from *North America*, but as many of these are unskillfully taken up from the places where they naturally grow, which is in thickets, so that their roots intermix, which renders it more difficult to get them up with good roots, and coming in the winter, many of the plants fail, and those which do live, rarely continue in health many years, especially if the plants are large; therefore those persons who collect these shrubs to send to *England*, should make choice of such as are of two or three years growth, and of those plants which have come from seeds, rather than suckers from older plants; or if they would collect the seeds, and sow them immediately in a garden, on a proper soil, they might raise good plants for the purpose; which is very difficult to do in *England*, for the seeds seldom arrive here till toward

spring, so do not grow the first year; and when the plants do come up, it is very difficult to keep them alive the two first years.

RHUS. *Tourn. Inst. R. H. 611. tab. 381. Sumach.*

The Characters are,

The empalement of the flower is permanent, erect, and cut into five parts. The flower has five oval, erect, spreading petals, and five short stamina, terminated by small summits; it has a roundish germen as large as the petals, with scarce any style, crowned by three small stigmas. The germen afterward becomes a roundish hairy berry, inclosing a single hard seed of the same form.

The Species are,

1. RHUS foliis pinnatis obtusiusculè serratis, ovato-lanceolatis subtus villosis. Sumach with winged leaves, which are obtusely sawed, ovally spear-shaped, and hairy on their under side; Elm-leaved Sumach.

2. RHUS foliis pinnatis integerrimis, cordato-oblongis acuminatis, ramis petiolisque villosissimis. Sumach with entire winged leaves, which are oblong, heart-shaped, end in acute points, having very hairy branches and foot-stalks; *Virginian* Sumach.

3. RHUS foliis pinnatis serratis, lanceolatis utrinque glabris. Sumach with winged leaves, which are spear-shaped, and smooth on both sides.

4. RHUS foliis pinnatis serratis lanceolatis, subtus incanis, paniculâ compactâ. Sumach with sawed, spear-shaped, winged leaves, which are hoary on their under side, with a compact panicle.

5. RHUS foliis pinnatis, obsolete serratis, lanceolatis, utrinque glabris, paniculâ compositâ. Sumach with winged spear-shaped leaves, which are slightly sawed, and a compound panicle.

6. RHUS foliis pinnatis integerrimis, petiolo membranaceo articulato. *Flor. Leyd. Prod. 24.* Sumach with entire winged leaves, and a jointed membranaceous foot-stalk; narrow-leaved Sumach.

7. RHUS foliis pinnatis, foliolis ovatis, obtusè serratis, petiolo membranaceo villoso. Sumach with winged leaves, oval lobes, which are bluntly sawed, and a hairy foot-stalk, having jointed membranes or wings.

8. RHUS foliis ternatis, foliolis ovatis subtus tomentosis. Three-leaved Sumach with oval leaves, which are downy on their under side.

9. RHUS foliis ternatis, foliolis subpetiolatis, rhombeis angulatis, subtus tomentosis. *Lin. Sp. Plant. 266.* Three-leaved Sumach with angular rhomboid lobes, having foot-stalks downy on their under side.

10. RHUS foliis ternatis, foliolis sessilibus cuneiformibus lævibus. *Vir. Cliff. 25.* Three-leaved Sumach, whose lobes are smooth, wedge-shaped, and sit close to the stalk.

11. RHUS foliis ternatis, foliolis ovatis nervosis, marginibus sepius dentatis, utrinque viridibus. Sumach with trifoliate leaves, having oval veined lobes, which are generally indented on their edges, and green on both sides.

12. RHUS foliis ternatis, foliolis petiolatis lineari-lanceolatis integerrimis, subtus tomentosis. *Hort. Cliff. 111.* Sumach with trifoliate leaves, whose lobes stand upon foot-stalks, are linear, spear-shaped, entire, and downy on their under side.

13. RHUS foliis ternatis, lineari-lanceolatis integerrimis sessilibus utrinque viridibus. Sumach with trifoliate leaves, having linear, spear-shaped, entire lobes, sitting close to the foot-stalk, green on both sides.

14. RHUS foliis ternatis, foliolis ovatis acuminatis integerrimis, petiolatis, floribus paniculatis terminalibus. Three-leaved Sumach with oval acute-pointed lobes, which are entire, upon foot-stalks, and flowers growing in panicles, which terminate the branches.

15. *RAUS foliis simplicibus obovatis. Lin. Sp. Plant. 267.* Sumach with single, obverse, oval leaves; *Venice* Sumach, or *Coccygia*.

The first sort of Sumach grows naturally in *Italy, Spain, and Turkey*. The branches of this tree are used instead of Oak for tanning of leather, and I have been informed that the *Turkey* leather is all tanned with this shrub. This has a ligneous stalk, which divides at bottom into many irregular branches, which rise to the height of eight or ten feet; the bark is hairy, of an herbaceous brown colour; the leaves are winged, composed of seven or eight pair of lobes, terminated by an odd one, bluntly sawed on their edges, are hairy on their under side, of a yellowish green colour, and placed alternately on the branches; the flowers grow in loose panicles at the end of the branches, which are of a whitish herbaceous colour, each panicle being composed of several spikes of flowers sitting close to the foot-stalks. The leaves and seeds of this sort are used in medicine, and are esteemed very restraining, stiptick, and good for all kinds of fluxes and hæmorrhages; used both inwardly and outwardly they resist putrefaction, and stop gangrenes and mortifications.

The second sort grows naturally in almost every part of *North America*. This hath a woody stem, with many irregular branches, which are generally crooked and deformed. The young branches are covered with a soft velvet-like down, resembling greatly that of a young stag's horn both in colour and texture, from whence the common people have given it the appellation of stag's-horn; the leaves are winged, composed of six or seven pair of oblong heart-shaped lobes, terminated by an odd one, ending in acute points, hairy on their under side, as is also the midrib. The flowers are produced in close tufts at the end of the branches, and are succeeded by seeds, inclosed in purple, woolly, succulent covers, so that the bunches are of a beautiful purple colour in autumn; and the leaves, before they fall in autumn, change to a purplish colour at first, and, before they fall, to a Feuilemort. This shrub is used for tanning of leather in *America*, and the roots are often prescribed in medicine in the countries where the plant grows naturally.

The third sort grows naturally in many parts of *North America*; this is commonly titled by the gardeners *New England* Sumach. The stem of this sort is stronger, and rises higher than that of the former; the branches spread more horizontally; they are not quite so downy as those of the last, and the down is of a brownish colour; the leaves are composed of many more pair of lobes, which are smooth on both sides; the flowers are disposed in loose panicles, which are of an herbaceous colour.

The fourth sort grows naturally in *Carolina*; the seeds of this were brought from thence by the late Mr. *Catesby*, who has given a figure of the plant in his *Natural History of Carolina*. This is by the gardeners called the *Scarlet Carolina* Sumach; it rises commonly to the height of seven or eight feet, dividing into many irregular branches, which are smooth, of a purple colour, and pounced over with a grayish powder, as are also the foot-stalks of the leaves. The leaves are composed of seven or eight pair of lobes, terminated by an odd one; these are not always placed exactly opposite on the midrib, but are sometimes alternate. The upper side of the lobes are of a dark green, and their under hoary, but smooth. The flowers are produced at the end of the branches in very close panicles, which are large, and of a bright red colour.

The fifth sort grows naturally in *Canada, Maryland, and* several other parts of *North America*. This hath smooth branches, of a purple colour, covered with a gray pounce. The leaves are composed of seven or eight pair of lobes,

terminated by an odd one; the lobes are spear-shaped, sawed on their edges, of a lucid green on their upper surface, but hoary on their under, and are smooth. The flowers are produced at the end of the branches in large panicles, which are composed of several smaller, each standing upon separate foot-stalks; they are of a deep red colour, and the whole panicle is covered with a gray pounce, as if it had been scattered over them.

The sixth sort grows naturally in most parts of *North America*, where it is known by the title of *Beech* Sumach, probably from the places where it grows. This is of humbler growth than either of the former, seldom rising more than four or five feet high, dividing into many spreading branches, which are smooth, of a light brown colour, closely garnished with winged leaves, composed of four or five pair of narrow lobes, terminated by an odd one; they are of a light green on both sides, and in autumn change purplish. The midrib, which sustains the lobes, has on each side a winged or leafy border, which runs from one pair of lobes to another, ending in joints at each pair, by which it is easily distinguished from the other sorts. The flowers are produced in loose panicles at the end of the branches, of a yellowish herbaceous colour.

These six sorts are hardy plants, and will thrive in the open air here. The first and fourth sorts are not quite so hardy as the others, so must have a better situation, otherwise their branches will be injured by severe frost in the winter; they are easily propagated by seeds, which, if sown in autumn, the plants will come up the following spring, but if they are sown in the spring, they will not come up till the next spring; they may be either sown in pots, or the full ground. If they are sown in pots in autumn, the pots should be placed under a common frame in winter, where the seeds may be protected from hard frost; and in the spring, if the pots are plunged into a very moderate hot-bed, the plants will soon rise, and have thereby more time to get strength before winter. When the plants come up, they must be gradually hardened to bear the open air, into which they should be removed as soon as the weather is favourable, placing them where they may have the morning sun; in the summer, they must be kept clean from weeds, and in dry weather watered; toward autumn it will be proper to stint their growth by keeping them dry, that the extremity of their shoots may harden, for if they are replete with moisture, the early frosts in autumn will pinch them, which will cause their shoots to decay almost to the bottom, if the plants are not screened from them. If the pots are put under a common frame in autumn, it will secure the plants from injury, for while they are young and soft, they will be in danger of suffering, if the winter proves very severe; but in mild weather they must always enjoy the open air, therefore should never be covered but in frost. The spring following, just before the plants begin to shoot, they should be shaken out of the pots, and carefully separated, so as not to tear the roots, and transplanted into a nursery in rows three feet asunder, and one foot distance in the rows. In this nursery they may stand two years to get strength, and then may be transplanted where they are to remain.

This method of propagating the plants from seeds is seldom practised after a person is once possessed of the plants, for they are very subject to send up a great number of suckers from their roots, whereby they are easily propagated. The suckers of all the sorts may be taken up, and planted in a nursery for a year or two to get strength, and then may be planted where they are to remain.

These shrubs are generally planted in plantations of flowering shrubs in large gardens, where they make a fine variety in autumn, especially the second, fourth, and fifth

forts, with their large purple or red panicles, which have a good effect; but, where these are planted, their suckers should be every year taken off, otherwise they will grow up to a thicket, and destroy the old plants.

The seventh fort grows naturally in the east. The seeds of this were sent to the Royal Garden at *Paris*, where they succeeded; and from thence I received the plant, which grew very well in the open air at *Chelsea* three years, but the severe winter in 1740 destroyed it, so that it is not quite so hardy as the other forts. This rises with a shrubby stalk six or eight feet high, sending out many irregular branches. The young shoots and foot-stalks of the leaves are covered with a soft, brown, hairy down; the leaves are composed of three or four pair of oval lobes, terminated by an odd one; the inner lobes are small, the outer large; the end lobe is heart-shaped, ending in an acute point; they are sawed on their edges, and are hoary on their under side; the midrib, which sustains the lobes, has two leafy membranes running along the sides from joint to joint, which are narrow below, and gradually increase in their breadth to the next joint. When the leaves are broken, they emit a milky juice from the wound. As I have not seen the flowers of this fort, I can give no account of them.

This does not put out suckers from the root so freely as the *American* kinds, so must either be propagated by layers, or cutting off some of the roots, and planting them upon a gentle hot-bed; by which method it may be propagated, but my plant was too weak for this purpose, when it was destroyed.

The eighth fort grows naturally at the *Cape of Good Hope*. This hath a strong woody stalk, which rises ten or twelve feet high, covered with a gray bark, sending out many smooth branches, garnished with trifoliate leaves, standing upon pretty long foot-stalks. The lobes of the leaves are oval, entire, hoary on their under side, but smooth, and of a lucid green on their upper; the flowers are produced from the wings of the leaves in small bunches; they are of an herbaceous colour.

The ninth fort also grows naturally at the *Cape of Good Hope*. This rises with a woody stalk to the height of seven or eight feet, covered with a brown bark, putting out many irregular branches, garnished with trifoliate leaves, standing upon long foot-stalks. The lobes of this fort are angular, shaped like a rhombus, downy on their under side, but of a dark green on their upper. The flowers come out in slender bunches from the side of the branches, of a whitish herbaceous colour, and soon fall away.

The tenth fort grows naturally at the *Cape of Good Hope*. This rises with a woody stalk like the eighth, dividing into many branches, covered with a brown bark, garnished with trifoliate leaves, whose lobes are wedge or heart-shaped, of a lucid green, and sit close to the foot-stalk. This fort does not flower here, so far as I can find, for I have had some of the plants in my care above forty years, but they have not flowered as yet.

The eleventh fort is a native of the *Cape of Good Hope*. This hath some resemblance of the former, but the lobes of the leaves are twice as large, and are oval, with some indentures on their edges; they have several transverse veins running from the midrib to the edges, and are very stiff, of a bright lucid green on both sides. This fort has not flowered here so far as I can learn.

The twelfth fort came from the *Cape of Good Hope*, where it grows naturally. This rises with a woody stalk seven or eight feet high, dividing into several irregular branches, covered with a dark brown bark, garnished with narrow, spear-shaped, trifoliate leaves, standing upon pretty long foot-stalks, downy on their under side, but of a lucid green on their upper. The flowers are small, of an herbaceous

colour, and are produced in small loose bunches from the side of the branches.

The thirteenth fort is a native of the *Cape of Good Hope*. This rises with an upright woody stalk five or six feet high, sending out many branches, covered with a smooth brown bark, garnished with narrow, spear-shaped, trifoliate, entire leaves, standing upon short foot-stalks, of a lucid green, and have a deep furrow lengthways through the middle. This fort has not yet flowered in *England*.

All these *African* forts are too tender to live through the winter in the open air in *England*, so they are planted in pots or tubs, and housed in autumn; during the winter they must be treated in the same way as other hardy green-house plants. They all retain their leaves through the year, so make a good variety when intermixed with other plants in the green-house in winter. They may be propagated by cuttings, which should be planted in pots the beginning of *April*, and plunged into a very moderate hot-bed, covering them close with hand or bell-glasses, screening them from the sun in the heat of the day. The cuttings should be now and then refreshed with water, but it should not be given in too great quantity. If they succeed, they will put out roots in about two months; when they begin to shoot, they should be gradually hardened to bear the open air, into which they must be removed, placing them in a sheltered situation; when the cuttings have filled the pots with their roots, they should be shaken out, and parted carefully, planting each into a separate small pot, placing them in the shade till they have taken new root, when they may be intermixed with other exotick plants in a sheltered situation for the summer, and in autumn removed into the green-house.

The fourteenth fort grows naturally in the island of *Ceylon*. This rises with a woody stalk ten or twelve feet high, clothed with trifoliate leaves, standing upon pretty long foot-stalks. The lobes of the leaves are oval; they are thick, smooth, and of a lucid green. The flowers are small, of an herbaceous colour, and are produced in loose panicles at the end of the branches. These seldom appear in *England*.

This plant is tender, so must be placed in a moderate stove, otherwise it will not live through the winter in *England*. It may be propagated by cuttings in the same way as the former forts, but requires a warmer bed than those to promote their putting out roots. When they have good roots, they should be each transplanted into a separate small pot, and plunged into the tan-bed, and treated in the same way as other tender exotick plants.

The fifteenth fort grows naturally in *Spain*, *Italy*, and the *Levant*, where the leaves are used for tanning of leather; this rises with an irregular shrubby stalk to the height of ten or twelve feet, sending out many spreading irregular branches, covered with a smooth brown bark, garnished with single, obverse, oval leaves, rounded at their points, which stand upon long foot-stalks; they are smooth, stiff, and of a lucid green, having a strong midrib, from whence several transverse veins run toward the border. The flowers come out at the end of the branches upon long hair-like foot-stalks, which divide, and branch into large hair-like bunches, of a purplish colour; they are small, white, and composed of five small oval petals, which spread open.

This plant is cultivated for sale in the nursery-gardens near *London*; it is propagated by layers, which should be laid down in autumn, and by next autumn they will have taken root, when they may be taken off from the old plants, and transplanted in a nursery, where they may grow a year or two to get strength, and then be planted where they are to remain. This shrub is so hardy, as not to be injured by frost in *England*.

RIBES. *Lin. Gen. Plant.* 247. The Currant-tree.

The Characters are,

The flower has a bellied empalement, cut at the top into five concave obtuse segments; it hath five small, obtuse, erect petals, growing to the border of the empalement, and five awl-shaped stamina inserted in the empalement, terminated by incumbent compressed summits. The roundish germen is situated under the flower, supporting a bifid style, crowned by obtuse stigmas, which afterwards becomes a globular umbilicated fruit, with one cell, containing many roundish compressed seeds.

The Species are,

1. RIBES *inerme, racemis glabris pendulis, floribus planiusculis.* *Lin. Sp. Plant.* 200. Currant without thorns, smooth hanging bunches, and plain flowers; common Currant.

2. RIBES *inerme, racemis erectis, bracteis flore longioribus.* *Lin. Sp. Plant.* 200. Smooth Currant with erect bunches, and bractæ longer than the flower; sweet Alpine Currant.

3. RIBES *inerme, racemis pilosis, floribus oblongis.* *Lin. Sp. Plant.* 201. Currant without spines, having hairy branches and oblong flowers; black Currant.

4. RIBES *inerme, racemis glabris, floribus campanulatis.* Currant with unarmed smooth branches, and bell-shaped flowers.

The first sort grows naturally in the northern parts of Europe, but has been long cultivated in the gardens, and greatly improved, so that at present there are the following varieties in the English gardens, viz. the common Currant with small red fruit, the same with white fruit, and another with pale fruit, which is commonly called the *Champaign* Currant; but, since the two sorts of *Dutch* Currants have been introduced, and become plenty in the gardens, the old red and white Currants have been almost banished, so that they are rarely to be found in the English gardens at present.

The second sort is kept in a few gardens for the sake of variety, but, as the fruit is very small, and has little flavour, it is not much cultivated.

The third sort grows naturally in *Helvetia*, *Sweden*, and other northern countries, and is sometimes cultivated in gardens for its fruit, of which is made a rob, which is greatly esteemed for sore-throats, from whence the fruit has been called *Squinancy Berries* for their great use in quinsies. As this fruit has a strong disagreeable flavour, it is rarely admitted to the table.

The fourth sort grows naturally in *Pennsylvania*, from whence the plants were sent to Mr. *Peter Collinson* several years past, and has been dispersed to most parts of *England*. This has been by some thought to be the same with the common black Currant, but those who have long cultivated it, know it is very different. The shoots of this being much smaller and more compact, the bark is of a darker colour; the leaves are smaller, thinner, smoother, and have not a rank smell like those of the common sort. The flowers are smaller, bell-shaped, and grow in thinner bunches; the fruit is smaller, and not so round; the plants of this do not produce much fruit, nor is it so good as to merit cultivation, so the plant is only kept by way of curiosity. The fruit of the red and white Currants are greatly esteemed for the table, and are also very good in fevers; they are cooling and grateful to the stomach, quench thirst, and are somewhat restringent. The jelly made with the juice of this fruit and sugar is very grateful in fevers, and is used as sauce to the table. This fruit may be procured good much longer than most others upon the plants by planting them in different situations, for if they are planted against pales or walls exposed to the south, the fruit will ripen in *June*, and by planting some against north walls, if they are screened from birds, and covered in autumn from frost, they may be kept till *November*, and, as the fruit is greatly used for tarts, it is very convenient to have a succession of it for so long a time.

The *Champaign* Currant differs from the other only in the colour of the fruit, which is of a pale red or flesh colour. The taste is so near to the other, as not to be distinguished, but, this being of a different colour, makes a variety on the table.

There are plants of all these sorts with variegated leaves, which are kept in some gardens for the sake of variety, but, as these variegations go off when the plants are vigorous, they scarce deserve notice.

These sorts may be easily propagated by planting their cuttings any time from the middle of *September* to the end of *October*, upon a spot of fresh earth, either in rows at one foot asunder, or in beds, which in the spring must be kept very clear from weeds. These may remain one or two years in the nursery, during which time they must be pruned up for the purposes designed, *i. e.* either to clear stems about one foot high, if for standards, or, if for walls, pales, or espaliers, they may be trained up flat: then they should be planted out where they are to remain, for the younger they are planted the better they will succeed; the best season for which is soon after the leaves begin to decay, that they may take root before winter, so that they may be in no danger of suffering from drought in the spring.

These plants are generally planted in rows at about ten feet asunder, and four distance in the rows in those gardens, where the fruit is cultivated for sale; but the best method is to train them against low espaliers, in which manner they will take up much less room in a garden, and their fruit will be much fairer.

The distance they should be placed for an espalier, ought not to be less than ten or twelve feet, that their branches may be trained horizontally, which is of great importance to their bearing.

Those that are planted against pales or walls, should also be allowed the same distance. If they are planted against a south-east wall or pale, it will cause their fruit to ripen at least a fortnight or three weeks sooner than those in the open air, and those which are planted against a north wall or pale, will be proportionably later, so that by this method the fruit may be continued a long time in perfection, especially if those against the north pales are matted in the heat of the day.

These plants produce their fruit upon the former year's wood, and also upon small snags which come out of the old wood; so that in pruning them, these snags should be preserved, and the young shoots shortened in proportion to their strength. The only method, very necessary to be observed in pruning of them, is, not to lay their shoots too close, and never to prune their snags to make them smooth. This, with a small care in observing the manner of their growth, will be sufficient to instruct any person how to manage this plant, so as to produce great quantities of fruit.

These plants will thrive and produce fruit in almost any soil or situation, and are often planted under the shade of trees; but the fruit is always best when they are planted in the open air, and upon a light loamy soil.

RICINOIDES. See *Iatropha*.

RICINUS. *Tourn. Inst. R. H.* 532. tab. 307. *Palma Christi*, vulgò.

The Characters are,

It hath male and female flowers disposed in the same spike. The male flowers, which are situated on the lower part of the spike, have swelling empalements cut into three parts. The flowers have no petals, but have a great number of slender stamina, which are connected in several bodies, and are terminated by roundish twin summits. The female flowers, which are situated on the upper part of the spike, have empalements cut into five segments, and are armed with prickles; they have no petals, but

in the center is situated an oval germen, which is closely shut up in the empalement, supporting three short styles, which are bifid, crowned by single stigmas. The germen afterward turns to a roundish fruit, having three furrows, divided into three cells, opening with three valves, each cell containing one almost oval seed.

The Species are,

1. *RICINUS foliis peltatis serratis, subtus glaucis, petiolis glanduliferis.* Ricinus with target-shaped sawed leaves, which are gray on their under side, and foot-stalks bearing glands.

2. *RICINUS foliis peltatis subserratis, lobis amplioribus utrinque virentibus.* Ricinus with target-shaped leaves, which are somewhat sawed, whose lobes are large, and green on both sides.

3. *RICINUS foliis peltatis inaequaliter serratis, capsulis bifidis.* Tab. 219. Ricinus with target-shaped leaves, which are unequally sawed, and prickly capsules to the fruit.

4. *RICINUS foliis peltatis serratis, capsulis rugosis non echinatis.* Tab. 220. *Palma Christi* with target-shaped sawed leaves, and rough capsules to the fruit, which are not prickly.

5. *RICINUS foliis peltatis serratis, lobis maximis, caule geniculato, capsulis echinatis.* Ricinus with target-shaped sawed leaves, having the largest lobes, a jointed stalk, and prickly covers to the seeds.

6. *RICINUS foliis peltatis serratis, lobis maximis, caule geniculato, capsulis inermis.* *Palma Christi* with sawed target-shaped seeds, having very large lobes, a jointed stalk, and smooth covers to the seeds.

7. *RICINUS foliis palmatis serratis, profundius divisis, capsulis echinatis.* Ricinus with hand-shaped sawed leaves, which are deeply divided, and prickly covers to the seeds.

8. *RICINUS foliis palmatis serratis, profundius divisis, capsulis inermis.* *Palma Christi* with hand-shaped sawed leaves, which are deeply divided, and smooth covers to the seeds.

The first sort grows naturally in *Sicily*, and other warm parts of *Europe*. This rises with a strong herbaceous stalk to the height of ten or twelve feet; the joints are at a great distance from each other; the stalk and branches are of a gray colour; the leaves are large, and have long foot-stalks; they are deeply divided into seven lobes, which are sawed on their edges, and are gray on their under side; at the division of the lobes is a sort of navel, where the foot-stalk joins the leaves. The flowers are disposed in long spikes, which arise at the division of the branches; the lower part of the spikes are garnished with male flowers, which have swollen empalements, divided into three parts, which open, and shew a great number of slender stamina, terminated by whitish summits, connected at their base into several small bunches. The female flowers, which occupy the upper part of the spike, have prickly empalements, which inclose the roundish germen, upon which sit three short styles, crowned by oblong stigmas. The germen afterward becomes an oval capsule with three deep channels, closely armed with soft spines, and divided into three cells, each containing one oblong striped seed.

The second sort grows naturally in the islands of the *West-Indies*, where it is called *Agnus Castus*, or *Oil-tree*. This is often confounded with the former; most of the botanists suppose they are the same plant; but as I have cultivated both more than forty years, in which time I have never observed either of them vary, so I think there can be no doubt of their being different plants. This hath brown stalks, which rise six or seven feet high; the leaves are broader, and not so deeply divided as those of the former; they are of a deep green on both sides, and are unequally sawed. The spikes of flowers are shorter, the seed-vessels rounder, and of a brownish colour; and the seeds are much less, and of a reddish brown colour.

The third sort grows naturally in the *West-Indies*, and is often confounded with the former, but is very different. The stalk of this sort is thick, herbaceous, and of a grayish green; the joints are closer than those of the former sorts; it rises about four feet high; the leaves are large, of a deep green on their upper side, but grayish on their under; they are deeply cut into six or seven lobes or segments, which are unequally sawed on their edges. The spikes of flowers are loose, the covers of the capsules are green, and closely armed with soft spines; the seeds are smaller and lighter coloured than those of the second sort.

The fourth sort grows naturally in both *Indies*. This rises with an herbaceous stalk about four feet high; the lower part is purplish, the upper of a deep green; the joints of this are pretty far asunder; the leaves are of a deep green on their upper side, but are paler on their under; they are not so deeply divided as some of the other sorts, and are more regularly sawed; the spikes of flowers are large. The male flowers have more stamina, and their summits are yellow; the capsules are oval and rough, but have no spines; the seeds are small, and of a brown colour.

The fifth sort grows naturally in *Africa* and both the *Indies*. This rises with a large reddish stalk to the height of ten or twelve feet, with many joints; the leaves are the largest of any species yet known; I have measured some of them which were more than two feet and a half diameter; they are of a dark green, unequally sawed on their edges, and not so deeply cut as those of some other sorts. The spikes of flowers are large; the empalement of the flower is brown; the summits on the stamina of the male flowers are whitish; the capsules are large, oval, and closely armed with soft spines; the seeds are very large, and beautifully striped.

The sixth sort grows naturally in the *Spanish West-Indies*, from whence the late Mr. *Robert Millar* sent me the seeds. The plants of this sort are in every respect like those of the fifth, but the capsules which inclose the seeds are smooth; and this difference is permanent, therefore may be put down as a distinct species.

The seventh sort grows naturally in *Carolina*, and several other parts of *America*. Of this there are two varieties, if not distinct species; one of them has a red stalk, and the other a pale green; they are distinguished by the inhabitants of *America*, by the title of red and white Oil seed. The stalks of these seldom rise more than three feet high, divided at the top into two or three branches; the leaves are much less than those of the other sorts, and deeper divided; their borders are unequally sawed; the segments of the leaves are frequently cut on their sides. The spikes of flowers are smaller and more compact than those of the former sorts; the capsules are smaller, rounder, and of a light green, and are closely armed with soft spines; the seeds are small, and are finely striped.

The eighth sort grows naturally in the *Spanish West-Indies*, and also at the *Cape of Good Hope*. This is a lower plant than the seventh sort; the stalks are of a brownish colour; the leaves are small, deeply cut, and sawed on their edges; the spikes of flowers are short, the capsules are smooth, and the seeds are small and finely striped.

There are several other species which grow naturally in both *Indies*, which have not been examined by any curious botanist; for I have received seeds of three or four sorts, which appeared to be very different from any of the known sorts, but the seeds were too old to grow.

The sorts here enumerated, I have cultivated several years, and have always found they have kept their difference, so that I have no doubt of their being distinct species; and unless they are thus tried, there is no possibility of determining their specific difference; for when plants are

found growing in different soils and situations, they have such different appearances, as may deceive the most skilful botanist.

The plants are generally annual in these countries, though in their native places of growth they continue longer; in *England* the plants are often preserved through the winter (especially the first sort) but young plants are much preferable to those which are thus preserved; therefore few persons are at the trouble to keep them, unless when the seasons prove so bad as that their seeds do not ripen, whereby the species might be lost, if the plants are not preserved through the winter.

These plants are propagated by seeds, which must be sown upon a hot-bed in the spring, and when the plants are come up, they should be each planted into a separate pot, and plunged into a fresh hot-bed. As these plants grow very fast, their roots will in a short time fill the pots; therefore they should be shifted into larger, toward the latter end of *May*; when the season is warm, they may be hardened to the open air by degrees; and then if some of the plants are shaken out of the pots, and planted out into a very rich border, and in dry weather duly watered, they will grow to a very large size, particularly the first and fifth sorts, which I have seen upward of ten feet high in one season, and these plants have produced a great quantity of flowers and seeds; but if you intend to preserve any of the plants through the winter, they must be shifted into larger pots from time to time, as their roots shall require, placing them in the open air during the summer season in some warm situation, where they may remain until the middle or end of *October*, when they must be removed into the house with other exotick plants, observing to water them sparingly in winter, and also to admit the free air in mild weather; for they only require to be protected from frost and cold winds, so that they will endure the winter in a warm green-house, without any addition of artificial warmth.

These plants deserve a place in every curious garden for the singular beauty of their leaves (notwithstanding their flowers make no great appearance), especially those sorts which may be propagated every year from seeds, because those persons who have no green-house to place them into in winter, may cultivate them as other annual plants; amongst which these, being placed either in pots or borders, afford an agreeable variety; but it must be observed, as these are large growing plants, never to place them too near other plants of less growth, because these will overbear and destroy them; and those which are planted in pots, should be allowed room for their roots to expand, and must be frequently watered, otherwise they will not grow very large.

The inhabitants of the *West-Indies* draw an oil from the seeds of these plants, which serves for the use of their lamps; and as the plants come up as weeds in those warm countries, so they are at no trouble to cultivate the plants, but employ their negroes to collect the seeds from the plants which grow naturally, whereby they are furnished with the oil at a small expence. This oil is good to kill lice in childrens heads.

The seeds of the first sort is the *Cataputia major* of the shops; these have been formerly given by some persons to purge watery humours, which they do both upward and downward with great violence, so that at present these seeds are rarely used.

RIPENING of FRUIT early.

In order to have early fruit, a wall should be erected ten feet high, in length according to the numbers of trees intended for three years forcing; the method of constructing these walls, is fully explained under the article WALL.

This being done, a border may be marked out about four feet wide on the south-side of it, and some scantlings of wood, about four inches thick, must be fastened on a low wall, built to prevent the earth of the border from falling into the walk, and also to secure the timber from rotting, to rest the glass-lights upon; which lights are to slope backward to the wall, to shelter the fruit as there shall be occasion.

Bars about four inches wide, cut out of whole deal, must be placed between these glasses, so that the lights may rest on them. There must also be a door shaped to the profile of the frame at each end, that it may be opened at either of the ends, according as the wind blows.

The frame before-mentioned should be made so, that when the first part has been forced, the frame may be moved the next year forward, and the succeeding year forward again, so that the trees will be forced every third year; and having two years to recover themselves, will continue strong for many years.

These trees should be well grown before they are forced, otherwise they will soon be destroyed; and the fruit produced on grown trees, will be much fairer and better tasted, than on fresh planted trees.

The fruit which may be planted in these frames are,

The Avant, the *Albemarle*, the Early *Newington*, and Brown Nutmeg Peaches.

Mr. *Fairchild's* Early, the *Elruge* and *Newington* Nectarines; the Masculine Apricot; the *May Duke* and *May Cherry*.

As for Grapes, the White Chasselas and Black Sweet-water.

It has been found by experience, that the trees will be injured if the heat be applied before *January*; and that the time for applying the heat for bringing either Duke or *May* Cherries, is about the beginning of that month, and applying heat at the same time would do for Apricots; so that the Masculine Apricot will, by the beginning of *March*, be as large as Duke Cherries, and will be ripe by the beginning of *May*.

Cherries thus forced, will not hold so well as Apricots, though the former will last, perhaps, for seven years in good plight, but Apricots will thrive and prosper thus many years.

Fairchild's Early Nectarine commonly ripens about the end of *May*, if they are forced at the same time, and the *Brugnon* Nectarine will follow that.

As for the distance of these trees one from another, it need not be so great as is directed for those planted in the open air, because they will never shoot so vigorously nor last so long, therefore eight or nine feet will be sufficient.

The trees against that part of the wall, which is designed for forcing, should be pruned as soon as their leaves begin to decay, that the buds on the branches, which are left, may be benefited, by receiving all the nourishment of the branches, whereby they will become turgid and strong, by the time the walls are heated.

Apricots, Grapes, Nectarines, Peaches, and Plums, if *April* proves cold, the forcing heat must be continued till *May* is settled, to keep the fruit growing; but some of the glasses should be opened in the morning in *March* and *April*, when the wind is still and the sun warm; and they should be permitted to receive the showers that fall, while the fruit is growing; but while they are in blossom, no rain should come near them, because, if there should be any moisture lodged in the bosom of the flowers, and the sun should shine hot through the glasses, it would be apt to destroy them.

Another thing which ought to be observed in planting fruit in these frames is, to plant those fruits which come forward together, and those which come late by themselves, because

because it will be prejudicial to the forward fruit, to give them any more heat when they have done bearing, when at the same time the latter fruits set amongst them may require more heat, and to be continued longer, some of them, perhaps, requiring an artificial heat till *May*.

There may also a row or two of scarlet Strawberries be planted near to the back of this frame, and these you may expect will be ripe by the end of *March*, or beginning of *April*.

As for the Vines, they may probably be brought to blossom in *April*, and have ripe Grapes in *June*.

RIVINIA. *Plum. Nov. Gen.* 48. *tab.* 39.

The Characters are,

The empalement of the flower is permanent, composed of four oval, concave, coloured leaves. The flower has no petals; it has eight stamina, which are longer than the empalement, terminated by small oval summits, and a large roundish germen, supporting a short style, crowned by an obtuse stigma. The germen afterward turns to a roundish berry sitting in the empalement, including one hard seed.

The Species are,

1. RIVINIA *foliis lanceolatis petiolatis integerrimis, caule fruticoso ramoso*. Rivinia with spear-shaped entire leaves, having foot-stalks, and a shrubby branching stalk.

2. RIVINIA *scandens racemosa, amplis solani foliis, baccis violaceis*. *Plum. Nov. Gen.* 48. Climbing branching Rivinia, with Nightshade leaves, and Violet-coloured berries.

The first sort rises with shrubby stalks about four feet high, dividing into several spreading branches, covered with a gray spotted bark, garnished with spear-shaped entire leaves, standing upon long slender foot-stalks; they are smooth, of a lucid green, and pretty thick consistence, standing alternate, at pretty great distances on the branches. The flowers are produced in long bunches from the side and at the end of the branches, each standing upon a slender foot-stalk near half an inch long; these have no petals, but their empalements are of a scarlet colour; within these are situated eight stamina, which are longer than the empalement, terminated by small oval summits; in the center is situated a roundish germen, terminating in a point, supporting a short style. The germen turns to a roundish berry with a thin pulp, surrounding one roundish hard seed; these berries are of a scarlet colour when ripe, and afterward change to a purple; they are by the inhabitants called Currants, but are generally esteemed poisonous.

The second sort rises with a climbing woody stalk to the height of twenty feet, covered with a dark gray bark, garnished with oval spear-shaped leaves; they are smooth and entire. The flowers come out in long bunches from the side of the branches, shaped like those of the other, and are succeeded by blue berries about the same size as those of the former. This sort grows naturally in *Antigua*, from whence I have received the seeds; it was also found growing at the *Havannah*, by the late *Dr. Houstoun*, who found the first growing in *Jamaica*.

They are both propagated by seeds, which remain long in the ground before they vegetate; I have had them lie two years before the plants have appeared, but they never rise the same year the seeds are sown.

These berries should be sown in pots, and plunged into a moderate hot-bed. As the plants will not come up the same year, so the pots should be removed into the stove before winter, and plunged into the tan-bed; during the winter season, the earth must be sometimes refreshed, but must not be too moist. In the spring the pots may be taken out of the stove, and plunged into a fresh hot-bed to bring up the plants; but if they should not then rise, the earth must not be disturbed, because the plants may come up the following season.

When the plants come up and are fit to remove, they

should be each transplanted into a separate small pot, and plunged into a hot-bed, and must be treated in the same way as other plants from the same countries.

They retain their leaves all the year, so make a variety in the stove in winter, and when they flower, make a fine appearance, though their flowers are but small; for as they are produced in long bunches, from almost every joint toward the end of the branches, so the whole plant is well adorned during their continuance.

ROBINIA. *Lin. Gen. Plant.* 775. False Acacia.

The Characters are,

The empalement of the flower is small, and divided into four parts, the three under segments being narrow, but the upper one is broad. The flower is of the Pea-bloom kind; the standard is large, roundish, obtuse, and spreads open. The two wings are oval, and have short appendixes, which are obtuse. The keel is roundish, compressed, obtuse, and is extended the length of the wings. In the center is situated ten stamina, nine joined together, and the other standing single, terminated by roundish summits. It hath an oblong cylindrical germen, supporting a slender style, crowned by a hairy stigma. The germen afterward becomes an oblong compressed pod, inclosing kidney-shaped seeds.

The Species are,

1. ROBINIA *pedunculis racemosis, foliis impari-pinnatis*. *Hort. Upsal.* 212. Robinia with foot-stalks supporting long bunches of flowers, and unequal winged leaves; common Bastard Acacia, called in *America* Locust-tree.

2. ROBINIA *pedunculis racemosis, foliis impari pinnatis, leguminibus echinatis*. Robinia with foot-stalks supporting long bunches of flowers, unequal winged leaves, and prickly pods.

3. ROBINIA *foliis impari-pinnatis, foliolis ovatis, racemis pedunculisque hispida*. Robinia with unequal winged leaves, having oval lobes, whose branches and foot-stalks of the flowers are armed with stinging spines; false Acacia, with a Rose-coloured flower.

4. ROBINIA *foliis impari-pinnatis, foliolis ovatis acuminatis, ramis nodosis glabris, pedunculis racemosis*. Robinia with unequal winged leaves, whose lobes are oval and acute-pointed, knobbed smooth branches, and flowers growing in long bunches.

5. ROBINIA *foliis impari-pinnatis, foliolis oblongo-ovatis, pedunculis racemosis confertis*. Robinia with unequal winged leaves, having oblong oval lobes, and foot-stalks with long bunches of flowers growing in clusters.

6. ROBINIA *foliis impari-pinnatis, foliolis obversè-ovatis, racemis aggregatis axillaribus, leguminibus membranaceo-tetragonis*. Robinia with unequal winged leaves, whose lobes are obversely oval, long bunches of flowers growing in clusters from the sides of the branches, and pods having four-winged membranes.

7. ROBINIA *foliis duplicato-pinnatis, foliolis ovatis sessilibus, floribus spicatis terminalibus*. Robinia with doubly-winged leaves, whose lobes are oval, sit close to the midrib, and spikes of flowers terminating the branches.

8. ROBINIA *foliis pinnatis, foliolis lanceolatis oppositis, racemis axillaribus pedunculis longioribus*. Robinia with winged leaves, having spear-shaped lobes, placed opposite, and long bunches of flowers on the sides of the branches, upon longer foot-stalks.

9. ROBINIA *foliis impari-pinnatis, foliolis oblongis acuminatis, racemis axillaribus, leguminibus oblongo-ovatis*. Robinia with unequal winged leaves, having oblong acute-pointed lobes, and bunches of flowers proceeding from the sides of the branches.

10. ROBINIA *pedunculis simplicibus, foliis quaternatis petiolatis*. *Hort. Upsal.* 212. Robinia with single foot-stalks, and leaves growing by fours upon foot-stalks.

The first sort is the common false Acacia, which is a native of *North America*. The seeds of this were first brought to *Paris* from *Canada* by *Mons. Robine*, and soon after the seeds were brought from *Virginia* to *England*, where the trees were raised in several gardens, which for some years, while young, were in great esteem; but as they grew larger, their branches were frequently broken by strong winds in the summer, which rendered them unightly, so that for several years they were seldom planted in gardens; but of late years it is become fashionable again, and great numbers of the trees have been raised, so at present there are few gardens in which there are not some of these trees planted.

This sort grows to a very large size in *America*, where the wood is much valued for its duration; most of the houses which were built at *Boston* in *New England*, upon the first settling of the *English*, was with this timber, which continues very sound at this time.

It grows very fast while young, so that in two or three years from seed, the plants will be eight or ten feet high; and it is not uncommon to see shoots of this tree six or eight feet long in one summer. The branches are armed with strong crooked thorns, garnished with winged leaves, composed of eight or ten pair of oval lobes, terminated by an odd one; they are of a bright green, entire, and sit close to the midrib. The flowers come out from the side of the branches in pretty long bunches, hanging downward like those of *Laburnum*, each flower standing on a slender foot-stalk. They are of the butterfly or *Pea-blossom* kind, white, and smell very sweet. They appear in *June*, and when the trees are well charged with flowers, they make a fine appearance, and their odour perfumes the circumambient air; but they are of short duration, seldom continuing more than one week in beauty; after the flowers fade, the green becomes oblong compressed pods, which in warm seasons come to perfection in *England*, but ripen pretty late in the autumn.

The leaves of this tree do not come out till late in the spring, and they fall off pretty early in the autumn, which renders it less valuable than it would otherwise be, were their leaves of longer duration.

The second sort is less common than the first. There was a large tree of this kind some years growing in the garden of the bishop of *London* at *Fulham*, which produced plenty of seeds. The pods of this sort are much shorter, and closely beset with short prickles, but in other respects agrees with the first sort.

The third sort grows naturally in *Carolina*, where it sometimes rises to the height of twenty feet, but in *England* at present, it seems to be of low growth; the branches spread out near the ground, and produce their flowers very young, which is a sure sign of its not growing tall here. The branches of this tree, and also the foot-stalks of the flowers, are closely armed with small brown spines, like some sorts of *Roses*; the leaves are like those of the first sort, but their lobes are larger and rounder. The flowers come out in bunches like those of the former, but are larger and of a deep *Rose* colour.

The fourth sort grows naturally at *Campeachy*, from whence the late *Dr. Housoun* sent the seeds. This rises with a strong woody stem to the height of thirty or forty feet, sending out many strong branches on every side, which have large swelling knots, and are closely garnished with single winged leaves, composed of eight or nine pair of oval lobes, ending in points, terminated by an odd one; these are curiously marked with purple spots on their under side, which appear faintly on their upper. The flowers are produced in long close spikes, standing almost erect; they are about half the size of the flowers of the last sort, and are of a fine *Rose* colour.

The fifth sort was found growing naturally at *Campeachy* by the late *Dr. Housoun*. This rises with a woody branching stalk twelve or fourteen feet high; the old branches are covered with a dark brown bark, but the young shoots and the foot-stalks of the flowers are covered with an iron-coloured down; the leaves are unequally winged; the lobes are oblong, obtuse, and of a pretty thick consistence; they are smooth on their upper side, but have several transverse veins on their under. The flowers are produced at the end of the branches in long close bunches; there are six or seven of them gathered together in clusters. The flowers are but small, and are of a yellowish red colour; the pods of this are like those of the first sort.

The sixth sort grows naturally in *Jamaica*, where the inhabitants give it the appellation of *Dogwood*. This hath a strong woody stem, which rises forty feet high, and divides into many branches, covered with a dark brown spotted bark, garnished with unequal winged leaves, composed of three or four pair of obverse oval lobes, terminated by an odd one. The flowers come out in branching bunches from the side of the branches; these generally appear at a time when the trees are destitute of leaves, and as they have large clusters of flowers at every joint, so the trees seem covered with them. The bunches at the extremity of the branches are the largest, and are formed pyramidally. The flowers are but small, and do not open so fully as those of the first sort, but are of a pale *Rose* colour, so make a fine appearance; these are succeeded by pods, having four broad membranaceous wings running longitudinally at their four corners, and join at their base, covering the pods entirely; each of the pods contain four or five oblong kidney-shaped seeds.

The seventh sort was discovered by *Plumier*, in some of the *French* settlements of the *West-Indies*, and was found by the late *Dr. Housoun* growing naturally at *Campeachy*. This rises with a strong woody stem near thirty feet high, sending out many spreading branches, covered with a light gray bark, spotted with white, garnished with double winged leaves, whose lobes are oval, and sit close to the midrib; they are of a lucid green on their upper side, but of a pale green on their under. The flowers are produced in long loose pyramidal bunches toward the end of the branches, those on the lower part of the bunch having long foot-stalks, which diminish gradually to the top, so as to form a pyramid; these bunches are almost erect. The flowers are of a scarlet colour, so make a fine appearance.

The eighth sort was found growing naturally at *Campeachy* by the late *Dr. Housoun*. This rises with a woody stem to the height of twenty feet, covered with a very light gray bark, garnished with equal winged leaves, composed of ten or eleven pair of oval lobes, placed opposite, of a lucid green on the lower part of the branches, but those toward the end are covered with a soft iron-coloured down. The flowers come out in long bunches from the side of the branches; they are blue, and stand upon long foot-stalks; these are succeeded by pods, shaped like those of the first sort, but are downy.

The ninth sort was discovered by the late *Dr. Housoun* growing naturally at *Campeachy*. This rises with a strong woody stem upward of thirty feet high, dividing at the top into many strong branches, covered with a dark grayish bark, spotted with white, garnished with winged leaves, composed of six or seven pair of lobes, terminated by an odd one, of a lucid green on their upper side, but pale on their under. The flowers are produced in long loose bunches from the side of the branches; they are of a pale *Rose* colour, and have very long foot-stalks; these are succeeded by oval pods swelling in the middle, where is lodged one or two kidney-shaped seeds.

The tenth sort grows naturally in *Siberia* and *Tartary*. This hath a shrubby stalk eight or ten feet high, sending out several branches, which grow erect, covered with a smooth yellowish bark; the leaves have each two pair of oval pointed lobes, which stand upon short foot-stalks. The flowers are produced upon single foot-stalks, which come out at the joints of the branches; they are yellow, and shaped like those of the *Laburnum*, but are smaller.

The first sort is generally propagated in the *English* nurseries, by suckers taken from the roots of the old trees, or by cutting off some of the roots, and planting them upon a gentle hot-bed; these will put out shoots, and become plants; but these are not so valuable as those which are raised from seeds, because they do not make near so great progress in their growth, and are very subject to send forth many suckers from their roots, whereby the ground will be filled with them to a great distance.

If this is propagated by seeds, they should be sown on a bed of light earth, about the latter end of *March*, or the beginning of *April*; and if the bed is well exposed to the sun, the plants will appear in about five or six weeks, and will require no farther care but to keep them clear from weeds. In this bed the plants may remain till the following spring, when they should be transplanted into a nursery about the latter end of *March*, placing them in rows at three feet distance row from row, and a foot and a half asunder in the rows. In this nursery they may remain two years, by which time they will be fit to transplant where they are designed to grow; for as these trees send forth long tough roots, so if they stand long unremoved, the roots will extend themselves to a great distance; therefore they must be cut off when the plants are transplanted, which sometimes occasions their miscarrying.

These trees will grow well upon almost every soil, but best in a light sandy ground, in which they will shoot six or eight feet in one year; and while the trees are young, they make an agreeable appearance, being well furnished with leaves, but when they are old, the branches being frequently broken by winds, render them unsightly, especially if they stand in an exposed place: also when the trees grow old, their branches decay and make a bad appearance, which occasioned their being rooted out of several gardens some years past. This is commonly known by the title of *Locust* tree in *America*; there are quantities of the seeds annually sent to *England* with that title.

The second sort is propagated in the same manner as the first, and the trees grow to the same size.

The third sort is at present scarce in the gardens about *London*, but in *Devonshire* it is in greater plenty, where the inhabitants give it the title of *Raspberry* plant, from the young shoots being covered with bristly hairs like the *Raspberry* plants; this does not produce seeds in *England*, so it is propagated by layers, and also cutting off part of the roots, and planting them upon a gentle hot-bed, where they will put out fibres, shoots, and become new plants. This sort should have a warmer situation than the two former, though the ordinary winters in this country never injure it, but in very severe winters the young shoots are sometimes killed in exposed places. It loves a light moist soil.

The fourth, fifth, sixth, seventh, eighth, and ninth sorts, are tender, so cannot be maintained in *England*, unless they are placed in a stove in winter. These are propagated by seeds, which should be sown in small pots, and plunged into a hot-bed of tanners bark; if the seeds are good, the plants will appear in six weeks or two months; when these are fit to transplant, they should be carefully shaken out of the pots, and their roots separated, putting each plant into a small pot, then plunged into a hot-bed of tanners

bark, and must have the same treatment as other tender plants from the same countries.

The tenth sort is propagated by seeds, which should be sown in a shady situation in autumn, then the plants will come up the following spring; but if the seeds are sown in the spring, the plants seldom rise the same season. When the plants come up, they will require no other care, but to keep them clean from weeds till autumn, when, if the plants have made any progress, they should be transplanted on a north border, at about six inches distance, where they may grow two years, and then should be planted where they are to remain, which should be in a cool moist soil.

RONDELETIA. *Plum. Nov. Gen.* 15. tab. 12.

The Characters are,

The flower has a permanent empalement sitting upon the germen, cut into five acute points. It has one funnel-shaped petal, with a cylindrical tube longer than the empalement, cut into five roundish segments at the brim, which are reflexed. It has five awl-shaped stamina, terminated by single summits; the roundish germen is situated under the flower, supporting a slender style the length of the tube, crowned by an obtuse stigma. The germen afterward becomes a roundish crowned capsule with two cells, inclosing two or three angular seeds in each.

The Species are,

1. RONDELETIA foliis sessilibus. *Lin. Sp. Plant.* 172. Rondeletia with leaves sitting close to the branches.
2. RONDELETIA foliis petiolatis. *Flor. Zeyl.* 80. Rondeletia with leaves growing upon foot-stalks.

The seeds of this plant were first sent me by Mr. *Robert Millar*, who collected them on the north side of the island of *Jamaica*; he also observed the trees growing plentifully in the *Spanish West-Indies*; I have also since received the seeds from *Barbadoes*, which have succeeded at *Chelsea*. This rises with a woody stalk eight or ten feet high, branching out on every side, covered with a smooth greenish bark, garnished with oblong leaves, ending in acute points; they are entire, and sit very close to the branches; their upper surface is of a lucid green, the under is paler; they are a little crumpled on their surface, and stand alternate. The flowers come out in bunches at the end of the branches; they are white, and have little scent.

The second sort grows naturally in *Malabar*. This rises with a woody stalk six or seven feet high, dividing into several branches, covered with a smooth bark, garnished with stiff, oblong, oval leaves, of a lucid green, standing alternate on the lower part of the branches, but by pairs toward the extremity; they have short foot-stalks, and are entire. The flowers are produced in large bunches at the end of the branches; they are of a yellowish white colour, and have a fragrant odour: these are succeeded by roundish capsules, having two cells, each containing three or four angular seeds.

These plants being very tender, cannot be preserved in *England*, unless they are kept in a warm stove. They are propagated by seeds, which should be sown on a hot-bed early in the spring; when the plants are come up and fit to remove, they must be transplanted into separate small pots, and plunged into a moderate hot-bed of tanners bark, where they must be treated in the same manner as hath been directed for other tender plants from the same country.

ROSA. *Tourn. Inst. R. H.* 636. tab. 408. The Rose-tree.

The Characters are,

The empalement of the flower is divided into five parts at the top, but the base is globular and bell-shaped. The flower hath five oval heart-shaped petals inserted in the empalement, and a great number of short hair-like stamina, inserted in the neck of the empalement, terminated by three-cornered summits. It hath many germen situated in the bottom of the empalement, each hav-

ing a short hairy style, inserted to the side of the germen, crowned by obtuse stigmas. The fleshy base of the empalement afterward becomes a top-shaped coloured fruit with one cell, including many hairy oblong seeds, fastened on each side to the empalement.

The Species are,

1. ROSA caule aculeato, petiolis inermibus, calycibus semipinnatis. Flor. Suec. 406. Rose with a prickly stalk, unarmed foot-stalks, and empalements which are half-winged; commonly called Wild Briar, Dog Rose, or Hep-tree.
2. ROSA caule petiolisque aculeatis, calycis foliolis indivisis. Flor. Suec. 407. Rose with stalks and foot-stalks armed with spines, and the small leaves of the empalement undivided; commonly called the Burnet-leaved Rose.
3. ROSA foliis utrinque villosis, fructu spinoso. Haller. Helv. 350. Rose whose leaves are hairy on both sides, and the fruit prickly; Apple-bearing Rose.
4. ROSA aculeata, foliis odoratis, subtus rubiginosis. Haller. Helvet. 350. Rose with spines and sweet-scented leaves, which are rusty on their under side; commonly called Sweet Briar.
5. ROSA caule petiolisque aculeatis, foliis pinnatis, foliolis apice incis, fructu globoso. Rose with the stalk and foot-stalk armed with spines, winged leaves, whose lobes are cut at their points, and a globular fruit; Scotch Rose.
6. ROSA caule inermi, pedunculis hispida, calycis foliolis indivisis, fructibus oblongis. Rose with a smooth stalk, a prickly foot-stalk to the flower, the small leaves of the empalement undivided, and oblong fruit.
7. ROSA foliis utrinque villosis, calycis foliolis acutè serratis, fructu glabro. Rose with leaves which are hairy on both sides, the small leaves of the empalement sharply sawed, and a smooth fruit.
8. ROSA caule aculeato scandente, foliolis glabris serratis perennantibus. Rose with a prickly climbing stalk, and smooth, sawed, ever-green leaves.
9. ROSA caule aculeato, foliolis quinque glabris perennantibus. Lin. Sp. Plant. 482. Rose with a prickly stalk, and five smooth lobes to the leaves, which are ever-green; ever-green Musk Rose.
10. ROSA inermis, foliis pinnatis serratis utrinque glabris, calycis foliolis indivisis. Rose without thorns, having winged leaves, which are smooth on both sides, and the leaves of the empalement undivided; wild Virginia Rose.
11. ROSA caule aculeato, foliis pinnatis, foliolis ovatis serratis utrinque glabris, pedunculis brevissimis. Rose with a prickly stalk, winged leaves, having oval sawed lobes, which are smooth on both sides, and short foot-stalks to the flower; the single yellow Rose.
12. ROSA caule aculeato, foliis pinnatis, foliolis rotundioribus serratis, petalis emarginatis bicoloribus. Rose with a prickly stalk, winged leaves having rounder sawed lobes, the petals of the flower indented at the top, and of two colours; the Austrian Rose.
13. ROSA caule aculeato scandente, foliis senis glabris, floribus umbellatis. Rose with a prickly climbing stalk, leaves having seven smooth lobes, and flowers growing in umbels; greater Musk Rose.
14. ROSA caule aculeato, pedunculis hispida calycibus semipinnatis glabris. Lin. Sp. Plant. 491. Rose with a prickly stalk, bristly foot-stalks, and smooth half-winged empalements; the Dutch hundred-leaved Rose.
15. ROSA caule aculeato, pedunculis hispida, calycibus pinnatifidis hirsutis. Rose with a prickly stalk, bristly foot-stalks to the flowers, and wing-pointed hairy empalements; Damask Rose.
16. ROSA caule aculeato, pedunculis lævibus, calycibus semipinnatis glabris. Lin. Sp. Plant. 492. Rose with a prickly stalk, smooth foot-stalks to the flowers, and smooth half-winged empalements; common great white Rose.

17. ROSA caule aculeato, foliis subtus hirsutis, calycibus semipinnatis villosis. Rose, with a prickly stalk, leaves which are hairy on their under side, and half-winged hairy empalements to the flowers; the Blush Belgick Rose.

18. ROSA caule petiolisque aculeatis, foliis subtus villosis, calycibus semipinnatis hispida. Rose with prickly stalks and foot-stalks, leaves hairy on their under side, and bristly half-winged empalements; commonly called Provence Rose.

19. ROSA caule inermi pedunculis aculeatis, calycibus semipinnatis. Rose with an unarmed stalk, prickly foot-stalks, and half-winged empalements to the flowers; the Blush Rose.

20. ROSA caule subinermi, foliis quinque subtus villosis, calycis foliolis indivisis. Rose with a stalk almost unarmed, leaves having five lobes, hairy on their under side, and the leaves of the empalement undivided; the red Rose.

21. ROSA foliis pinnatis serratis subtus villosis, aculeis oppositis, calycis foliolis indivisis. Rose with winged sawed leaves, which are hairy on their under side, spines placed opposite, and the small leaves of the empalement undivided; the Cinnamon Rose.

22. ROSA caule petiolisque aculeatis, pedunculis calycibusque pilosissimis. Rose with armed stalks, the foot-stalks and the empalements of the flower very hairy; commonly called Moss Provence Rose.

There are a great variety of double Roses now cultivated in the English gardens; most of them have been accidentally obtained from seeds, so that they must not be ranged as distinct species, therefore I shall only insert their common names, by which they are known in the gardens, that those, who are inclined to collect all the varieties, may be at no loss for their titles. The sorts before enumerated, I believe, are distinct species, as their specific characters are different, though it is difficult to determine which of them are really so, therefore I do not positively assert they are distinct, though I have great reason to believe they are so.

The varieties of Garden Roses which are not before mentioned:

The monthly Rose,
The striped monthly Rose,
The York and Lancaster Rose,
Mrs. Hart's Rose,

} are all supposed to be varieties of the Damask Rose.

The red Belgick Rose is supposed a variety of the Blush Belgick.

The single Velvet Rose,
The double Velvet Rose,
The Royal Velvet Rose,

} are all varieties; the last I raised from the seeds of the pale Provence Rose.

The childing Rose,
The marbled Rose,
The double Virgin Rose,

} have great affinity with each other.

The Cabbage Provence is only a variety of the common Provence.

The Blush or pale Provence is a variety of the red Provence.

The white monthly,
The white Damask,

} are varieties of the Damask Rose.

The Frankfort Rose may be a distinct species, but is of little value; the flowers rarely open fair, and have no odour.

The double sweet Briar,
The ever-green sweet Briar,
The double Blush sweet Briar,

} are varieties of the common sort.

The Austrian Rose, with red and yellow flowers, is only an accidental variety.

The double yellow Rose, is a variety of the single yellow.

The Rosa Mundi is a variety of the red Rose.

The small, white, and semidouble white, are varieties of the common white.

The first sort is very common in hedges in most parts of *England*, so is not cultivated in gardens. The hedges of this are used in medicine for making a conserve. There are two or three varieties of this Rose commonly met with in hedges, one with a white, another with a red flower, and one with smooth leaves; the two first are evidently varieties, but I doubt if the last is not a distinct species.

The second sort grows naturally in many parts of *England*. This seldom rises above three feet high. The stalks are slender, closely armed with small spines; the leaves are small, and are composed of three pair of roundish lobes, terminated by an odd one; the flowers are white, and have an agreeable musky scent. This propagates fast by its creeping roots.

The third sort grows naturally in the northern counties in *England*; this rises with strong stalks to the height of seven or eight feet. The young branches are covered with a smooth brown bark; the spines are but few, and are very strong; the leaves are large, and hairy on both sides; they are composed of three pair of oblong oval lobes, terminated by an odd one; these are deeply sawed on the edges; the flowers are large, single, and of a red colour, and are succeeded by large roundish hedges or fruit, which are set with soft prickles; these have a pleasant acid pulp surrounding the seeds, therefore are by some persons preserved, and made into a sweetmeat, which is served up in desserts to the table.

The fourth sort is the common Sweet-Briar, which is so well known as to need no description. This is found growing naturally in some parts of *Kent*.

The fifth sort is the Dwarf *Scotch* Rose, of which there are two varieties, one with a variegated flower, and the other of a livid red colour. This sort seldom rises more than a foot high. The stalks are covered with a brown bark, and are closely armed with small spines; the leaves are very small, resembling those of Burnet; the flowers are small, and sit close to the branches; the fruit is round, and of a deep purple colour, inclining to black when ripe.

The sixth sort rises to the height of six or seven feet. The stalks and branches have no spines, but are covered with a smooth reddish bark; the leaves are composed of three pair of thin oval lobes, terminated by an odd one, of a bright green, and very slightly sawed on their edges, standing pretty far asunder upon the midrib; the foot-stalks of the flowers are armed with bristly hairs; the five leaves of the empalement are long, slender in the middle, but terminate in an oval leafy point; the flowers are single, of a bright red colour; these are succeeded by long spear-shaped hedges, which are smooth. The plants produce a second crop of flowers about the end of *August*, but these fall off, and are not succeeded by hedges.

The seeds of the seventh sort were sent me by *Robert More*, Esq; from *Spain*, where he found the plants growing naturally; this rises with strong upright stalks about three feet high, armed with strong thorns. The leaves are hairy on both sides; the lobes are roundish, sawed on their edges; the small leaves of the empalement are acutely sawed; the flowers are single, of a bright red colour; these are followed by large, smooth, roundish hedges, which ripen the end of *August*.

The eighth sort was discovered by Signior *Micheli*, growing naturally in the woods near *Flrence*, who sent it to Dr. *Boerhaave* of *Leyden*, in whose curious gardens I saw it growing in the year 1727. This hath slender stalks, which trail upon the ground, unless they are supported, and, if trained up to a pole or the stem of a tree, will rise twelve or fourteen feet high; they are armed with crooked reddish spines, garnished with small leaves, composed of three pair of oval acute-pointed lobes, terminated by an odd one, of

a lucid green, and are sawed on their edges; they continue green all the year; the flowers are small, single, white, and have a musky odour; these in their natural place of growth continue in succession great part of the year, but their time of flowering in *England* is in *June*.

The ninth sort grows naturally in *Spain*; the seeds of this were sent me by *Robert More*, Esq; who found the plants growing there naturally. This rises with erect stalks five or six feet high, covered with a green bark, and armed with strong, crooked, white spines. The leaves are composed of five oval lobes, ending in acute points; they are smooth, of a lucid green, and are slightly sawed on their edges; these continue all the year, and make a goodly appearance in winter. The flowers grow in large bunches or umbels at the end of the branches; they are single, white, and have a strong musky odour; they appear in *August*, and, if the autumn proves favourable, will continue in succession till *October*.

The tenth sort grows naturally in *Virginia* and other parts of *North America*; this rises with several smooth stalks to the height of five or six feet. The young branches are covered with a smooth purple bark; the leaves are composed of four or five pair of spear-shaped lobes, terminated by an odd one, of a lucid green on their upper side, but pale on their under, and are deeply sawed on their edges; the flowers are single, of a livid red colour; the empalement is divided into five long narrow segments, which are entire. This is kept in gardens for the sake of variety, but the flowers have little scent.

The eleventh sort is the single yellow Rose; this hath weak stalks, which send out many slender branches, closely armed with short, crooked, brown spines. The leaves are composed of two or three pair of oval thin lobes, terminated by an odd one, of a light green, sharply sawed on their edges; the flowers grow upon short foot-stalks; they are single, of a bright yellow colour, but have no scent.

The twelfth sort is commonly called the *Austrian* Rose. The stalks, branches, and leaves, are like those of the last, but the leaves are rounder; the flowers are larger; the petals have deep indentures at their points; they are of a bright yellow within, and of a purplish copper colour on the outside; they are single, have no scent, and soon fall away. There is frequently a variety of this with yellow flowers upon one branch, and copper colour upon another. This sort of Rose loves an open free air and a northern aspect.

The thirteenth sort is the Musk Rose; this rises with weak stalks to the height of ten or twelve feet, covered with a smooth greenish bark, armed with short strong spines. The leaves are smooth, composed of three pair of oval spear-shaped lobes, terminating in points, ending with an odd one; they are of a light green colour, sawed on their edges; the flowers are produced in large bunches in form of umbels at the end of the branches; they are white, and have a fine musky odour. There is one with single, and another with double flowers of this sort. The stalks of these plants are too weak to support themselves, so the plants should be placed where they may have support.

The fourteenth sort is the *Dutch* hundred-leaved Rose; this rises with prickly stalks about three feet high. The leaves have sometimes three, and at others five lobes; the lobes are large, oval, smooth, of a dark green, with purple edges; the foot-stalk of the flower is set with brown bristly hairs; the empalement of the flower is smooth, half-winged; the flowers are very double, and of a deep red colour, but have little scent.

The fifteenth is the *Damask* Rose; this rises with prickly stalks eight or ten feet high, covered with a greenish bark, armed with short spines. The leaves are composed of two pair

pair of oval lobes, terminated by an odd one; they are of a dark green on their upper side, but pale on their under; the borders frequently turn brown, and are slightly sawed; the foot-stalks of the flowers are set with prickly hairs; the empalement of the flower is wing-pointed and hairy; the flowers are of a soft pale red, and not very double, but have an agreeable odour; the hips are long and smooth.

The sixteenth is the common large white Rose, so well known as to need no description. Of this there are two varieties, one with a half double flower, having but two or three rows of petals, and the other has a smaller flower, and the shrub is of lower growth.

The seventeenth sort is called the Blush *Belgick* Rose; this rises about three feet high, with prickly stalks. The leaves are composed either of five or seven lobes, which are oval, hairy on their under side, slightly sawed on their edges; the foot-stalks of the flowers and the empalements are hairy, and without spines; the empalements are large and half-winged; the flowers are very double, of a pale flesh colour, and have but little scent. It generally produces great quantities of flowers. The red *Belgick* Rose differs from this only in the colour of the flower, which is of a deep red.

The eighteenth sort is the common *Provence* Rose, which is well known in the *English* gardens, being cultivated in great plenty in the nurseries, and is one of the most beautiful sorts yet known. The flowers of this sort are sometimes very large, and the petals are closely folded over each other like Cabbages, from whence it is called the Cabbage Rose. The flowers of this sort of Rose have the most fragrant odour of all the sorts, therefore is better worth propagating.

The nineteenth sort is the Blush Rose. The stalks of this rise from three to four feet high; and are not armed with spines; the leaves are hairy on their under side; the foot-stalks of the flowers are armed with some small spines; the empalement of the flower is half-winged; the flowers have five or six rows of petals, which are large, and spread open; they are of a pale blush colour, and have a musky scent.

The twentieth sort is the common red Rose, whose flowers are used in medicine. The stalks of this grow erect, and have scarce any spines; they rise from three to four feet high; the leaves are composed of three or five large oval lobes, which are hairy on their under side; the small leaves of the empalement are undivided; the flowers are large, but not very double, spread open wide, and decay soon; they are of a deep red colour, and have an agreeable scent. The *Rosa Mundi* is a variety of this with striped flowers.

The twenty-first sort is the double Cinnamon Rose; this is one of the smallest flowers, and the earliest of all the kinds. The stalks rise about four feet high, covered with a purplish smooth bark, and have no spines but at the joints immediately under the leaves, where they are placed by pairs; they are short and crooked. The leaves are composed of three pair of oval lobes, terminated by an odd one; they are hairy on their under side, and are sawed on their edges; the leaves of the empalement of the flower are narrow and entire; the flower is small, double, and has a scent like Cinnamon, from whence it has the title of Cinnamon Rose.

The twenty second sort is called the Moss *Provence* Rose, from the resemblance which the flowers of this have to those of the common *Provence* Rose, yet it is undoubtedly a distinct species, for although the stalks and shoots of this are very like those of the common, yet the plants are difficult to propagate, which the common sort is not. This very rarely sends up suckers from the root, and when the branches are laid down, they are long before they put out roots, so that this sort has been frequently propagated

by budding it upon stocks of other sorts of Roses, but the plants so raised are not so durable as those which are propagated by layers.

The stalks and branches of this sort are closely armed with brown spines; the foot-stalks of the flowers and the empalements, are covered with long hair-like moss; the flowers are of an elegant crimson colour, and have a most agreeable odour.

Most of the sorts of Roses are of foreign growth, and have been at various times introduced into the *English* gardens, but they are generally natives of northern countries, or grow upon the cold mountains in the warmer parts of *Europe*, so they are very hardy in respect to cold, but love an open free air, especially the yellow Rose, the *Austrian* Rose, and the monthly Rose. The two former will not flower in a warm soil and situation, nor near the smoke of *London*; and the monthly Rose will not flower much better, unless it is planted in a free open air, for it seldom flowers in the smoke of *London*.

The usual time of these shrubs producing their flowers, is from the middle or latter end of *May* till the middle or end of *July*.

But in order to continue these beauties longer than they are naturally disposed to last, it is proper to plant some of the monthly Roses near a warm wall, which will occasion their budding at least three weeks or a month before those in the open air, and, if you give them the help of a glass before them, it will bring their flowers much forwarder, especially where dung is placed to the backside of the wall (as is practised in raising early fruits); by this method I have seen fair Roses of this kind blown in *February*, and they may be brought much sooner against hot walls, where people are curious this way.

You should also cut off the tops of such shoots which have been produced the same spring, early in *May*, from some of these sorts of Roses which are planted in the open air, and upon a strong soil; this will cause them to make new shoots, which will flower late in autumn, as will also the late removing the plants in spring, provided they do not suffer by drought.

The next sort of Rose which flowers in the open air, is the Cinnamon, which is immediately followed by the *Damask* Rose, then the Blush, *York*, and *Lancaster* come, after which the *Provence*, *Dutch* hundred-leaved, white, and most other sorts of Roses follow, and the latest sorts are the Moss Roses, which, if planted in a shady situation, seldom flower until *September*, and, if the autumn proves mild, will continue often till the middle of *October*.

The plants of these two sorts should be placed against a wall, pale, or other building, that their branches may be supported, otherwise they are so slender and weak, as to trail upon the ground. These plants should not be pruned until spring, because their branches are somewhat tender, so that when they are cut in winter, they often die after the knife; these produce their flowers at the extremity of the same year's shoots in large bunches, so that their branches must not be shortened in the summer, lest thereby the flowers should be cut off. These shrubs will grow to be ten or twelve feet high, and must not be checked in their growth, if you intend they should flower well, so that they should be placed where they may be allowed room.

The lowest shrub of all the sorts here mentioned is the *Scotch* Rose, which rarely grows above one foot high, so that this must be placed among other shrubs of the same growth. The red Rose and the *Rosa Mundi*, commonly grow from three to four feet high, but seldom exceed that, but the *Damask*, *Provence*, and *Frankfort* Roses; grow to the height of seven or eight feet; so that in planting them, great care should be taken to place their several kinds, according

to their various growth, amongst other shrubs, that they may appear beautiful to the eye.

The yellow Rose, as also the *Austrian* Rose, are both natives of *America*. These were originally brought from *Canada* by the *French*; the other varieties, which are now in the gardens, have been accidentally obtained from seeds, and are preserved by budding them on the other sorts. The shrubs of these Roses seldom shoot so strong as most of the other sorts, especially in the light land near *London*, where they rarely produce their flowers. These are esteemed for their colour, being very different from all the other sorts of Roses, but, as their flowers have no scent, and are of short duration, they do not merit the price they are generally sold at.

The *Frankfort* Rose is of little value, except for a stock to bud the more tender sorts of Roses upon, for the flowers seldom open fair, and have no scent; but, it being a vigorous shooter, renders it proper for stocks to bud the yellow and *Austrian* Roses, which will render them stronger than upon their own stocks, but the yellow Roses seldom blow fair within eight or ten miles of *London*, though in the northern parts of *Great-Britain* they flower extremely well. This sort must have a northern exposure, for, if it is planted too warm, it will not flower.

The *Damask* and monthly Rose seldom flower well in small confined gardens, nor in the smoke of *London*, therefore are not proper to plant in such places, though they frequently grow very vigorously there. These always begin to shoot the first of any of the sorts in the spring, therefore frequently suffer from frosts in *April*, which often destroys all their flowers.

All the sorts of Roses may be propagated either from suckers, layers, or by budding them upon stocks of other sorts of Roses, which latter method is only practised for some peculiar sorts, which do not grow very vigorous upon their own stocks, and send forth suckers very sparingly, or where a person is willing to have more sorts than one upon the same plant; but, where this is designed, it must be observed to bud only such sorts upon the same stock as are nearly equal in their manner of growth, for if there be a bud of a vigorous-growing sort, and others of weak growth, budded in the same stock, the strong one will draw all the nourishment from the weaker, and entirely starve them.

If these plants are propagated by suckers, they should be taken off annually in *October*, and transplanted out either into a nursery in rows (as hath been directed for several other sorts of flowering shrubs), or into the places where they are to remain; for if they are permitted to stand upon the roots of the old plants more than one year, they grow woody, and do not form so good roots as if planted out the first year, so there is more danger of their not succeeding.

But the best method to obtain good-rooted plants, is to lay down the young branches in autumn, which will take good root by the autumn following, when they may be taken from the old plants, and transplanted where they are to remain. The plants which are propagated by layers, are not so apt to send out suckers from their roots as those which are from suckers, therefore should be preferred before them, because they may be much easier kept within compass, and these will also flower much stronger. The plants may be transplanted any time from *October* to *April*, but, when they are designed to flower strong the first year after planting, they should be planted early, though, as I said before, if they are planted late in the spring, it will cause them to flower in autumn, provided they do not suffer by drought.

Most of these sorts delight in a rich moist soil and an open situation, in which they will produce a greater quantity of flowers, and those much fairer, than when they are

upon a dry soil, or in a shady situation. The pruning, which they require, is only to cut out their dead wood, and take off all the suckers, which should be done every autumn; and, if there are any very luxuriant branches, which draw the nourishment from the other parts of the plant, they should be taken out, or shortened, to cause them to produce more branches, if there be occasion for them to supply a vacancy; but you must avoid crowding them with branches, which is as injurious to these plants as to fruit-trees, for, if the branches have not equal benefit of the sun and air, they will not produce their flowers so strong, nor in so great plenty, as when they are more open, so that the air may circulate more freely between them.

ROSA SINENSIS. See *Hibiscus*.

ROSA THE GUILDER. See *Opulus*.

ROSMARINUS. *Tourn. Inst. R. H.* 195. tab. 92. *Rosemary*.

The Characters are,

The flower has a tubulous empalement, compressed at the top, the mouth erect, and divided into two lips; the upper lip is entire, and the under bifid. It hath one petal, whose tube is longer than the empalement; the brim is ringent; the upper lip is short, erect, and divided into two parts, whose borders are reflexed; the lower lip is reflexed, and cut into three parts. It hath two awl-shaped stamina, inclining toward the upper lip, terminated by single summits, and a four-pointed germen, with a style the shape, length, and in the same situation with the stamina, crowned by an acute stigma. The germen afterward becomes four oval seeds sitting in the bottom of the empalement.

The Species are,

1. ROSMARINUS foliis linearibus marginibus reflexis, subtus incanis. *Rosemary* with linear leaves, which are reflexed on their edges, and hoary on their under side; *Garden Rosemary* with a narrower leaf.

2. ROSMARINUS foliis linearibus obtusis, utrinque virentibus. *Rosemary* with obtuse linear leaves, which are green on both sides; or broad leaved wild *Rosemary*.

These two sorts have been frequently supposed the same, and their difference accidental, but I have long cultivated both, and have raised them from seeds without finding them vary, so I believe they are distinct species. The leaves of the second sort are broader than those of the first, and their points are obtuse; the flowers are also much larger, and of a deeper colour; the stalks grow larger, and spread out their branches wider; the whole plant has a stronger scent. These differences the gardeners, who cultivate the plants for the market, observe.

There are two other varieties of these plants, one of the first sort with striped leaves, which the gardeners call the *Silver Rosemary*; the other is of the second sort, which is striped with yellow; this the gardeners call the *Gold striped Rosemary*. The plants of this sort are pretty hardy, so will live in the open air through our common winters, if they are upon a dry soil.

These plants grow plentifully in the southern parts of *France*, in *Spain*, and in *Italy*, where, upon dry rocky soils near the sea, they thrive prodigiously, and perfume the air so as to be smelt at a great distance from the land; but, notwithstanding they are produced in warm countries, yet they are hardy enough to bear the cold of our ordinary winters very well in the open air, provided they are planted upon a poor, dry, gravelly soil, on which they will endure the cold much better than upon richer ground, where the plants will grow more vigorously in summer, and so be more subject to injury from frost, nor will they have so strong an aromack scent as those upon a dry barren soil.

Those sorts with striped leaves are somewhat tender, especially that with silver stripes, so should either be planted near a warm wall, or in pots, to be sheltered in winter under a frame, otherwise they will be subject to die in frosty weather.

These

RUBIA foliifera Hort. Cliff. 35.

J. Miller delin. et. sculp.

These sorts may be propagated by planting slips or cuttings in the spring of the year, just before the plants begin to shoot, upon a bed of light fresh earth, and, when they are rooted, they may be transplanted into the places where they are designed to grow; the best time is about the beginning of *September*, that they may take new root before the frosty weather comes on; for, if they are planted too late in autumn, they seldom live through the winter, especially if the weather proves very cold, so that if you do not transplant them early, it will be the better method to let them remain unremoved until *March* following, when the frost is over, observing never to transplant them at a season when the dry east winds blow, but rather defer the doing of it until the season is more favourable; for, if they are planted when there are cold drying winds, their leaves are apt to dry up, which often kills them; but, if there happen to be some warm showers soon after they are removed, it will cause them to take root immediately, so that they will require no farther care, but to keep them clear from weeds.

Although these plants are tender when planted in a garden, yet, when they are by accident rooted in a wall (as I have several times seen them), they will endure the greatest cold of our winters, though exposed much to the cold winds, which is occasioned by the plants being more stunted and strong, and their roots being drier.

The flowers of the narrow-leaved garden sort are used in medicine, as are also the leaves and seeds.

ROYENA: *Lin. Gen. Plant.* 491.

The Characters are,

The flower has a bellied permanent empalement, whose mouth is obtuse and five-pointed. It has one petal, having a tube the length of the empalement, but the brim is divided into five parts, which turn back. It hath ten short stamina growing to the petal, terminated by oblong, erect, twin summits, and an oval hairy germen sitting upon two styles a little longer than the stamina, crowned by single summits. The empalement afterward turns to an oval capsule with four furrows, having one cell with four valves, containing four oblong triangular seeds.

The Species are,

1. ROYENA foliis ovatis scabriusculis. *Hort. Cliff.* 149. Royena with oval rough leaves.

2. ROYENA foliis lanceolatis glabris. *Prod. Leyd.* 441. Royena with smooth spear shaped leaves.

3. ROYENA foliis lanceolatis hirsutis. *Prod. Leyd.* 441. Royena with hairy spear-shaped leaves.

The first sort has been long an inhabitant of some curious gardens in *England*, but it is not very common here, for it is very difficult to propagate.

This plant grows eight or ten feet high, and puts out its branches on every side, so may be trained up to a regular head: the branches are clothed with oval shining leaves, which are placed alternately, and continue all the year, so make an agreeable variety among other exotick plants in the green-house, during the winter season. The flowers are produced from the wings of the leaves along the branches, but as they have little beauty, few persons regard them. I have not observed any fruit produced by these plants in *England*.

The second sort grows naturally at the *Cape of Good Hope*. This rises with a shrubby stalk five or six feet high, sending out many slender branches, covered with a purplish bark, and garnished with small oval leaves, less than those of the Box-tree; they are smooth, entire, and of a lucid green, continuing all the year. The flowers come out from the wings of the leaves round the branches; they are white, and shaped like a pitcher; these are succeeded by roundish purple fruit, which ripen in the winter.

The third sort grows naturally at the *Cape of Good Hope*.

This rises with a strong woody stalk seven or eight feet high, covered with a gray bark, sending out many small branches alternately, which are garnished with spear-shaped hoary leaves, covered with soft hairs. The flowers come out upon short foot-stalks from the side of the branches; they are of a worn-out purple colour, and small.

These plants are too tender to live through the winter in the open air in *England*, therefore they must be removed into the green-house in autumn, and treated in the same way as Orange-trees, with which culture the plants will thrive.

The first and third sorts are difficult to propagate here, for the branches which are laid down seldom put out roots, and those which do, are two years before they will have made roots sufficient to transplant, and their cuttings very rarely succeed; these are the only methods by which they can be increased in those countries, where they do not produce seeds. The best time to plant the cuttings is in *September*; these should be planted in small pots, and plunged into a very moderate hot-bed. The pots should be closely covered down with hand-glasses to exclude the external air, and the cuttings refreshed with a little water every eighth or tenth day, according as the earth becomes dry, for much moisture will kill them. If the cuttings shoot, they must be gradually inured to bear the open air, and when they are well rooted, they should be each planted in a separate small pot, and afterward treated as the old plants.

If the plants put out any young shoots from the bottom, they should be carefully laid down in the ground while young, because when the shoots are tender, they are more apt to put out roots than after they are become woody and hard; these branches should be slit in the same manner as is practised in laying of Carnations: they must be frequently, but gently watered during the warm weather in summer, but in cold weather it must be sparingly given them; when these are rooted, they may be taken off, and treated in the same way as the cuttings.

The second sort is very apt to send up suckers from the roots, which may be taken off with the roots, and thereby increased; or those which do not put out roots, may be laid down in the same manner as the former; and the cuttings of this more frequently succeed than those of the other, so that this sort is much easier propagated.

RUBIA. *Tourn. Inst. R. H.* 113. tab. 38. Madder.

The Characters are,

The empalement of the flower is small, cut into four segments, and sits upon the germen. The flower has one bell-shaped petal, having no tube, but is divided into four parts. It hath four oval-shaped stamina, which are shorter than the petals, terminated by single summits, and a twin germen under the flower, supporting a slender style, divided into two parts upward, and crowned by two headed stigmas. The germen afterward becomes two smooth berries joined together, each having one roundish seed with a navel.

The Species are,

1. RUBIA foliis senis lanceolatis supernè glabris. Madder with six spear-shaped leaves in whorls, whose upper surfaces are smooth; dyer's Madder.

2. RUBIA foliis inferioribus senis, supernè quaternis binifve, utrinque asperis. Madder with the lower leaves, growing by sixes round the stalks, and the upper ones by fours or pairs, which are rough on both sides; rough wild Madder.

3. RUBIA foliis quaternis. *Prod. Leyd.* 254. Madder with four leaves, which are placed round the stalks.

The first sort, which is cultivated for the root that is used in dyeing and staining of linens, grows naturally in the *Levant*. This hath a perennial root, and an annual stalk; the root is composed of many long, thick, succulent fibres, almost as large as a man's little finger; these are joined at the top in a head, like the roots of Asparagus, and run very

very deep into the ground; I have taken up roots, whose strong fibres have been more than three feet long; from the upper part (or head of the root) come out many side roots, which extend just under the surface of the ground to a great distance, whereby it propagates very fast; for these send up a great number of shoots, which, if carefully taken off in the spring, soon after they are above ground, become so many plants. These roots are of a reddish colour, somewhat transparent, and have a yellowish pith in the middle, which is tough, and of a bitterish taste; from the root arise many large four-cornered jointed stalks, which in good land will grow five or six feet long, and, if supported, sometimes seven or eight; they are armed with short herbaceous prickles, and at each joint are placed five or six spear-shaped leaves; their upper surfaces are smooth, but their midrib on the under side is armed with rough herbaceous spines; the leaves sit close to the branches in whorls. From the joints of the stalk come out the branches, which sustain the flowers; they are placed by pairs opposite, each pair crossing the other; these have a few small leaves toward the bottom, which are by threes, and upward by pairs opposite; the branches are terminated by loose branching spikes of yellow flowers, which are cut into four parts, resembling stars. These appear in *June*, and are sometimes succeeded by seeds, which never ripen in *England*.

The second sort grows naturally in *Spain*. This hath perennial roots like those of the first sort, but are much larger; the stalks of this are smaller than those of the first sort, and are almost smooth; their lower parts are garnished with narrow leaves, placed by sevens in whorls round the stalks, but upward they diminish to four, three, and two toward the top; these are rough on both sides; at each joint of the stalk come out two short foot stalks opposite, having two small rough leaves, ending with branching foot-stalks, sustaining small yellow flowers.

The third sort grows naturally in *Spain* and the *Balearic Islands*; I received the seeds of this sort from *Gibraltar*, and also from *Minorca*, where the plants grew out of the crevices of the rocks. The roots of this sort are much smaller than those of the two former, but are less succulent; they strike deep into the ground, and send up several slender four-cornered stalks, which are perennial; these grow a foot and a half long, and divide into many branches, whose joints are very near each other; they are garnished with short, stiff, rough leaves, placed by fours round the stalk, of a lucid green, and continue all the year.

There is a sort which grows naturally in *Wales*, and also upon *St. Vincent's Rock*, which has four leaves at each joint, but these are narrower and longer than those of the third sort; the stalks of this are perennial, and the leaves evergreen, so that *Mr. Ray* has mistaken this plant, having supposed it to be the second, which hath annual stalks rising much higher, therefore I should rather think it might be the third sort, if they were equally hardy; but the third sort is so tender, as to be always killed by severe frosts in *England*.

The first sort is that which is cultivated for the use of the dyers and callico printers, and is so essential to both manufactories, as that neither of those businesses can be carried on without this commodity; and the consumption of it is so great here, as that upon a moderate computation, there is annually so much of it imported from *Holland*, as the price of it amounts to more than one hundred and eighty thousand pounds sterling, which might be saved to the publick, if a sufficient quantity of it were planted in *England*, where it might be cultivated to greater advantage than in *Holland*, the lands here being better adapted to grow this plant. But as the growing of this plant in quantity, has been for several years discontinued, so the method of cul-

ture is not well known to many persons here; and as there is at present an inclination in the publick to regain this lost branch of trade (for formerly there was not only enough of this commodity raised in *England* for our own consumption, but also great quantities of it were sent abroad), so we shall here give a full account of the culture of the plant, and also of the method of preparing the root for use; and shall begin with the method now practised in *Zealand*, where the best and greatest quantity of Madder is now raised.

In all the *Netherlands*, there is no where better Madder cultivated than in *Schowen*, one of the islands of *Zealand*, which is performed in the following manner:

The land which is designed for Madder, if it is strong and heavy, is ploughed twice in autumn, that the frost in winter may mellow it and break the clods; then it is ploughed again in the spring, just before the time of planting the Madder, but if the ground is light, then it is ploughed twice in the spring; at the last ploughing it is divided into lands of three feet broad, with furrows between each land, four or five inches deep. Madder requires a loamy substantial soil, not too stiff and heavy, nor over light and sandy; for although it may thrive tolerably well in the latter, yet such land cannot have a second crop of Madder planted upon it in less than eight or ten years interval; but in *Schowen*, where the land is substantial, they need not stay longer than three or four years, in which interval the ground is sown with Corn, or planted with any kinds of pulse. It is granted, that the best land for producing of Madder is in *Schowen*, where a gemet of land, which is three hundred square rods of twelve feet each, will yield from one thousand pounds to three thousand pounds weight, according to the goodness of the land and the favourableness of the seasons; but in light land, the quantity is from five hundred to a thousand pounds weight.

The time for planting of Madder begins toward the end of *April*, and continues all *May*, and sometimes in very backward springs, there is some Madder planted the beginning of *June*. The young shoots from the sides of the root are taken off from the mother plant, with as much root as possible; these are called *Kiemen*, and are planted with an iron dibble in rows at one foot asunder, and commonly four *Kiemen* in a row.

The quantity of these slips (or *Kiemen*) as is required to plant one gemet of land, are sold at different prices, according to the price which Madder bears, or to the demand for the plants; they are often sold from sixteen to twenty guilders, and sometimes they have been sold for ten or eleven pounds *Flemish*, but the lowest price is from fifteen guilders to three pounds *Flemish*.

The expence of planting out a gemet of land with slips (or *Kiemen*) costs for labour only, from sixteen to twenty guilders, according as the land is heavy or light: there are generally employed six men to plant, two to rake the ground; these earn each a guilder a day; and five or six women or boys, called *carpers* or *pluckers* of the shoots or *Kiemen*, these earn twelve *Dutch* pence a day, or two *schillings*.

The first year the Madder is planted, it is customary to plant Cabbages or dwarf *Kidney-beans*, in the furrows between the beds, but there is always great care taken to keep the ground clean from weeds; this is generally contracted for at two pounds *Flemish* at each gemet of land.

In *September* or *October*, when the young Madder is cleaned for the last time that season, the green Haulm (or stalks) of the plants, is carefully spread down over the beds, without cutting any part off, and in *November* the Haulm of the Madder is covered over with three or four inches of earth.

This covering of the Madder is performed either with the plough or with the spade; if it is done by the first, it costs

costs two guilders and a half, or three guilders in strong land each gemet, and over and above this, one guilder and a half to level the tops of the beds, and make them smooth; but it is better performed with the spade, only it is more chargeable, for that costs from eight to ten guilders each gemet, but at the same time the clods are better broken, and the surface of the beds made smooth and even.

The second year in the beginning of *April*, which is about the time the Kiemen or young shoots are beginning to come out, the earth on the top of the beds should be scuffled over and raked, to destroy the young weeds, and make the surface smooth and mellow, that the Kiemen may shoot out the easier above ground; this labour costs three shillings each gemet.

The second summer there must be the same care taken to keep the Madder clean as in the first, and then nothing is planted in the furrows, or suffered to grow there; at the last time of cleaning the ground, in *September* or *October*, the green Haulm is again spread down upon the beds; and in *November*, the Madder is again covered with earth in the same manner as the first year.

By this method of culture, one can see how necessary it is to plant the Madder in beds, for thereby it is much easier covered with the earth of the furrows; and hereby the earth of the beds is every time heightened, whereby the Madder roots will be greatly lengthened, and the Kiemen or young shoots will have longer necks, and by being thus deeply earthed, will put out more fibres and have much better roots, without which they will not grow; and it is of equal use to the mother plants, for by this method the roots will be longer; and in this consists the goodness and beauty of the Madder, for those which have but few main roots, are not so much esteemed as those which are well furnished with side roots, called Tengels; a Madder plant that has many of these roots, is called a well-bearded Madder plant; therefore one must never cut off the side roots, for by so doing there will be a less crop of Madder, and but few Kiemen or young shoots can be produced; besides, by the loss of moisture, sometimes the plants will droop and become weak; and there is great profit in having a large quantity of Kiemen to draw in the spring, which are in plenty the second and third years.

The Madder roots are seldom dug up the second year, but generally after it has grown three summers, therefore the culture of the third year is the same as in the second, during the spring and summer.

Before the first day of *September*, it is forbidden to dig up any Madder in this island; but on that day early in the morning, a beginning is made, and the person who carries the first cart load to the stove, has a premium of a golden rider, or three ducats.

The digging up the Madder of a gemet of land, costs from thirty-six to one hundred guilders, according to the goodness of the crop, and the lightness or stiffness of the ground, but in light land it costs from nine to ten pounds *Flemish*; the persons who are adroit in this business, are generally paid five shillings *Flemish* per day.

The Madder produces flowers in the middle of summer, and sometimes a few seeds, but they never ripen here; nor would they be of use to cultivate the plants, since it is so easily done by the Kiemen.

Some years past they began to plant here the great wild Madder, which was called *French Madder*, but this was not esteemed so good for use as the tame Madder, from which it differs much, so that was not continued. The more bitter of taste the roots of the Madder are, when taken out of the ground before it is brought to the stove, the less it will lose of its weight in drying, and is the better afterward for use.

When the Madder is dug out of the ground, it is carried to the stove, and there laid in heaps; in that which is called the cold stove, and separated with hurdles made of wicker, and memorandums kept of each parcel, and to what countryman it belongs, that each may be dried in their turns, and prepared or manufactured, for which turn generally lots are cast beforehand. The Madder thus carried to the stove is Relzyn.

This Relzyn is carried about six o'clock in the morning, into the tower or steeple, hoisted in baskets by ropes to the rooms, and divided or spread where it remains till the next day, two or three o'clock in the morning, about twenty or twenty-one hours; then those roots which have lain in the hottest places are removed to cooler, and those in the cooler are removed to the hotter places nearer the oven. This is continued for four or five days, according as there has been more or less carried there; but it is always the goods of one person, that every one may have his own, and of as equal quality as possible, when it is delivered out.

When the Madder is sufficiently dried in the tower, then it is threshed on the threshing floor, which is made clean from dirt or filth, and then it is brought to the kiln, and there spread on a hair-cloth for about twenty hours, during which time the kiln is made more or less hot, according as the roots are more or less thick, or the weather more or less cold.

From the kiln the Madder is moved to the pounding-house, and is there pounded on an oaken block made hollow, with six stampers platted at the bottom with iron bands; these stamps are kept in motion by a mill very much resembling a grist-mill, which is turned by three horses; the presence of the pounding-master is here always required, to stir the Madder continually with a shovel, to bring it under the stampers. When the Madder is thus properly pounded, it is sifted over a tub till there is enough to fill a cask: this first pounding, which chiefly consists of the thinnest and smallest roots, and the outside husks with some earth, which by drying and threshing could not be separated, is called Mor Mull.

What remains in the sieve is put on the block again, and pounded a second time; and when the pounding-master guesses a third part is pounded, then the Madder is taken out again, and sifted over another tub, and put into a separate cask, and this is called Gor gemeens; that which remains in this second operation, not enough pounded in the sieve, is for the third time put on the block, and pounded till it is all reduced to powder, which is called Kor krap.

When the Madder is cleansed from the dirt and Mull, and is entirely pounded at once, then it is called Oor Onberooft, so that this Onberooft actually consists of the Gemeens and Krap pounded together, and sifted without separating them from each other.

When there is two-thirds of Krap, and one-third Gemeens, which was separately prepared or manufactured, then they are called two and one, or marked $\frac{2}{3}$.

The sweepings of the stove, as also of the ground and beams being swept together is not lost, but is put amongst the Mull, or sold by itself.

The sweepings of the mill, and every part of the pounding place, is also gathered together, and put into a cask; this is called Den Beer.

When the Madder is thus prepared and put into casks, it is in *Zealand* examined by sworn assayers and tried, if it is not faulty packed up; that is, whether in the preparing it is properly manufactured, or falsely packed up, and to see if every part of the cask is filled with Madder of equal goodness and quality, not burned in the drying, or mixed with dirt; which the assayers, by certain trials, and by weighing and washing of the Madder,

der, can know, if it is according to the statutes of the country.

There are sundry statutes made and published by the states of *Zealand*, concerning the preparing of Madder; as one of the 28th of *July*, 1662, one on the 29th of *September*, and 31st of *October*, 1671, another on the 23d of *September*, 1699, and the last on the 28th of *April*, 1735: by which statutes, among other things, it is strictly forbidden, That no person shall prepare Kraps, in which there shall be more than two pounds of dirt in a hundred weight, nor above eight pounds in the like weight of *Onberooftde*, or in *Gemeens* more than twelve pounds in a hundred weight.

If the Madder upon trial is found good, the arms of the city or village, and the sign of the stove where the Madder was prepared, is painted on the cask with black paint. The trial of the Madder is in no place more exact, or more religiously observed, than in the city of *Zirkzee*, therefore the merchants in *Germany*, who know this, always prefer the Madder of that place to all others, and will not buy any which has not the arms of *Zirkzee* painted upon the casks, if they are to be had.

We before mentioned the tower, the kiln, &c. where the Madder is dried and prepared for use, the draughts of these are exhibited in the annexed plans, with their explanation; but that a better judgment may be formed of their use, we shall here take notice, that the tower is the place where the Madder is first dried. This tower is heated by fifteen or sixteen pipes or flues of brick-work, which run on each side the tower under the floor, and are covered with low burnt tiles, some of which are loose; so that by taking up these, the heat is moderated, and conducted to any part of the tower, the person who has the care of drying the Madder pleases.

This tower has four or five lofts made of strong laths; they are four or five feet above each other, upon which the Madder is laid; these are heated by an oven, which is placed in the room where the work people live, and is by them called the *Glory*.

The kiln is in a room, whose length is equal to the breadth of the stove, and is entirely arched over at the top; the oven, by which the kiln is heated, is called the *Hog*; this is built upon a stone wall, which rises a foot or two above ground; and the small arch, by which the heat passes through every part, has several square little holes in the brick work, that the heat may come out; over these holes, on the top of the kiln, are laid wooden laths the whole length, and upon them a hair-cloth, on which the Madder is laid to dry, before it is carried to the pounding place. In the Madder-stoves there is no other fuel used but *Friezland* turf, which gives an equal and moderate heat.

In the Madder-stoves, the people work more by night than day; first, because at the time of year when the Madder is brought into the stoves, the nights are much colder than the days; and secondly, that the madder, who must be always attentive to his work, may not be interrupted by visitors; and thirdly, because they see less dust; but principally, because the Madder, which is pounded in the night, is of a much better colour than that which is pounded in the day.

In the Madder-stoves are always constant workmen, one who is the dryer, who has the care of drying the Madder in the tower and the kiln; for the right performance of this, art and experience are required, the goodness of the Madder greatly depending on the right drying. This person is a sort of foreman, and has the direction of all the workmen; his pay is five stivers, for every hundred weight of Madder which is prepared in the stove; he has one person under him for his assistant, to perform part of the laborious work, and to be always at hand; this man is paid eighteen or

nineteen shillings per week *Flemish*, which is the constant wages.

The third person is the pounder, who is always present when the Madder is pounding, who with a particular shovel which is small, and fitted to the cavity of the pounding block, stirs the Madder from time to time, to bring it under the stampers; he is paid four stivers for every hundred weight of Madder.

The fourth is a driver, who with a team of three horses, causes the mill to turn and pound the Madder; his pay for himself and the three horses, from eight to nine stivers per hundred weight, according as he can bargain.

Besides these four, there are five other assistants, who lay the Madder on and take it off; this is often performed by the wives and boys of the other workmen; these five have fifty stivers for every three thousand pounds of Madder which is prepared, so they have each ten stivers.

There are nineteen or twenty Madder-stoves in the island of *Schowen*, which, at an average, prepare in one crop, that lasts from *September* to *February*, ten thousand weight of Madder each, which in the whole amounts to two million-pounds weight; and if we suppose, that the Madder is sold at an average for four pounds *Flemish* per hundred weight, which is a moderate price, one may soon reckon what advantage the culture of this dyeing commodity produces to this one island.

The countrymen pay to the owners of the Madder-stoves, two guilders for preparing every hundred weight of *Mull*, and for each hundred weight of hard Madder; that is, of *Kraps*, *Gemeens*, or *Onberooftde*, three guilders, according as they will have them prepared.

In *Zealand*, Madder is cultivated by every kitchen-gardener, each having a quantity to take up annually, in proportion to the size of his garden, and most of the farmers there do the same; for as the roots require three years growth to have them in perfection, so they every spring plant a certain allotment of land for the purpose. The ground which has produced Madder, will be fresh and well prepared for other crops, in like manner as the land upon which *Asparagus* roots have grown to be taken up for forcing upon hot-beds in winter, which is practised by most of the kitchen-gardeners near *London*, for these roots are commonly allowed three years growth, by those persons who value themselves on having large *Asparagus*; so there is a great affinity in the culture of both these roots, for the land which will produce one of these crops is always good for the other. It is therefore much to be wished, that the kitchen-gardeners in *England* would undertake the culture of Madder, who are much more likely to succeed in it than any other persons; but it is feared the trouble of drying and manufacturing the roots for use, is a principal objection to this.

The building of a Madder-stove quite new from the foundation, costs in the whole about twenty-four hundred pounds *Flemish*, which is twelve hundred pounds sterling.

The above account is the method of cultivating Madder in *Zealand*, where the best Madder is now produced; to this I shall add, what I have observed of the growing of Madder in other parts of *Holland*, as also the experience I have had of the growth of Madder in *England*, with an account of the method of planting it here.

In the year 1727, I observed a great quantity of this plant cultivated in *Holland*, between *Helwoetstuyts* and the *Brill*; and it being the first time I had ever seen any considerable parcel of it, I was tempted to make some enquiries about its culture, and take some minutes of it down upon the spot, which I shall here insert, for the use of such as may have curiosity to attempt the culture of it.

In autumn they plough the land, where they intend to plant Madder in the spring, and lay it in high ridges, that the frost may mellow it; in *March* they plough it again, and at this season they work it very deep, laying it up in ridges eighteen inches asunder, and about a foot high; then about the beginning of *April*, when the Madder will begin to shoot out of the ground, they open the earth about their old roots, and take off all the side shoots which extend themselves horizontally, just under the surface of the ground, preserving as much root to them as possible; these they transplant immediately upon the tops of the new ridges, at about a foot apart, observing always to do this when there are some showers, because then the plants will take root in a few days, and will require no water.

When the plants are growing, they carefully keep the ground hoed, to prevent the weeds from coming up between them: for if they are smothered by weeds, especially when young, it will either destroy or weaken them so much, that they seldom do well after. In these ridges they let the plants remain two seasons, during which time they keep the ground very clean; and at *Michaelmas*, when the tops of

the plants are decayed, they take up the roots and dry them for sale. This is what I could learn of their method of cultivating this plant, to which I will subjoin a few observations of my own, which I have since made upon the culture of Madder in *England*.

The land upon which I have found Madder thrive best, is a soft sandy loam, and if it has been in tillage some years, it will be better than that which is fresh broken up. This should have at least a depth of two feet and a half, or three feet of good earth, and must be quite clear from couch, or the roots of any bad weeds; for as the roots of Madder should remain three years in the ground, so where there are any of those weeds which spread and multiply at their roots, they will intermix with the Madder roots, and in three years will have taken such possession of the ground, as to greatly weaken the Madder, and render it very troublesome to separate when the Madder is taken up.

The ground should be ploughed deep before winter, and laid in ridges to mellow; and if it is not too strong, there will be no necessity for ploughing it again, till just before the time of planting the Madder, when the land should be ploughed as deep as the beam of the plough will admit; and there should be men following the plough in the furrows, who should dig a full spit below the furrow, and turn it up on the top of the baulk; by preparing the ground of this depth, the roots of the Madder will strike down, and be of greater length, in which the goodness of the crop chiefly consists. The land being thus prepared and made level, will be fit to receive the plants. The best time for planting of the Madder, is about the middle, or in the latter end of *April*, according as the season is more or less forward, which must be determined by the young shoots; for when these are about two inches above ground, they are in the best state for planting.

In the taking up of these shoots for planting, the ground should be opened with a spade, that they may be separated from the mother plants with as much root as possible; for if the roots are broken off, they will not succeed: these plants should be drawn up no faster than they are planted, for if they lie long above ground, they will shrink, and their tops will wither, and then they often miscarry; therefore if they are brought from a distant place, there should be great care taken in the packing of them up for carriage; especial regard should be had not to pack them so close, or in so great quantity, as to cause them to heat, for that will soon spoil them; but if they are a little withered by lying out of the ground, their roots should be set upright in water for a few hours, which will stiffen and recover them again.

In the planting of Madder, there are some who make the rows but one foot asunder, others one foot and a half, some two feet, and others who allow them three feet distance. I have made trial of the three last distances, and have found when the roots have been left three years in the ground, that three feet distance row from row is the best; but if it is taken up in two years, two feet asunder may do very well; and the distance in the rows plant from plant, should be one foot, or a foot and a half.

If there is no danger of the ground being too wet in winter, the plants may be planted on the level ground; but if on the contrary, the ground should be raised in ridges where each row of plants is to be set, that their roots may not reach the water in winter, for if they do, it will stop their downright growth; and this is the reason for the *Dutch*, who plant Madder in the *Low Countries*, raising their ridges so high as two or three feet, and in *Zealand*, where the ground is drier, they raise the beds four or five inches above the intervals, that the wet may drain off from the beds where the Madder is planted.

The method of planting is as follows, *viz.* The ground

being made smooth, a line is drawn cross it to mark out the rows, that they may be strait for the more convenient cleaning, and for the better digging or ploughing of the ground between the rows; then with an iron-shod dibble, holes are made, at the distance which the plants are to stand from each other. The depth of the holes must be in proportion to the length of the roots of the plants, which must be planted the same depth they had been while they were upon the mother plants; for if any part of the root is left above ground, the sun and winds will dry them, which will retard the growth of the plants; and, should any part of the green be buried in the ground, it will not be so well, though, of the two, the latter will be less prejudicial, especially if there is not too much of the green buried. When the plants are put into the holes, the earth should be pressed close to them to secure them from being drawn out of the ground, for crows and rooks frequently draw the new plants out of the ground, before they get new roots, where there is not this care taken; so that in two or three days, I have known half the plants on a large piece of land destroyed by these birds.

If there happens to be some showers of rain fall in a day, or two after the plants are planted, it will be of great service to them, for they will presently put out new roots, and become strong, so that, if dry weather should afterward happen, they will not be in so much danger of suffering thereby, as those which are later planted. There are some who, from a covetous temper of making most use of the ground, plant a row of dwarf Peas, or Kidney-beans, between each row of Madder, and pretend that hereby the land is kept cleaner from weeds; but I am very certain the crop of Madder is injured thereby much more than the value of those things which grow between the rows, as I have experienced; therefore I advise those persons who plant Madder, never to sow or plant any thing between the rows, but to keep the Madder quite clean from weeds, or any other kind of vegetable.

In order to keep the ground thus clean, it should be scuffled over with a *Dutch* hoe, as soon as the young weeds appear; at which time a man can perform a great deal of this work in a day, and if it is done in dry weather, the weeds will die as fast as they are cut down; whereas, when the weeds are left to grow in the spring, so as to get strength, they are not so soon destroyed; and the expence of hoeing the ground then will be more than double; besides, there will be danger of cutting down some of the weaker plants with the weeds, if the persons employed to perform this work are not very careful, therefore it is much cheaper, as also better for the Madder, to begin this work early in the spring, and to repeat it as often as the weeds render it necessary; for by keeping the ground thus constantly clean, the Madder will thrive the better.

During the first summer, the only culture which the Madder requires, is that of keeping it clean in the manner before directed, and, when the shoots or haulm of the plants decay in autumn, it should be raked off the ground; then the intervals between the rows should be either dug with a spade, or ploughed with a hoeing plough, laying up the earth over the heads of the plants in a roundish ridge, which will be of great service to the roots. The *Dutch* cover the haulm of their Madder with earth, leaving it to rot upon the ground; this perhaps may be necessary in their country to keep the frost out of the ground, but, as I have never found that the severest winters in *England* have injured the Madder roots, there is not the same necessity for that practice here.

The following spring, before the Madder begins to shoot, the ground should be raked over smooth, that the young shoots may have no obstruction, and, if there should be any young

A Section of the Tower

A Plan of the Pounding House.

A Section of the Pounding House.

young weeds appearing on the ground, it should be first scuffled over to destroy the weeds, and then raked over smooth; after this the same care must be taken in the following summer to keep the ground clean, and, if it is performed by the hoe plough, the earth of the intervals should be thrown up against the side of the ridges, which will earth up the roots, and greatly increase their strength; but, before the ground of one interval is so hoed, the haulm of the plants should be turned over to the next adjoining interval, and, if they are permitted so to lie for a fortnight or three weeks, and then turned back again on those intervals which were hoed, observing first to scuffle the ground to destroy any young weeds, which may have appeared since the stirring of the ground, then the alternate intervals should be ploughed in like manner, turning the earth up against the opposite sides of the roots; by this method the intervals will be alternately ploughed, and the plants earthed up, whereby the ground will be kept clean and stirred, which will greatly promote the growth of the roots; and by this method the superficial shoots will be subdued, and the principal roots greatly strengthened. The following autumn the ground should be cleared of the haulm and weeds, and the earth raised in ridges over the roots, as in the foregoing year.

The third spring the roots will furnish a great supply of young plants, but, before these appear, the ground should be cleaned and raked smooth, that the shoots may have no obstruction to their coming up; and, when the young plants are fit to take off, it should be performed with care, always taking off those which are produced at the greatest distance from the crown of the mother plants, because those are what rob them most of their nourishment, and the wounds made by separating them from the old roots are not near so hurtful as those near the crown, for the stripping off too many of the shoots there will retard the growth of the plants.

The culture of the Madder in the third summer, must be the same as the second, but, as the roots will then be much stronger, the earth should be laid up a little higher to them at the times when the ground is cleaned; and, if all the distant superficial shoots, which come up in the intervals, are hoed or ploughed off, it will be of service to strengthen the larger downright roots, and, as the haulm will now be very strong and thick, the frequent turning it over, from one interval to another, will prevent its rotting, for if it lies long in the same position, the shoots which are near the ground, where there will be always more or less damp, and being covered with the upper shoots, the air will be excluded from them, which will cause them to rot; for the shoots of Madder are naturally disposed to climb upon any neighbouring support, and in places where they have been supported, I have seen them more than ten feet high; but the expence of staking the plants to support their shoots, would be much too great to be practised in general, therefore the other method of turning the haulm over from one interval to the other, will be found of great use, for hereby it is kept from decaying, and by so doing the sun is alternately admitted to each side of the roots, which is of more consequence to the growth of the Madder than most people conceive, from many repeated trials I have found, that where the haulm has decayed or rotted in summer, it has greatly retarded the growth of the roots. There have been some ignorant pretenders who have advised the cutting off the haulm in summer, in order to strengthen the roots, but whoever practises this, will find to their cost the absurdity of this method, for I have fully tried this many years ago, and have always found that every other root, upon which this was practised, was at least a third part smaller than the intermediate roots, whose haulm was left entire. The occasion of my first making this experiment

was, because the plants had been set too near each other, and the season proving moist, had increased the number and strength of the shoots, so that they were so thick, as that many of them began to rot; to prevent which, I cut off the shoots of every other plant to give room for the others to spread; but soon after this was done, the plants produced a greater number of shoots than before, which were weaker, and the effect it had upon the roots was as before related; since then I have frequently repeated the experiment on a few roots, and have always found the effect the same.

As soon as the haulm of the Madder begins to decay in autumn, the roots may be taken up for use, because then the roots have done growing for that season, and will then be plumper and less liable to shrink than if they are dug up at another season; for I have always found that roots of every kind of plant, which are taken out of the ground during the time of their growing, are very apt to shrink, and lose more than half their weight in a short time.

When the season for digging up the Madder roots is come, it should be done in the following manner, *viz.* A deep trench should be dug out at one side of the ground next to the first row of Madder, to make a sufficient opening to receive the earth, which must be laid therein in digging up the row of roots, so that it should be at least two feet broad, and two spits and two shovelings deep: this should be made as close as possible to the roots, being careful not to break or cut them in doing it; then the row of roots must be carefully dug up, turning the earth into the trench before mentioned. In the doing of this, there should be to every person who digs, two or three persons to take out the roots as entire as possible, that none may be lost, and as much of the earth should be shaken out of the roots as can be done, for after the principal roots are taken up, there will be many of the long fibres remaining below, which break off; therefore, in order to get the roots as clean as possible, the whole spot of ground should be dug of the same depth as the first trench, and the pickers must follow the diggers to get them all out to the bottom. As the digging of the land to this depth is necessary, in order to take up the roots with as little loss as possible, it is a fine preparation for any succeeding plants; and I have always found that the ground, where the Madder has grown, produced better crops of all kinds than lands of equal goodness, which had not the like culture, especially those plants with tap-roots, as Carrots and Parsneps.

After the roots are taken up, the sooner they are carried to the place of drying, the finer will be their colour, for if they lie in heaps, they are apt to heat, which will discolour them; or if rain should happen to wet them much, it will have the same effect, therefore no more roots should be taken up than can be carried under shelter the same day.

The first place in which the roots should be laid to dry, must be open on the sides to admit the air, but covered on the top to keep out the wet. If a building is to be erected new, such as the tanners have for drying their skins will be as proper as any, for these have weather-boards from top to bottom, at equal distances, to keep out the driving rain, but the spaces between being open, admit the air freely; and if instead of plank-floors or stages above each other, they are laid with hurdles or basket work, upon which the roots are laid to dry, the air will have freer passage to the under side of the roots, which will dry them more equally.

In this place they may remain four or five days, by which time the earth, which adhered to the roots, will be so dry as to easily rub off, which should be done before the roots are removed to the cold stove, for the slower the roots are dried, the less they will shrink, and the better will be the colour of the Madder; and the cleaner the roots are from earth,

earth, the better the commodity will be for use when prepared.

After the roots have laid a sufficient time in this place, they should be removed into another building called the cold stove, in which there should be conveniencies of flues passing through different parts of the floor and the side walls; in this the roots should be laid thin upon the floors, and turned from time to time as they dry, taking those roots away, which are nearest to the flues that convey the greatest heat, placing them in a cooler part of the room, and removing such of them as had been in that situation to the warmer, from whence the other are taken. The constant care in this particular will be of great service to the quality of the Madder, for, when this is properly conducted, the roots will be more equally dried, and the commodity, when manufactured, will be much fairer and better for use.

When the outside of the roots has been sufficiently dried in this cold stove, they should be removed to the threshing floor, which may be the same as in a common barn where Corn is threshed. The floor of this should be swept, and made as clean as possible; then the roots should be threshed to beat off their skins or outside coverings; this is the part which is prepared separately from the inner part of the root, and is called Mull, which is sold at a very low price, being the worst sort of Madder, so cannot be used where the permanency or beauty of the colours are regarded; these husks are separated from the roots, pounded by themselves, and are afterward packed up in separate casks, and sold by the title of Mull. If this is well prepared, and not mixed with dirt, it may be sold for about fifteen shillings *per* hundred weight, at the price which Madder now bears, and this, as is supposed, will defray the whole expence of drying the crop.

After the Mull is separated from the roots, they must be removed to the warmer stove, where they must be dried with care, for if the heat is too great, the roots will dry too fast, whereby they will lose much in weight, and the colour of the Madder will not be near so bright; to avoid which, the roots should be frequently turned, while they remain in this stove, and the fires must be properly regulated. If some trials are made by fixing a good thermometer in the room, the necessary heat may be better ascertained than can be done any other way; but this will require to be greater at some times than at others, according as the roots are more or less succulent, or the weather more or less cold or damp; but it will always be better to have the heat rather less than over-hot, for, though the roots may require a longer time to dry with a slow heat, yet the colour will be the better.

When the roots are properly dried in this stove, they must be carried to the pounding-house, where they must be reduced to powder in the manner before related; but whether it is necessary to separate the Kraps from the Gemeens, as is now practised by the *Dutch*, the consumers of Madder will be better judges than myself.

There has been some objections of late made to the introducing or rather retrieving the culture of Madder in *England*, which it may be proper here to take notice of, lest they should have so much weight as to prevent many persons from engaging in it. The first which has been generally started is, that the land in this country is not so well adapted for growing Madder, as that in *Holland*, to which I can with truth affirm, that there are vast tracts of land here much better adapted for producing Madder than the best land in *Zealand*, and from the experience, which I have had of its growth, will produce a greater crop.

Another objection which I have heard, was the labour in *Holland* being cheaper than in *England*. The *Dutch* will always undersell us, so consequently will maintain this

branch of trade; but this is certainly a great mistake, for, though the labourers employed in cultivating Madder, may not earn so great wages as is generally paid in *England*, sure I am that the difference between an expert *English* labourer, and that of the best *Dutchman*, in the ploughing, hoeing, planting, &c. of Madder, is much greater than that of their pay; for I am sure a good *English* gardener or ploughman will do more business, and perform it better, in four days, than the best workman in *Holland* can do in six. What I now say is greatly within compass from my own knowledge; so that, supposing we were to proceed in the same manner now practised by the *Dutch*, this could be no objection to the cultivating of Madder; but we shall soon find ways of performing the most laborious part, at much less expence, by means of the hoeing-plough, which may be used to great advantage in the cultivation of Madder, whereby the expence will be much lessened, and, when once this is well established in *England*, there can be no doubt but that great improvements will be made both in the culture and method of preparing the commodity for use.

There has been objections made against farther trials of growing Madder, because some who have engaged in it, have not succeeded; but in answer to this, it must be observed, that their ill success was owing to a want of skill. Some of them continued to plant repeated crops of Madder on the same spot of ground, till the roots became so small, as scarce to pay the expence of digging up; and here it is proper to observe, that Madder should not be planted on the same land, till after an interval of seven or eight years, during which interval the ground may be sown with any sort of grain, or kitchen vegetables, which it will produce to great advantage after Madder, because the land will be wrought so deep. The *Dutch* always sow grain upon their Madder ground in the intervals of four years, and have great crops from it; and they are obliged, from the scarcity of land fit for this purpose, to plant the same ground after an interval of four years; but, as we are not under the same necessity, it will be much better to stay eight years, for the roots of Madder are very similar to those of *Asparagus*, and draw much the same nourishment from the ground; and it is well known that, when *Asparagus* roots are dug up, which have been growing three years, if the same ground is planted with *Asparagus* again in a few years, it will not thrive equal to that which is planted on ground, upon which *Asparagus* has not grown for several years; and this is always found to be the case even in kitchen-gardens near *London*, where, by the well working and frequent dunging of the ground, it may be supposed changed in three or four years, more than the fields can possibly be in eight or ten.

Madder should not be planted in very rich dunged land, for in such there will be very large haulm, but the roots will not be in proportion; and, where there is much dung or sea-coal ashes, the Madder roots will be of a darker colour, as it also will, where it is cultivated in the smoak of *London*, which is likewise the case with *Liquorice*, for that, which grows in a sandy loam at a distance from *London*, is always much brighter and clearer than that which grows in the rich lands in the neighbourhood of *London*.

If the cultivation of Madder is carried on properly in *England*, it will employ a great number of hands from the time harvest is over, till the spring of the year, which is generally a dead time for labourers, and hereby the parishes may be eased of the poor's rate, which is a consideration worthy of publick attention.

RUBEOLA. See *Asperula*, *Galium*, and *Sherardia*.

RUBUS. *Tourn. Inst. R. H.* 614. *tab.* 315. Bramble, or Raspberry Bush.

The Characters are,

The flower has a permanent empalement, which is cut into five spear-shaped segments; it hath five roundish petals, which are inserted in the empalement, and a great number of stamina, which are also inserted in the empalement, terminated by roundish compressed summits, with a great number of germen, having small hair-like styles on the side of the germen, crowned by permanent stigmas. The germen afterward becomes a berry, composed of many acini, collected into a head, each having one cell, in which is contained one oblong seed.

The Species are,

1. RUBUS foliis quinato-digitatis ternatisque, caule petiolisque aculeatis. Flor. Suec. 409. Bramble or Blackberry with hand-shaped leaves, having five and three lobes, and the foot-stalk and branches prickly; the common Blackberry.

2. RUBUS foliis ternatis nudis, caule aculeato. Hort. Cliff. 192. Bramble with naked trifoliate leaves, and a prickly stalk; the Dewberry.

3. RUBUS foliis quinato-pinnatis ternatisque, caule aculeato, petiolis canaliculatis. Flor. Suec. 408. Bramble with winged leaves, having five and three lobes, a prickly stalk, and channelled foot-stalks; prickly Raspberry.

4. RUBUS foliis ternatis subtus tomentosus, caule glabro. Raspberry with trifoliate leaves, which are woolly on their under side, and have a smooth stalk.

5. RUBUS foliis quinato-pinnatis ternatisque, caule aculeato, petiolis teretibus. Lin. Sp. Plant. 493. Bramble with winged leaves, having five and three lobes, a prickly stalk, and taper foot-stalks; Virginia Raspberry with a black fruit.

6. RUBUS foliis simplicibus palmatis, caule inermi multifloro. Hort. Cliff. 192. Raspberry with single hand-shaped leaves, and an unarmed stalk, having many flowers; commonly called flowering Raspberry.

7. RUBUS foliis ternatis nudis, caulibus petiolisque hispidis. Lin. Sp. Plant. 493. Bramble with naked leaves growing by threes, and hairy stalks and foot-stalks.

8. RUBUS foliis ternatis nudis, flagellis repentibus herbaccis. Flor. Suec. 411. Bramble with naked trifoliate leaves, and creeping herbaceous stalks; dwarf Rock Bramble.

9. RUBUS foliis ternatis, caule inermi unifloro. Flor. Suec. 412. Bramble with trifoliate leaves, and an unarmed stalk having one flower.

10. RUBUS foliis simplicibus lobatis, caule unifloro. Flor. Suec. 413. Bramble with single leaves, having lobes, and a stalk bearing one flower; the Cloudberry.

The first sort grows naturally on the side of banks, and in hedges in most parts of England, so is not cultivated in gardens; this is so well known as to need no description. Of this there are the following varieties:

1. The common Bramble with white fruit, which was found in a hedge near Oxford by Mr. Jacob Bobart. The branches of this sort are covered with a light green bark; the leaves are of a brighter green than the common sort, and the fruit is white, but it seldom produces fruit in gardens.

2. The Bramble without thorns; this is in every respect like the first, but the branches and foot-stalks have no thorns.

3. The Bramble with elegant cut leaves; this differs from the first, by having the leaves more finely cut.

4. The Bramble with double flowers; this differs from the first in having very double flowers, so is frequently planted in gardens for ornament.

5. The Bramble with variegated leaves; this is by some preserved in gardens, but it is very apt to become plain, if planted in good ground.

These sorts are easily propagated by laying down their branches, which will put out roots at every joint very freely. They may be transplanted any time from September to March, and will grow in almost any soil or situation.

The second sort hath weaker trailing stalks than the first;

the leaves are trifoliate, and the lobes are larger than those of the other; the fruit is smaller, the acini larger, and but few in each, which are of a deeper black colour. This grows naturally in England, and is known by the title of Dewberry.

The third sort is the Raspberry, which grows naturally in the woods in the northern parts of England, but is cultivated in gardens for its fruit, which supplies the table at the season when they are ripe. There are two or three varieties of this, one with a red, and the other a white fruit, and the third generally produces two crops of fruit annually; the first ripens in July, and the second in October, but those of the latter season have seldom much flavour. These are accidental varieties, but the fourth sort I believe to be a distinct species, for the leaves are trifoliate, larger than those of the common sort, woolly on their under side, and the branches and stalks have no thorns. This produces but few fruit, and those are small, which has occasioned its being neglected.

The Raspberry is generally propagated by suckers, though I should prefer such plants as are raised by layers, because they will be better rooted, and not so liable to send out suckers as the other, which generally produce such quantities of suckers from their roots, as to fill the ground in a year or two; and where they are not carefully taken off, or thinned, will cause the fruit to be small, and in less quantities, especially when the plants are placed near each other, which is too often the case, for there are few persons who allow these plants sufficient room.

In preparing these plants, their fibres should be shortened; but the buds, which are placed at a small distance from the stem of the plant, must not be cut off, because those produce the new shoots the following summer. These plants should be planted about two feet asunder in the rows, and four or five feet distance row from row; for if they are planted too close, their fruit is never so fair, nor will ripen so kindly, as when they have room for the air to pass between the rows. The soil in which they thrive best, is a fresh strong loam, for in warm light ground they do not produce so great plenty of fruit, for they naturally grow in cold land, and in shade; therefore when they are planted in a warm situation and a light soil, they do not succeed.

The season for dressing of them is in October, at which time all the old wood that produced fruit the preceding summer, should be cut down below the surface of the ground, and the young shoots of the same year must be shortened to about two feet in length; then the spaces between the rows should be well dug, to encourage their roots; and if you bury a very little rotten dung therein, it will make them shoot vigorously the following summer, and their fruit will be much fairer. During the summer season, they should be kept clear from weeds, which, with the before-mentioned culture, is all the management they will require; but it is proper to make new plantations once in three or four years, because when the plants are suffered to remain long, they will produce few and small fruit.

The Virginian flowering Raspberry is commonly propagated in the nurseries as a flowering shrub. The flowers of this sort are as large as small Roses, and there is a succession of them for two months or more, so that they make an agreeable variety during their continuance. This sort frequently produces fruit in England, which are not so large as those of the common sort, and have little flavour. These ripen in September, or the beginning of October.

The Virginian Raspberry rises with purplish stalks a little higher than the common sort; the leaves are of a lucid green on their upper side, but hoary on their under; their foot-stalks are taper; the fruit is shaped like those of the common Blackberry, and are of a deep black when ripe; the

the fruit has little flavour, so the plants are never cultivated for their fruit here. It ripens late in autumn.

The eighth sort grows naturally upon rocky hills in the northern counties of *England*, and most of the northern parts of *Europe*. This hath trailing herbaceous stalks, which put out roots at their joints, whereby it propagates in plenty; the leaves are trifoliate; the lobes are large, and of a lucid green; the fruit are small, so not worth cultivating.

The ninth sort grows naturally in *Norway*, *Sweden*, and *Siberia*; this hath an upright stalk about three inches high, garnished with small trifoliate leaves; the stalk is terminated by one purple flower, which is succeeded by a small red fruit, having the scent and flavour of Strawberries. This plant grows naturally upon mossy bogs, so cannot be cultivated to any purpose on dry ground, and is preserved in a few gardens for the sake of variety.

The tenth sort grows naturally upon some of the highest hills in the north of *England* and *Scotland*, also upon high boggy places in the northern parts of *Europe*. This plant cannot be transplanted into gardens so as to thrive; the stalks rise about six or eight inches high, and are generally garnished with two lobated leaves, standing at a distance from each other. The stalk is terminated by a single flower, which is succeeded by a small black fruit, not much unlike that of the Dewberry.

RUDBECKIA. *Lin. Gen. Plant.* 878. Dwarf Sunflower, *vulgò*.

The Characters are,

It hath female and hermaphrodite florets, inclosed in one common empalement, composed of two orders of leaves, the scales of which are plain, broad, and short. The rays or border of the flower is composed of female half florets, which end with two or three indentures; these have germen sitting upon proper receptacles, but have neither style or stamina, and are barren. The hermaphrodite florets are tubulous, funnel-shaped, and indented in five parts at the brim. They have five short hair-like stamina in each, terminated by cylindrical summits, and a germen sitting in the common empalement, having a slender style, crowned by a reflexed stigma, divided in two parts. The germen afterward becomes single, oblong, four-cornered seeds, crowned by their proper cup, which has four indentures.

The Species are,

1. RUDBECKIA *foliis indivisis spatulato-ovatis; radii petalis emarginatis.* *Lin. Sp. Plant.* 907. Rudbeckia with oval, spattle-shaped, undivided leaves, and the petals of the rays indented; commonly called Dwarf American Sunflower.

2. RUDBECKIA *foliis lanceolato-ovatis alternis indivisis, petalis radii bifidis.* *Flor. Virg.* 104. Rudbeckia with oval, spear-shaped, undivided leaves, placed alternate, and the petals of the ray bifid; commonly called Dwarf Carolina Sunflower.

3. RUDBECKIA *foliis inferioribus trilobis, superioribus indivisis.* *Hort. Upsal.* 269. Rudbeckia with under leaves, having three lobes, and the upper ones entire.

4. RUDBECKIA *foliis inferioribus compositis acutè dentatis, caulinis simplicibus dentatisque.* Rudbeckia with compound, indented, lower leaves, those upon the stalks single and indented.

5. RUDBECKIA *foliis omnibus quinatis, acutè dentatis exterioribus trilobatis.* Rudbeckia with all the leaves composed of five lobes, which are sharply indented, and the outer ones divided into three.

6. RUDBECKIA *foliis inferioribus compositis, caulinis quinatis ternatisque, summis simplicibus.* Rudbeckia with compound lower leaves, those on the stalks quinquifoliate and trifoliate, and the top ones single.

The first sort grows naturally in *Virginia*, and several other parts of *North America*. The root of this will continue four or five years, but unless there is care taken to

shelter it in winter, the plants are often destroyed by cold or too much wet. This sort sends out heads, by which it may be propagated; the leaves are oblong, oval, and hairy; the stalks rise a foot and a half high, having one or two leaves near the bottom. The foot-stalk which supports the flower, is naked near a foot in length, and is terminated by one pretty large yellow flower, shaped somewhat like the Sunflower, from whence it was titled Dwarf Sunflower. The petals or rays of the flower are very stiff, and slightly indented at their points; the middle or disk of the flower is very prominent, pyramidal, and of a dark purple colour. These flowers are of long duration, for I have frequently observed one flower has continued in beauty near six weeks; and as the plants produce many flowers, so there is a succession of them on the same plant, from the middle of *July* till the frost puts a stop to them, which renders the plants more valuable. This sort will sometimes produce good seeds in *England*, when the seasons are favourable; but they are generally propagated here by offsets or slips, unless when good seeds can be procured either here or from *America*. The best time to separate the offsets is in the spring, because the plants continue to flower so late in autumn, as to render it impracticable to perform it till it is late, so that the frost will set in before the slips can have taken root. The plants will live abroad in the open air through the winter, if they are planted in a dry soil and a warm situation; but it will always be prudent to shelter two or three plants under a common hot-bed frame in winter to preserve the kind, because in very severe winters those in the open air are often killed.

The second sort grows naturally in *Carolina*, and also in *Virginia*. This is a perennial plant like the former, but very rarely produces seeds in *England*; nor do the plants put out heads, whereby it may be propagated like the other, so that it is at present not very common here. The leaves of this sort are longer and broader than those of the other, and are smooth, having three veins; the foot-stalks which support the flowers are taller, and have two or three narrow leaves on each, which are placed alternate: on the top is one flower with long narrow Peach-coloured petals, which are reflexed backward; the middle or disk is very prominent, and of a dark purple colour, but the summits being of a gold colour, adds a lustre to the other. This sort may be treated in the same manner as the other; it flowers at the same season, but the flowers are not of so long duration as those of the former.

The third sort grows naturally in several parts of *North America*. This is a biennial plant, which in warm summers perfects its seeds in *England*; the lower leaves of this sort are divided into three lobes, but those upon the stalks are undivided; they are hairy, and shaped like those of the first sort; the stalks branch out on their sides, and are better garnished with leaves than either of the other. The flowers are very like those of the first sort, but smaller; the plants will live through the winter in the open air in mild seasons, and may be propagated by slips or heads; but the best way is to raise the plants from seeds, because those will flower much better than such as are procured by slips; the second year the seedling plants will flower, and produce ripe seeds.

The fourth sort grows naturally in most parts of *North America*, and has been long an inhabitant in *European* gardens, where it was generally known by the title of Sunflower. The root of this is perennial, but the stalk is annual; the lower leaves are composed of five broad lobes, which are deeply cut into acute points, some of them are jagged almost to the midrib; the outer lobe is frequently cut into three deep segments. The stalks rise seven or eight feet high, and divide upward into several branches; they are smooth, green, garnished with single leaves, which are oval,

oval, heart shaped; some of these are indented on their edges, and others are entire. The foot-stalks which sustain the flowers are naked, and terminated by a single flower with yellow petals or rays, shaped like those of the Sun-flower, but smaller. This does not produce seeds here, but is easily propagated by parting of the roots, in the same manner as the perennial Sun-flower. It is very hardy in respect to cold, but loves a moist soil.

The fifth sort has a perennial root like the former, and is a native of the same country. This hath smooth green stalks, which rise higher than those of the former; the leaves are all composed of five lobes, which are much narrower, and end with sharper points than those of the former, which are very acutely indented on their sides. The flowers are smaller, and the petals narrower than those of the former sort, but appear at the same season. It is equally hardy with the former, and may be propagated in the same way.

The sixth sort grows naturally in *North America*, and also in *Siberia*, from both which countries I have received the seeds. This hath a perennial root like the two former; the leaves at bottom are composed of seven or nine lobes, some of which are entire, and others are jagged to the midrib; they are smooth, and of a dark green; the stalks rise six feet high, and divide into many branches. They are of a purple or iron colour, very smooth, garnished with leaves, which toward the bottom are hand-shaped, composed of five lobes, and the upper have but three; those at the top are single. The flowers are smaller than those of the two former sorts, but are of the same shape and colour.

The three last mentioned sorts may be propagated in plenty, by parting of their roots; the best time for this is in *October*, when their stalks will begin to decay; for if they are removed in the spring, they will not produce many flowers the same year. They love a moist soil, and should be allowed room, for if they are too near other plants, they will rob them of their nourishment. They are proper furniture for large gardens, where they may be allowed room, or in walks round fields, because they require little culture.

RUELLIA. *Plum. Nov. Gen. 12. tab. 2.*

The Characters are,

The flower has a permanent empalement cut into five narrow acute segments at the top, which are erect. It has one petal, with a tube the length of the cup, which inclines at the neck; the brim spreads open, and is cut into five segments, the two upper being large and reflexed. It hath four stamina situated in the tube, connected in pairs, terminated by short summits, and a roundish germen, supporting a slender style, crowned by a bifid stigma. The germen afterward becomes a taper capsule, pointed at each end, having two cells, inclosing roundish compressed seeds.

The Species are,

1. RUELLIA foliis ovatis crenatis, pedunculis bifloris. Ruellia with oval crenated leaves, and foot-stalks bearing two flowers.

2. RUELLIA foliis petiolatis, floribus verticillatis subsessilibus. *Hort. Upsal. 178.* Ruellia with leaves having foot-stalks, and flowers growing in whorls fitting close to the stalks.

3. RUELLIA foliis petiolatis, pedunculis longis subdivisis nudis. *Lin. Hort. Upsal. 179.* Ruellia with leaves having foot-stalks, and long naked foot-stalks to the flowers, which are divided.

4. RUELLIA foliis subcrenatis lanceolato-ovatis, capitulis ovatis, foliolis bifidis. *Lin. Sp. Plant. 635.* Ruellia with oval spear-shaped leaves, which are somewhat crenated, oval pods, and prickly, hairy, small leaves.

The first sort grows naturally in many of the islands in the *West-Indies*; the roots of this are composed of many swelling fleshy tubers, which are like those of the Day Lily,

but smaller. The stalk rises about four or five inches high, sending out two or three short side branches, garnished with leaves placed opposite; some of these are small and shaped like a spatula, others are much larger; they have short foot-stalks, and are a little crenated on their edges. The flowers are produced on the side, and at the end of the stalk; those on the side have two flowers upon each foot-stalk, which come out opposite, but those at the top sustain three. The flowers have narrow tubes about an inch long, spreading out to a sort of bell-shape; at the top they are cut into five obtuse segments, which are large, and spread open; they are of a fine blue, but of short duration, each flower seldom lasting in beauty one day; after the flower fades, the germen becomes a taper pod one inch and a half long, having two cells, which, when ripe, burst with a touch, and cast out the seeds to a distance.

The second sort grows naturally in *Carolina*; the root of this is fibrous and perennial; the stalks rise about a foot high; they are four-cornered, and have two longitudinal furrows; the joints are three or four inches asunder, at each stand two oval leaves upon very short foot-stalks. The flowers come out from the wings of the leaves, two or three rising from the same point, sitting very close to the stalks; they are small, and of a pale purple colour, but are very fugacious; they open early in the morning, but fade by ten or eleven o'clock in the forenoon; these are succeeded by short taper pods, surrounded by the hairy segments of the empalement.

The third sort grows naturally in the *West-Indies*. This hath a perennial root, composed of many fleshy fibres; the leaves lie close to the ground; the stalks grow five or six inches high, with leaves placed by pairs at each joint, standing upon foot-stalks. The foot-stalks which sustain the flowers are naked, and divide into two smaller, each sustaining one small purple flower, which is very fugacious; their empalements are cut into very narrow segments to the bottom. After the flowers are past, the germen becomes a taper capsule about an inch long, including roundish compressed seeds.

The fourth sort grows naturally in both *Indies*; I received the seeds of this from *Carthagera* in *New Spain*. This hath a ligneous creeping root; the stalks are single, taper, and rise about five or six inches high; the leaves are oval, spear-shaped, and have very short foot-stalks; they are a little waved on their edges, are hairy, and curled. The flowers are produced from the side of the stalk, which are yellow, coming out between rough, hairy, small leaves. The seeds ripen in *September*.

These plants are propagated by seeds, which must be sown in the spring in pots, and plunged into a moderate hot-bed; when the plants come up, they must be transplanted each into a separate small pot, and plunged into a fresh hot-bed of tanners bark, and must be shaded from the sun, until they have taken new root; after which time, they must have free air admitted to them every day in warm weather. If the plants thrive well, those of the first and third sorts will produce flowers the *July* following, and will perfect their seeds in *August*; but the roots will continue, provided they are plunged into the bark-bed in the stove, and kept in a moderate temperature of heat.

The second sort is not a plant of long continuance, seldom abiding longer than two years; but if it is treated in the same manner as the two other, it will ripen seeds the second year, so may be propagated easily.

The fourth sort does not so constantly produce seeds as the three others, so is not so common in *England* at present. This requires the same treatment as the other sorts.

If the seeds of these plants are permitted to scatter in the neighbouring pots, the plants will come up without care,

fo may be transplanted into pots, and plunged into the tan-bed.

RUMEX. *Lin. Gen. Plant.* 407. Dock.

The Characters are,

The empalement of the flower is permanent. The flower has three petals, which are larger than the empalement, to which they are very like. It hath six short hair-like stamina, terminated by erect twin summits, and a three-cornered germen, supporting three hair-like reflexed styles, thrusting out of the clefts of the petals, crowned by large jagged stigmas. The germen afterward becomes a three-cornered seed, included in the petals of the flower.

The Species are,

1. RUMEX *floribus hermaphroditis, valvulis integerrimis, foliis oblongo-lanceolatis.* Dock with hermaphrodite flowers having entire valves, and oblong spear-shaped leaves; commonly called Patience Rhubarb.

2. RUMEX *floribus hermaphroditis, valvulis integerrimis graniferis, foliis cordatis obtusis.* Rumex with hermaphrodite flowers, having entire valves, bearing grains, and obtuse heart-shaped leaves; called Monks Rhubarb.

3. RUMEX *floribus hermaphroditis pedicellatis, foliis lanceolatis longissimis.* Rumex with hermaphrodite flowers growing upon small foot-stalks, and the longest spear-shaped leaves; or Water Dock.

4. RUMEX *floribus hermaphroditis, valvulis dentatis graniferis, foliis cordato-oblongis.* Hort. Cliff. 138. Rumex with hermaphrodite flowers, indented grain-bearing valves, and oblong heart-shaped leaves; or sharp-pointed Dock.

5. RUMEX *floribus hermaphroditis, valvulis integris graniferis, foliis lanceolatis undulatis acutis.* *Lin. Sp.* 335. Rumex with hermaphrodite flowers, entire grain-bearing valves, and acute, spear-shaped, waved leaves; or curled sharp-pointed Dock.

6. RUMEX *floribus hermaphroditis, valvulis integerrimis, unica granifera foliis cordato-lanceolatis.* Hort. Cliff. 138. Rumex with hermaphrodite flowers, entire valves, and heart-formed spear-shaped leaves; the bloody Dock.

7. RUMEX *floribus hermaphroditis verticillatis, valvulis acutè dentatis, foliis lanceolatis.* Rumex with hermaphrodite flowers growing in whorls, acutely-indented valves, and spear-shaped leaves; sharp-pointed Dock with a golden flower.

8. RUMEX *floribus hermaphroditis, valvulis dentatis, foliis cordato-oblongis, obtusiusculis crenulatis.* *Lin. Sp.* 335. Rumex with hermaphrodite flowers, indented valves, and blunt, oblong, heart-shaped leaves; common broad-leaved, or Butter Dock.

9. RUMEX *floribus hermaphroditis, foliis lyrtis.* Guet. *Stam.* 1. p. 7. Rumex with hermaphrodite flowers, and lyre-shaped leaves; the Fiddle Dock.

10. RUMEX *floribus hermaphroditis, valvulis dentatis graniferis, foliis linearibus.* Lech. *Scan.* 26. Rumex with hermaphrodite flowers, indented grain-bearing valves, and linear leaves.

11. RUMEX *floribus hermaphroditis pedunculis longioribus, valvulis profunde dentatis, foliis cordato-oblongis.* Rumex with hermaphrodite flowers growing upon longer foot-stalks, valves which are deeply indented, and oblong heart-shaped leaves; or Aleppo Dock.

12. RUMEX *floribus hermaphroditis, valvulis trifido setaceis, unica granifera.* Hort. Upsal. 89. Rumex with hermaphrodite flowers and bristly three-pointed valves; or annual Egyptian Dock.

13. RUMEX *floribus hermaphroditis valvulis lævibus, caule arborco, foliis subcordatis.* Vir. Cliff. 32. Rumex with hermaphrodite flowers, smooth valves, a tree like stalk, and leaves which are almost heart-shaped; Tree Sorrel.

14. RUMEX *floribus hermaphroditis, valvulis nudis dentatis*

planis reflexis. Hort. Upsal. 90. Rumex with hermaphrodite flowers, and plain, naked, indented, reflexed valves.

15. RUMEX *floribus hermaphroditis geminatis, valvularum alis maximis membranaceis reflexis, foliis indivisis.* Hort. Cliff. 130. Rumex with hermaphrodite flowers growing by pairs, very large membranaceous wings to the valves, which are reflexed, and undivided leaves.

16. RUMEX *floribus hermaphroditis distinctis, valvularum alis maximis membranaceis, foliis erosis.* Flor. Leyd. Prod. 230. Rumex with hermaphrodite flowers growing upon distinct spikes, very large membranaceous wings to the valves, and leaves appearing as if bitten.

The first sort was formerly much more cultivated in the English gardens than at present; the roots of this has been generally used for the Monks Rhubarb, and has been thought the true, but others suppose the second sort should be used as such. The root is large, and divides into many thick fibres; their outer cover is brown, but they are yellow within, with some reddish veins; the leaves are broad, long, and acute-pointed; their foot-stalks are of a reddish colour; the stalks rise six or seven feet high, and divide toward the top into several erect branches, garnished with a few narrow leaves, terminating with loose spikes of large staminate flowers. These appear in June, and are succeeded by pretty large three-cornered seeds, whose coverings are entire, which ripen in autumn.

The second sort grows naturally on the Alps, but has been long cultivated in the English gardens. This hath large roots, which spread and multiply by their offsets; they are shorter and thicker than those of the first sort, of a very dark brown on their outside, and yellow within. The leaves are of the round heart-shape, standing upon long foot-stalks. The stalks rise from two to three feet high; they are thick, and have a few small roundish leaves on the lower part, but the upper part is closely garnished with spikes of white flowers, standing erect close to the stalks. These appear the latter end of May, and are succeeded by large triangular seeds, which ripen in August.

The third sort grows naturally in ponds, ditches, and standing waters, in many parts of England; this is supposed to be the *Herba Britannica* of the ancients. It hath large roots, which strike deep into the loose mud, sending out leaves which are above two feet long, drawing to a point at each end. The stalks rise five or six feet high when the plants grow in water, but in dry land seldom more than three; these are garnished with narrow leaves among the spikes of flowers to the top. The flowers stand upon slender foot-stalks, which are reflexed; they are of an herbaceous colour, appear in June, and the seeds ripen in autumn.

The fourth sort grows naturally in moist places in many parts of England; this is the *Oxylapathum* of the shops, which is directed by the college to be used in medicine; but the markets are supplied with roots of the common Docks, which are indifferently gathered by those who collect them in the fields, where the eighth sort is much more common than this. The roots of this sort are slender and run downright, sending out a few small fibres; the stalks rise about two feet high, garnished at bottom with leaves four inches long, and one and a half broad in the middle; they are rounded at their base, where they are slightly indented, but end in acute points; they are plain, and slightly crenated on their edges. From the joints of the stalk come out alternately slender long foot-stalks, which sustain the spikes of flowers, which grow in small whorls round the stalks, at about an inch distant; these have scarce any leaves upon the foot-stalks between the whorls of flowers, so may be easily distinguished from the small Water Dock, which has many.

The fifth sort is more commonly found growing naturally about *London* than the fourth; the leaves of this are much longer than those of the former, and are indented on their sides, which are also waved; the stalks rise about the same height as those of the former. The spikes of flowers from their side are shorter, and closer garnished with flowers on pretty long foot-stalks; the covering of the seed is entire.

The sixth sort is very like the fourth in appearance, but the leaves have deep blood-coloured veins, and some small spots of the same on their surface; the stalks are red, and rise about the same height as the fourth; but the covering of the seed is entire, whereas those of the fourth are indented, so may be readily distinguished. It grows naturally in many parts of *England*.

The seventh sort grows naturally in several parts of *England*; this is a biennial plant, which perishes soon after the seeds are ripe; the stalks rise near two feet high; they are of a deep purple colour, garnished with spear-shaped leaves toward the bottom, which are four inches long, and almost one broad in the middle, but those on the upper part of the stalk are very narrow, and not more than two inches long; the spikes of flower come out from the sides of the stalks alternately. The flowers grow in thick whorls, which sit close to the stalks; these are of a bright yellow, and the covers of the seeds are sharply indented.

The eighth sort is the most common Dock by the sides of roads and banks in every part of *England*; the leaves of this sort are broad and rounded at their points, though some of them end more acutely than others; they are near a foot long, and five inches broad toward their base, having many transverse veins running from the midrib to their borders. The stalks rise from two to three feet high, branching out on their sides, having a few leaves on their lower part, of the same shape with the other, but smaller. The flowers grow in whorls, sitting very close to the stalks; some plants have indented coverings to their seed, and others have entire coverings; both these are frequently found intermixed, so that I doubt of their being distinct species. The leaves of this Dock were formerly much used for wrapping up of butter, and from thence the plant was called Butter Dock.

The ninth sort grows naturally in many places near *London*; this is a biennial plant, which perishes soon after the seeds are ripe. The stalks of this rise about a foot high, and branch out from the bottom; the leaves grow near the root; they are about two inches and a half long, and are hollowed on their sides, so as to resemble the sides of a fiddle; the stalks are generally bent at their joints. The flowers grow in whorls round the stalks, to which they fit very close; they are hermaphrodite; the covers of the seeds are sharply indented.

The tenth sort is sometimes found growing naturally in *England*, upon places where the water has stood in winter. This seldom rises more than five or six inches high, but divides into two or three branches; the leaves are about three inches long, and a quarter of an inch broad, smooth, and stand upon short foot-stalks. The flowers grow in whorls round the branches, to which they fit very close; these are succeeded by small triangular seeds, having indented covers.

The eleventh sort came originally from *Aleppo*; this is a biennial plant; the leaves are nine or ten inches long, smooth, of a light green, and three inches broad at their base, where they are indented, and end in acute points. The stalks rise from two to three feet high, sending out many branches from their sides, garnished with large whorls of herbaceous flowers, standing upon pretty long foot-stalks; these are succeeded by three-cornered seeds, whose coverings are deeply indented.

The twelfth sort grows naturally in *Egypt*; this is an an-

nual plant; the stalk rises about ten inches high, sending out a few horizontal branches toward the bottom; the leaves are about two inches long, and half an inch broad at the broadest part. The flowers grow in whorls round the stalks; they are very small, and the hair-like beards, which adhere to the covering of the seed, being long, obscure the flowers, so they are scarce visible to the naked eye.

All these sorts of Docks rise easily from seeds, and, if introduced into a garden, will become troublesome weeds, if their seeds are permitted to scatter; therefore few persons care to propagate any of them, except the two first sorts, which are cultivated for their use in medicine. The seeds of all the Docks should be sown in autumn soon after they are ripe, for those seeds which are sown in the spring, rarely grow the same year: when the plants come up, they will require no other care but to thin them where they are too close, and keep them clean from weeds. They all delight in a moist rich soil.

The thirteenth sort is commonly known among the gardeners, by the title of Sorrel-tree. This came originally from the *Fortunate*, or *Canary Islands*, but has been long an inhabitant in some *English* gardens; it rises with a ligneous stalk ten or twelve feet high, covered with a smooth brown bark, sending out many slender branches, garnished with smooth, roundish, heart-shaped leaves, standing alternately upon pretty long foot-stalks. The flowers come out in loose panicles toward the end of the branches; they are of an herbaceous colour, and are sometimes succeeded by triangular seeds with smooth covers, but they rarely ripen in *England*. This plant is easily propagated by cuttings, which may be planted in any of the summer months, in a bed of loamy earth, and shaded from the sun until they have taken pretty good root; then they should be taken up, and planted in pots, placing them in the shade till they have taken new root; after which they may be removed to a sheltered situation, among other hardy greenhouse plants, till autumn, when they must be removed into the greenhouse, and treated in the same way as other hardy kind of plants, which only want protection from frost.

The fourteenth sort is a low annual plant, which grows naturally in *Italy* and *Spain*. This is generally found on swampy moist ground; the stalks are slender, branching at the bottom, and rise about four inches high; the lower part is garnished with small, oval, succulent lobes; their upper part is furnished with small herbaceous flowers growing in whorls, and have no leaves between them; they are succeeded by small seeds, whose covers are sharply indented and reflexed. These appear in *June*, and the seeds ripen in *August*, which, if permitted to scatter, will furnish a supply of young plants the following spring; or if the seeds are then sown, the plants will come up the following spring, and require no other care but to thin them, and keep them clean from weeds.

The fifteenth sort is an annual plant; this hath pretty thick succulent stalks, which rise a foot high, and divide into many branches; the leaves are of the round heart-shaped and undivided, having very long foot-stalks. The flowers grow in loose spikes at the end of the branches; these are succeeded by large covers to the seeds, which are inflated, and have broad membranaceous borders; the seeds are triangular, and ripen in autumn.

The sixteenth sort grows naturally in *Egypt*. This is also an annual plant, whose stalks rise a foot and a half high, dividing upward into several branches; the stalks are garnished with arrow-pointed leaves about three inches long, whose sides are irregularly torn, as if they had been gnawed by insects; they stand upon pretty long foot-stalks, and have smooth surfaces; the flowers are disposed in loose spikes; some spikes have only male flowers, and others

have all hermaphrodite flowers, and some plants have only male, and others hermaphrodite flowers. The latter are succeeded by triangular seeds, inclosed in large inflated covers, of a deep red colour, having membranaceous borders. The seeds of this ripen in autumn.

The seeds of both these sorts grow very freely, if sown in a bed of light earth in the spring, where the plants are designed to remain. When they come up, they will require no other care, but to keep them clean from weeds, and thin them where they are too close.

RUSCUS. *Tourn. Inst. R. H. 79. tab. 15.* Knee-holly, or Butchers broom.

The Characters are,

It hath male and female flowers in distinct plants; the male flowers have erect spreading empalements, composed of six oval convex leaves, whose borders are reflexed; they have no petals, but an oval nectarium the size of the empalement, which is erect and inflated, opening at the mouth; they have no stamina, but each has three spreading summits, sitting on the top of the nectarium, which are joined at their base. The female flowers have empalements, but no petals, and nectariums like the male; they have no stamina, but have an oblong oval germen hid within the nectarium, supporting a cylindrical style, crowned by an obtuse stigma, standing above the mouth of the nectarium. The germen afterward becomes a globular berry with two or three cells, inclosing two globular seeds.

The Species are,

1. *Ruscus foliis supra floriferis nudis. Hort. Cliff. 465.* Ruscus with leaves which bear flowers on their upper side, and are naked; Knee-holly, or Butchers-broom.

2. *Ruscus foliis subtus floriferis nudis. Hort. Cliff. 465.* Ruscus with leaves which bear flowers beneath, and are naked.

3. *Ruscus foliis subtus floriferis sub foliolo. Hort. Cliff. 465.* Ruscus with flowers under the leaves.

4. *Ruscus racemo terminali hermaphroditico. Hort. Cliff. 469.* Ruscus with hermaphrodite flowers in long bunches, terminating the stalks.

5. *Ruscus foliis ternis ovatis acuminatis, supra floriferis nudis.* Ruscus with oval acute-pointed leaves, which are placed by threes, and flowers on their upper side.

6. *Ruscus foliis ovatis acuminatis, supra floriferis nudis, caulibus flexuosis.* Ruscus with acute-pointed leaves, bearing flowers on their upper side, and flexible stalks.

7. *Ruscus foliis margine floriferis. Hort. Cliff. 464.* Ruscus with flowers growing on the borders of the leaves.

8. *Ruscus caule fruticoso ramoso, foliis lanceolatis rigidis, floribus pedunculatis terminalibus.* Ruscus with a shrubby branching stalk, spear-shaped stiff leaves, and flowers growing upon foot-stalks, terminating the branches.

The first sort is very common in the woods in divers parts of England, and is rarely cultivated in gardens. The roots of this kind are sometimes used in medicine, and the green shoots are cut, bound into bundles, and sold to the butchers, who use it as besoms to sweep their blocks, from whence it had the name of Butchers-broom. It is also called by some Knee-holly.

This hath roots composed of many thick fibres, which twine about each other, from which arise several stiff green stalks about three feet high, sending out from their side several short branches, garnished with stiff, oval, heart-shaped leaves, placed alternately on every part of the stalk, ending with sharp prickly points. The flowers are produced in the middle on the upper side of the leaves; these are male in some, and female in other plants; they are small, and cut into six parts, of a purple colour, sitting close to the midrib; they appear in June, and the female flowers are succeeded by berries, almost as large as Cherries, of a sweetish taste, which ripen in winter, when they are of a beautiful red colour.

As this plant grows wild in most parts of England, it is rarely admitted into gardens, but, if some of the roots are planted under tall trees in large plantations, they will spread into large clumps, and, as they retain their leaves in winters, at that season they will have a good effect. The seeds of this plant generally lie a year in the ground before they vegetate, and the plants so raised are long before they arrive to a size big enough to make any figure, so it is not worth while to propagate them that way, especially as the roots may be easily transplanted from the woods. The roots and seeds of this plant have been used in medicine; the young shoots of this plant in the spring, are sometimes gathered and eaten by the poor like those of Asparagus; the branches of this plant, with their ripe fruit upon them, are frequently cut, and put into basons, mixing them with the stalks of ripe seeds of male Piony, and those of the wild Iris or Gladwyn, which together make a pretty appearance in rooms, at a season of the year when there are few flowers, and these will continue a long time in beauty.

The second sort grows naturally in the mountainous parts of Italy, but is preserved for the sake of variety in many English gardens. The roots of this have large knotty heads with long thick fibres like those of the former sort, from which arise many tough limber stalks near two feet high, garnished by stiff, oblong, oval leaves, ending in points, placed alternately on the stalks. The flowers are produced on the under surface of the leaves near the middle, sitting close to the midrib; they are small, of an herbaceous white colour; the female flowers are succeeded by small red berries, about the size of those of Juniper.

It stands in most dispensaries among the plants used in medicine, and has been commended for opening obstructions in the kidneys, and to provoke urine.

The third sort grows naturally upon shady mountains in Italy, Hungary, and other parts of Europe. The root of this is composed of many thick fibres like those of the former, from which arise many tough limber stalks, which are about ten inches high, garnished with spear-shaped leaves, having several longitudinal veins, placed for the most part alternate, but sometimes they are opposite. On the middle of the upper surface of these comes forth a small leaf of the same shape, and at the same point, from the bosom of the small leaves, come out the flowers, which are of a pale yellow colour. The female flowers are sometimes succeeded by berries almost as large as those of the first sort, which are red, and ripen in winter. This is sometimes called Bilingua, or double Tongue, from the leaves growing one out of another. It stands in dispensaries as a medicinal plant, but is rarely now used.

The fourth sort grows naturally in the Archipelago, but is frequently planted in the English gardens; it is called Laurus Alexandrina, i. e. Alexandrian Bay, and is supposed to be the plant with which the ancients crowned their victors and poets. The stalks of this being very pliable, may be easily wrought into coronets for this purpose; and the leaves of this plant having a great resemblance to those which are represented on the ancient busts, seem to confirm this opinion.

The roots of this are like those of the former species; the stalks are slender and much more pliable; they rise about four feet high, and send out many side branches, garnished with oblong acute-pointed leaves, rounded at their base, of a lucid green, placed alternately, sitting close to the branches. The flowers are produced in bunches at the end of the branches, which are hermaphrodite, of an herbaceous yellow colour, and are succeeded by berries like those of the first sort, which ripen in winter.

The fifth sort grows naturally in *Zant* and some of the other islands in the *Morea*. The roots of this are like those of the former sorts; the stalks rise about two feet high; they are slender, pliable, and garnished with oval leaves, placed by threes round the stalk, rounded at both ends, terminating in acute points. The flowers grow on the under side of the leaves, fastened to the midrib; they are naked, and have pretty long foot-stalks; the segments or petals are very narrow; the fruit I have not seen, so can give no account of it.

The sixth sort grows naturally in *Italy*, where it was discovered by Signior *Micheli* of *Florence*. The roots of this are much longer than those of the first sort; the stalks rise near five feet high, are very pliant, and send out several side branches, garnished with stiff oval leaves, ending in acute points. The flowers are produced on the upper surface of the leaves, sitting close to the midrib; they are small, of an herbaceous white colour, and are succeeded by berries, which are smaller than those of the first sort, of a pale red when ripe.

All these sorts are very hardy, and will thrive in almost any soil or situation, so are very proper for planting round the verges of close woods, or under large trees in wilderness quarters, for, as they are always green, they make a good appearance in winter, after the deciduous trees have cast their leaves; they are easily propagated by parting of their roots. The best time for this is in autumn, but, when this is performed, the roots should not be divided into small parts, because that will weaken them so much, that they will make but little figure, until they have had two or three years growth; they may also be propagated by sowing of their seeds; but this is a very tedious method, so is seldom practised.

The seventh sort sends out pliant stalks, which rise seven or eight feet high, and have several short branches proceeding from their sides, which are garnished with stiff leaves, rounded at the foot-stalk, ending in acute points. The flowers are produced in clusters on the edges of the leaves, which are white, and are succeeded by berries of a yellowish red colour, not so large as those of the first sort.

This sort is tender, and must therefore be planted in pots, and in winter removed into the green-house; but it should be placed where it may have free air in mild weather, for it only requires to be screened from frost; in the summer it must be set abroad with other hardy green-house plants. With this management the plants will send forth stems six or eight feet high, furnished with leaves from bottom to top, and will be closely set with flowers upon their edges, which make a very beautiful and odd appearance. This is also propagated by parting the roots, as the former, which should not be done very often, because, if the roots are not permitted to remain some time to get strength, they will produce but weak shoots, and very few flowers. This sort grows plentifully at *Madeira*, from whence the seeds may be procured; but they commonly remain in the ground a year before the plants come up, so should be sown in pots, and placed under a hot-bed frame in winter, to screen the seeds from the frost, and the following spring the plants will appear.

The eighth sort was discovered by the late Dr. *Houfston* growing naturally at *Carthage* in *New Spain*; this rises with shrubby stalks eight or ten feet high, which divide into many branches, garnished with stiff spear-shaped leaves, sometimes ranged in whorls round the stalks, and at others they are opposite. The flowers are produced in loose bunches at the end of the branches, standing upon slender foot-stalks; they are small, of a red colour, and shaped like those of the first sort.

This plant is tender, so must be kept in a stove during the winter, otherwise it will not live in *England*.

RUTA. *Tourn. Inst. R. H. 257. tab. 133. Rue.*

The Characters are,

The flower has a permanent empalement cut into five parts; it has four or five oval petals, which are narrow at their base, and eight or ten awl-shaped spreading stamina, the length of the petals, crowned by erect summits, with a gibbous germen having a cross furrow, supporting an erect awl-shaped style, crowned by a single stigma. The germen afterward becomes a gibbous capsule with five lobes, and five cells opening in five parts at the top, filled with rough angular seeds.

The Species are,

1. RUTA foliis decompositis, floribus octandris, staminibus corollâ longioribus. Rue with decomposed leaves, and flowers having eight stamina, which are longer than the petals; or broad-leaved Garden Rue.

2. RUTA foliis decompositis, foliolis oblongo-ovatis, staminibus corolla æquantibus. Rue with decomposed leaves, the small leaves oblong, oval, and stamina equalling the petals.

3. RUTA foliis inferioribus decompositis, foliolis linearibus, summis quinquesidis trifidisque. Rue with decomposed linear leaves below, and the upper ones five or three-pointed; or smaller wild Rue.

4. RUTA foliis decompositis, floribus decandris, marginibus petalorum ciliatis. Rue with decomposed leaves, flowers having ten stamina, and the borders of the petals of the flower hairy; or broad-leaved Aleppo Rue.

5. RUTA foliis compositis, floribus decandris, petalis florum ciliatis. Rue with compound leaves, flowers having ten stamina, and hairy petals to the flower; or narrow-leaved Aleppo Rue.

6. RUTA foliis simplicibus indivisis. *Lin. Sp. Plant. 384.* Rue with single undivided leaves.

7. RUTA caule erecto corymbose, foliis compositis, floribus decandris, staminibus corollâ longioribus. Rue with an erect corymbus stalk, compound leaves, and flowers having ten stamina, which are longer than the petals.

The first sort is the common Rue, which has been long cultivated in the gardens, and is that which is directed to be used in medicine, but of late years the second sort has so generally prevailed, as almost to supplant the first, in the gardens about *London*, that being harder than the first, is not so liable to be killed by severe frost.

This rises with a shrubby stalk to the height of five or six feet, sending out branches on every side, garnished with decomposed leaves, whose small leaves (or lobes) are wedge-shaped, of a gray colour, and have a strong odour. The flowers are produced at the end of the branches, in bunches almost in form of umbels; they are composed of four yellow concave petals, which are cut on their edges, and eight yellow stamina, which are longer than the petals, terminated by roundish summits. The germen becomes a roundish capsule, with four lobes punched full of holes, containing rough black seeds.

The second sort hath a shrubby stalk, which rises three or four feet high, sending out many branches, garnished with decomposed leaves, narrower than those of the former sort, of a bluish gray colour, and have a strong odour. The flowers grow in longer and looser bunches than the former; they have four short, concave, yellow petals, and eight short stamina of equal length with the petals. The seed-vessel is like that of the former, but smaller.

The third sort grows naturally in *Spain*. The lower leaves of this are compounded of several parts, which are joined to the midrib in the same manner as the branching winged leaves, garnished with small linear leaves, standing without order. The stalks rise from two to three feet high, branching out from the bottom, and are garnished with leaves, divided into five parts, those at the top into three, which are

are as small and narrow as those at the bottom, of a gray colour, but not so stinking as those of the other. The flowers grow at the end of the branches in loose spikes, which are generally reflexed; the petals of the flower are yellow; these are succeeded by small seed-vessels, filled with angular black seeds.

The seeds of the fourth sort came first from *Aleppo*, but has been brought from the *Cape of Good Hope*. This hath strong shrubby stalks, which rise three feet high, dividing into many branches, garnished with decomposed leaves, larger than those of the common sort, and have a stronger odour. The flowers are disposed almost in form of an umbel at the end of the branches; they have five concave yellow petals, whose borders are set with fine hairs, and ten stamina, which are of equal length with the petals. The seed-vessels of this are much larger than those of the common sort.

The fifth sort grows naturally at *Aleppo*. This hath shrubby stalks which are smaller, and do not rise so high as those of the former sort. The leaves are much narrower and grayer than those, but have the same strong odour; the flowers are smaller, having five petals, which are pretty close set with small hairs; they have ten thick stamina, five of which are alternately longer than the petals; the seed-vessels are like those of the first sort.

The sixth sort grows naturally in *Spain*. This rises with several single stalks from the root near a foot and a half high, garnished with single narrow leaves, of a yellowish green colour, placed alternately on the stalks, to which they fit very close; at the base of these come out one or two very small leaves, of the same shape and colour. The flowers grow in small clusters at the end of the stalks; they have each five oblong yellow petals, and ten stamina of equal length, terminated by awl-shaped summits.

The seventh sort rises with an erect stalk two feet high, garnished with compound leaves, whose smaller leaves are narrow, obtuse, of a grayish colour, but have not so strong an odour as the former. The upper part of the stalk divides in form of a corymbus, sustaining upon naked foot-stalks small bunches of yellow flowers, which have five concave petals, and ten stamina, which are much longer than the petals, terminated by roundish summits.

All these plants may be propagated either by sowing of their seeds, or by planting slips or cuttings, both of which must be done in the spring. The manner of propagating them from cuttings, being the same as for Lavender, *Stœchas*, and other hardy aromattick plants, need not be here repeated; if they are propagated by seeds, there needs no farther care but to dig a bed of fresh earth in the spring, making it level, then to sow the seed thereon, and rake the ground smooth; after which you must observe to keep the bed clear from weeds until the plants come up about two inches high, when they should be transplanted out into fresh beds, where they may remain for use. All these plants must have a dry soil, otherwise they are very subject to be destroyed in winter. The two *Aleppo* Rues, and the wild Rue, are somewhat tenderer than the common sort, but these will endure our ordinary winters very well in the open air, especially if they are planted on a dry soil.

The sixth and seventh sorts are tenderer than either of the other, and of shorter duration. The seeds of the seventh sort were sent me from *Gibraltar Hill*, where the plant grows naturally. This doth not ripen its seeds here, unless the summers are warm, and, in hard winters, the plants are generally killed, unless they are removed into shelter.

The sixth sort will live through the winter in the open air, provided it is planted in a poor dry soil, and the second year it will perfect seeds; but, as it is of short duration,

young plants should be annually raised to succeed the others.

All the sorts of Rue will live much longer, and are less liable to be injured by frost in winter, when they grow in a poor dry rubbishy soil, than in good ground, for in rich moist land the plants grow very vigorously in summer, and are so replete with moisture, that a small frost will kill their tender shoots; whereas in poor dry ground, their growth will not be great, but their shoots will be hard and compact, so more able to resist the cold.

RUTA CANINA. See Scrophularia.

RUTA MURARIA, Wall-rue, or white Maiden-hair.

This plant is found growing out of the joints of old walls in divers parts of *England*, where it is gathered for medicinal use, but, as it cannot be cultivated in gardens, so as to grow to advantage, I shall not say any thing more of it in this place.

RUYSCHIANA. Boerb. Ind. alt. 1. p. 172.

The Characters are,

The flower hath a permanent tubulous empalement, cut into five segments at the top, the upper one being broader and blunter than the other; it is of the lip kind, having a tube longer than the empalement. The chaps are large and swelling; the upper lip is erect, arched, and gently indented at the top; the lower lip is trifid; the two side segments are narrow, and stand erect; the middle is broad, reflexed, and indented at the point. It hath four stamina, two of which are long, situated under the upper lip; the other two are shorter, and situated just below them; they are terminated by oblong summits, fastened in the middle; it has four germen, situated at the bottom of the empalement, supporting a slender style the length of the stamina, crowned by a bifid reflexed stigma. The germen afterward becomes four oblong seeds, which ripen in the empalement.

The Species are,

1. RUYSCHIANA floribus spicatis, foliis bracteisque linearibus glabris indivisis. Ruyschiana with spiked flowers, linear leaves, and bractææ, which are smooth and undivided.

2. RUYSCHIANA floribus spicatis, foliis linearibus trifidis hirsutis. Ruyschiana with spiked flowers, and hairy, linear, three-pointed leaves.

3. RUYSCHIANA floribus axillaribus, foliis lanceolatis dentatis glabris. Ruyschiana with flowers growing at the wings of the stalks, and smooth, indented, spear-shaped leaves.

The first sort grows naturally in *Austria* and *Hungary*. This hath a perennial root, and an annual four-cornered stalk, which rises about two feet high, garnished with two smooth linear leaves. At each joint of the stalk come out two or three very narrow small leaves, of the same shape. The flowers are produced in whorled spikes at the top of the stalks, having small narrow leaves under each whorl. They have tubulous empalements cut into five segments at the top, four of which are narrow, and end in acute points; the other, which is on the upper side of the flower, is broader, and rounded at the point. The tube of the flower is longer than the empalement, is swelling, and large at the chaps; the upper lip is broad, erect, and arched over the tube; the lower lip is shorter, having two short side segments, which are erect; the middle segment is broad, rounded, indented at the point, and is reflexed back to the tube. It has four stamina, which lie close under the upper lip, arched in the same manner; two of these are as long as the style, which stands in the same position; the other two are shorter, and are situated just below the other; they are terminated by oblong summits, fastened in the middle to the stamina. The style is crowned by a bifid, reflexed, narrow stigma; the flowers appear in *June*, are of a fine blue colour, and are succeeded by four oblong seeds, which ripen in the empalement.

The second sort grows naturally in *Siberia*; this hath a perennial root. The stalks are four-cornered, hairy, rising a foot and a half high, garnished with hairy linear leaves, cut into three parts; the flowers grow in short whorled spikes at the end of the stalk, having some very narrow leaves under each whorl; the tube of the flower is longer, more equal in size than that of the former, and the middle segment of the lower lip is not so much reflexed. In other respects, the flowers are the same.

The third sort grows naturally in *Tartary*; this hath a perennial root; the stalks do not grow erect like the first, but spread nearer to an horizontal position; they have two large leaves opposite at each joint, and four smaller, two on each side between the larger; they are smooth, have sharp indentures on their edges, and stand erect. The flowers come out from the side of the stalks at the base of the leaves, two or three standing together on each side the stalk; their empalements are purple, cut into five acute segments at the top, the upper lip having three broad, and the lower two narrower. The flowers are of a paler blue than those of the first sort.

These plants are propagated by seed, which should be sown the latter end of *March*, in a bed of light earth in an open exposure; in five or six weeks after the plants will appear, when they should be carefully cleared from weeds. When the plants are about two inches high, they should be transplanted into a bed or border of light undunged earth,

observing to shade them from the sun until they have taken root; after which time they will require no farther care, but to keep them constantly clear from weeds till *Michaelmas*, when they should be removed into the places where they are designed to remain for good.

When the plants are first transplanted into the nursery-bed, they should be placed about six inches asunder every way, which will be sufficient room for them to grow the first season; this will admit of the hoe to come between the plants to destroy the weeds, which is by much a better method than pulling out the weeds by hand, and is much sooner performed. For as the hoe stirs the ground between the plants, it not only cuts down the weeds which were up and visible, but also destroys all those whose seeds were sprouted, and would have soon after appeared; so that one hoeing, if well performed, in dry weather, will more effectually destroy the weeds than two hand-weedings would do; besides, the stirring the ground is of great service to the plants.

At *Michaelmas*, when the plants are transplanted for good, they should be carefully taken up with balls of earth to their roots, and planted in the middle of the borders, intermixing them with other hardy plants of the same growth, in the pleasure-garden, where they will make a pretty appearance when they are in flower.

As these plants do not continue many years, it will be proper to raise a supply of young ones to succeed them.

SABINA. See Juniperus.

SACCHARUM. *Lin. Gen. Plant.* 68. The Sugar-cane.

The Characters are,

It hath no empalement, but a woolly down longer than the flower incloses it. The flower is bivalve; the valves are acute-pointed, concave, and chaffy. It has three hair-like stamina the length of the valves, terminated by oblong summits, and an awl-shaped germen, supporting two rough styles, crowned by single stigmas. The germen afterward becomes an oblong acute-pointed seed, invested by the valves.

We have but one Species of this genus, viz.

SACCHARUM *floribus paniculatis*. *Hort. Cliff.* 26. Sugar-cane with flowers growing in panicles.

This plant grows naturally in both *Indies*, where it is cultivated for its juice, which, when boiled, affords that sweet salt which is called Sugar.

The Canes were formerly cultivated in the south of *France* for the same purpose, but it was in small quantities only, for in sharp winters they were killed, unless they were covered, so they had only the summer for their growth, which was too short for their getting sufficient strength to produce Sugar enough to answer the expence, so the planting of these Canes there has been long discontinued; they were also planted in several parts of *Spain*, before they were introduced to *France*, and are at present cultivated in plenty in *Andalusia*, from whence great quantities of Sugar are

S A C

annually sent to *Madrid*, but there are few now planted in the other parts of *Spain*.

The root of this plant is jointed, like those of the other sorts of Cane or Reeds, from which arise four, five, or more shoots in number, proportionable to the age or strength of the root. These rise eight or ten feet high, according to the goodness of the ground in which they grow; for in some moist rich soils there have been Canes measured, which were near twenty feet long; but these were not near so good as those of middling growth, as they abounded with juice, which had but a small quantity of the essential salt in it, so that the expence of fuel and trouble of boiling, was more than the Sugar would defray. The Canes are jointed; the joints are more or less distant from each other, in proportion to the soil. The leaves are placed at each joint; the base or lower part of the leaf embraces the Cane to the next joint above its insertion, before it expands; they are three or four feet long from the joint where they unfold to their point, according to the vigour of the plant, and have a deep whitish furrow, or hollowed midrib, which is broad, prominent on the under side; the edges of the leaves are thin, and armed with small sharp teeth, which are scarce to be discerned by the naked eye, but will cut the skin of a tender hand, if it be drawn along it. The flowers are produced in panicles at the top of the stalks, composed of many spikes, which are nine or ten inches long, and are again subdivided into smaller spikes; these have long down which

which inclose the flowers, so as to hide them from sight; afterward the germen becomes an oblong-pointed seed, which ripens in the valves of the flower.

This plant is preserved by way of curiosity in several gardens in *England*, but being too tender to thrive here unless it is preserved in a warm stove, it cannot be brought to any great perfection. I have seen some of the plants growing, which were seven or eight feet high, and at the bottom as large as a common walking cane, but they have not produced their panicles of flowers here.

It is here propagated by slips taken from the sides of the older plants; those which grow near the root, and have fibres to them, will most certainly grow; so that when the shoots are produced at some distance from the ground, the earth should be raised about them, that they may put out fibres before they are separated from the mother plant. These slips should be planted in pots, and plunged into a moderate hot-bed of tanners bark; then they must be treated in the same way as other tender plants from the same countries, keeping them constantly plunged in the tan-bed in the stove, and as their roots increase in size, the plants should from time to time be shifted into larger pots; but this must be done with caution, for if they are over-potted, they will not thrive: they will require to have water frequently in warm weather, but it must not be given them in too great plenty, especially in cold weather. As the leaves of the plants decay, they should be cleared from about the stalks, for if these are left to dry upon them, it will greatly retard their growth. The stove in which this plant is placed, should be kept in winter to the same temperature of heat as for the Pine-apple, and in hot weather there should be plenty of free air admitted to the plants, otherwise they will not thrive.

I shall here subjoin some account of the method of propagating and cultivating the Sugar-cane in *America*, with some observations and experiments which have been made by a few curious persons in the *British Islands*, and shall propose some farther trials to be there made, in the culture and management of this useful plant, which are founded upon the experience I have had in the culture of some plants, which are similar in their growth with the Sugar-cane.

The land which is most proper for the growth of Sugar-canes, is such as hath a sufficient depth of soil, and is not too moist and strong, but rather light and easy to work; for although strong moist ground will produce much taller and bigger Canes than the other, yet the quantity of Sugar will be much less, not near so good, and will require a greater quantity of fuel, and a longer time to boil, before the Sugar can be made; which is also the case with all fresh land, where there has not been any Canes growing before; therefore many of the most expert planters burn their land when it is first cleared for planting of Canes, to abate its fertility; but if when land is first cleared of the wood, and the roots of bad weeds, it is sown with Indigo, which such fresh ground will produce much better than the old, or such as has been long cultivated, there may be two or three crops of this taken, which will prepare the land for the Sugar-canes, without being at the trouble of burning it; but the growing of Indigo has been so little practised in the *British Islands of America* for many years past, as to be esteemed unworthy the notice of a Sugar-planter; whereas, if they would sometimes change their crops to other species, they would soon find an advantage in the growth of their Canes; but the usual practice is to continue the Canes always upon the same land as long as it will produce them, without changing the species, or allowing the ground a fallow to rest and recover itself. By this method there are some plantations so much exhausted, as that the crop of Sugar will scarce defray the expence of culture.

Another thing should always be observed in the planting of fresh land with Canes, which is to allow them much more room than is generally done; for as the ground is strong, so there will a greater number of shoots come out from each plant, and not having room to spread at bottom, they will draw each other up to a great height, and be full of watery juice, the sun and external air being excluded from the Canes by the multiplicity of leaves, both which are absolutely necessary to ripen and prepare the salts during the growth of the Canes.

If the ground is proper for the Sugar-canes, and they are planted at a good distance from each other, the same plantation may be continued above twenty years without replanting, and produce good crops the whole time; whereas in the common method, they are generally replanted in six or seven, and in some of the poor land they are continued but two or three.

The Canes are in those warm countries propagated by cuttings or joints of proper lengths; these are from fifteen to twenty inches long, in proportion to the nearness of their joints or eyes. These cuttings are generally taken from the tops of the Canes, just below the leaves, but if they were chosen from the lower part, where they are less succulent and better ripened, they would not produce so luxuriant Canes, but their juice would be less crude, and contain a greater quantity of salts, which will be obtained by less boiling than those which are planted in the common way: this is well known to the judicious to hold true, in most kinds of vegetables, for it is by thus carefully propagating all kinds of esculent plants, either in the choice of the best seeds or cuttings, that most of the kinds have been so greatly improved of late years.

The distance which the planters usually allow to their Canes, is from three to four feet, row from row, and the hills are about two feet asunder in the rows; in each of these hills they plant from four to seven or eight cuttings, which is a very great fault, and is the cause of most of their blights so much complained of lately; for if all these grow, which is frequently the case, they rob each other of their nourishment; and if a dry season happens before they have acquired strength, they are very soon stunted in their growth, so are attacked by insects, which spread and multiply so greatly, as to cover a whole plantation in a little time; when this happens, the Canes are seldom good after, therefore it would be the better way to root them entirely up, when they are so greatly injured, for they very rarely recover this perfectly; for although the insects are not the cause of the disease, yet they confirm it, and cause it to spread.

Therefore, if instead of planting so many, there was but one good cutting planted in each hill, or to prevent miscarriage, two at most; and if both succeeded, the weakest were drawn out soon after they had taken, it will be found of great service to prevent these blights; and although the number of Canes will not be near so great from the same space of ground, yet the quantity of Sugar will be full as much, and will require little more than a fourth part of fuel to boil it.

I have been assured by two of the most sensible and judicious planters of Sugar in *America*, that they have made some experiments of the horse-hoeing culture for their Canes, which answered much beyond their expectations; one of those gentlemen told me, he planted one acre in the middle of a large piece of Canes, in rows at five feet asunder, and the hills were two feet and a half distant, and but one cutting to each hill. The ground between the rows was from time to time stirred with the horse-plough, to destroy the weeds and earth the plants; with this culture the Canes were double the size of those in the same piece,

which were cultivated in the usual way; and when the Canes were cut, those which had been thus planted and managed, were ground and boiled separately; the produce of Sugar was full as great as the best acre in the same piece, and the expence of boiling was little more than a sixth part of the other, and he sold the Sugar for six shillings *per* hundred weight more than he could get for the other.

The time for planting the Canes is always in the rainy seasons, and the sooner they are planted after the rains have began to fall, the more time they will have to get strength before the dry weather sits in; for when they have put out good roots, and are well established in the ground, they will not be so liable to suffer by the drought, as those which have but newly taken root.

The season being come for planting, the ground should be marked out by a line, that the rows of Canes may be strait, and at equal distances; but first it will be proper to divide the piece into lands of sixty or seventy feet broad, leaving intervals between each of about twenty feet; these will be found of great use when the Canes are cut, for roads in which the carriages may pass to carry off the Canes to the mill; for where there is not such provision made, the carriages are obliged to pass over the heads of the Canes, to their no small prejudice: besides, by these intervals, the sun and air will have freer passage between the Canes, whereby they will be better ripened, and their juice will be fuller of salts. The middle of these intervals may be planted with Yams, Potatoes, or other esculent plants, which may be taken off before the Canes are cut, that the passage may be clear for the carriages; but a path should be left on the sides of each land, for the more convenient riding or walking of the overseer of the plantation, to view and observe how the labour is performed.

The common method now practised in planting of the Canes is, to make a trench with the hoe, which is performed by hand; into this one negro drops the number of cuttings intended for planting, at the distance the hills are designed; these are by other negroes placed in their proper position; then the earth is drawn about the hills with a hoe; all this is performed by hand; but if the right use of ploughs was well known, the work might be much better performed, and for less than half the expence; therefore instead of making a trench with a hoe, a deep furrow is made with a plough, and the cuttings properly laid therein, the ground will be deeper stirred, and there will be more depth for placing the Canes.

If the ground is to be afterward kept clean with the horse-hoe, the rows of Canes should be planted five feet asunder, that there may be room for the horse and plough to pass between them; the distance of the hills from each other should be two feet and a half, and but one Cane should be permitted to remain in each hill. After the Canes are planted, and have made some shoots, the sooner the horse-plough is used the better will the Canes thrive, and the ground will be easier kept clean from weeds; for if these are torn up when they are young, they will presently die; whereas, when they are suffered to grow large before they are disturbed, they are with great difficulty destroyed.

As the growth of the Canes is promoted according to the cleanness of the ground, so there cannot be too much care taken to keep the Canes perfectly clear of weeds; the beginning of this work soon will render it less troublesome, and it may be performed at a less expence, than when it is neglected for some time. When this is performed with a plough, the earth in the interval should be thrown up to the rows of Canes, first on one side of the row, being careful not to disturb the roots of the Canes, as also not to bury their new shoots; and in the second operation, the earth should be turned over to the other side of the rows, with

the same care as before. By this turning and stirring of the land, it will be rendered looser, and the earthing of the plants will greatly strengthen them; so that from each hill there will be as many shoots produced, as can be well nourished, and the sun and air will have free ingress among the rows, which will be of the greatest service to the Canes.

When the Canes are from seven to ten feet high, and of a proportionable size; the skin smooth, dry, and brittle, if they are heavy; their pith gray, or inclinable to brown; the juice sweet and glutinous, they are esteemed in perfection.

The time for cutting of the Canes is usually after they have grown six months; but there should not be a fixed period for this, for in some seasons and in different soils, there will be more than a month's difference in their maturity; and those who have made the experiments of cutting their Canes before they were ripe, and letting others stand till after they were ripe, have found the Sugar made from the latter, was much finer than that of the former, though the quantity was not quite so great; however, it will always be best to let them stand till they are in perfection before they are cut, but not longer.

They have also found those Canes which are cut toward the end of the dry seasons, before the rains begin to fall, have produced better Sugar than those which are cut in the rainy seasons, when they are more replete with watery juice; there has also been much less expence of fuel to boil it, which is a material article in large plantations; therefore the better the Canes are nourished in their growth, and the more air and sun is admitted to pass between their rows, the less expence it will be in the boiling and preparing of the Sugar.

In the boiling of Sugar, they use a mixture of wood-ashes and lime, which is called Temper, without which the Sugar will not granulate. The quantity of this mixture, is proportioned to the quality of the ground on which the Canes grew.

SAFFRON. See Crocus.

SAGE. See Salvia.

SAGITTARIA. *Lin. Gen. Plant.* 946. Arrow-head.

The Characters are,

It hath male and female flowers on the same plant; the male flowers have a permanent empalement of three concave leaves; they have three roundish petals, which spread open, and many awl-shaped stamina collected into a head, terminated by erect summits. The female flowers are situated below the male; these have a three-leaved empalement, and three petals as the male, but no stamina; they have many compressed germen collected in a head, sitting upon very short styles, and have permanent acute stigmas. The germen afterward becomes oblong compressed seeds, having longitudinal borders, and are collected in globular heads.

The Species are,

1. SAGITTARIA *foliis omnibus sagittatis acutis petiolis longissimis.* Arrow-head with all the leaves arrow-pointed, and long foot-stalks.

2. SAGITTARIA *foliis sagittatis spatulisque, petiolis longioribus.* Arrow-head with arrow-pointed and spatule-shaped leaves, having longer foot-stalks.

The first sort grows naturally in standing waters in most parts of *England*; the root is composed of many strong fibres, which strike into the mud; the foot-stalks of the leaves are in length proportionable to the depth of the water in which they grow, so they are sometimes almost a yard long; they are thick and fungous; the leaves which float upon the water are shaped like the point of an arrow, the two ears at their base spreading wide asunder, and are very sharp-pointed. The flowers are produced upon long stalks, which rise above the leaves, standing in whorls round them at the joints; they have each three broad white

petals, which spread open, and in the middle is a cluster of stamina with purple summits. The flowers are succeeded by rough heads, containing many small seeds.

The second sort grows plentifully in standing waters near Paris, but has not been found wild in England. This never grows so large as the former; the leaves vary greatly, some of them are oblong, round-pointed, and shaped like a spatula; others are arrow-pointed, but these have their points less acute than those of the former; the flowers are smaller, in which it differs from the former; and as all the plants where this grows retain their difference, so it may be supposed a different species.

SALICARIA. See Lythrum.

SALICORNIA. Tourn. Cor. App. 51. tab. 485. Jointed Glasswort, or Saltwort.

The Characters are,

The flower hath a rugged, swelling, four-cornered empalement, which is permanent. It has no petal, and but one stamina the length of the empalement, crowned by an oblong twin summit, with an oblong oval germen, supporting a single style, crowned by a bifid stigma. The germen afterward becomes a single seed, inclosed in the swelling empalement.

The Species are,

1. SALICORNIA articulis apice crassioribus obtusis. Lin. Mat. Med. 8. Jointed Glasswort with thick obtuse points.

2. SALICORNIA articulis apice acutioribus, caule fruticoso ramoso. Glasswort with acute points to the joints, and a shrubby branching stalk.

The first sort grows plentifully in most of the salt marshes which are overflowed by the tides, in many parts of England. This is an annual plant, with thick succulent jointed stalks, which trail upon the ground. The flowers are produced at the ends of the joints toward the extremity of the branches, which are small, and scarce discernable by the naked eye.

The second sort grows naturally in Sheepey Island; this hath a shrubby branching stalk about six inches long; the points of the articulations are acute, the stalks branch from the bottom, and form a kind of pyramid; they are perennial, and produce their flowers in the same manner as the former.

The inhabitants near the sea coast, where these plants grow, cut them up toward the latter end of summer, when they are fully grown; and after having dried them in the sun, they burn them for their ashes, which are used in making of glass and soap. These herbs are, by the country people called Kelp, and are promiscuously gathered for use.

From the ashes of these plants is extracted the salt, called Sal Kali, or Alkali, which is much used by the chemists.

The manner of gathering and burning of these herbs, is mentioned under the article of SALSOLA, so I shall not repeat it in this place.

SALIX. Tourn. Inst. R. H. 590. tab. 364. The Sallow, or Willow-tree.

The Characters are,

It hath male and female flowers upon separate plants; the male flowers are disposed in one common imbricated katkin. The scales have each one oblong spreading flower, which has no petal, but a cylindrical nectarious gland in the center. It has two slender erect stamina, terminated by twin summits, having four cells. The female flowers are disposed in katkins as the male; these have neither petals or stamina, but an oval-narrowed germen, scarce distinguishable from the style, crowned by two bifid erect stigmas. The germen afterward becomes an oval awl-shaped capsule with one cell, opening with two valves, containing many small oval seeds, crowned with hairy down.

There are several species of this genus, which grow naturally in the northern parts of Europe, which are of no

use, being low creeping shrubs, many of them seldom rising a foot high, so are never cultivated, therefore I shall pass them over, and only enumerate those which are planted for use.

The Species are,

1. SALIX foliis lanceolatis acuminatis serratis utrinque pubescentibus, serraturis infimis glandulosis. Hort. Cliff. 473. Willow with spear-shaped, acute-pointed, sawed leaves, which are downy on both sides, and glands below the saws; or common white Tree Willow.

2. SALIX foliis serratis glabris, floribus triandris. Lin. Sp. Plant. 1015. Willow with smooth sawed leaves, and flowers having three stamina.

3. SALIX foliis serratis glabris, flosculis pentandris. Hort. Cliff. 454. Willow with smooth sawed leaves, and flowers having five stamina; or broad-leaved, smooth, sweet Willow.

4. SALIX foliis serratis ovatis acutis glabris, serraturis cartilagineis, petiolis calloso punctatis. Hort. Upsal. 295. Willow with smooth, oval, acute, sawed leaves, having cartilaginous indentures, and foot-stalks with callous punctures; or yellow Willow.

5. SALIX foliis serratis glabris lanceolatis petiolatis, stipulis trapeziformibus. Flor. Leyd. Prod. 83. Willow with smooth, spear-shaped, sawed leaves, having foot-stalks, and trapezium-shaped stipulæ; or Almon-leaved Willow.

6. SALIX foliis serratis glabris ovato-lanceolatis, petiolis dentato-glandulosis. Flor. Lapp. 349. Willow with oval, spear-shaped, smooth, sawed leaves, and indented glandules to the foot-stalk; the Crack Willow.

7. SALIX foliis serratis glabris lanceolatis, inferioribus oppositis. H. Scan. 252. Willow with smooth, spear-shaped, sawed leaves, the lower of which grow opposite.

8. SALIX foliis subintegerrimis lanceolato-linearibus longissimis acutis subtus sericeis, ramis virgatis. Flor. Suec. 813. Willow with the longest, linear, spear-shaped, acute leaves, which are almost entire, and silky on their under side, and rod-like branches.

9. SALIX foliis serratis glabris lanceolatis, omnibus alternis. Willow with smooth, spear-shaped, sawed leaves, all growing alternate; or Almond-leaved Willow, which casts its bark.

10. SALIX foliis integerrimis lanceolatis longissimis utrinque virentibus. Willow with the longest, spear shaped, entire leaves, which are green on both sides; or the least brittle Willow.

11. SALIX foliis serratis glabris lineari-lanceolatis, ramis pendulis. Hort. Cliff. 454. Willow with smooth, sawed, linear, spear-shaped leaves, and hanging branches; or the weeping Willow.

12. SALIX foliis serratis glabris lanceolato linearibus, superioribus oppositis obliquis. Flor. Leyd. 83. Willow with linear, spear-shaped, smooth, sawed leaves, the upper of which are placed obliquely opposite; or the yellow dwarf Willow.

13. SALIX foliis ovatis rugosis, subtus tomentosissimis undatis supernè denticulatis. Flor. Leyd. Prod. 83. Willow with oval rough leaves, which are waved, woolly on their under side, and indented towards the top; or the broad-leaved Willow, or Sallow.

14. SALIX foliis oblongo-ovatis acuminatis rugosis, subtus tomentosissimis. Willow with oblong, oval, acute-pointed, rough leaves, which are woolly on their under side; or common Sallow.

The first sort is the common white Willow, which is frequently found growing on the sides of rivers and ditches in many parts of England. It grows to a large size, if the branches are not lopped off; the shoots are covered with a smooth, pale, green bark; the leaves are spear-shaped; they are very white on their under side, and their upper is covered

covered with short, white, woolly hairs, though not so closely as the under; the katkins are short and pretty thick. The wood of this is very white, and polishes smooth.

The second sort grows to be a large tree, the young branches are covered with a grayish bark; the leaves are smooth, of a lucid green, eared at their base, ending in acute points, sawed on their edges, and are green on both sides; the branches grow pretty erect, and are flexible, so this is frequently planted in osier-grounds for the basket-makers. The katkins of this are long, narrow, the scales open, and are acute-pointed.

The third sort hath thick strong shoots, covered with a dark green bark; the leaves are broad, rounded at both ends, very smooth, sawed on their edges, and when rubbed have a grateful odour. It is sometimes called the Bay-leaved Willow, and at others the sweet Willow; it grows quick, and is a tree of middling size; the branches are brittle, so are not proper for many purposes.

The fourth sort has slender tough shoots, which are of a yellow colour; the leaves are oval, acute-pointed, smooth, and sawed on their edges; the saws are cartilaginous, and the foot-stalks of the leaves have callous punctures. This is very pliable, so is much planted in the osier-grounds for the basket-makers, but it never grows to a large size.

The fifth sort grows to a pretty large size; the shoots are erect, covered with a light green bark; the leaves are spear-shaped, of a lucid green on both sides, sawed on their edges, standing upon short foot-stalks; they have stipulæ in form of a trapezium, at the base of the foot-stalk. The twigs of this sort are flexible, and fit for the use of basket-makers.

The sixth sort grows to a middling size; the shoots of this are very brittle, so are unfit for the basket-makers, and are covered with a brownish bark; the leaves are of a lucid green on both sides, and sawed on their edges; the katkins are long and slender; the scales are pretty long, acute-pointed, and stand open. It is commonly called Crack Willow, from the branches being very brittle.

The seventh sort is a tree of middling size; the shoots are very pliable, and fit for the basket-makers, so is much planted in the osier-grounds; they are of a reddish colour; the leaves are spear-shaped, smooth, and sawed on their edges; those on the lower part of the branches are placed opposite, but on the upper they are alternate, and of a yellowish green.

The eighth sort makes very long shoots, but the tree seldom grows to a large size; the leaves are very long, entire, and are set close upon the branches; they are of a dark green on their upper side, but very woolly and white on their under, ending in acute points. The young branches are woolly, and their buds are very turgid. This is pretty much planted in the osier-grounds, for the use of basket-makers.

The ninth sort is a tree of middling growth; it casts its bark annually; the shoots are brittle; they have a yellowish bark; the leaves are spear-shaped, sawed on their edges; they are eared on both sides at their base, and are placed alternate, of a light green on both sides. This is not very commonly cultivated, the twigs being too brittle.

The tenth sort hath very pliant branches, so is much planted in the osier-grounds. The leaves of this are very long, spear-shaped, entire, and are green on both sides. It grows to a middling size, if planted in moist land.

The eleventh sort grows naturally in the *Levant*, but has been several years cultivated in the *English* gardens. This will grow to a middling size; the branches are long, slender, and hang down on every side, so form natural arches; the leaves are narrow, spear-shaped, smooth, and sawed on their edges. It is well known in the gardens, by the title of Weeping Willow.

The twelfth sort is a tree of lower growth; the branches of this are erect; the leaves are smooth, narrow, spear-shaped, sawed on their edges, of a dark or bluish green, and toward the upper part of the branches are placed opposite. It is found by the side of ditches, in many parts of *England*.

The thirteenth sort grows naturally upon dry land, and on high situations, but rarely is of a large size; the bark is smooth, and of a dark gray colour; the branches are brittle, so are unfit for basket-makers, but it is frequently cultivated in hedges for fuel in many parts of *England*. It is called Mountain Osier. The leaves are oval, rough, woolly, and indented toward the top. There is a variety of this in the gardens with variegated leaves.

The fourteenth sort is the common Sallow; this differs from the last, in having longer leaves, which end in acute points; they are woolly on their under side, and fit closer to the branches; these are not distinguished by the farmers, who cultivate them equally.

There are some other sorts of Willows which are planted in the osier-grounds, distinguished by the basket-makers and dealers in them, under titles they have applied to them, which are little known to others; these are annually cut down, and always kept low, but when they are not cut down, and have room to grow, will become large trees; so that they may be planted for the same purposes as the first sort, and will make a variety when intermixed with it, though they are commonly cultivated for their twigs, which produce good profit to the owners of the land.

All the sorts of Willows may be easily propagated by planting cuttings or sets, either in the spring or autumn, which readily take root. Those sorts which grow to be large trees, are cultivated for their timber, so are generally planted from sets, which are about seven or eight feet long; these are sharpened at their larger end, and thrust into the ground by the sides of ditches and banks, where the ground is moist; in which places they make a considerable progress, and are a great improvement to such estates, because their tops will be fit to lop every fifth or sixth year. This is the usual method now practised in most parts of *England*, where the trees are cultivated, as they are generally intended for present profit; but if they are designed for large trees, or are cultivated for their wood, they should be planted in a different manner, for those which are planted from sets of seven or eight feet long, always send out a number of branches toward the top, which spread, and form large heads fit for lopping; but their principal stem never advances in height, therefore where regard is paid to that, they should be propagated by short young branches, which should be put almost their whole length in the ground, leaving only two, or at most but three buds out of the ground, and, when these have made one year's shoot, they should be all cut off except one of the strongest and best situated, which must be trained up to a stem, and treated in the same way as timber trees. If these are planted with such design, the rows should be four feet asunder, and the sets two feet distance in the rows; by planting them so close, they will naturally draw each other upward, and, when they are grown so large as to cover the ground and meet, they should be gradually thinned, so as at the last to leave every other row, and the plants in the rows about eight feet asunder. If they are so treated, the trees will grow to a large size, and rise with upright stems to the height of forty feet or more.

When these cuttings are planted, it is usual to sharpen those ends to a point, which are put into the ground, for the better thrusting of them in; but the best way is to cut them horizontally just below the bud or eye, and to make holes with an iron instrument in the ground where each

cutting is to be planted, and, when they are put in, the ground should be pressed close about the cuttings with the heel to settle it; and prevent the air from penetrating to the cuttings.

The after care must be to keep them clear from weeds the two first seasons, by which time they will have acquired so much strength, as to over-power and keep down the weeds; they will also require some trimming in winter to take off any lateral shoots, which, if suffered to grow, would retard their upright progress.

There are great tracts of land in *England* fit for this purpose, which at present produce little to the owners, and might, by the planting of these trees, turn to as good account as the best Corn land. The larger wood, if found, is commonly sold to the turners for many kinds of light ware, but may be applied to many other purposes.

The Sallows are commonly planted in cuttings about three feet long, made from strong shoots of the former year; these are thrust down two feet deep into the ground. The cuttings should be placed about three feet row from row, and eighteen inches asunder in the rows, observing always to plant the rows the sloping way of the ground (especially if the tides overflow the place); because, if the rows are placed the contrary way, all the filth and weeds will be detained by the sets, which will choak them up.

The best season for planting these cuttings in the open-grounds is in *February*, for if they are planted sooner, they are apt to peel, if it proves hard frost, which greatly injures them. These plants are always cut every year, and, if the soil be good, they will produce a great crop, so that the yearly produce of one acre has been often sold for fifteen pounds, but ten pounds is a common price, which is much better than Corn land, so that it is great pity these plants are not more cultivated, especially upon moist soils, upon which few other things will thrive.

SALSOLA. *Lin. Gen. Plant.* 275. Glasswort.

The Characters are,

The empalement of the flower is permanent, composed of five oval obtuse leaves; the flower has no petals, but hath five short stamina, which are inserted in the divisions of the empalement; it hath a globular germen, with a short two-pointed style, crowned by recurved stigmas. The germen afterward becomes a globular capsule, with one cell wrapped up in the empalement, inclosing one large seed.

The Species are,

1. SALSOLA herbacea, foliis subulatis mucronatis, calycibus ovatis axillaribus. *Lin. Sp. Plant.* 222. Herbaceous Salsola with awl-shaped sharp-pointed leaves, and oval empalements proceeding from the sides of the stalks.

2. SALSOLA herbacea, foliis linearibus mucronatis, calycibus obtusis axillaribus. Herbaceous Salsola with linear acute-pointed leaves, and obtuse empalements proceeding from the sides of the stalks.

3. SALSOLA herbacea, foliis inermibus. *Cuett. Stamp.* 426. Herbaceous Salsola with smooth leaves.

4. SALSOLA frutescens, foliis ovatis acutis carnosis. *Lin. Sp. Plant.* 223. Shrubby Salsola with oval, fleshy, acute-pointed leaves.

5. SALSOLA herbacea, foliis subulatis mucronatis, calycibus explanatis. *Lin. Sp. Plant.* 222. Herbaceous Salsola with pointed awl-shaped leaves, and spreading empalements.

The first sort grows naturally in the salt marshes in divers parts of *England*. It is an annual plant, which rises about five or six inches high, sending out many side branches, which spread on every side, garnished with short awl-shaped leaves, which are fleshy, and terminate in acute spines. The flowers are produced from the side of the branches, to which they sit close, and are encompassed by short prickly leaves; they are small, of an herbaceous colour. The seeds

are wrapped up in the empalement of the flower, and ripen in autumn, soon after which the plants decay.

The second sort grows naturally on the sandy shores of the south of *France*, *Spain*, and *Italy*. This is also an annual plant, which sends out many diffused stalks, garnished with linear leaves an inch long, ending with sharp spines. The flowers come out from the side of the stalks in the same manner as those of the former; their empalements are blunt, and not so closely encompassed with leaves as those of the other.

The third sort rises with herbaceous stalks near three feet high, spreading wide. The leaves on the principal stalk, and those on the lower part of the branches, are long, slender, and have no spines; those on the upper part of the stalk and branches are slender, short, and crooked. At the base of the leaves are produced the flowers, which are small, and hardly perceptible; the empalement of the flower afterward encompasses the capsule, which contains one coheated seed.

The fourth sort grows naturally in *Spain*. This hath shrubby perennial stalks, which rise three or four feet high, sending out many side branches, garnished with fleshy, oval, acute-pointed leaves, coming out in clusters from the side of the branches; they are hoary, and have no stiff prickles. The flowers are produced from between the leaves toward the ends of the branches; they are so small as scarce to be discerned, unless they are closely viewed. The seeds are like those of the other kinds.

The fifth sort grows naturally in *Tartary*. This is an annual plant, whose stalks are herbaceous, and seldom rise more than five or six inches high. The leaves are awl-shaped, ending in acute points; the empalements of the flowers spread open; the flowers are small, and of a Rose colour, but soon fade; the seeds are like those of the other sorts.

All the sorts of Glasswort are sometimes promiscuously used for making the Sal Alkali, but it is the third sort which is esteemed best for this purpose. The manner of making it is as follows: Having dug a trench near the sea, they lay laths across it, on which they lay the herb in heaps, and, having made a fire below, the liquor, which runs out of the herbs, drops to the bottom, which at length thickening becomes Sal Alkali, which is partly of a black, and partly of an Ash-colour, very sharp and corrosive, and of a saltish taste. This, when thoroughly hardened, becomes like a stone, and is there called Soude or Sode. It is transported from thence to other countries for making of glass.

SALVIA. *Tourn. Inst. R. H.* 180. tab. 83. Sage.

The Characters are,

The empalement of the flower is tubulous, of one leaf, large at the mouth, where it is cut into four parts. The flower is of the lip kind, of one petal; the lower part is tubulous, the upper is large and compressed; the lower lip is broad and trifid. It has two short stamina, which stand transverse to the lip, and are fixed in the middle to the tube, to whose tops are fixed glands, upon the upper side of which sit the summits; it has a four-pointed germen, supporting a long slender style, situated between the stamina, crowned by a bifid stigma. The germen afterward becomes four roundish seeds, which ripen in the empalement.

The Species are,

1. SALVIA foliis lanceolatis-ovatis integris crenulatis, floribus verticillato-spicatis. Sage with spear-shaped, oval, entire leaves, which are slightly crenated on their edges, and flowers growing in whorled spikes.

2. SALVIA foliis infimis cordatis, summis oblongo-ovatis serratis tomentosis, floribus verticillato-spicatis. Sage with heart-shaped lower leaves, the upper of which are oblong, oval,

oval, sawed, and woolly, and flowers growing in whorled spikes.

3. *SALVIA foliis lanceolatis sæpius articulatis subtus tomentosis, floribus spicato-verticillatis, calycibus ventricosis.* Sage with spear-shaped leaves, which are frequently eared, and woolly on their under side, flowers growing in whorled spikes, and bellied empalements; commonly called Sage of Virtue.

4. *SALVIA foliis lineari-lanceolatis integerrimis tomentosis, floribus spicatis calycibus brevissimis ventricosis acutis.* Sage with linear, spear-shaped, woolly, entire leaves, spiked flowers, and the shortest bellied empalements, ending in acute points.

5. *SALVIA foliis infimis pinnatis, summis ternatis rugosis, floribus spicatis, caule fruticoso tomentoso.* Sage with winged lower leaves, the upper ones trifoliate and rough, flowers growing in spikes, and a shrubby woolly stalk.

6. *SALVIA foliis lanceolato-ovatis integris crenulatis, floribus spicatis, calycibus obtusis.* Hort. Cliff. 12. Sage with spear-shaped, oval, entire leaves, which are slightly crenated, spiked flowers, and blunt empalements.

7. *SALVIA foliis compositis pinnatis.* Hort. Cliff. 13. Sage with compound winged leaves.

8. *SALVIA foliis infimis pinnatis, summis simplicibus crenatis, floribus verticillatis caulibus procumbentibus hirsutissimis.* Sage with winged lower leaves, the upper ones single and crenated, flowers growing in whorls, and the most hairy trailing stalks.

9. *SALVIA foliis cordatis obtusis crenatis subtomentosis, corollis calyce angustioribus.* Lin. Sp. Plant. 25. Sage with heart-shaped, blunt, crenated leaves, which are somewhat woolly, and the petals narrower than the empalement.

10. *SALVIA foliis subrotundis integerrimis, basi truncatis dentatis.* Hort. Cliff. 13. Sage with roundish entire leaves, which are torn, and indented at their base.

11. *SALVIA foliis subrotundis serratis, basi truncatis dentatis.* Hort. Cliff. 13. Sage with roundish sawed leaves, which are torn, and indented at their base.

12. *SALVIA foliis oblongo-ovatis integerrimis, calycibus patulis coloratis.* Tab. 225. fig. 2. Sage with oblong, oval, entire leaves, and spreading coloured empalements.

The first sort is the common large Sage, which is cultivated in gardens, of which there are the following varieties: 1. The common green Sage. 2. The Wormwood Sage. 3. The green Sage with a variegated leaf. 4. The red Sage. 5. The red Sage with a variegated leaf; these are accidental variations, and therefore are not enumerated as species. The common Sage grows naturally in the southern parts of *Europe*, but is here cultivated in gardens for use; but that variety, with red or blackish leaves, is the most common in the *Englifo* gardens, and the Wormwood Sage is in greater plenty here than the common green-leaved Sage, which is but in few gardens. The common Sage is so well known, as to require no description.

The second sort is generally titled Balsamick Sage by the gardeners. The stalks of this do not grow so upright as those of the common Sage; they are very hairy, and divide into several branches, which are garnished with broad, heart-shaped, woolly leaves, standing upon long foot-stalks; they are sawed on their edges, and their upper surfaces are rough; the leaves, which are upon the flower-stalks, are oblong and oval, standing upon shorter foot-stalks, and are very slightly sawed on their edges; the flowers grow in whorled spikes toward the top of the branches; the whorls are pretty far distant, and but few flowers in each; they are of a pale blue, about the size of those of the common sort. This Sage is preferred to all the others for making tea.

The third sort is the common Sage of Virtue, which is also well known in the gardens and markets. The leaves

of this are narrower than those of the common sort; they are hoary, and some of them are indented on their edges toward the base, which indentures have the appearance of ears. The spikes of flowers are longer than those of the two former sorts, and the whorls are generally naked, having no leaves between them. The flowers are smaller, and of a deeper blue than those of the common red Sage.

The fourth sort grows naturally in *Spain*. The leaves of this are very narrow and entire, standing in clusters on the side of the stalks; they are very hoary, and the branches are covered with a hoary down; the leaves on the upper part of the stalk are narrower than those of *Rosemary*; the flowers grow in closer spikes than either of the former, and are of a light blue colour.

The fifth sort grows naturally about *Smyrna*, from whence the late Dr. *William Sherard* sent the seeds. This rises with a shrubby stalk four or five feet high, and divides into several branches, which grow erect. The leaves on the lower branches are winged, being composed of two or three pair of small lobes, terminated by one large one. Those which grow on the flowering branches are trifoliate, the two inner lobes being small, and the outer one is large, ending in a point; they have the flavour of *Wormwood*, and their upper surface is rough. The flowers grow in long spikes at the end of the branches; the whorls are pretty close to each other, and have no leaves between them; the flowers are large, of a flesh colour.

The sixth sort grows naturally in *Crete*. This hath a shrubby stalk, which rises four or five feet high, dividing into several branches, garnished with spear-shaped, oval, woolly leaves, which are entire, and slightly crenated on their edges. The flowers grow in spikes at the end of the branches; they are of a pale blue colour, and have obtuse empalements. The branches of this Sage have often punctures made in them by insects, at which places grow large protuberances as big as Apples, in the same manner as the galls upon the Oak, and the rough balls on the Briar.

The seventh sort grows naturally in the *Levant*. This is an annual plant with trailing stalks. The leaves on the lower part of the stalks are composed of two or three small pair of lobes, terminated by one large one; those farther up are trifoliate, the outer lobe being four times the size of the side ones. The flowers grow in whorls round the stalks; they are large, and of a deep blue colour, as are also their empalements.

The eighth sort grows naturally about *Smyrna*, where the late Dr. *Sherard* gathered the seeds. This is a perennial plant with trailing stalks, which grow near two feet long, garnished toward the bottom with leaves, composed of two pair of small lobes, terminated by a large one, but those toward the top are single, and stand opposite. The flowers are produced in whorls round the stalks; they are large, and of a flesh colour, but are not succeeded by seeds here.

The ninth sort grows naturally at *Mexico*. This is an annual plant, which rises with an erect, four cornered, branching stalk three feet high, garnished with large heart-shaped leaves, of a bright green colour, which are obtusely crenated on their edges, having several veins on their lower side, which diverge from the midrib to the sides. Their foot-stalks are long and slender; the flowers are produced in close spikes at the end of the branches; they are of a fine blue colour, and their tubes are narrower than the empalement.

The tenth sort grows naturally at the *Cape of Good Hope*. This rises with a shrubby stalk seven or eight feet high, covered with a light-coloured bark, sending out branches the whole length, which grow almost horizontally; they are garnished with roundish gray leaves, which are entire, and seem torn at their base, where they are also indented.

The flowers are produced in thick short spikes at the end of the branches; they are very large, and of a dark gold colour.

The eleventh sort grows naturally at the *Cape of Good Hope*. This rises with a shrubby stalk four or five feet high, dividing into branches, garnished with oval sawed leaves of a gray colour, which have one or two indentures at their base that seem torn. The flowers come out in whorls toward the end of the branches; they are of a fine blue colour, and larger than those of the common Sage; these appear in succession most of the summer months, and those which come early, are often succeeded by seeds, which ripen in autumn.

The twelfth sort has been lately raised in the *Dutch gardens* from seeds, which were brought from the *Cape of Good Hope*. It has great resemblance to the former, but the branches are stronger and grow more erect; the leaves are longer, and not so broad; their edges are not sawed; the flowers grow in long loose spikes at the end of the branches; they are larger, and of a paler blue than the other; their empalements are broader, spread wider, and are of a pale blue colour, in which consists their difference.

All the sorts of Sage may be propagated by seeds, if they can be procured; but, as some of them do not perfect their seeds in *England*, and most of the sorts, but especially the common kinds for use, are easily propagated by slips, it is not worth while to raise them from seeds. The slips should be planted the beginning of *April* on a shady border, where, if they are now and then refreshed with water, if the season should prove dry, they will soon take root. When the slips have made good roots, they may be taken up with balls of earth to their roots, and transplanted where they are to remain, which should always be upon a dry soil, and where they may have the benefit of the sun, for if they are planted on a moist soil, or in a shady situation, they are very subject to be destroyed in winter; nor will these plants endure the cold so well, when planted upon a rich soil, as those which have a barren, dry, rocky soil, which is the case of most of the verticillate plants, for these will often grow upon walls, where, although they are more exposed to the cold than those plants in the ground, they are always found to remain in severe winters when the others are destroyed. The side shoots and tops of these plants may be gathered in the summer, and dried, if designed for tea, otherwise they are best taken green from the plants for most other uses. The roots of the common sorts of Sage will last several years, if they are in a dry warm soil, but, where they are often cropped for use, the plants will become ragged, so there should be a succession of young ones raised every other year.

The fifth, sixth, and eighth sorts, are somewhat tender, so will not live through the winter in the open air in *England*; therefore these must be planted in pots, and in winter must be removed under a hot-bed frame, that they may have a great share of fresh air whenever the season is mild, for if they are too much drawn, they seldom flower well, and make but an indifferent appearance. In summer they must be exposed amongst other exotick plants in some well-sheltered situation, for they are pretty hardy, and only require to be sheltered from the frost. These plants must be often refreshed with water in warm weather, otherwise they will shrivel and decay, and they should be new-potted at least twice every summer, because their roots will greatly increase, which, if confined in the pots too long, will turn mouldy, and decay.

The seventh and ninth sorts are annual plants, so are only propagated by seeds; these may be sown upon a bed of light earth in the places where they are to remain. The seeds of the seventh sort should be sown in autumn,

and then the plants will come up the following spring, but, if they are kept out of the ground till spring, the plants will not come up till the next year. Those of the ninth sort may be sown the beginning of *April* upon a warm border, where the plants will appear in *May*, and require no other care but to thin them where they grow too close, and keep them clean from weeds, and, if they should grow tall, they must be supported, otherwise the strong winds will break them down; but the seventh sort spreads its branches upon the ground, so will require no support, therefore this only requires to have room, and to be kept clean from weeds.

The tenth, eleventh, and twelfth sorts are natives of a warmer country, so these require protection in winter; they are easily propagated by cuttings in the spring and summer months. If these are planted early in the spring, it will be the better way to plant them in pots, which should be plunged into a very moderate hot-bed, and, if they are shaded from the sun in the heat of the day, and gently refreshed with water, they will put out good roots in about two months, when they should be inured gradually to the open air, into which they should be removed soon after. The cuttings which are raised early in the season, will become strong plants before winter, so will be in a better condition to resist the cold than those which are weak.

If the cuttings are planted in summer, they will require no artificial heat, so that if these are planted on a bed of fresh loamy earth, and covered close down with a bell or hand-glass, and shaded from the sun in the heat of the day, giving them now and then a little water, they will take root freely, and when they begin to shoot, they should have free air admitted to them by raising the glass on one side, and so gradually exposed to the open air. When the cuttings are well-rooted, they should be each transplanted into a separate small pot, and placed in a shady situation till they have taken new root; then they may be removed to a sheltered situation, where they may remain till the approach of frost, when they must be carried into shelter, and in winter treated in the same manner as other hardy green-house plants, which only require protection from frost, observing not to over-water them during the cold weather, but in summer, when they are in the open air, they will require it often.

SALVIA AGRESTIS. See *Teucrium*.

SAMBUCUS. *Tourn. Inst. R. H. 606. tab. 376.* The Elder-tree.

The Characters are,

The flower has a small permanent empalement of one leaf, cut into five parts; it has one concave wheel-shaped petal cut into five obtuse segments at the brim, which are reflexed, and five awl-shaped stamina the length of the petal, terminated by roundish summits, with an oval germen situated under the flower, having no style, in room of which is a swelling gland, crowned by three obtuse stigmas. The germen afterward becomes a roundish berry with one cell, including three angular seeds.

The Species are,

1. SAMBUCUS caule arboreo ramoso, floribus umbellatis. *Flor. Leyd. Prod. 243.* Elder with a branching tree-like stalk, and flowers growing in umbels; or common Elder with black berries.

2. SAMBUCUS foliis pinnatifidis, floribus umbellatis, caule fruticoso ramoso. Elder with wing-pointed leaves, flowers growing in umbels, and a shrubby branching stalk; commonly called Parsley-leaved Elder.

3. SAMBUCUS racemis compositis ovatis, caule arboreo. *Lin. Sp. Plant. 270.* Elder with oval compound bunches of flowers, and a tree-like stalk; or red-berryed Mountain Elder.

4. *SAMBUCUS caule herbaceo ramoso, foliolis dentatis.* Tab. 226. Elder with a branching herbaceous stalk, and the small leaves indented; or dwarf Elder.

5. *SAMBUCUS caule herbaceo ramoso, foliolis linearilanceolatis acutè dentatis.* Elder with an herbaceous branching stalk, and linear spear-shaped lobes, which are sharply indented; dwarf Elder with a cut leaf.

6. *SAMBUCUS cymis quinquepartitis, foliis subpinnatis.* Lin. Sp. Plant. 269. American Elder with leaves almost winged.

The first sort here mentioned is the common Elder, which is so well known as to need no description. Of this there are the following varieties, *viz.* The white and green-berried Elder, and the variegated-leaved Elder. The latter is undoubtedly a variety, but I much doubt if the white is not a distinct species, for the lobes of the leaves are much less, and very slightly sawed on their edges, whereas those of the common sort are deeply sawed; they are also smoother, and of a lighter green; the plants which have been raised from the berries, have not altered, so there is great reason for supposing them different species; but as I have made but one trial of this, I am unwilling to determine upon a single experiment, but shall leave it as a doubt till further trial is made.

The second sort is generally titled Parsley-leaved Elder by the gardeners; this is by some supposed to be only a variety of the first, but there can be little reason for doubting of its being a distinct species. The lobes of these leaves are narrower than those of the first, and are cut into several fine segments; these are again deeply indented on their edges regularly, in form of winged leaves. The stalks of this are much smaller than those of the first, and the shoots are short; the leaves have not so strong an odour, and their berries are a little smaller.

The third sort grows naturally upon the mountains in *Germany* and *Italy*. This sends up many shrubby stalks from the root, which rise ten or twelve feet high, which divide into many branches, covered with a brown bark; the leaves come out opposite; those on the lower part of the branches are composed generally of two pair of lobes, terminated by an odd one; these are shorter and broader than those of the common Elder, and are deeply sawed on their edges; the leaves on the upper part of the branches have frequently but three lobes; they are of a pale green colour, and pretty smooth. The flowers come out at the end of the shoots in oval bunches, which are composed of several smaller; they are of an herbaceous white colour, and are succeeded by berries, which are red when ripe.

The fourth sort grows naturally in many of the midland counties in *England*, where it is frequently a troublesome weed in the fields; this is called dwarf Elder, Danewort, and Walwort. It hath creeping roots, which spread far in the ground, so propagates very fast where-ever the plant once gets possession; the stalks are herbaceous, and rise from three to five feet high, in proportion to the goodness of the ground, and send out a few side branches toward the top, garnished with winged leaves, composed of six or seven pair of narrow lobes, terminated by an odd one, of a deep green, a little indented on their edges. The flowers grow in umbels at the top of the stalks; they are of the same form with those of the common Elder, but smaller, and are spotted with red. These are succeeded by black berries like those of the common Elder, but smaller.

This plant is frequently used in medicine; it purges serous watery humours by stool, and is therefore much recommended for the dropsy, in which disorder I have known the juice of this plant perform wonders in a short time; it was administered three times a week, two spoonfuls was the dose given at each time. It is also accounted a good medicine for the gout, and scorbutick disorders. The young

shoots of the common Elder are frequently sold for this in the markets, from which it may be easily distinguished, by the number and shape of the lobes on each leaf: the common Elder has seldom more than five lobes, which are broader and much shorter than those of the dwarf Elder, and are pretty deeply sawed on their edges; but the leaves of the dwarf Elder have nine, eleven, or thirteen lobes to each leaf, which are long, narrow, and very slightly indented on their edges.

The roots of the fifth sort do not creep so much in the ground as those of the fourth; the stalks are herbaceous, but do not rise so high, and are closer garnished with leaves, which have seldom more than seven lobes to each, and toward the top of the stalks but five; these are long and narrower than those of the former, and are deeply cut on their edges, ending with winged acute points. The flowers are produced in umbels at the top of the stalks, which are shaped like those of the former, and are succeeded by the like berries.

The sixth sort grows naturally in *Canada*, and several other parts of *North America*, where it grows as large as our common Elder. This sort, when young, and the shoots are full of sap, is tender, so that the frost often kills them almost to the ground; but when the plants become woody, they are rarely hurt. The leaves of this are narrower than those of the common Elder, and are composed of many more pinnæ; the berries are also smaller, in which the difference chiefly consists.

The three first and sixth sorts may be easily propagated from cuttings, or by sowing their seeds; but the former being the most expeditious method, is generally practised. The season for planting of their cuttings is any time from *September* to *March*; in the doing of which, there needs no more care than to thrust the cuttings about six or eight inches into the ground, and they will take root fast enough, and may afterwards be transplanted where they are to remain, which may be upon almost any soil or situation; they are extreme hardy, and if their seeds are permitted to fall upon the ground, they will produce plenty of plants the succeeding summer.

The first sort is often planted for making fences, because of the quick growth; but as the bottom becomes naked in a few years, it is not so proper for that purpose; neither would I recommend it to be planted near habitations, because at the season when it is in flower, it emits such a strong scent, as will occasion violent pains in the heads of those who abide long near them; besides, the crude parts which are continually perspired through the leaves, are accounted unwholesome, though the leaves, bark, and other parts, are greatly esteemed for many uses in medicine.

The fourth sort propagates itself fast enough where-ever it is once planted, by its creeping roots, so that it is very difficult to keep it within bounds, therefore is not a proper plant for gardens; but those who are inclined to keep it for medicinal use, need only plant one or two of the roots in any abject part of a garden or field, and the place will soon be spread over with it.

The fifth sort is preserved in botanick gardens for the sake of variety, but is seldom admitted into other gardens. This propagates by the root, though not so fast as the other.

The common Elder will grow upon any soil, or in any situation; the trees are frequently seen growing on the top, and out of the side of old walls; and they are often seen growing close to ditches, and in very moist places, so that where-ever the seeds are scattered, the plants will come up, as they often do from the hollow of another tree. The leaves and stalks of this plant are so bitter and nauseous, that few animals will browse upon it. I have often seen the trees growing in parks, where there has been variety

of animals, and have observed they were untouched, when almost all the other trees within reach have been cropped by the cattle.

The young shoots of this tree are strong and very full of pith, but as the trees grow old, their wood becomes very hard, and will polish almost as well as that of the Box-tree, so is often used for the same purposes, when Box-wood is scarce.

The bark, leaves, flowers, and berries of this tree, are used in medicine. The inner bark is esteemed good for dropfies; the leaves are outwardly used for the piles and inflammations. The flowers are inwardly used to expel wind, and the berries are esteemed cordial and useful in hysteric disorders, and are frequently put into gargarisms for sore mouths and throats.

SAMOLUS. *Tourn. Inst. R. H.* 143. tab. 60. Round-leaved Water Pimpernel.

The Characters are,

The empalement of the flower is permanent, erect, and cut into five segments. It has one petal, with a short spreading tube; the brim is plain, obtuse, and cut into five parts. It has five short stamina placed between each segment of the petal, terminated by summits which join together. The germen is situated under the flower, supporting a slender style, crowned by a headed stigma. The germen afterward becomes an oval capsule with one cell, cut half through into five valves, filled with small oval seeds.

We have but one Species of this plant, which is,

SAMOLUS *valerandi*. *J. B.* Round-leaved Water Pimpernel.

This plant grows wild in swampy places, where the water usually stands in winter, and is seldom preserved in gardens. It is an annual plant, which flowers in June, and the seeds are ripe in August; at which time, whoever hath a mind to cultivate this plant, should sow the seeds on a moist soil, where the plants will come up, and require no father care, but to keep them clear from weeds.

SAMYDA. *Lin. Gen. Plant.* 525.

The Characters are,

The flower has a rough bell shaped empalement of one leaf, which is cut at the brim into five points. It has no petal, but has fifteen short awl-shaped stamina, inserted in the empalement, terminated by oval summits, and a hairy globular germen, supporting a cylindrical style, crowned by a headed stigma. The germen afterward becomes an oval berry with four furrows, having four cells, including many kidney-shaped seeds, immersed in the oval receptacle.

The Species are,

1. SAMYDA *foliis ovatis serratis, floribus axillaribus*. Samyda with oval sawed leaves, and flowers growing from the wings of the stalks.

2. SAMYDA *foliis compositis pinnatis*. Samyda with compound winged leaves.

These plants grow naturally in the *West-Indies*; the first sort rises with a shrubby stalk five or six feet high, sending out several weak branches, garnished with oval leaves drawing to a point, sawed on their edges, of a light green colour. The flowers come out from the wings of the leaves upon short foot-stalks; they have a five-leaved empalement, which is of a bright-red within; the stamina, which are about fifteen in number, are inserted in the middle of the empalement, and stand erect; in the center is situated an oval germen, which turns to a berry with four cells, containing small seeds.

The other sort has leaves shaped like those of the Walnut-tree, but are smaller, and the inside of the empalement is of a purple colour, in which it differs from the first.

These plants are propagated by seeds, which must be procured from the countries where they naturally grow;

these must be sown upon a hot-bed in the spring, and when the plants come up, they must be planted in small pots, and plunged into a hot-bed of tanners bark, and treated in the same way as other tender plants from the same countries. They must be always kept in the bark-bed in the stove, otherwise they will make but little progress in *England*.

SANGUINARIA. *Dill. Hort. Elth.* 252. Puccoon.

The Characters are,

The empalement of the flower is composed of two oval concave leaves, which fall away. It hath eight oblong, obtuse, spreading petals, which are alternately narrow. It has many single stamina, which are shorter than the petals, terminated by single summits, and an oblong compressed germen, having no style, crowned by a permanent thick stigma, with two channels. The germen becomes an oblong bellied capsule with two valves, pointed at both ends, inclosing round acute-pointed seeds.

We have but one Species of this genus, viz.

SANGUINARIA. *Hort. Cliff.* 202. Puccoon.

There are some other varieties of this plant mentioned in the *Eltham* garden, but they are not distinct species, for they vary annually, therefore it is to no purpose to mention their variations.

It is a native of most of the northern parts of *America*, where it grows plentifully in the woods; and in the spring, before the leaves of the trees come out, the surface of the ground is, in many places, covered with the flowers, which have some resemblance to our Wood Anemone, but they have short naked pedicles, each supporting one flower at the top. Some of these flowers will have ten or twelve petals, so that they appear to have a double range of leaves, which has occasioned their being termed double flowers; but this is only accidental, the same roots in different years producing different flowers. The roots of this plant are tuberous, and the whole plant has a yellow juice, which the *Indians* use to paint themselves with.

This plant is hardy enough to live in the open air in *England*, but it should be planted in a loose soil and a sheltered situation, not too much exposed to the sun. It is propagated by the roots, which may be taken up and parted every other year; the best time for doing of this is in September, that the roots may have time to send out fibres before the hard frost sets in. The flowers of this plant appear in April, and when they decay, the green leaves come out, which will continue till *Midsummer*; then they decay, and the roots remain unactive till the following autumn; so that unless the roots are marked, it will be pretty difficult to find them, after their leaves decay, for they are of a dirty brown colour on the outside, so are not easily distinguished from the earth.

SANGUIS DRACONIS. See Palma.

SANGUISORBA. *Lin. Gen. Plant.* 136. Burnet.

The Characters are,

The empalement of the flower is composed of two short leaves placed opposite, which fall away. The flower hath one plain petal, cut into four obtuse segments, which join at their base. It has four stamina the length of the petal, terminated by small roundish summits, and a four-cornered germen, situated between the empalement and petal, supporting a short slender style, crowned by an obtuse stigma. The germen afterward turns to a small capsule with two cells, filled with small seeds.

The Species are,

1. SANGUISORBA *spicis ovatis*. *Hort. Cliff.* 39. Sanguisorba with oval spikes; or greater Burnet.

2. SANGUISORBA *spicis cylindricis, foliolis cordato-oblongis, rigidis, serratis*. Sanguisorba with cylindrical spikes, the lobes of the leaves oblong, heart-shaped, stiff, and sawed.

3. SANGUISORBA *spicis orbiculatis compactis*. Sanguisorba with round compact spikes.

4. SANGUI

4. *SANGUISORBA spicis longissimis*. Hort. Cliff. 39. Sanguisorba with the longest spikes; or greatest Canada Burnet.

The first sort grows naturally in moist meadows in divers parts of England. The stalks of this rise from two to three feet high, branching toward the top, and are terminated by thick oval spikes of flowers, of a grayish brown colour, which are divided into four segments almost to the bottom. These are succeeded by four oblong cornered seeds. The leaves of this sort are composed of five or six pair of lobes placed along a midrib, terminated by an odd one; they are thin, sawed on their edges, and a little downy on their under side.

The second sort grows naturally in Piedmont. This rises with stiff upright stalks more than three feet high, branching out toward the top, each branch being terminated by a cylindrical spike of brown flowers, shaped like those of the former sort, but smaller. The leaves are long, their foot-stalks are very strong, and much longer than those of the first sort; the leaves have seven or eight pair of stiff lobes, terminated by an odd one; these are heart-shaped, deeply sawed on their edges, of a lucid green on their upper side, but pale on their under, having pretty long foot-stalks, at the base of which come out two small roundish leaves or ears, which are deeply indented. This retains its difference when propagated by seeds, so is undoubtedly a distinct species.

The leaves of the third sort are smaller than those of the first, having but four pair of lobes to each, terminated by an odd one; they are bluntly sawed on their edges, and have very short foot-stalks, of a pale green on their upper side, and hoary on their under. The stalks rise about two feet high, branching pretty much toward their top, and are terminated by round heads or spikes of reddish flowers, which are succeeded by seeds in autumn. It grows naturally in Spain.

The fourth sort grows naturally in North America. This hath leaves like those of the first sort, but are a little stiffer, composed of four or five pair of lobes, terminated by an odd one; those on the lower part of the midrib stand alternate, but the two upper pair are opposite, of a light green colour, and deeply sawed on their edges. The stalks rise three feet high, dividing toward the top into small branches, which stand erect, and are terminated by long spikes of flowers, of an herbaceous white colour, each standing upon a short foot-stalk.

There is another with long spikes of red flowers, which grows naturally in the same countries, whose stalks rise higher; the spikes of flowers are thicker; the lobes of the leaves are broader, and are whiter on their under side; but whether this is a distinct species, or an accidental variety of the fourth, I cannot as yet determine.

All these sorts are very hardy perennial plants, and will thrive in almost any soil or situation. They may be propagated either by seeds or parting of the roots; if they are propagated by seeds, they should be sown in the autumn, for when they are sown in the spring, they seldom grow the same year. When the plants come up, they must be kept clean from weeds till they are strong enough to transplant, when they may be planted in a shady border at about six inches distance each way, observing to water them till they have taken new root; after which they will require no other care but to keep them clear from weeds till autumn, when they may be transplanted to the place where they are to remain; the following summer they will produce flowers and seeds, but their roots will abide many years.

If the roots are parted, it should be done in autumn, that they may get good root before the dry weather comes on in the spring.

The other sorts of Burnet are referred to the article POTERIUM.

SANICULA. Tourn. Inst. R. H. 326. tab. 173. Sanicle.

The Characters are,

It is a plant with an umbellated flower. The universal umbel hath but few rays; the involucre is situated but half round on the outside; the partial umbels have many clustered rays, and their involucre surround them on every side; the flowers have five compressed petals, which are bifid, and turn inward; they have five erect stamina, which are twice the length of the petals, terminated by roundish summits, and a bristly germen, situated under the flower, supporting two awl-shaped styles, which are reflexed. The germen afterward becomes a rough oval pointed fruit, dividing into two parts, each containing one seed.

There is but one Species of this plant at present in England, viz.

SANICULA officinarum. C. B. P. Sanicle, or Self-heal.

This plant is found wild in woods and shady places in several parts of England, but being a medicinal plant, may be propagated in gardens for use. It may be increased by parting the roots any time from September to March, but it is best to do it in autumn, that the plants may be well rooted before the dry weather in spring comes on; they should have a moist soil and a shady situation, in which they will thrive exceedingly.

SANTOLINA. Tourn. Inst. R. H. 460. tab. 260. Lavender-cotton.

The Characters are,

It hath a compound flower with a scaly hemispherical empalement. The flower is uniform, composed of many funnel-shaped hermaphrodite florets, which are longer than the empalement, cut into five parts at the top, which turn backward; they have five very short hair-like stamina, terminated by cylindrical summits, and an oblong four-cornered germen, supporting a slender style, crowned by two oblong, depressed, torn stigmas. The germen afterward becomes a single, oblong, four-cornered seed, which is either naked or crowned with very short down, ripening in the common empalement.

The Species are,

1. *SANTOLINA pedunculis unifloris, foliis quadrifariam dentatis*. Hort. Cliff. 397. Lavender-cotton with one flower upon a foot-stalk, and leaves indented four ways; or common Lavender-cotton.

2. *SANTOLINA pedunculis unifloris, calycibus globosis, foliis quadrifariam dentatis tomentosis*. Lavender-cotton with one flower upon a foot-stalk, globular empalements, and woolly leaves, which are indented four ways.

3. *SANTOLINA pedunculis unifloris, caulibus decumbentibus, foliis linearibus quadrifariam dentatis*. Lavender-cotton with one flower upon a foot-stalk, declining stalks, and linear leaves, which are four ways indented.

4. *SANTOLINA pedunculis unifloris, foliis linearibus longissimis bifariam dentatis*. Lavender-cotton with one flower upon a foot-stalk, and very long linear leaves, which are two ways indented.

5. *SANTOLINA pedunculis unifloris, capitulis globosis, foliis linearibus integerrimis*. Lavender-cotton with one flower upon a foot-stalk, globular heads, and linear entire leaves.

6. *SANTOLINA pedunculis unifloris, foliis linearibus confertis obtusis*. Lavender-cotton with one flower upon a foot-stalk, and linear obtuse leaves growing in clusters.

7. *SANTOLINA pedunculis unifloris, foliis longioribus tomentosis, duplicato dentatis*. Lavender-cotton with one flower upon a foot-stalk, and longer woolly leaves, which are twice indented.

8. *SANTOLINA corymbis simplicibus coarctatis, foliis pinnatifidis dentatis*. Lin. Sp. 842. tab. 227. fig. 1. Lavender-cotton with single corymbuses of flowers, which are closed together at the top, and wing-pointed indented leaves.

9. *SANTOLINA corymbis simplicibus fastigiatis, foliis trilobis cuneiformibus.* *Lin. Sp. Plant.* 843. Lavender-cotton with single corymbuses of flowers, which are closed together at the top, and leaves having three wedge-shaped lobes.

10. *SANTOLINA corymbis simplicibus fastigiatis, foliis semitridis linearibus.* *Lin. Sp. Plant.* 843. Lavender-cotton with single corymbuses, which are closed together at the top, and linear leaves half divided into three points.

11. *SANTOLINA corymbis compositis fastigiatis, foliis inferioribus linearibus dentatis superioribus ovatis serratis.* *Hort. Cliff.* 398. Lavender-cotton with compound corymbuses, which are closed together at the top, the under leaves linear and indented, and the upper oval and sawed.

The first sort is the common Lavender-cotton, which has been long known in the *English* gardens; it was formerly titled *Abrotanum fœmina*, or female Southernwood, and by the corruption of words was called *Brotany* by the market people; it grows naturally in *Spain, Italy*, and the warm parts of *Europe*. This hath a ligneous stalk dividing into many branches, garnished with slender hoary leaves, that are four ways indented, and have a rank strong odour when handled. The branches are terminated by a single flower, composed of many hermaphrodite florets, which are fistular, cut into five parts at the top, of a sulphur colour, and are included in one common scaly empalement, having no borders or rays. These are succeeded by small, oblong, striated seeds, which are separated by scaly chaff, and ripen in the empalement; the plants love a dry soil and a sheltered situation. The leaves, and sometimes the flowers, are used in medicine, and are reputed good to destroy worms.

The second sort has a shrubby stalk, which branches out like the former, but the plants seldom grow so tall. The branches are garnished very closely below with leaves shaped like those of the other sort, but shorter, thicker, and whiter; the flowers are much larger, and the brims of the florets are more reflexed; they are of a deeper sulphur colour than the other. It grows naturally in *Spain*.

The third sort is of lower stature than either of the former, seldom rising more than fifteen or sixteen inches high. The branches spread horizontally near the ground, and are garnished with shorter leaves than either of the former, which are hoary, and finely indented; the stalks are terminated by single flowers of a bright yellow colour, which are larger than those of the first sort.

The fourth sort rises higher than either of the former. The branches are more diffused; they are slender, smooth, and garnished with very narrow long leaves, which are of a deep green colour, but two ways indented; the stalks are slender, naked toward the top, and terminated by single flowers of a gold colour.

The fifth sort hath shrubby stalks, which rise about three feet high, sending out long slender branches, garnished with single linear leaves, of a pale green colour. The stalks are terminated by large, single, globular flowers, of a pale sulphur colour.

The sixth sort is somewhat like the fifth, but the branches are shorter, thicker, and closer garnished with leaves, which come out in clusters. The flower-stalks are sparsely disposed, and have leaves to their top; the flowers are small, and of a yellow colour.

The seventh sort hath shrubby stalks, which rise three feet high, garnished with broader leaves than either of the former, whose indentures are looser but double; they are hoary, and when bruised have an odour like *Chamomile*. The leaves are placed pretty far asunder, and the stalks are garnished with them to the top. The stalks are divided likewise at the top into two or three foot stalks, each sustaining one pretty large sulphur-coloured flower.

The eighth sort is an annual plant, which grows natu-

rally in the *Mediterranean*. This rises with herbaceous slender stalks one foot high, which are hoary, sending out branches, which diminish in their length to the top; these are garnished with wing-pointed leaves, which are in clusters; they have an agreeable odour when bruised. The branches are terminated by clusters of flowers, of a bright yellow colour.

The ninth sort grows naturally at the *Cape of Good Hope*. This rises with a shrubby stalk five or six feet high, sending out slender branches, garnished with short flat leaves, cut into three parts at the top, of a gray colour, and sit close to the branches. The flowers are disposed in a single corymbus at the end of the branches, and are very closely connected together; they are of a pale sulphur colour, and have roundish scaly empalements.

The tenth sort is also a native of the *Cape of Good Hope*. This hath a shrubby stalk very like the former, but the leaves of this are linear, cut half their length into three points, and sometimes into five. The flowers are like those of the former sort.

The eleventh sort grows naturally at the *Cape of Good Hope*. This hath a low shrubby stalk, dividing into several branches, garnished with two sorts of leaves; those on the lower part are oblong, and cut on their edges into acute points; but the upper are short, stiff, and slightly indented at their ends. The flowers are disposed in a compound corymbus at the end of the branches, of a pale yellow colour.

The first of these plants is cultivated in gardens for medicinal use, and the six next are propagated by the gardeners near *London* for furnishing balconies, and other little places in and near the city, by way of ornament. The seven sorts first mentioned are hardy plants, which will thrive in the open air, provided they are planted in a poor dry soil, for in such ground the plants will be stunted, so will be hard and better able to resist the cold, and will have a better appearance than those which are in rich ground, whose branches will be long and diffused, so by hard rains or strong winds are displaced, and sometimes broken down; whereas, in poor land, they will grow compact, and the plants will continue much longer.

All these plants may be cultivated so as to become ornaments to a garden, particularly in small bosquets of evergreen shrubs, where, if these are artfully intermixed with other plants of the same growth, and placed in the front line, they will make an agreeable variety, especially if care be taken to trim them twice in a summer to keep them within bounds, otherwise their branches are apt to straggle, and in wet weather to be borne down and displaced, which renders them unsightly; but, when they are kept in order, their hoary and different-coloured leaves will have a pretty effect in such plantations.

They may be propagated by planting slips or cuttings during the spring, in a border of light fresh earth, but must be watered and shaded in hot dry weather until they have taken root; after which they will require no farther care, but to keep them clear from weeds till autumn, when they should be transplanted where they are designed to remain; but, if the ground is not ready by that time to receive them, it will be proper to let them remain in the border until spring, for if they are transplanted late in autumn, they are liable to be destroyed by cold in winter.

The eighth sort is an annual plant, so is propagated only by seeds, which must be sown the latter end of *March* upon a moderate bed, and when the plants appear, they should be treated in the same way as the *Balsamine*, and other hardy kinds of annuals; the latter end of *May* they should be transplanted into a warm border of light earth, where they will flower, and in warm seasons will perfect their seeds.

The other kinds are too tender to live through the winter in the open air in *England*, so they are kept in pots, and removed into the green-house in autumn; but, as these only require protection from hard frost, so they must not be treated too tenderly, for then their branches will be weak and unsightly, therefore they should be placed with the more hardy exotick plants, where they may have a large share of air whenever the season is mild. These are easily propagated by planting cuttings any time in summer, which must be shaded till they have taken root.

SAPINDUS. *Tourn. Inst. R. H.* 659. *tab.* 440. The Sopeberry-tree.

The Characters are,

The empalement of the flower is composed of four plain, oval, coloured leaves. The flower has four oval petals, which are less than the empalement; it has eight stamina, which are the length of the petals, terminated by erect summits, and an oval germen with three or four lobes, supporting a short style, crowned by a single stigma. The germen afterward becomes one, two, or three globular berries, including nuts of the same form. There is rarely above one of these pregnant, the other are abortive.

The Species are,

1. SAPINDUS *foliis pinnatis decurrentibus*. Sopeberry-tree with winged running leaves.

2. SAPINDUS *foliis pinnatis*. Sopeberry-tree with winged leaves.

The first sort grows naturally in the islands of the *West-Indies*, where it rises with a woody stalk from twenty to thirty feet high, sending out many branches, garnished with winged leaves, composed of several pair of spear-shaped lobes. The midrib has a membranaceous or leafy border running on each side from one pair of lobes to the other, which is broadest in the middle between the lobes; the flowers are produced in loose spikes at the end of the branches; they are small and white, so make no great appearance. These are succeeded by oval berries as large as middling Cherries, sometimes single, at others two, three, or four are joined together; these have a saponaceous skin or cover, which incloses a very smooth roundish nut of the same form, of a shining black when ripe. The skin or pulp which surrounds the nuts, is used in *America* to wash linen, but it is very apt to burn and destroy it, if often used, being of a very acrid nature.

The second sort grows in *India*. This hath a strong woody stalk, which rises about twenty feet high, sending out many strong ligneous branches, covered with a smooth gray bark, and garnished with winged leaves, composed of many spear-shaped lobes; they are of a pale green, and sit close to the midrib, which has no border or wing like the other. The end of the branches are divided into two or three foot-stalks, each sustaining a loose spike of flowers like those of the other sort; these are succeeded by roundish berries like those of the former.

These plants are propagated by seeds; they must be put into small pots, and plunged into a hot-bed of tanners bark. In five or six weeks the plants will appear, when the glasses of the hot-bed should be raised every day in warm weather, to admit fresh air to the plants. In three weeks or a month after the plants appear, they will be fit to transplant, when they must be shaken out of the pots, and carefully parted, so as not to injure their roots, and each planted into a separate small pot, and plunged into the hot-bed again, observing to shade them from the sun until they have taken new root; after which time they must have free air admitted to them every day when the weather is warm, and will require to be frequently watered.

After the plants are well rooted, they will make great progress, especially the second sort, so should be inured to bear the open air by degrees, for this will live in a green-

house in winter, and in summer may be exposed in the open air; but the first is not so hardy, so must be treated more tenderly. I have frequently raised these plants from seeds to the height of two feet in one summer, and the leaves have been a foot and a half in length, so that they made a fine appearance; but these did not survive the winter, whereas those which were exposed to the open air in *July*, and thereby stinted in their growth, continued their leaves fresh all the winter. These were placed in a stove upon shelves, where the warmth was very moderate, with which these plants will thrive better than in a greater heat.

SAPONARIA. *Lin. Gen. Plant.* 449. Sopewort.

The Characters are,

The flower has a permanent empalement of one leaf, which is cut into five points. It has five petals, whose tails are narrow, and the length of the empalement; their borders are broad, obtuse, and plain. It has ten awl-shaped stamina, which are alternately inserted into the petals, and are terminated by obtuse prostrate summits, and a taper germen, supporting two erect parallel styles, crowned by acute stigmas. The germen afterward becomes a close capsule the length of the empalement, having one cell, filled with small seeds.

The Species are,

1. SAPONARIA *calycibus cylindricis, foliis ovato-lanceolatis*. *Hort. Cliff.* 165. Sopewort with cylindrical empalements, and oval spear-shaped leaves; vulgarly called Sopewort.

2. SAPONARIA *calycibus cylindricis, foliis ovatis nervosis semiamplexicaulibus*. Sopewort with cylindrical empalements, and oval veined leaves, half embracing the stalks.

3. SAPONARIA *calycibus pyramidatis quinquangularibus, foliis oblongo-ovatis acuminatis*. Sopewort with pyramidal five-cornered empalements, and oblong, oval, acute-pointed leaves.

4. SAPONARIA *calycibus pyramidatis quinquangularibus, foliis ovato-lanceolatis, semiamplexicaulibus*. Sopewort with pyramidal five-cornered empalements, and oval spear-shaped leaves, half embracing the stalks.

5. SAPONARIA *calycibus cylindricis villosis, caule dichotomo erecto patulo*. *Hort. Upsal.* 106. Sopewort with cylindrical hairy empalements, and erect spreading stalks, which are divided by pairs.

The first sort is the common Sopewort of the shops; this grows naturally in many parts of *England*, and is rarely admitted into gardens; it has a creeping root, so as in a short time to fill a large space of ground, from which arise many purplish stalks about two feet high, which are jointed, garnished with opposite leaves at each; these are oval, spear-shaped, smooth, and of a pale green. The foot-stalks of the flowers arise from the wings of the leaves opposite; they sustain four, five, or more purple flowers each, which have generally two small leaves placed under them. The stalk is also terminated by a loose bunch of flowers, growing in form of an umbel; they have each a large swelling cylindrical empalement, and five broad obtuse petals, which spread open, of a purple colour. These are succeeded by oval capsules with one cell, filled with small seeds.

The decoction of this plant is used to cleanse and scour woollen cloths: the poor people in some countries used it instead of sope for washing, from whence it had its title.

There is a variety of this with double flowers, which is preserved in gardens, but the roots are very apt to spread, if they are not confined, so these plants should not be placed in borders among better flowers; but as the flowers continue in succession from *July* to the middle of *September*, so a few of the plants may be allowed a place in some abject part of the garden, for they will thrive in any situation, and propagate fast enough by their creeping roots.

The second sort was found growing in a wood near *Lichbarrow* in *Northamptonshire*, by *Mr. Gerard*. It has been

generally esteemed a *Lufus Naturæ*, and not a distinct species, but I have never found it alter in forty years; but as it doth not produce seeds, so there is no certainty of its being a distinct species. The roots of this do not spread like those of the first; the stalks are shorter, thicker, and do not grow so erect; they rise a foot high; the joints are very near and swelling; the leaves are produced singly on the lower part of their stalks, but toward the top they are often placed by pairs; they are oval-shaped, and hollowed like a ladle. The flowers are disposed loosely on the top of the stalk; they have large cylindrical empalements, and are of a purple colour. This plant is preserved for the sake of variety in some gardens, but as there is little beauty in the flowers, it does not merit a place in gardens for pleasure. It is easily propagated by parting of the roots in autumn, and loves a moist shady situation.

The third sort is an annual plant, which grows naturally among Corn in the south of *France* and *Italy*. This rises with an upright stalk a foot and a half high, branching out into several divisions by pairs opposite, as are also the leaves; they sit close to the stalks, are smooth, and of a gray colour. The flowers are produced at the end of the branches, each standing upon a long naked foot-stalk; their empalements are large, swelling, and pyramidal, having five acute corners or angles; the petals are but small; they have long necks or tails, which are narrow; their upper part is obtuse, and of a reddish purple colour.

The fourth sort grows naturally in *Spain*. This is also an annual plant; it rises with a strong smooth stalk about two feet high, garnished with oval spear-shaped leaves, which are fleshy, of a gray colour, and very smooth; these half embrace the stalks with their base; the upper part of the stalk divides into branches, which are again subdivided into long naked foot-stalks, each sustaining a single flower; the empalement of the flower is large, pyramidal, and swelling, having five acute angles. The flowers are composed of five obtuse red petals, which spread open above the empalement.

The fifth sort grows naturally in the *Lewant*. This is a low annual plant, seldom rising more than four inches high, but divides into branches by pairs from the bottom, which spread asunder. The leaves are very small; the flowers come out single from the wings of the leaves; they have hairy cylindrical empalements, out of which the petals of the flower do but just peep, so are not obvious at any distance. The whole plant is very clammy to the touch. As this plant makes no figure, so it is only kept for variety.

These plants are easily propagated by seeds, which should be sown where the plants are to remain, and will require no other care but to keep them clean from weeds, and thin them where they are too close. If the seeds are sown in autumn, or are permitted to scatter, the plants will come up without care.

SAPOTA. *Plum. Nov. Gen. 43. tab. 4.* The Mammee Sapota.

The Characters are,

The flower has a permanent empalement, composed of five oval acute-pointed leaves. It has five roundish heart-shaped petals, connected at their base, ending in acute points; and five short stamina the length of the tube, terminated by arrow-pointed summits, with an oval germen, supporting a short style, crowned by an obtuse stigma. The germen afterward becomes an oval succulent fruit, inclosing one or two oval hard nuts or stones.

The Species are,

1. SAPOTA foliis oblongo-ovatis, fructibus turbinatis glabris. Sapota with oblong oval leaves, and smooth turbinated fruit.

2. SAPOTA foliis lanceolatis, fructu maximo ovato, seminibus ovatis utrinque acutis. Sapota with spear-shaped leaves, a

very large oval fruit, and oval seeds, which are pointed at both ends.

The name of Sapota is what these fruit are called by the natives of *America*, to which some add the appellation of Mammee; but there is no other name given to these fruits by the *English*, since they have settled in the *West-Indies*, so far as I can learn.

The first of these trees is common about *Panama*, and some other places in the *Spanish West-Indies*, but is not to be found in any of the *English* settlements in *America*.

The second sort is very common in *Jamaica*, *Barbadoes*, and most of the islands in the *West-Indies*, where the trees are planted in gardens for their fruit, which is by many persons greatly esteemed.

This sort grows in *America* to the height of thirty-five or forty feet, having a strait trunk, covered with an Ash-coloured bark. The branches are produced on every side, so as to form a regular head, and are beset with leaves a foot in length, and near three inches broad in the middle. The flowers which are produced from the branches, are of a cream colour; when these fall away, they are succeeded by large oval or top-shaped fruit, which are covered with a brownish skin, under which is a thick pulp of a Russet colour, very luscious, called Natural Marmalade, from its likeness to Marmalade of Quinces.

As these trees are natives of very warm countries, they cannot be preserved in *England*, unless they are placed in the warmest stoves, and managed with great care. They are propagated by planting the stones; but as these will not keep good long out of the ground, the surest method to obtain these plants is, to have the stones planted in tubs of earth as soon as they are taken out of the fruit, and the tubs placed in a situation where they may have the morning sun, and kept be duly watered. When the plants come up, they must be secured from the vermin, and kept clear from weeds, but should remain in the country till they are about a foot high, when they may be shipped for *England*; but they should be brought over in the summer season, and, if possible, time enough for the plants to make good roots after they arrive. During their passage, they must have some water, while they continue in a warm climate; but as they come into colder weather, they should have very little moisture, and must be secured from salt water, which will soon destroy the plants if it gets at them.

When these plants arrive in *England*, they should be carefully taken out of the tubs, preserving some earth to their roots, and planted into pots, and then plunged into a moderate hot-bed of tanners bark, observing, if the weather is hot, to shade the glasses with mats, to screen the plants from the sun, until they have taken new root; observing also, not to water them too much at first, especially if the earth in which they come over is moist, because too much water is very injurious to the plants before they are well rooted, but afterward they must be frequently refreshed with water in warm weather, and must have a large share of air admitted to them, otherwise their leaves will be infested with insects, and become foul; in which case they must be washed with a sponge to clean them, without which the plants will not thrive.

In the winter these plants must be placed in the warmest stove, and in cold weather they should have but little water given to them. As these plants grow in magnitude, they should be shifted into pots of a larger size, but they must not be over-potted, for that will infallibly destroy them.

SARRACENA. *Tourn. Inst. R. H. 657. tab. 476.* The Sidesaddle Flower.

The Characters are,

The flower has a double empalement; the under is composed of three leaves, which fall away; the upper has five coloured leaves, which

which are permanent. It has five oval inflexed petals which inclose the stamina, whose tails are oblong, oval, and erect, and a great number of small stamina, terminated by target-shaped summits. In the center is situated a roundish germen, supporting a short cylindrical style, crowned by a target-shaped five-cornered stigma covering the stamina, and is permanent. The germen afterward becomes a roundish capsule with five cells, filled with small seeds.

The Species are,

1. *SARRACENA foliis gibbis*. Hort. Cliff. 427. *Sarracena* with gibbous leaves.

2. *SARRACENA foliis strictis*. Lin. Sp. Plant. 510. *Sarracena* with closed leaves.

The first sort grows naturally upon bogs in most parts of North America. This hath a strong fibrous root, which strikes deep into the soft earth, from which arise five, six, or seven leaves, in proportion to the strength of the plant; these are hollow like a pitcher, narrow at their base, but swell out large at the top; their outer sides are rounded, but on their inner they are a little compressed, and have a broad leafy border running longitudinally the whole length of the tube; and to the rounded part of the leaf there is on the top a large appendage or ear standing erect, of a brownish colour; this surrounds the outside of the leaves about two-thirds of the top. From the center of the root, between the leaves, arises a strong, round, naked foot-stalk about a foot high, sustaining one nodding flower at the top, which has a double empalement; the outer one is of one leaf, divided into five parts to the bottom, where they are connected to the foot-stalks; these segments are obtuse, and bend over the flower, so as to cover the inside of it; they are of a purple colour on the outside, but green within, having purple edges; the inner empalement, which is composed of three green leaves, falls off; within these are five oval petals of a purple colour, which are hollowed like a spoon; these cover the stamina and summits, with part of the stigma also. In the center is situated a large, roundish, channelled germen, supporting a short style, crowned by a very broad five-cornered stigma, fastened in the middle to the style, covering the stamina like a target; this is green, but the five corners which are stretched out beyond the brim are each cut into two points, and are purplish. Round the germen are situated a great number of short stamina, joining the sides of the germen closely, which are terminated by target-shaped furrowed summits, of a pale sulphur colour. When the flower decays, the germen swells to a large roundish capsule with five cells, covered by the permanent stigma, filled with small seeds.

The second sort grows naturally in Carolina, upon bogs and in standing shallow waters. The leaves of this sort grow near three feet high, small at the bottom, but widening gradually to the top. They are hollow, and arched over at the mouth like a friar's cowl. The flowers of this grow on naked pedicles, rising from the root to the height of three feet; the flowers are green.

These plants are esteemed for the single structure of their leaves and flowers, which are so different from all the known plants, as to have little resemblance of any yet discovered, but there is some difficulty in getting them to thrive in England, when they are obtained from abroad; for as they grow naturally on bogs, or in shallow standing waters, so unless they are constantly kept in wet, they will not thrive; and although the winters are very sharp in the countries where the first sort naturally grows, yet being covered with water, and the remains of decayed plants, they are defended from frost.

The best method to obtain these plants is, to procure them from the places of their natural growth, and to have them taken up with large balls of earth to their roots, and

planted in tubs of earth, which must be sometimes watered during their passage, otherwise they will decay before they arrive; for there is little probability of raising these plants from seeds, so as to produce flowers in many years, if the seeds do grow, so that young plants should be taken up to bring over, which are more likely to stand here than those which have flowered two or three times. When the plants are brought over, they should be planted in pots, which should be filled with soft spongy earth, mixed with rotten wood, moss, and turf, which is very like the natural soil in which they grow. These pots should be put into larger pots which will hold water, with which they must be constantly supplied, and placed in a shady situation in summer; but in the winter they must be covered with moss, or sheltered under a frame, otherwise they will not live in this country, for as the plants must be kept in pots, so if these are exposed to the frost, it will soon penetrate through them, and greatly injure, if not destroy, the plants; but when they are placed under a common frame, where they may have the open air at all times in mild weather, and be sheltered from hard frost, the plants will thrive and flower very well.

SASSAFRAS. See *Laurus*.

SATUREJA. *Tourn. Inst. R. H.* 197. Savory.

The Characters are,

The flower hath an erect, tubulous, striated empalement of one leaf, indented at the brim in five points; it hath one ringent petal, whose tube is cylindrical and shorter than the empalement; the chaps are single, the upper lip erect and obtuse, having an acute indenture at the point. The under lip is spreading, divided into three equal parts. It has four bristly stamina, two of which are almost the length of the upper lip; the other two are shorter, terminated by summits which touch each other, and a four-pointed germen, supporting a bristly style, crowned by two bristly stigmas. The germen afterward becomes four seeds, which ripen in the empalement.

The Species are,

1. *SATUREJA pedunculis bifloris*. Vir. Cliff. 87. Savory with two flowers upon each foot-stalk; or Summer Savory.

2. *SATUREJA floribus verticillatis, foliis ovatis acutis*. Fler. Leyd. Prod. 324. Savory with whorled flowers, and oval acute-pointed leaves; or the true Thymbra.

3. *SATUREJA pedunculis dichotomis lateralibus solitariis, foliis mucronatis*. Lin. Sp. Plant. 568. Savory with single diverging foot-stalks on the sides of the branches, and sharp-pointed leaves; or Winter Savory.

4. *SATUREJA capitulis terminalibus, foliis lanceolatis*. Lin. Sp. Plant. 567. Savory with heads of flowers terminating the stalks, and spear-shaped leaves.

5. *SATUREJA foliis ovatis serratis, corymbis terminalibus dichotomis*. Lin. Sp. Plant. 568. Savory with oval sawed leaves, and flowers growing in a divided corymbus, terminating the stalks.

6. *SATUREJA verticillis lanuginosis, dentibus calycinis setaceis pilosis*. Hort. Cliff. 306. Savory with woolly whorls of flowers, whose indentures of their empalements are brittle and hairy; commonly called Mastick Thyme.

7. *SATUREJA verticillis fastigiatis concatenatis, foliis linearilanceolatis*. Lin. Sp. Plant. 567. Savory with bunched whorls of flowers, and linear spear-shaped leaves; Julian's Thymbra, or the true Savory.

8. *SATUREJA pedunculis corymbosis, lateralibus geminis, bracteis calyce brevioribus*. Lin. Sp. Plant. 568. Savory with corymbuses of flowers growing by pairs from the wings of the leaves, and bractæ shorter than the empalements.

9. *SATUREJA floribus spicatis, foliis carinatis punctatis ciliatis*. Lin. Mat. Med. 283. Savory with spiked flowers, and keel-shaped hairy leaves, having spots.

The first fort is generally known in the gardens, by the title of Summer Savory. It is an annual plant, which grows naturally in the south of *France* and *Italy*, but is cultivated in the *English* gardens for the kitchen, and also for medicinal use. It rises with slender erect stalks a foot high, sending out branches by pairs, garnished with leaves placed opposite; they are stiff, a little hairy, and have an aromack odour if rubbed. The flowers grow from the wings of the leaves toward the upper part of the branches, each foot-stalk sustaining two flowers, of the lip kind, having a short cylindrical tube; the upper lip is erect, and indented at the point; the lower is divided into three almost equal parts; they are of a pale flesh colour, and are succeeded by seeds, which ripen in autumn.

The second fort grows naturally in *Crete*. This rises with a shrubby stalk two feet high, dividing into several slender ligneous branches, garnished with small stiff oval leaves, ending in acute points, of an aromack odour when bruised. The flowers grow in thick whorls round the stalks toward the top; they have short, hairy, five-pointed empalements; the flower is shaped like that of the former, but is larger, and of a brighter red colour. This plant rarely ripens its seeds in *England*.

The third fort is well known in the gardens by the title of Winter Savory. It is a perennial plant, which grows naturally in the south of *France* and *Italy*, but is here cultivated in gardens both for food and physick. This hath a shrubby, low, branching stalk a foot high, garnished with two very narrow leaves at each joint, which are stiff, and stand opposite; from the base of these come out a few small leaves in clusters. The flowers grow from the wings of the leaves upon short foot stalks; they are shaped like those of the first fort, but are larger, and of a paler colour, and are succeeded by seeds, which ripen in autumn; but the plants will continue several years, especially if they are planted on a poor dry soil.

The fourth fort grows naturally in *North America*. This hath a perennial root; the stalk rises about a foot and a half high; it is stiff, angular, and branches out toward the top. The leaves are stiff, spear-shaped, pointed, and have a strong scent of Pennyroyal; the stalks are terminated by white flowers, collected into globular heads. These are seldom succeeded by perfect seeds in *England*.

The sixth fort grows naturally in *Spain*, and is known in the *English* gardens by the title of Herb Mastick, or Mastick Thyme. This hath a shrubby branching stalk a foot and a half high, covered with a brown bark: the branches are slender, but ligneous, garnished with leaves like those of Thyme, but a little larger. The flowers grow in roundish whorls toward the top of the branches, which have a down about them, whereby the plant is easily distinguished from all the other of this tribe. The flowers are small, white, and stand in hairy bristly empalements; the whole plant has a very grateful odour. It does not produce seeds here.

There is another variety of this (if not a distinct species) which has weaker branches, smaller hairy leaves, and very small hairy whorls of flowers, but not woolly like the former. The seeds of this were sent me from *Spain*, but I have not had trial enough yet of the plants, to determine if it is really different from the other.

The seventh fort grows naturally in *Spain* and some parts of *Italy*. It hath very slender ligneous stalks, which grow erect nine inches high, sending out two or three slender side branches toward the bottom, garnished with narrow, spear-shaped, stiff leaves, which are placed opposite. The flowers grow in whorls above each other for more than half the length of the stalk, and seem as if they were bundled together. They are small and white, but the seeds seldom ripen here; the whole plant has a pleasant aromack scent.

The eighth fort grows naturally in *Crete*. This hath very slender ligneous stalks a foot and a half high, garnished with small, oval, stiff, acute-pointed leaves, whose borders are reflexed. The flowers grow in roundish whorls upon short foot-stalks, which rise by pairs from the wings of the leaves; they are small and white, and if the season proves warm, the seeds will ripen in autumn.

The ninth fort grows naturally in *Crete*. It has a low shrubby stalk, with branches on every side, and are hoary, garnished with stiff, narrow, acute pointed leaves, which are hollowed like the keel of a boat. The flowers grow in short roundish spikes at the end of the branches; they are small and white; the whole plant is hoary, and very aromack. This never produces seeds in *England*.

The first fort is only cultivated by seeds; these should be sown the beginning of *April* upon a bed of light earth, either where they are to remain, or for transplanting; if the plants are to stand unremoved, the seeds should be sown thinly, but if they are to be transplanted, they may be sown closer. When the plants appear, they must be kept clean from weeds, and afterward they may be treated in the same way as Marjoram.

The second, seventh, and ninth forts, are too tender to live through the winter in the open air in *England*. These are generally propagated by slips or cuttings, which take root very readily during any of the summer months; if these cuttings or slips are planted in a shady border, or are shaded from the sun with mats, they will put out roots in two months, fit to be transplanted, when they should be each transplanted into a small pot, and placed in the shade till they have taken new root; then they may be placed in a sheltered situation, where they may remain till the end of *October*; then they should be placed under a common hot-bed frame, where they may be exposed to the open air, at all times when the weather is mild; but they must be protected from hard frost, which will destroy them.

As these plants seldom live above three or four years, so there should be a supply of young plants raised to preserve the species, otherwise they may be soon lost. In winter they should not have much wet, for they are very subject to grow mouldy by moisture, but especially if the free air is excluded from them, or if their branches are drawn up weak, they soon decay.

The third fort is very hardy, so if this is sown or planted upon a dry lean soil, it will endure the greatest cold of our winters. I have seen some of the plants growing upon the top of an old wall, where they were fully exposed to the cold, and these survived severe frost, when most of those which were growing in the ground were destroyed. This may be propagated either by seeds in the same way as the first, or by slips, which, if planted in the spring, will take root very freely. These plants will last several years, but when they are old, their shoots will be short and not so well furnished with leaves, so will not be so good for use as young plants, therefore it will be proper to raise a supply of young plants every other year.

The fifth fort has a perennial root, but the stalks decay every autumn. There are two varieties of this, one of them has narrow leaves and larger heads than the other, and the leaves have very little scent; whereas those of the common fort smell so like Pennyroyal, as not to be distinguished by those who do not see the plants. This fort sometimes produces good seeds here, from which the plants may be easily propagated; they may also be increased by planting cuttings in the spring, in the same manner as is practised for Mint; these will take root freely, and if they are afterwards planted in a moist soil, they will thrive exceedingly; but as the plant is never used here, so it is only kept for variety in some curious gardens.

The eighth sort is annual, and so tender as rarely to perfect its seeds here, so that there is great difficulty to preserve it. The cuttings or slips of this will take root, by which the plant may be continued two or three years; but these must be sheltered in winter under a frame and kept dry, for wet at that season will soon destroy them.

SATYRIUM. *Lin. Gen. Plant.* 901.

The Characters are,

It hath a single stalk; the flowers have no empalement, but sit upon the germen: they have five oblong oval petals, three outer and two inner, joined in a helmet; they have a one-leaved nectarium, situated on the side between the division of the petals. The upper lip is short and erect, the under is plain and hangs downward; their base represents the hinder part of the scrotum. They have two short slender stamina sitting upon the pointal, having oval summits, with double cells shut up in the upper lip of the nectarium, and an oblong twisted germen situated under the flower, having a short style growing on the upper lip of the nectarium, crowned by an obtuse compressed stigma. The germen afterward becomes an oblong capsule with one cell, having three keels and three cells, opening under the keels three ways, filled with small seeds.

The Species are,

1. SATYRIUM *bulbis palmatis, foliis linearibus, nectarii labio resupinato trilobo, intermedia majore.* *Act. Upsal.* 1740. p. 19. Satyrium with handed bulbs, linear leaves, and the under lip of the nectarium with three lobes, the middle being the largest.

2. SATYRIUM *bulbis indivisis, foliis lanceolatis, nectarii labio trifido, intermedia lineari, obliqua præmorsa.* *Act. Upsal.* 1740. tab. 18. Satyrium with an undivided bulb, spear-shaped leaves, and the lip of the nectarium trifid, the middle segment being linear and obliquely bitten; the Lizard Flower, or great Goatstones.

3. SATYRIUM *bulbis palmatis, foliis oblongis obtusis, nectarii labio lineari trifido, intermedia obsoleta.* *Act. Upsal.* 1740. p. 18. Satyrium with handed bulbs, oblong blunt leaves, and the lip of the nectarium divided into three linear parts, the middle one being obsolete; by some called the Frog Orchis.

4. SATYRIUM *bulbis fasciculatis, foliis lanceolatis, nectarii labio trifido acuto, intermedia majore.* *Act. Upsal.* 1740. Satyrium with clustered bulbs, spear-shaped leaves, and the lip of the nectarium divided into three acute parts, the middle one being the largest.

The first sort grows naturally upon the *Alps*. This has a broad handed bulbous root; the stalk rises nine inches high, garnished with very narrow leaves; those on the lower part are four inches long, but on the upper part they are scarce one inch; their base embraces the stalk. The flowers grow in a thick short spike at the top, of a dark purple colour; the lip of the nectarium has three lobes, the middle one being the largest.

The second sort grows naturally in several parts of *England*. This has a solid bulbous root; the stalk is strong, fifteen inches high; the lower part is garnished with leaves near five inches long, which embrace the stalk with their base. The spike of flowers which occupy the upper part of the stalk, is six inches in length; the flowers are of a dirty white, with some linear stripes and spots of a brown colour; the beard or middle segment of the lip of the nectarium, is two inches long, and appears as if it was obliquely bitten off.

The third sort grows naturally on dry pastures, and upon chalk hills in several parts of *England*. This has a handed bulbous root; the stalk rises a foot high; the lower part is garnished with leaves three inches long and half an inch broad, whose base embraces the stalk. The flowers terminate the stalk in a long slender spike; the nectarium of this

varies in colour, it is sometimes of a dusky purple, and at others of a yellowish green colour.

The fourth sort grows near *Verona*, and upon the *Alps*. This hath several small bulbs, which are joined together; the stalk rises eight inches high; the lower part is garnished with spear-shaped leaves three inches long, which embrace the stalk with their base. The flowers terminate the stalk in a short thick spike, which are of an herbaceous white colour.

All these plants are difficult to propagate, so the best way to obtain them, is to take up their roots at a proper season, and transplant them into the gardens, putting the several sorts into different soils, as near to that in which they naturally grow as possible, and to leave the ground undisturbed; for if their roots are injured, the plants seldom thrive after. The management of this plant being the same as for the Orchis, I shall not repeat it here.

SAVINE. See Juniperus.

SAVORY. See Satureja.

SAURURUS. *Lin. Gen. Plant.* 414. Lizard's-tail.

The Characters are,

The flowers are disposed in a katkin or tail; they have an oblong permanent empalement of one leaf. They have no petal, but have six long hair-like stamina, placed three on each side opposite, terminated by oblong erect summits; and an oval germen with three lobes, having no style, but is crowned by three blunt permanent stigmas. The germen afterward becomes an oval berry with one cell, inclosing one oval seed.

We have but one Species of this genus at present.

the *English* gardens, viz.

SAURURUS *foliis cordatis petiolatis, spicis solitariis recurvis.* *Hort. Upsal.* 91. Lizard's-tail with heart-shaped leaves, having foot-stalks, and single recurved spikes of flowers.

This plant grows naturally in many parts of *North America*. The root is fibrous and perennial; the stalk rises a foot and a half high, having some longitudinal furrows; the leaves are heart-shaped, smooth, about three inches long, and two broad at their base, ending in obtuse points, standing upon foot-stalks, which are placed alternately. The spike of flowers comes out from the wings of the leaves toward the top of the stalk; it is taper, about two inches long, but make little appearance, and are not succeeded by seeds in *England*. The stalk decays in autumn.

This is preserved by botanists for the sake of variety, but, as it has no beauty, it is very rarely admitted into other gardens; it is propagated by its creeping root, which may be parted either in autumn, soon after the stalks decay, or in the spring, before the roots begin to shoot; it loves a moist soil and a shady situation.

SAXIFRAGA. *Tourn. Inst. R. H.* 252. tab. 129. Saxifrage.

The Characters are,

The flower hath a short permanent acute empalement, cut into five parts; it has five plain petals, and ten awl-shaped stamina, terminated by roundish summits, with a roundish acute-pointed germen, sitting upon two styles, crowned by obtuse stigmas. The germen afterward becomes an oval capsule with two horns opening between their tops, filled with small seeds.

The Species are,

1. SAXIFRAGA *foliis caulinis reniformibus lobatis, caule ramoso, radice granulata.* *Hort. Cliff.* 167. Saxifrage with kidney-shaped leaves upon the stalks, with lobes, a branching stalk, and roots like grains of Corn; or white Saxifrage.

2. SAXIFRAGA *foliis radicans aggregatis lingulatis, cartilagineo-ferratis, caule ramoso.* Saxifrage with tongue-shaped leaves at the root, which are joined together, having cartilaginous saws, and a branching stalk.

3. *SAXIFRAGA foliis radicatis aggregatis cuneiformibus cartilagineo-ferratis, caule paniculato.* Saxifrage with the lower leaves wedge-shaped, joined together, with edges having cartilaginous saws, and a paniculated stalk.

4. *SAXIFRAGA foliis radicatis aggregatis lingulatis, cartilagineo-ferratis, caule pyramidato.* Saxifrage with the lower leaves joined together, which are tongue-shaped, having cartilaginous saws, and a pyramidal stalk.

5. *SAXIFRAGA foliis caulinis dentatis reniformibus petiolatis.* *Lin. Sp. Plant.* 403. Saxifrage with kidney-shaped leaves on the stalks, which stand on foot-stalks, and are indented.

6. *SAXIFRAGA foliis reniformibus dentatis, caule nudo paniculato.* *Lin. Sp. Plant.* 401. Saxifrage with indented kidney-shaped leaves, and a naked paniculated stalk.

7. *SAXIFRAGA foliis obovatis dentatis petiolatis, caule nudo paniculato.* *Lin. Sp. Plant.* 399. Saxifrage with oblong, oval, indented leaves, having foot-stalks, and a naked paniculated stalk; commonly called *London Pride*, or *None-so-pretty*.

8. *SAXIFRAGA foliis lanceolatis denticulatis, caule nudo paniculato, floribus sulcapitatis.* *Lin. Sp. Plant.* 401. Saxifrage with spear-shaped indented leaves, a naked paniculated stalk, and flowers collected in heads.

9. *SAXIFRAGA foliis obovatis crenatis subsessilibus, caule nudo, floribus congestis.* *Lin. Sp. Plant.* 401. Saxifrage with oblong, oval, crenated leaves sitting close to the root, a naked stalk, and flowers growing in close bunches.

10. *SAXIFRAGA foliis caulinis linearibus alternis ciliatis, radicalibus aggregatis.* *Lin. Sp. Plant.* 402. Saxifrage with linear leaves on the stalk, which are set with fine hairs alternate, and those at the root joined together.

11. *SAXIFRAGA foliis caulinis ovatis oppositis imbricatis, summis ciliatis.* *Flor. Suec.* 359. Saxifrage with oval leaves on the stalks, which are opposite, and lie over each other, and upper leaves having fine hairs.

12. *SAXIFRAGA foliis caulinis linearibus integris trifidisve, solenibus procumbentibus, caule erecto nudiusculo.* *Lin. Sp. Plant.* 405. Saxifrage with linear leaves on the stalks, which are entire or trifid, trailing side shoots, and erect stalks, which are almost naked; commonly called *Ladies Cushion*.

There are many more species of this genus than are here enumerated, some of which grow naturally in *Great-Britain*; but, as they are very rarely admitted into gardens, it would be needless to mention them in this work.

The first sort is the common white Saxifrage, which grows naturally in the meadows in most parts of *England*. The roots of this plant are like grains of *Corn*, of a reddish colour without, from which arise kidney-shaped hairy leaves, standing upon pretty long foot-stalks. The stalks are thick, a foot high, hairy, and furrowed; these branch out from the bottom, and have a few small leaves like those below, which sit close to the stalk; the flowers terminate the stalk, growing in small clusters; they have five small white petals, inclosing ten stamina and the two styles. The roots and leaves of this plant are used in medicine.

There is a variety of this, which was found wild by *Mr. Joseph Blind*, gardener at *Barns*, who transplanted it into his garden, and afterward distributed it to several curious persons, since which time it hath been multiplied so much, as to become a very common plant in most gardens near *London*, where it is planted in pots to adorn court-yards, &c. in the spring, and is very ornamental at that season in the borders of the flower-garden.

This plant is propagated by offsets, which are sent forth from the old roots in great plenty. The best season for transplanting them is in *July*, after their leaves are decayed, when they must be put into undunged earth, and placed in the shade until autumn; but in winter they may be exposed to the sun, which will cause them to flower somewhat earlier

in the spring. In *April* these plants will flower, and, if they are in large tufts, will make a very handsome appearance; when they are transplanted, they should be put in bunches, that they may produce a greater number of flowers.

The second sort grows naturally on the *Alps*; this hath a perennial fibrous root. The leaves grow in circular heads, embracing each other at their base, after the manner of the common *Houlceek*; they are tongue-shaped, rounded at their points, and have a white cartilaginous sawed border. The stalk rises a foot high, is of a purplish colour, a little hairy, and sends out several horizontal branches. The flowers grow in small clusters at the end of the branches; they are white, and have several small red spots on the inside.

It is easily propagated by offsets, which are sent out in plenty; they may be taken off at almost any season when the weather is mild, and should be planted in a very dry soil and a shady situation.

The third sort grows naturally on the *Alps*. The leaves of this are gathered into circular heads like the former, but are not more than half an inch long, wedge-shaped, the upper part being broad and rounded, but diminish to their base, where they are narrow; their borders are edged, and indented in the same manner as those of the former. The stalk, in the places where the plant grows naturally, seldom rises more than six inches high, but, when transplanted into gardens, is often more than a foot; these have small leaves sitting close to them. The flowers are disposed in loose panicles on the top of the stalks; they are white, spotted with red, and may be propagated in the same manner as the former.

The fourth sort grows naturally on the mountains in *Italy*. The leaves of this are gathered into heads like those of the two former; they are tongue-shaped, rounded at their points, and have cartilaginous sawed borders. The stalk rises two feet and a half high, branching out near the ground, forming a natural pyramid to the top; the flowers have five white wedge-shaped petals, and ten stamina, placed circularly the length of the tube, terminated by roundish purple summits. When these plants are strong, they produce very large pyramids of flowers, which make a fine appearance, so are very ornamental for halls, or to place in chimneys, where, being kept in the shade, and screened from wind and rain, they will continue in beauty much longer, than if kept in the open air.

This plant is easily propagated by offsets, which are put out from the side of the old plants in plenty. They are usually planted in pots filled with light earth, and in the summer season placed in the shade, but in the winter should be exposed to the sun, and all the offsets should be taken off, leaving the plant single, which will cause it to produce a much stronger stem for flowering, for where there are offsets about the old plant, they exhaust the nourishment from it, whereby it is rendered much weaker. These offsets must be each planted in a separate small pot, filled with fresh earth, to succeed the old plants, which generally perish after flowering; these offsets will produce flowers the second year, so there should be annually some of them planted to succeed the others.

The fifth sort grows naturally on the *Helvetian* mountains. This hath a perennial root. The stalk is erect, a foot high, channelled and hairy; it is garnished with kidney-shaped leaves, which are sharply indented; the stalks are terminated by small clusters of flowers, marked with several red spots. It is propagated by parting of the roots; the best time for this is in autumn, that the plants may have good roots before the dry weather in the spring. It loves a shady situation and a loamy soil.

The sixth sort grows naturally on the *Alps* and *Pyrenean* mountains. The root is fibrous and perennial; the leaves are thick, kidney-shaped, and crenated on their edges, of a deep green on their upper side, but pale on their under, standing upon long, thick, hairy foot-stalks, which branch into a panicle, sustaining several small white flowers, marked with red spots; the stamina of this are longer than the petals. It propagates very fast by offsets, which should be taken off in autumn, and planted in a shady situation, where they will thrive fast enough.

The seventh sort is known by the titles of *London Pride*, or *None-so-pretty*. It grows naturally on the *Alps*, and also in great plenty upon a mountain called *Mangerton*, in the county of *Kerry* in *Ireland*. The roots of this are perennial; the leaves are oblong, oval, placed circularly at bottom; they have broad, flat, furrowed foot-stalks, and are deeply crenated on their edges, which are white; the stalk rises a foot high, is of a purple colour, stiff, slender, and hairy; it sends out from the side on the upper part several short foot-stalks, which are terminated by white flowers spotted with red; the stamina are longer than the petals of the flower, as are also the two styles; these have red stigmas. It may be propagated in the same way as the former, and loves a shady situation.

The eighth sort grows naturally in *North America*. This is a perennial plant with a fibrous root, from which arise several spear-shaped leaves seven or eight inches long, and two broad, having small indentures on their edges; they are a deep green, and of a thick consistence. The stalk is naked, and rises a foot and a half high, branching at the top in form of a panicle, sustaining very small herbaceous flowers, which are collected into small heads. It is propagated by parting the root; the best time is in autumn; it loves a moist soil and a shady situation, and is never injured by cold.

The ninth sort grows naturally upon some mountains in *Wales*. This hath a fibrous perennial root, from which come out oblong, roundish, indented leaves, deeply indented, or rather sawed on their edges, sitting very close to the root. The stalk rises about five inches high, is naked, and terminated by a close compact cluster of white flowers; if they are planted in a shady situation, they will continue almost a month. This must have a loamy soil, otherwise it will not thrive.

The tenth sort grows naturally upon the *Austrian* mountains. It has also been found growing in plenty in *Knotsford-More* in *Cheeshire*; this is a perennial plant. The leaves are gathered in clusters at the bottom; they are spear-shaped; the stalk rises about six inches high, garnished with narrow leaves the whole length, placed alternately, and sit close to them; the flowers are produced in small clusters at the top of the stalk; they have five yellowish petals, having several red spots on their inside. This plant is difficult to propagate in gardens, for it naturally grows upon bogs, so that unless it is planted in such loose rotten earth, and kept constantly moist, it will not thrive.

The eleventh sort grows naturally upon the *Pyrenean* and *Helvetian* mountains, as also upon *Ingleborough-Hill* in *Yorkshire*, *Snowden* in *Wales*, and other high places in the north of *England*. This is a perennial plant, whose stalks trail upon the ground, and are seldom more than two inches long, garnished with small oval leaves standing opposite, which lie over each other like the scales of fish; they are of a brown green colour, and have a resemblance of *Heath*. The flowers are produced at the end of the branches, of a deep blue, so make a pretty appearance during their continuance, which is great part of *March*, and the beginning of *April*. This is propagated by parting of the roots; the best time for doing it is in autumn: it must have a shady

situation and a moist soil, otherwise it will not thrive in gardens.

The twelfth sort grows naturally upon the *Alps*, *Pyrenees*, and *Helvetian* mountains; it is also found growing plentifully on *Ingleborough-Hill* in *Yorkshire*, *Snowden* in *Wales*, and some other places in the north. This is a perennial plant, whose branches spread flat upon the ground, and put out roots at their joints, garnished with fine soft leaves like moss, some of which are entire, and others cut into three points. The branches join so close together, as to form a soft roundish bunch like a pillow or cushion, from whence some have given it the appellation of *Ladies Cushion*; the flower-stalks rise three or four inches high; they are slender, erect, and have two or three small leaves, some are entire, and others trifid; they are of a bright green colour, and soft to the touch; the flowers grow in small bunches at the top of the stalk; they are small, of a dirty colour, so make no great appearance.

This sort propagates fast enough by its trailing branches, provided it is planted in a moist soil and a shady situation, but it will not thrive in dry ground, or where it is much exposed to the sun. The best time to remove any of these plants is in autumn, that they may have the benefit of the winter's rain to establish them well before the dry weather of the spring comes on, for when they are planted late, they are very subject to die, unless they are supplied with water, and they seldom make any figure the first year.

SCABIOSA. *Tourn. Inst. R. H.* 463. tab. 263 & 264. Scabious.

The Characters are,

The common empalement is composed of many leaves, containing many flowers; it has several series of leaves surrounding the receptacle upon which they sit; the inner are gradually smaller. The flowers have a double empalement, and sit upon the germen; the outer is short, membranaceous, folded, and permanent; the inner is divided into five awl-shaped capillary segments. The florets have one erect tubulous petal, cut into four or five parts at the brim; they have four weak, awl-shaped, hair-like stamina, terminated by oblong prostrate summits. The germen is situated under the receptacle of the florets, supporting a slender style, crowned by an obtuse stigma, which is obliquely indented; it afterward becomes an oblong oval seed sitting in the common empalement, and crowned by the cup of the flower.

The Species are,

1. SCABIOSA *corollulis quadrifidis radiantibus, caule hispido*. *Hort. Cliff.* 31. Scabious with quadrifid radiated florets, and a rough hairy stalk; or *Meadow Scabious* of the shops.

2. SCABIOSA *corollulis quadrifidis æqualibus, caule simplici, ramis, approximatis, foliis lanceolato-ovatis*. *Hort. Cliff.* 30. Scabious with quadrifid florets, which are equal, a single stalk, and branches growing near, with spear-shaped oval leaves.

3. SCABIOSA *corollulis quadrifidis æqualibus, squamis calycinis ovatis obtusis*. *Lin. Sp. Plant.* 98. Scabious with quadrifid florets, which are equal, and the scales of the empalement oval and obtuse.

4. SCABIOSA *corollulis quadrifidis fistulosis æqualibus, squamis calycinis acutis, caule paniculato, foliis rigidis pinnatifidis*. Scabious with quadrifid fistulous florets, which are equal, acute scales to the empalement, a paniculated stalk, and stiff wing-pointed leaves.

5. SCABIOSA *corollulis quadrifidis æqualibus, somnitibus longioribus, squamis calycinis acutis, foliis radicalibus lanceolatis integerrimis, caulinis divisis*. Scabious with quadrifid equal florets, longer stamina, acute scales to the empalement, and the lower leaves spear-shaped and entire, but those on the stalks divided.

6. SCABIOSA *corollulis quadrifidis radiantibus, caule hispido, foliis lanceolatis pinnatifidis, foliolis imbricatis*. *Lin. Sp. Plant.* 99.

Scabious with radiated quadrifid florets, a rough hairy stalk, and spear-shaped wing-pointed leaves, with lobes set over each other in the manner of tiles.

7. *SCABIOSA corollulis quadrifidis æqualibus, calycibus squamosis nitidis obtusis, caule dichotomo, foliis pinnatifidis.* Scabious with equal quadrifid florets, neat scaly empalements, which are obtuse, a stalk divided by pairs, and wing pointed leaves.

8. *SCABIOSA corollulis quadrifidis radiantibus, caule simplici, foliis linearibus tomentosis.* Scabious with radiated quadrifid florets, a single stalk, and linear woolly leaves.

9. *SCABIOSA corollulis quinquefidis æqualibus, caule erecto hispido, foliis lanceolatis denticulatis hirsutis, semi-amplexicaulibus.* Scabious with equal quinquefid florets, an erect stalk, which is rough hairy, and spear-shaped hairy leaves, which are somewhat indented, and half embrace the stalks.

10. *SCABIOSA corollulis quinquefidis, foliis pinnatis serratis, receptaculis florum globosis.* Scabious with quinquefid florets, winged sawed leaves, and globular receptacles to the flower.

11. *SCABIOSA corollulis quinquefidis radiantibus, foliis linearilanceolatis integerrimis, caule suffruticoso.* Scabious with radiated quinquefid florets, linear, spear-shaped, entire leaves, and an under-shrub stalk.

12. *SCABIOSA corollulis quinquefidis, foliis lanceolatis subintegerrimis.* Hort. Cliff. 31. Scabious with quinquefid florets, and spear-shaped leaves, which are almost entire.

13. *SCABIOSA corollulis quinquefidis radiantibus, foliis bipinnatis linearibus.* Lin. Sp. Plant. 101. Scabious with radiated quinquefid florets, and linear doubly-winged leaves.

14. *SCABIOSA corollulis quinquefidis, foliis pinnatis, laciniis lanceolatis, pedunculis nudis lævibus longissimis.* Prod. Leyd. 190. Scabious with quinquefid florets, winged leaves, having spear-shaped segments, and long, naked, smooth foot-stalks.

15. *SCABIOSA corollulis quinquefidis, foliis dissectis, receptaculis florum subulatis.* Hort. Cliff. 31. Scabious with five-pointed florets, cut leaves, and awl-shaped receptacles to the flowers.

16. *SCABIOSA corollulis quinquefidis, foliis dissectis, receptaculis florum subrotundis.* Hort. Cliff. 31. Scabious with five-pointed florets, cut leaves, and roundish receptacles to the flowers.

17. *SCABIOSA corollulis quinquefidis, foliis inferioribus integris crenatis, caulinis inciso-crenatis, caule fruticoso.* Scabious with five-pointed florets, the lower leaves entire and crenated, those upon the stalks bluntly cut, and a shrubby stalk.

18. *SCABIOSA corollulis quinquefidis, foliis inferioribus crenatis, caulinis duplicato-pinnatis, caule fruticoso hirsuto.* Scabious with five-pointed florets, the under leaves crenated, those on the stalks doubly-winged, and a shrubby hairy stalk.

19. *SCABIOSA corollulis multifidis, calycibus florum longioribus, caule ramoso, foliis dissectis.* Scabious with many-pointed florets, longer empalements to the flowers, a branching stalk, and cut leaves.

The first sort grows naturally in the fields in divers parts of *England*; it hath a strong, thick, fibrous root, sending out many branching stalks, which rise three feet high; the lower leaves are sometimes almost entire, and at others they are cut into many segments almost to the midrib. The stalks are covered with stiff prickly hairs, garnished with smaller leaves at each joint, which are cut into narrow segments almost to the midrib. The flowers are produced upon naked foot-stalks at the end of the branches; they have a double empalement, which is hairy, and composed of several tubulous florets, cut into four points at the top, each having a particular empalement, resting upon the common placenta. The florets round the border are larger and deeper cut than those which compose the disk or mid-

dle; they have four weak stamina, which soon shrink after the flowers open. In the center is situated a style, which is longer than the floret, terminated by a roundish stigma. The flowers are of a pale purple colour, and have a strong faint odour. This is the sort intended by the College of Physicians for medicinal use, under the title of *Scabiosa*.

The second sort grows naturally in moist woods and pastures in most parts of *England*, and is directed by the College of Physicians to be used, under the title of *Morsus Diaboli*, or Devil's Bit; this hath a short tap-root, which appears as if the end of it were bitten or cut off, from whence it had the titles of *Succisa*, and *Morsus Diaboli*. The leaves are oval, spear-shaped, and smooth; the stalks are single, about two feet high, garnished with two leaves at each joint, shaped like those below, but smaller; they generally send out two short foot-stalks from their upper joint, standing opposite, which are each terminated by one small blue flower, as is also the principal stalk with one larger. These are constructed in the same way as the former. As these plants are to be found plentifully in the fields and woods, they are seldom admitted into gardens.

The third sort grows naturally in *Transylvania*. It is an annual plant, which is preserved by botanists for variety; but as the flowers have little beauty, so it is rarely allowed a place in other gardens. The stalks rise four or five feet high, dividing into several branches; the leaves are hairy, cut almost to the midrib. The flowers are small, of a pale-purplish colour; the seeds ripen in autumn; if they are permitted to scatter, the plants will come up without care.

The fourth sort grows naturally in *Spain* and *Portugal*. It is an annual plant; the stalk is stiff, and rises upward of three feet high, dividing toward the top into several branches, which are again divided into naked foot-stalks, each sustaining one small, pale, purplish flower, composed of many florets; the leaves are stiff, and cut into many winged points.

The fifth sort grows naturally upon the *Alps* and *Apennines*. This hath a perennial root, from which come out many entire, smooth, spear-shaped leaves; the stalk is single, sending out two short naked foot-stalks from the upper joint; the leaves upon the stalks are cut pretty deeply on their edges. The flowers are nearly of the same size and form with those of the first sort. It may be propagated by seeds, and will thrive in a shady moist border, requiring no other care but to keep the ground clean, and allow them room to spread.

The sixth sort is a biennial plant, which grows naturally in some parts of *Italy*, and also in *Tartary*. It rises with a strong branching stalk four or five feet high, closely armed with stiff prickly hairs; the lower leaves are spear-shaped, cut deeply on the sides in winged points; those upon the stalks are more entire, some of them are sharply sawed on their edges, and those at the top are linear and entire. The flowers grow from the sides and at the top of the stalks; they are white, and each floret sits in a bristly empalement. The seeds ripen in autumn; it rises from scattered seeds, and requires no care.

The seventh sort grows naturally in *Isiria*. This hath a perennial root; the lower leaves are almost entire; the stalk is stiff, and rises two feet high, dividing into two upward, which spread asunder; and in the division arises a naked foot-stalk, which (as also the side branches) are terminated by flowers, composed of many white florets, inclosed in a scaly empalement, whose scales are obtuse; the leaves on the stalks are wing-pointed and stiff.

The eighth sort grows naturally upon the mountains in *Italy*. This has a perennial root, from which arise three or four stalks, whose lower parts are garnished with linear leaves, of a silvery colour, ending in acute points; the upper

per part of the stalk is naked, sustaining at the top one pale blue flower, made up of several four-pointed florets. It is propagated by seeds as the other sorts, and loves a soft loamy soil and a shady situation.

The ninth sort grows naturally on the *Alps*. This has a perennial root, from which arise several pretty strong hairy stalks three feet high, garnished with spear-shaped leaves, placed opposite, which embrace the stalks half round with their base; they are of a dark green on their upper side, but pale on their under, hairy, having a few indentures on their edges, and ending in acute points. The flowers are produced at the top of the stalks in the same manner as those of the first sort, and are like them. This is hardy, and loves a light loamy soil and a shady situation; it is propagated by seeds.

The tenth sort grows naturally on the *Alps*. This has a perennial root, composed of many strong fibres, from which arise several strong channelled stalks upward of four feet high, garnished with winged leaves, composed of four or five pair of lobes, which are unequal in size and irregularly placed, sawed on their edges, and end in acute points. The flowers are produced on naked foot-stalks at the end of the branches; the receptacles are globular; the flowers are of a whitish yellow, and the seeds ripen in autumn. This may be propagated either by seeds or parting of the roots; it loves a loamy soil.

The eleventh sort grows naturally in *Sicily*. This rises with a shrubby stalk three feet high, dividing into several ligneous knotty branches, garnished with narrow silvery leaves, which are entire. The flowers stand upon very long naked foot-stalks at the end of the branches; they are made up of many five-pointed tubulous florets, of a fine blue colour. These are not succeeded by seeds here. It is propagated by slips or cuttings, which readily take root if they are planted in any of the summer months, if they are shaded from the sun, and duly refreshed with water. When these have made good root, some of them may be planted on a dry border near to a south wall, where they will live in common winters; but as they are frequently destroyed by severe frost, so some of the plants should be planted in pots, and in winter placed under a common frame, where they may be protected from frost, but in mild weather enjoy the free air.

The twelfth sort grows naturally in *Crete*. This hath a shrubby stalk, which rises about the same height as the former, and divides into many branches; the leaves are shorter, much broader, and not so white as those of the former sort; the flowers are not so large, and are of a pale purple colour. This flowers from the end of *June* till autumn, but it does not ripen seeds in *England*. It is propagated by slips or cuttings in the same way as the former, and requires the same treatment.

The thirteenth sort grows naturally in *Germany*. This hath a perennial root, sending out many leaves near the ground, which are divided into narrow segments to the midrib; these segments are cut on their edges into regular acute points, like winged leaves; the stalks rise two feet high, garnished with very narrow cut leaves; they divide into several long foot-stalks, each being terminated by a yellowish flower, with radiated borders. This may be propagated by seeds, and will thrive any where.

The fourteenth sort grows naturally in the *Levant*. This is a low perennial plant, with a branching stalk; the lower leaves are cut, but the upper leaves are narrow and entire, of a silvery colour. The flowers are small, of a pale colour, and have no scent, so is only kept in botanick gardens for the sake of variety. It is propagated by seeds, and is hardy enough to live in the open air.

The fifteenth sort grows naturally in *India*. This is an

annual plant, which is commonly cultivated in gardens for ornament. Of this there is a great variety in the colour of their flowers; some of them are of a purple, approaching to black, others are of a pale purple, some are red, and others have variegated flowers; these also vary in the shape of their leaves, some of them having finer cut leaves than others; and sometimes from the side of the flower-cup; there comes out many slender foot-stalks, sustaining small flowers, in like manner as the *Hen and Chicken Daisies*; but as these are accidental varieties which come from the same seeds, they need not be particularly enumerated here.

The flowers of this sort are very sweet, and continue a long time. The plants are propagated by sowing of their seeds; the best time for which is about the latter end of *May* or the beginning of *June*, that the plants may get strength before winter; for if they are sown too early in the spring, they will flower the autumn following, and the winter coming on soon, will prevent their ripening seeds; besides, there will be fewer flowers upon those, than if they had remained strong plants through the winter, and had set forth their flower-stems in spring; for these will branch out, and produce a prodigious number of flowers, continuing a succession of them on the same plants from *June* to *September*, and produce good seeds in plenty.

The seeds of these plants should be sown upon a shady border of fresh earth (for if they are sown upon a place too much exposed to the sun, and the season should prove dry, few of them will grow.) When the plants come up, they may be transplanted into other beds or borders, observing to water and shade them until they have taken root; after which they will require no farther care, but to keep them clear from weeds till *Michaelmas*, when they may be transplanted into the middle of the borders in the pleasure-garden, where the several sorts being intermixed, will make an agreeable variety.

The sixteenth sort grows naturally in *Spain*. This is an annual plant; the stalks rise three feet high; they are hairy, and garnished with oblong leaves, which are deeply notched on their edges; those on the upper part of the stalk are cut almost to the midrib into fine segments. The flowers stand upon long foot-stalks at the top of the stalks; these have globular receptacles; the florets are large, and spread open like a star; they are of a pale purple colour; in favourable seasons the seeds ripen in *September*, but in cold moist years they do not ripen here. It is propagated by seeds, which should be sown in beds of light loamy earth, where the plants are to remain; when the plants come up, they must be thinned and kept clear from weeds, which is all the culture they require.

The seventeenth sort grows naturally at the *Cape of Good Hope*. This hath a weak shrubby stalk, which divides into several branches, rising about five feet high, garnished with oval spear-shaped leaves, which are entire, and deeply crenated on their edges, of a light green, and a little hairy. The flower-stalk is produced at the end of the branches, sustaining one pale flesh-coloured flower, composed of many five-pointed florets. This plant continues flowering great part of summer, and sometimes it produces good seeds in *England*.

The eighteenth sort is also a native of the *Cape of Good Hope*. It hath a shrubby stalk like the former; the stalks are hairy, and divide into several branches, garnished toward the bottom with spear-shaped, entire, crenated leaves, but those on the upper part of the stalk are doubly winged. The flowers are produced upon long naked stalks at the end of the branches; they are large, of a pale flesh colour, but have no scent; they continue in succession all the summer, and sometimes the early flowers are succeeded by seeds, which ripen in autumn.

Both these sorts may be propagated by cuttings, which may be planted in a shady border during any of the summer months. When these have put out good roots, they should be taken up and planted in pots, and placed in the shade till they have taken new root; then they may be removed to a sheltered situation, where they may remain till the frost begins, when they should be removed to shelter, for they are too tender to live in the open air through the winter; but as they only require protection from frost, so they should have as much free air as possible in mild weather, to prevent their being drawn up weak; and in the middle or latter end of *April*, they may be placed in the open air in a warm situation, afterward treating them as other hardy foreign plants.

The nineteenth sort grows naturally about *Aleppo*. This is an annual plant, with a very branching stalk near three feet high, garnished with leaves at each joint that are variously cut. The flowers are produced upon long foot-stalks at the end of the branches; they have very long empalements; the florets round the border are cut into several fringed segments. They are of a flesh colour, and continue in succession from *July* to autumn, and in favourable seasons the seeds ripen here pretty well. This is propagated by seeds, which should be sown, and the plants afterward treated in the same way as the common Sweet, or *Indian Scabious*.

SCANDIX. *Tourn. Inst. R. H.* 326. *tab.* 173. *Shepherds Needle, or Venus-comb.*

The Characters are,

It hath an umbelliferous flower; the general umbel is long and has few rays; the particular umbels have many: the general umbel has no involucre, the particular have a five-leaved one the length of the umbels: the general umbel is deformed, and has hermaphrodite florets in the disk, and female in the rays. The flowers have five inflexed heart-shaped petals; the inner are small, and the outer large; and five slender stamina, terminated by roundish summits, with an oblong germen, supporting two permanent styles, crowned by obtuse stigmas. The germen afterward turns to a long fruit, divided in two parts, each having one furrowed seed, convex on one side, and plain on the other.

The Species are,

1. SCANDIX *feminibus laevibus rostro longissimo.* *Hort. Cliff.* 101. Scandix with smooth seeds, and the longest beak; common *Shepherds Needle*.

2. SCANDIX *feminibus subulatis hispida, floribus radiatis, caulibus laevibus.* *Lin. Sp. Plant.* 257. Scandix with prickly awl-shaped seeds, radiated flowers, and smooth stalks.

3. SCANDIX *feminibus pedunculo villosa brevioribus.* *Flor. Leyd.* 111. Scandix with short hairy foot-stalks.

4. SCANDIX *feminibus hispida, involucri umbello multifida, caulibus asperis.* Scandix with bristly seeds, many-pointed involucre to the umbels, and rough stalks.

5. SCANDIX *feminibus sulcatis angulatis.* *Hort. Cliff.* 101. Scandix with angular furrowed seeds.

6. SCANDIX *feminibus ovatis hispida, corollis uniformibus, caule laevi.* *Lin. Sp. Plant.* 257. Scandix with oval rough seeds, the petals of the flowers uniform, and a smooth stalk.

The first sort grows naturally in stiff lands amongst the Corn in many parts of *England*, so is not cultivated in gardens. It is an annual plant; the leaves are finely divided into small segments, and have long foot-stalks; the stalks rise six inches high. The flowers are small, white, and like those of wild *Chervil*, and sit upon the top of the beak or horns, which are the rudiment of the pod. At the bottom of the small umbel five leaves embrace the stalk, with broad and short foot-stalks, which are afterward cut into small segments like the rest: the seed is long, and runs into a small point, resembling a large needle, but the umbels have great resemblance to the umbels of *Musk Crane's-bill*.

If the seeds are permitted to scatter, there will be a plentiful supply of young plants.

The second sort grows naturally in the south of *France, Italy, and Crete*. This is an annual plant, with low spreading stalks, garnished with very narrow fine cut leaves, placed thinly. The flowers are small, white, and stand in small umbels at the top of the stalks; these are succeeded by awl-shaped rough seeds.

The third sort grows naturally in the *Levant*. This is an annual plant, with fine cut leaves; the stalks rise eight inches high, garnished at each joint with a fine cut leaf, and terminated by an umbel of white flowers, with large heart-shaped petals. The horns of this are longer than of any other sort, and their foot-stalks are very short and hairy.

The fourth sort grows naturally in *Crete*. This hath larger leaves than either of the former, which are finely cut; the stalks grow a foot high, and divide into many rough channelled branches; the umbels have a many-leaved involucre, and the seeds are rough.

These four sorts will sow themselves where-ever they are once introduced, and require no other care but to thin them, and keep them clean from weeds.

The fifth sort grows naturally in *Germany*, but has been long kept in the *English* gardens, and of late years the seeds have been thrown out of gardens, so that the plants are frequently found growing naturally in the neighbourhood of those gardens. It has a very thick perennial root, composed of many fibres, of a sweet aromack taste like *Aniseed*, from which come forth many large leaves, that branch out somewhat like those of *Fern*, from whence it was titled *Sweet Fern*. The stalks grow four or five feet high; they are hairy and fistulous. The flowers are disposed in an umbel at the top of the stalk; they are white, and have a sweet aromack scent: the out-petal of the flower is large; the two side ones are of a middle size, but the two inner are small; these are succeeded by long, angular, furrowed seeds, having the taste and scent of *Aniseed*.

This sort propagates fast by seeds, which, if permitted to scatter, there will be plenty of the plants arise, and these may be transplanted to any abject part of the garden, for it will grow in any soil or situation, and will require no care.

The sixth sort grows naturally on the side of banks and foot-ways in many parts of *England*. This is an annual plant, whose seeds drop early in the summer; the plants come up in autumn, and flower early in the spring. The leaves of this are finely divided, very like those of the *Garden Chervil*, but are hairy; the stalks rise a foot and a half, or two feet high, dividing into branches. These sustain umbels of small white flowers, which are succeeded by short, hairy, crooked seeds.

There have been some instances of the ill effects of this plant, when taken inwardly; some who have eaten this herb in soups, by mistaking it for *Garden Chervil*, have narrowly escaped with their lives.

SCHINUS. *Lin. Gen. Plant.* 479. *Indian Mastick.*

The Characters are,

The flower hath a small empalement with five indentures at the top; it has five small petals, which spread open, and nine or ten slender stamina, with a roundish germen, supporting a short thick style, crowned by a single stigma. The germen afterward turns to a globular berry with one cell, inclosing one globular seed.

The Species are,

1. SCHINUS *foliis pinnatis, foliolis serratis, impari longissimo, petiolo aequali.* *Lin. Sp. Plant.* 388. Schinus with winged leaves, whose lobes are sawed, the end one being very long, and the foot-stalks equal.

2. SCHINUS *foliis pinnatis, petiolo marginato articulado subtus aculeato.* *Lin. Sp. Plant.* 389. Schinus with winged leaves,

leaves, and jointed bordered foot-stalks, having thorns on the under side.

These are all the species of this genus which I have seen growing in the *English* gardens, for the Iron Wood of *Jamaica*, which Dr. *Linnaeus* has ranged in this genus, has male and female flowers on different trees; and the male flowers which have blown here, are Polyandria, so cannot be here placed.

The first sort grows naturally in *Peru* and *Mexico*; from both these countries I have received the seeds. This rises with a woody stalk ten or twelve feet high, dividing into many branches, covered with a dark brown bark; the leaves are placed alternate on the branches; they are composed of several pair of lobes, from ten to fifteen, terminated by one lobe, which is longer than the others, of a lucid green, and when bruised emit a turpentine odour. The flowers are produced in loose bunches at the end of the branches; they are very small, white, and composed of five small petals, which have small empalements, indented in five parts at the brim.

This plant is propagated by seeds, which should be sown in pots, and plunged into a moderate hot-bed. If the seeds are good, the plants will appear in about five or six weeks; and if they are properly managed, by admitting fresh air daily to them, according to the warmth of the season, they will be fit to transplant in about five or six weeks after, when they should be each planted in a small pot, and plunged again into a moderate hot-bed, shading them from the sun till they have taken fresh root; then they must be gradually inured to the open air, into which they should be removed soon after, placing them in a sheltered situation, where they may remain till autumn; but they must be removed into shelter before the first frosts, otherwise their tops will be killed, and thereby the plants are frequently destroyed.

These plants are tender when young, so require a little warmth in winter; but after two or three years growth, they will live in a green-house, where, as they retain their leaves all the year, they will make a variety. It may also be propagated by layers and cuttings; the layers should be put down in the spring, and by the following spring they will be rooted; the cuttings should be planted in *April*, which will put out roots in about two months, and may afterward be treated as the seedling plants.

The second sort grows naturally in the *West-Indies*. This rises with a ligneous stalk eight or ten feet high, sending out many branches, which have a grayish bark, garnished with winged leaves, whose midrib is bordered and jointed, armed with crooked spines under each joint. The lobes are small, oblong, of a lucid green; the spines are short and crooked. This sort has not as yet produced flowers in the *English* gardens, so I can give no farther description of the plant.

It is propagated by seeds, which should be sown in small pots, and plunged into a hot-bed of tanners bark; these seeds will often lie three or four months in the ground, and sometimes a whole year; therefore if the plants should not come up the same year, the earth should not be disturbed in the pots, but placed in the winter in the bark-bed in the stove, and the spring following plunged again into a fresh hot-bed, which will bring up the plants if the seeds are good. When the plants are come up, and are fit to remove, they should be each planted in a separate small pot, and plunged into the tan-bed, where they must be shaded till they have taken new root, after which they must be treated as other tender stove-plants.

SCILLA. *Lin. Gen. Plant.* 378. Squills.

The Characters are,

The flower has no empalement; it has six oval petals, which

spread open like a star, and six awl-shaped stamina, terminated by oblong prostrate summits. It has a roundish germen, supporting a single style, crowned by a single stigma. The germen afterward becomes a smooth oval capsule with three furrows, divided into three cells, filled with roundish seeds.

The Species are,

1. SCILLA radice tunicatâ. *Hort. Cliff.* 123. Squill with a coated root; common Squill.

2. SCILLA radice squamatâ. *Hort. Cliff.* 123. Squill with a scaly root.

3. SCILLA radice solidâ, corymbo conferto hemispherico. *Lin. Sp. Plant.* 308. Squill with a solid root, and an hemispherical corymbus of flowers.

4. SCILLA radice solidâ, corymbo conferto conico. *Lin. Sp. Plant.* 309. Squill with a solid root, and a conical corymbus of flowers.

5. SCILLA radice solidâ, floribus lateralibus alternis subnutantibus. *Hort. Cliff.* 123. Squill with a solid root, and flowers growing alternately from the sides of the stalk, which nod.

6. SCILLA radice solidâ, floribus lateralibus crebriusculis paucioribus. *Hort. Cliff.* 123. Squill with a solid root, and erect flowers growing thinly.

7. SCILLA radice solidâ, foliis filiformibus linearibus floribus corymbosis, pedunculis nudis adscendentibus longitudine floris. *Lin. Sp. Plant.* 309. Squill with a solid root, slender linear leaves, flowers growing in a corymbus, and naked foot-stalks.

8. SCILLA radice solidâ, floribus paniculatis subnutantibus. Squill with a solid root, and flowers growing in panicles, which nod.

9. SCILLA radice solidâ, racemo conico, floribus numerosis adscendentibus. Squill with a solid root, and a conical spike of many flowers, rising above each other.

10. SCILLA radice solidâ, corymbo conferto hemispherico, scapo longissimo. Squill with a solid root, an hemispherical corymbus, and the longest stalk.

The first is the Squill or Sea Onion, whose roots are used in medicine, of which there are two sorts, one with a red, and the other a white root, which are supposed to be accidental varieties, but the white are generally preferred for medicinal use. The roots are large, somewhat spear-shaped, composed of many coats, lying over each other like Onions; at the bottom come out several fibres. From the middle of the root arise several shining leaves, which continue green all the winter, and decay in the spring; then the flower-stalk comes out, which rises two feet high, is naked half way, and terminated by a pyramidal thyrse of flowers, which are white, composed of six petals, which spread open like the points of a star. This grows naturally on the sea-shores, and in the ditches, where the salt water flows with the tide, in most of the warm parts of *Europe*, so cannot be propagated in gardens, the frost in winter always destroying the roots, and for want of salt water they do not thrive in summer. Sometimes the roots, which are brought for use, put out their stems, and produce flowers without being planted in earth, as they lie in the druggists shops.

The second sort grows naturally in *Spain*, *Portugal*, and the *Pyrencees*. This has a scaly root like the Lily, for which reason *Tournefort* separated it from the starry Hyacinth, and constituted a genus of it with the title of Lilio Hyacinthus. The root is oblong and yellow, very like those of *Martagon*; the leaves are shaped like those of the white Lily, but smaller; the stalk is slender, and rises a foot high; it is terminated by blue flowers like those of the starry Hyacinth.

The third sort grows naturally in *Portugal*. This hath a roundish, solid, bulbous root, like the Hyacinth. The leaves come out sparsedly, are very like those of the *English*

Hair-bells; the stalk rises seven or eight inches high, and is terminated by clustered flowers of a pale blue colour, which at first are disposed in a sort of umbel or depressed spike, but afterward draws up to a point, forming a conical corymbus.

The fourth sort grows naturally in *Spain* and *Portugal*. This has been long known in the *English* gardens by the title of Hyacinth of *Peru*. There are two varieties of this, one with a deep blue, and the other a white flower; the latter is more rare here than the former. The root of this is large, solid, and raised in the middle a little pyramidal, covered with a brown coat, from which come out five or seven leaves before winter, of a lucid green, keeled, and spread almost flat on the ground. From the center of these come out one, two, or three stalks, according to the strength of the root; these are thick, succulent, six or eight inches high, terminated by a conical corymbus of flowers, of a deep blue in some, and others are white, standing upon pretty long foot-stalks; they are composed of six petals, which spread open like a star. In the center of the petals is situated a large roundish germen, supporting a short style, crowned by a single stigma, and round the germen come out six short stamina, which spread asunder, terminated by oblong prostrate summits. The germen afterward turns to a roundish three-cornered capsule, having three cells, which are filled with roundish seeds.

The fifth sort grows naturally in *Byzantium*, and was introduced here about the year 1590. The root of this is large, solid, and of a purplish colour, from which come out five or six leaves a foot long, are keeled, channelled, and of a lucid green; between these arise two, three, or four purplish stalks about eight or nine inches high, sustaining toward the top five or six Star-flowers, which come out singly from the side of the stalk; they are of a Violet blue colour, having a prominent germen in the center, supporting a slender style, attended by six slender stamina, terminated by purple summits.

The sixth sort is commonly known in the gardens by the title of early starry Hyacinth. There are two varieties of this, one with a deep blue, and the other with a white flower; they grow naturally in some parts of *France* and *Germany*. The roots are solid, roundish, about the size of a Nutmeg, from which comes out a slender channelled stalk four or five inches high, having generally two leaves near the bottom, one situated above the other, which embrace the stalk with their base. The flowers are thinly placed toward the top of the stalk; the lower ones have foot-stalks an inch long, but those of the upper shorten gradually to the top; they are composed of six petals, spreading in form of a star, having a turgid germen in the center, supporting a short style, attended by six stamina, which in the blue flowers are of the same colour, and those in the white flowers are white.

The seventh sort is the small autumnal starry Hyacinth, which grows naturally in several parts of *England*, particularly on *St. Vincent's Rock* near *Bristol*, at the *Lizard-Point* in *Cornwall*, upon *Blackbeath* in *Kent*, and *Richmond-green*. This has a round, white, bulbous root, from which come forth a few narrow leaves about six inches long. In the center of these arise one or two slender stalks five or six inches high, naked, sustaining a small corymbus of flowers at the top, which are small, star-pointed, and of a pale blue colour; these appear the beginning of *September*, at which time the leaves come out, and continue growing all the winter, and in the spring they die away.

The eighth sort grows naturally in *Spain* and *Portugal*. It hath an oblong, white, bulbous root, from which come out five or six leaves a foot long, a little keeled. The flower-stalk rises nine or ten inches high, is firm, and

sustains many starry flowers at the top, disposed in a loose panicle, each standing upon a pretty long foot-stalk, which is erect, but the flower nods on one side; they are of a deep blue Violet colour, having a prominent germen, which afterward turns to a three-cornered capsule, having three cells, filled with roundish seeds.

The ninth sort grows naturally in *Italy*. This hath a solid, white, bulbous root, from which arise several leaves like those of the common sort. The stalk rises ten or eleven inches high, terminated by a conical racemus of flowers, of a deep purple colour.

The tenth sort has a very large bulbous root, from which come out several leaves, which at first are upright, but afterward bend toward the earth; they are of a thick substance and keeled, of a lucid green, with downy threads on their under side. Between the leaves arise the flower-stalk, which is a foot and a half long, round, firm, and naked, sustaining at the top a large cluster of flowers, formed into an hemispherical corymbus: these have six petals, which spread open in form of a star, of a purple colour, and have blue bottoms, with a dark blue vein running lengthwise in the middle of each petal.

There is another sort of this, which grows naturally in the *Lewant*, whose leaves are shaped like those of the *Peruvian* Hyacinth, but longer, and stand erect; this propagates very fast by offsets, but never flowers here. I have kept the roots in all situations almost forty years, and have not seen one flower.

These plants are all of them hardy, and may be propagated by seeds or offsets, the latter being the more expeditious way, is generally practised. The roots may be transplanted after the leaves are decayed, but, if they are removed after they have put out new fibres, they rarely succeed, at least they will not flower the following spring; they may be treated in every respect like the ordinary kinds of Hyacinths.

If they are propagated by seeds, they should be sown in autumn, soon after they are ripe, either in shallow boxes or pans, in the same manner as has been before directed for Hyacinths, to which the reader is desired to turn, to avoid repetition.

SCLAREA. *Tourn. Inst. R. H. 179. tab. 82. Clary.*

The Characters are,

The flower has a tubulous empalement, which widens at the top, and has five acute points at the brim; it is of the lip kind, with one petal, having a crooked tube, which enlarges at the chaps, where it is divided into two lips; the upper lip is erect and arched; the under lip is cut into three segments; it has two stamina, which are situated under the upper lip, terminated by oblong erect summits, and a four-pointed germen, supporting a forked style longer than the upper lip, crowned by a bifid stigma. The germen afterward becomes four roundish seeds, which ripen in the empalement.

The Species are,

1. SCLAREA foliis rugosis oblongo-cordatis serratis, floribus calyce longioribus concavis acuminatis. Clary with rough, oblong, heart-shaped, sawed leaves, those among the flowers concave, pointed, and longer than the empalement; or common Clary.

2. SCLAREA foliis oblongis dentato-angulatis tomentosiss, verticillis lanatis. Clary with oblong, angular, indented, woolly leaves, and the whorls of the flowers covered with down.

3. SCLAREA foliis oblongo-ovatis dentato-serratis tomentosiss, verticillis lanatis sessilibus. Clary with oblong oval leaves, which are woolly, indented like a saw, and woolly whorls of flowers sitting close to the stalk.

4. SCLAREA foliis ovatis sinuato-dentatis tomentosiss, caule erecto, verticillis lanatis sessilibus. Clary with oval, sinuated, indented

indented leaves, which are woolly, an erect stalk, and woolly whorls fitting close to the stalks.

5. *SCLAREA foliis cordato-oblongis crenatis summis amplexicaulibus, verticillis subnudis, corollarum galeis glutinosis.* Clary with oblong, heart-shaped, crenated leaves, those on the top embracing the stalk, almost naked whorls, and the helmet of the flower glutinous.

6. *SCLAREA foliis lanceolatis obsolete crenatis subtus tomentosis, verticillis minoribus subnudis.* Clary with spear-shaped leaves, which are slightly crenated, woolly on their under side, and very small whorls of flowers, which are almost naked.

7. *SCLAREA foliis cordato-oblongis crenatis glabris, floribus verticillato-spicatis.* Clary with oblong, heart-shaped, crenated, smooth leaves, and spiked whorled flowers.

8. *SCLAREA foliis cordato-lanceolatis acutis, bracteis coloratis, flore brevioribus.* Clary with heart-shaped acute-pointed leaves, and coloured bractæ, which are shorter than the flower.

9. *SCLAREA foliis rugosis pinnatifidis lanatis.* Clary with rough, wing-pointed, woolly leaves.

10. *SCLAREA foliis cordatis acutè crenatis, summis sessilibus, verticillis subnudis remotissimis.* Clary with heart-shaped leaves, which are sharply crenated, those on the top fitting close to the stalks, and naked whorls placed far asunder.

11. *SCLAREA foliis lanceolatis acuminatis, serratis, summis sessilibus, floribus verticillato-spicatis.* Clary with spear-shaped, acute-pointed, sawed leaves, the upper ones fitting close to the stalks, and spiked whorled flowers.

12. *SCLAREA foliis cordato-sagittatis serratis acutis.* Clary with heart-shaped crenated leaves, which are acutely sawed.

13. *SCLAREA foliis ovato-lanceolatis integerrimis, summis cordatis amplexicaulibus hirsutis.* Clary with oval, spear-shaped, entire leaves, those above heart-shaped, embracing the stalks, and hairy.

14. *SCLAREA foliis cordato-ovatis rugosis tomentosis, calycibus hispидis, radice tuberosâ.* Clary with oval, heart-shaped, rough, woolly leaves, prickly empalements, and a tuberous root.

15. *SCLAREA foliis hastato-triangularibus obsolete crenatis, caule tomentoso paniculato.* Clary with triangular halberd-pointed leaves, which are slightly crenated, and a woolly paniculated stalk.

16. *SCLAREA foliis ovatis, utrinque acuminatis serratis.* Clary with oval leaves, pointed at each end, and sawed.

The first sort grows naturally in *Syria*, but has been long cultivated in the *European* gardens, both for the kitchen and shops: it is a biennial plant, which perishes after it has borne seeds. The lower leaves of this are large, rough, wrinkled, oblong, and heart-shaped, and are sawed on their edges. The stalks are large, four-cornered, and clammy, about two feet high, garnished with leaves of the same shape as those at bottom, but smaller, sending out small side branches opposite; the flowers are disposed in large loose spikes at the top of the stalks, placed in whorls round them, of a pale blue colour, having two short hollow acute-pointed leaves under each, of a whitish colour. The empalement of the flower is divided into two lips, the upper ending in three, and the under in two spiculæ. The upper lip of the flower stands erect, is arched at the top, under which is the style, which is nearly of the same length, and the two stamina, which are shorter, sit close to the style. After the flowers are past, the germen turns to four roundish seeds, which ripen in the empalement. The whole plant has a very strong scent.

It is propagated by seeds, which should be sown in the spring, and when the plants are fit to remove, they should be either transplanted into beds, or if a large quantity is required, they may be planted in an open spot of ground in

rows two feet asunder, and one foot distance in the rows. After the plants have taken root, they will require no farther care, but to keep them clean from weeds. The winter and spring following the leaves, which are the only part used, will be in perfection, and in the summer they will run up to flower, and, after they have ripened their seeds, decay, so that there should be annually young plants raised for use.

The second sort grows naturally in *Istria* and *Dalmatia*. There are two varieties of this, one with very broad leaves, which are slightly indented on the sides; the other has longer leaves, which are deeply jagged. The leaves of both sorts are of a thick substance, very woolly, especially on their under side; their upper sides are rugged, and wrinkled like the first sort. The stalks are square, two feet high, sending out many branches opposite, garnished in the first with entire, oval, acute-pointed leaves, which embrace the stalks with their base, but those of the other are long, narrow, and have several deep indentures on their edges. The stalk and branches are terminated by spikes of flowers in whorls; under each of these whorls are two hollow green leaves, which are shorter than the empalement of the flowers; these empalements are divided into two lips, the upper ending in three, and the under in two spiculæ. The under lip or beard of the flower is white, and the helmet or galea is of a pale blue colour; the plants may be propagated in the same way as the first.

The third sort has some resemblance of the second; but the leaves are larger, very woolly, and glutinous, oblong, oval, deeply indented, and end with very acute points. The stalks are woolly, four-cornered, about two feet and a half high, sending out branches by pairs, terminated in loose spikes of whorled flowers, which are smaller than those of the other sorts. It grows naturally in *Portugal* and also in *Syria*; it is propagated by seeds in the same way as the first.

The fourth sort grows naturally in *Sicily* and in the *Archipelago*. The roots of this will continue three or four years; the leaves are oval, very thick, and woolly, and have a few indentures on their borders; the stalks are generally single and erect. When they send out any branches, it is only at bottom, and scarce ever more than two, which also grow erect. The flowers grow in pretty thick whorls almost the length of the stalks; they are shaped like those of the former. This may be propagated by seeds in the same manner as the former, but loves a dry soil.

The fifth sort grows naturally in some parts of *France* and *Germany*; it is generally found in meadows and rich pastures. It has a perennial root, composed of many strong ligneous fibres, from which come out many oblong heart-shaped leaves, of a deep green colour, whose surfaces are rough, crenated on their edges, and stand upon pretty long foot-stalks. The stalks rise three feet high; they are four-cornered; their lower parts are garnished with leaves, whose base embrace them; the flowers grow in long whorled spikes at the top; they are of a fine blue colour, having scarce any small leaves under the whorls. It is propagated by seeds, but the roots continue long.

The sixth sort grows naturally in *Syria*; this is an abiding plant, whose roots run deep in the ground. The leaves are spear-shaped, crenated on their edges, and a little woolly on their under side. The stalks are slender, stiff, and rise a foot and a half high, garnished with smaller leaves of the same shape, set by pairs; the flowers grow in small whorls, disposed in loose spikes at the top of the stalks; they are small, blue, and shaped like those of the other sorts. It is propagated by seeds in the same way as the other sorts.

The seventh sort grows naturally on the sides of highways about *Vienna* and in *Hungary*. This has an abiding root, sending

sending out smooth leaves about the size and shape of those of broad leaved Sage, but are indented on their edges. The stalks are slender, four-cornered, and rise a foot and a half high; their lower parts are garnished with leaves like those at the bottom, but smaller, and are terminated by small whorls of blue flowers. It is propagated by seeds in the same way as the first sort, but the roots will continue several years.

The eighth sort grows naturally in *Austria* and *Bohemia*. This has an abiding root, from which come out many heart spear-shaped leaves, crenated on their edges, of a bright green colour, and have many white spots, dispersed on their surface. The stalks are thick, four-cornered, and rise near three feet high, garnished with leaves by pairs, sitting close to the stalks, which are terminated by loose spikes of flowers in small whorls, whose bractæ are coloured. It is propagated by seeds as the former sorts.

The ninth sort grows naturally in *Syria*; this is a biennial plant. The leaves are very thick, woolly, narrow, and wing-pointed, cut into obtuse segments, nearly opposite on their sides, almost to the midrib, somewhat like a stag's-horn in shape; these spread flat on the ground. The stalk rises more than a foot high; it is thick, four-cornered, and very woolly, sending out branches by pairs, garnished with narrow long leaves, placed opposite at each joint, sawed on their edges. The flowers grow in loose whorled spikes at the top of the stalks; they are shaped like those of the fourth sort. It may be propagated by seeds in the same way as the first sort, but should have a dry soil, otherwise the plants are apt to rot in winter.

The tenth sort grows naturally in *India*, but is hardy enough to live in the open air in *England*. The root of this will abide several years in a dry soil; the lower leaves are heart shaped, acutely crenated on their edges. The stalk is four-cornered, and rises four or five feet high, having two or three pair of smaller leaves on the lower part, standing opposite. The upper part of the stalk, for the length of two feet, is garnished with whorls of flowers, which stand at two or three inches distance from each other, having no leaves under them. The empalement of the flower is hairy and blunt; the galea or helmet of the flower is arched, erect, blue, terminating in a blunt point; the two side segments of the under lip are of a Violet colour; the middle segment, which is indented at the point, is white, and curiously spotted with Violet on the inside; the two side indentures turn yellow, before the flower drops. When the flower is past, the germen turns to four large roundish seeds, which ripen in the empalement. It is propagated by seeds in the same manner as the other sorts.

The eleventh sort grows naturally in the *Levant*. This hath a perennial root, from which come out many spear-shaped leaves, of a dark green colour, sawed on their edges, ending in acute points. The stalks rise three feet high, sending out branches by pairs, garnished with leaves, which toward the top sit close to the stalk. The flowers grow in whorled spikes at the top; they are of a bright blue colour, and the top of the spike is terminated with very deep blue flowers. It is propagated by seeds in the same manner as the other sorts, and the roots will abide many years.

The twelfth sort grows naturally in moist land both in *Germany* and *Italy*; this hath an abiding root, composed of strong ligneous fibres. The leaves are heart-shaped, pointed like a halberd, of a pale or yellowish green colour, and sawed on their edges. The stalks are strong, four-cornered, and rise near four feet high, garnished below with smaller leaves, but the upper part of the stalk is closely set with whorls of large yellow flowers. The whole plant is very clammy, and has a strong scent somewhat like the

first species. This is propagated by seeds in the same way as the other sorts; it is very hardy, and will continue several years, and may be increased by parting of the roots in autumn.

The thirteenth sort grows naturally in *Spain*. This has a perennial root. The lower leaves are oval and spear-shaped; the stalks rise two feet high; they are four-cornered, and send out branches by pairs; the leaves on the upper part of the stalks are heart-shaped, and embrace the stalks with their base; the flowers are of a brimstone colour, shaped like those of the first sort; the style of this is much longer than the upper lip, and is terminated by a bifid stigma; the empalements are hairy, and end with acute points. It is propagated by seeds, which may be sown in the same way as the other sorts, and the plants may be treated in like manner.

The fourteenth sort grows naturally in *Italy*. This has large swelling roots like dugs, as those of the Piony, from which arise many oval heart-shaped leaves spreading on the ground; they have pretty long foot-stalks, and are hairy; between these arise strong four-cornered stalks four feet high, garnished with leaves placed opposite. The upper part of the stalk is garnished with loose spikes of whorled flowers, of a purple colour. This is propagated by seeds in the same way as the other sorts, and the roots will continue several years.

The fifteenth sort grows naturally in the *Canary Islands*. This hath a perennial shrubby stalk, which rises five or six feet high, dividing into many branches, covered with a flocky down, and garnished with halberd-shaped triangular leaves, placed opposite, standing upon long woolly foot-stalks. The top of the stalk branches out in many foot-stalks, forming a sort of panicle. The flowers are of a light blue colour, ranged in whorled spikes, having two small leaves under each whorl. It is propagated by cuttings, which may be planted any time in summer; after they have put out good roots, they should be each planted in a separate small pot, placing them in the shade till they have taken new root; then they may be placed among other hardy kinds of green-house plants in a sheltered situation till *October*, when they should be removed into shelter before hard frost comes on; but as they only require protection from hard frost, so they should have as much free-air as possible in mild weather.

The sixteenth sort grows naturally in *Mexico*. This rises with a shrubby stalk eight or ten feet high, sending out slender, four-cornered, hairy branches, of a purplish colour, garnished with oval leaves, pointed at both ends, and sawed on their edges, of a pale green colour, and hairy on their under side. The flowers grow in close thick spikes at the end of the branches, of a fine blue colour, and appear in winter, so make a pretty variety in the green-house at that season. This plant never produces seeds in *England*, so it is only propagated by cuttings, which may be planted during any of the summer months, in the same manner as the former sort; and the plants may be treated afterward in the same way, with this difference, which is to give it a dry situation in winter, for the young shoots are very apt to grow mouldy upon being in a damp air.

There are some other sorts of less note, which are preserved in botanick gardens for the sake of variety; but those here mentioned are worthy of a place in large gardens, where, if they are intermixed among other large growing plants, they will afford a pretty variety; especially the fifth, eighth, tenth, and eleventh sorts, which produce long spikes of beautiful flowers, and continue a long time in flower. The flowers of the twelfth sort are used in *Holland*, to give a flavour to the *Rhenish* wines, which are brewed at *Dort*.

SCOLYMUS. *Tourn. Inst.* 480. *tab.* 273. The Golden Thistle.

The Characters are,

It hath a flower composed of many hermaphrodite florets, included in an oval imbricated empalement, having many loose sharp-pointed scales. The florets are tongue-shaped, slightly indented in five parts. They have five short hair-like stamina, terminated by tubulous summits. The germen is situated under the floret, supporting a slender style, crowned with two reflexed stigmas. The germen afterward becomes a single seed, which is oblong, triangular, and ripens in the empalement, the seeds being separated by plain, roundish, indented chaff.

The Species are,

1. SCOLYMUS *foliis margine attenuatis*. *Lin. Sp. Plant.* 813. Golden Thistle with leaves, whose edges are thin; or annual Golden Thistle.

2. SCOLYMUS *foliis margine incrassatis*. *Lin. Sp. Plant.* 813. Golden Thistle with leaves, which are thicker on the borders.

The first sort grows naturally in the south of France and Italy. This is an annual plant, which rises with a branching stalk five or six feet high, having two leafy wings running along the sides from joint to joint, which are scoloped and indented; the borders are thinner than the other parts, and armed every way with very sharp spines; they are of a pale green, and sit close to the stalks. The flowers are produced at the top of the stalks, inclosed in leafy involucrements, which are longer than the flowers, and armed with very strong spines; within these are scaly empalements, which lie over each other like the scales of fish, armed with short spines. The flowers are composed of many golden florets.

The second sort grows naturally in Italy and Sicily. This hath a biennial root, from which spring up thick stalks about four feet high, branching out on the sides, garnished with stiff jagged leaves, whose borders are thicker than the other part, armed with spines like the former sort; the stalks have leafy borders as the other, which are strongly armed with spines. The flowers are produced at the top of the stalks, and are shaped like those of the former sort.

They are propagated by seeds, which should be sown in March on a bed of fresh undunged earth, in an open situation; when the plants are come up, they should be kept clear from weeds, and where they grow too close, some of them should be pulled out, so as to leave those which are designed to remain, about two feet asunder. This is all the culture which these plants require, for as they send forth tap roots, they do not bear transplanting well; therefore they must be sown where they are to remain. When the seasons prove dry, the plants will perfect their seeds in autumn, but in wet seasons they rarely ever produce good seeds in England, which renders it difficult to continue the species, without procuring fresh seeds from abroad.

These plants are preserved by those persons who are curious in botany for variety's sake, but are rarely admitted in other gardens.

SCOPARIA. Sweet-weed, or Wild Liquorice.

The Characters are,

The empalement of the flower is cut into four concave segments; the petal is also divided into four equal parts. It has four equal stamina, crowned by short summits, with a conical style, terminated by an acute stigma. The flower is succeeded by a conical capsule, containing many small seeds.

There is but one Species of this genus, viz.

SCOPARIA *dulcis*. *Lin. Sp. Plant.* 116. Wild Liquorice, or Sweet-weed.

This plant grows naturally in most of the islands in the West-Indies, where it often is very troublesome in the plantations, for there is a great quantity of seeds upon each

plant, which, if suffered to scatter, the plants appear soon after, and become troublesome weeds.

The stalks rise about two feet high; they have six angles, branching out on their upper part, and at each joint have three obtuse sawed leaves, standing upon short foot-stalks; the flowers come out from the wings of the stalk upon foot-stalks, two, three, or four arising from the same place; they are white, a little fringed on their edges, and are succeeded by conical capsules, opening with two valves, filled with small seeds.

There is a great affinity between this plant and the Capraria, so that they have been often confounded by botanists; and even those who have been more accurate, have joined them in the same genus; but their difference consists in the form of the flower and the length of their stamina. The four segments in the petals of this are equal, as are also the four stamina; whereas the petal of Capraria is ringent, and two of the stamina are shorter than the other.

This is an annual plant, preserved in curious gardens for the sake of variety, but has little beauty. The seeds must be sown upon a hot-bed, and the plants transplanted on another hot-bed to bring them forward; toward the end of May, when the weather is good, they may be transplanted with balls of earth to their roots to a warm border, where they will flower, and will ripen their seeds in autumn.

SCORDIUM. See Teucrium.

SCORPIURUS. *Lin. Gen. Plant.* 792. Caterpillars.

The Characters are,

The empalement of the flower is of one leaf, erect, blown up, lightly compressed, ending in five acute points. The flower is of the butterfly kind; it has a roundish standard, indented at the point, where it is reflexed and spreading. The wings are loose, almost oval, having obtuse appendages. The keel is half-moon-shaped; the belly is gibbous, pointed, and erect, cut in two parts below. It hath ten stamina, nine joined and one separate, terminated by small summits; and an oblong taper germen a little reflexed, supporting a rising inflexed style, terminated by a point for a stigma. The germen afterward becomes an oblong, taper, leathery, rough, channelled pod, twisted in many longitudinal cells, divided within, and on the outside contracted into knotty joints, each cell containing one seed.

The Species are,

1. SCORPIURUS *pedunculis unifloris, leguminibus testis undique squamis obtusis*. *Lin. Sp. Plant.* 744. Caterpillar with one flower upon a foot-stalk, and a pod covered with obtuse scales on every side.

2. SCORPIURUS *pedunculis bifloris, leguminibus extrorsum obtusè aculeatis*. *Lin. Sp. Plant.* 745. Caterpillar with two flowers on each foot-stalk, and the outside of the pods armed with blunt spines.

3. SCORPIURUS *pedunculis subtrifloris, leguminibus extrorsum spinis distinctis acutis*. *Lin. Sp. Plant.* 745. Caterpillar with foot-stalks, having three flowers, and the outside of the pods armed with sharp distinct spines.

4. SCORPIURUS *pedunculis subquadrifloris, leguminibus extrorsum spinis confertis acutis*. *Lin. Sp. Plant.* 745. Caterpillar with four flowers sometimes upon a foot-stalk, and the outside of the pods armed with sharp spines, which grow in clusters.

5. SCORPIURUS *foliis pinnatis*. Caterpillar with a winged leaf.

The first sort grows naturally in Italy and Spain. This is an annual plant, with trailing herbaceous stalks, and at each joint have one spatule-shaped leaf with a long foot-stalk. From the wings of the leaves come out the foot-stalks of the flowers, which sustain at the top one yellow butterfly flower, which is succeeded by a twisted thick pod, in size and appearance of a large caterpillar, from whence it had this title.

The second sort has stronger stalks than the first; the leaves are much broader; the foot-stalks support two smaller flowers; the pods are slender, longer, and more twisted than those of the first, and are armed with blunt spines on their outside.

The third sort hath slenderer stalks than either of the former; the leaves stand upon shorter foot-stalks, but are shaped like those of the first sort; the foot-stalks of the flowers are slender, and frequently support three flowers; the pods are slender, not so much twisted as the former, and are armed on their outside with sharp distinct spines.

The stalks and leaves of the fourth sort are very like those of the first, but the foot-stalks of the flowers are longer, and each of them have three or four small yellow flowers at the top; the pods are very slender, greatly contorted, and armed with sharp spines on their outside.

The fifth sort has very short stalks; the leaves are winged, composed of four pair of small lobes, terminated by an odd one. The flowers are very small, as are also their pods, which are less twisted than those of the three former.

All these plants are annual, and grow naturally in most of the warm countries in *Europe*, but the first sort has been long cultivated in the *English* gardens.

The plants are preserved in several curious gardens for their oddness more than for any great beauty: they are propagated by sowing their seeds upon a bed of light earth; and when the plants are come up, they must be kept clean from weeds, and should be thinned, so as to leave them about ten inches or a foot asunder, because their branches trail upon the ground; and if they have not room, they are apt to overbear each other.

These plants seldom thrive well, if they are transplanted; therefore the best method is, to put in three or four good seeds in each place where you would have the plants remain. When the plants come up, there should be only one of the most promising left in each place, which should be constantly kept clear from weeds; and when their pods are ripe, they should be gathered and preserved in a dry place till the following spring, to be sown.

The first sort is the best worth cultivating, the pods being large and more visible than the other, and are more in form of a caterpillar.

SCORZONERA. *Tourn. Inst. R. H.* 476. *tab.* 269. *Vipers-grass.*

The *Characters* are,

The common empalement is scaly, cylindrical, and imbricated. The flower is composed of several hermaphrodite florets, which are narrow, tongue-shaped, and indented in five parts. They have five short hair-like stamina, terminated by cylindrical summits. The germen is situated under the floret, supporting a slender style, crowned by two reflexed stigmas. The germen afterward turns to a single, oblong, channelled seed, crowned with a feathery down.

The *Species* are,

1. SCORZONERA *foliis infimis sinuato-dentatis, caulibus linearibus semiamplexicaulis.* Scorzonera with lower leaves indented, those on the stalks linear, and half embracing them with their base.

2. SCORZONERA *caule ramoso, foliis nervosis planis integerrimis.* Scorzonera with a branching stalk, and veined, plain, entire leaves.

3. SCORZONERA *caule subnudo unifloro, foliis nervosis planis.* *Hort. Cliff.* 382. Scorzonera with an almost naked stalk, having one flower, and plain veined leaves.

4. SCORZONERA *foliis lineari-ensiformibus integris carinatis.* *Lin. Sp. Plant.* 791. Scorzonera with linear, sword-shaped, entire leaves, which are keeled.

5. SCORZONERA *foliis lineari-subulatis integris planis, pedunculis cylindricis.* *Lin. Sp. Plant.* 791. Scorzonera with

linear, awl-shaped, entire, plain leaves, and cylindrical foot-stalks.

6. SCORZONERA *foliis subulatis integris, pedunculo incrassato, caule basi villosa.* *Lin. Sp. Plant.* 791. Scorzonera with awl-shaped entire leaves, a thick foot-stalk, and the stalk hairy at its base.

7. SCORZONERA *foliis linearibus multifidis, caule erecto.* Scorzonera with narrow many-pointed leaves, and an erect stalk.

8. SCORZONERA *foliis linearibus pinnatifidis, caulibus procumbentibus.* Scorzonera with narrow many-pointed leaves, and trailing stalks.

The first is the sort which is commonly cultivated in the *English* gardens for food and physick; this grows naturally in *Spain*. The root is Carrot-shaped, about the thickness of a finger, covered with a dark brown skin, is white within, and has a milky juice; the lower leaves are long, ending with a long acute point; they are waved and sinuated at their edges. The stalk rises three feet high, is smooth, branching at the top, and garnished with a few narrow leaves, whose base half embrace the stalk. The flowers terminate the stalks in scaly empalements, composed of many narrow, tongue-shaped, hermaphrodite florets, lying imbricatum over each other, like the scales on fish; they are of a bright yellow colour. After these are decayed, the germen which sits in the common empalement, turns to oblong cornered seeds, having a roundish ball of feathery down at the top.

The second sort is like the first, but the leaves are broader, entire, and are more veined; the stalk does not rise so high, and branches more.

The third sort is shorter than either of the former; the leaves are broader; the stalk is almost naked, and has one yellow flower at the top.

The fourth sort has narrow, keeled, sword-shaped leaves; the stalks are slender; they rise about two feet high, branch toward the top, and sustain pale yellow flowers, which are smaller than those of the former sorts.

The fifth sort has narrow awl-shaped leaves, which are shorter than those of the former; the stalk is taper, and branches at the top; the flowers are of a pale purple colour.

The sixth sort grows a foot and a half high; the leaves are narrow and awl-shaped; the foot-stalk immediately under the flower is thicker than below, and the lower part of the stalk is hairy; the flower is yellow.

The seventh sort rises with a smooth branching stalk two feet high, garnished with narrow leaves, having many winged points, resembling those of Buckshorn Plantain, but larger. The flowers are yellow, and stand upon long naked foot-stalks at the end of the branches.

The eighth sort is exactly like the seventh in every respect, excepting that of the stalks spreading on the ground; which is not accidental, for I have cultivated both sorts above thirty years, and have never found either of them alter.

The first sort only is cultivated for use, the others are preserved in botanick gardens for variety, but are seldom admitted into other gardens.

These plants may be propagated by sowing their seeds the beginning of *April*, upon a spot of light ground. The best method of sowing them is, to draw shallow furrows by a line about a foot asunder, into which you should scatter the seeds, thinly covering them over about half an inch thick, with the same light earth: when the plants are come up, they should be thinned where they are too close in the rows, leaving them at least six inches asunder; and at the same time all the weeds should be cut up. This must be repeated as often as is necessary, for if the weeds are permitted to grow among the plants, they will draw them up weak.

There

There are many people who sow these seeds promiscuously in a bed, and afterward transplant them out at the distance they would have them grow; but this is not so good a method as the former, because their roots commonly shoot downright, which, in being transplanted, are often broken, so that they never will make such fair roots as those which remain in the same place where they are sown; for when the extreme part of the root is broken, the milky juice flows out so, it seldom extends itself in length afterwards, but only shoots out into many forked small roots. These roots may be taken up when the leaves begin to decay, at which time they have done growing, though they may remain in the ground until spring, and may be taken up as they are used; but those which remain in the ground after February, will shoot up their flower-stems, after which they are not so good, being sticky and strong.

If you intend to save seeds of these plants, you should let a parcel of the best remain in the places where they grew; and when their stems are grown to their height, they should be supported with stakes, to prevent their falling to the ground, or breaking. In June they will flower, and about the beginning of August their seeds will ripen, when they should be gathered, and preserved dry till the spring following, for use.

SCROPHULARIA. *Tourn. Inst. R. H. 166. tab. 74.* Figwort.

The Characters are,

The flower has a permanent empalement, cut into five parts at the top. It hath one unequal petal, with a large globular tube. The brim is cut into five small parts; the two upper are large and erect; the two side ones spread open, and the under is reflexed. It has four slender deflexed stamina, two of which are the length of the petal, and two are shorter, terminated by twin summits; and an oval germen, supporting a single style, crowned by a single stigma. The germen afterward turns to a roundish pointed capsule with two cells, which open at the top, and are filled with small seeds.

The Species are,

1. SCROPHULARIA *foliis cordatis basi transversis, caule obtusangulo. Lin. Sp. Plant. 619.* Figwort with heart-shaped leaves, whose base are transverse, and a stalk having obtuse angles.

2. SCROPHULARIA *foliis cordatis petiolatis decurrentibus, caule acutangulo, racemis terminalibus. Hort. Upsal. 177.* Figwort with heart-shaped leaves, and an angular membranaceous stalk, terminated by a racemus of flowers.

3. SCROPHULARIA *foliis cordato-oblongis, basi appendiculatis, racemis terminalibus. Læst. Lin. Sp. Plant. 620.* Figwort with oblong heart-shaped leaves, having appendages at their base, and stalks terminated by a racemus of flowers.

4. SCROPHULARIA *foliis cordato-sagittatis, acutè serratis, racemis terminalibus.* Scrophularia with heart shaped arrow-pointed leaves, which are acutely sawed, and stalks terminated by a racemus of flowers.

5. SCROPHULARIA *foliis cordatis serratis, superioribus alternis, racemis axillaribus, pedunculis bifloris.* Figwort with heart-shaped sawed leaves, those on the upper part placed alternate, and bunches of flowers proceeding from the wings of the stalk, with two flowers on a foot-stalk.

6. SCROPHULARIA *foliis cordatis duplicato-serratis, racemo composito. Flor. Leyd. Prod. 296.* Figwort with heart-shaped doubly-sawed leaves, and compound bunches of flowers.

7. SCROPHULARIA *foliis difformibus, pedunculis axillaribus aggregatis. Flor. Leyd. Prod. 292.* Figwort with difformed leaves, and foot-stalks of flowers gathered together at the wings of the stalk.

8. SCROPHULARIA *foliis difformibus laciniatis villosis, racemis compositis axillaribus.* Figwort with difformed, cut, hairy, leaves, and compound bunches of flowers proceeding from the wings of the stalk.

9. SCROPHULARIA *foliis inferioribus pinnatis, summis integris duplicato-serratis, racemis axillaribus.* Figwort with the lower leaves winged, those at the top entire, doubly sawed, and bunches of flowers at the wings of the stalk.

10. SCROPHULARIA *foliis pinnatis, foliolis acutè dentatis, racemis terminalibus.* Figwort with winged leaves, whose lobes are acutely indented, and panicles of flowers terminating the stalk.

11. SCROPHULARIA *foliis linearibus pinnatis lucidis crassis, foliolis pinnatifidis racemis terminalibus.* Figwort with linear winged leaves, which are thick, shining, wing-pointed lobes, and stalks terminated by panicles of flowers.

12. SCROPHULARIA *foliis lanceolato-linearibus acutè serratis, infernè incis, racemo composito. Flor. Leyd. Prod. 294.* Figwort with linear spear-shaped leaves, which are sharply sawed, and a compound racemus of flowers.

13. SCROPHULARIA *foliis cordatis, pedunculis axillaribus solitariis dichotomis. Hort. Cliff. 322.* Figwort with heart-shaped leaves, single foot-stalks proceeding from their wings, which are divided by pairs.

14. SCROPHULARIA *foliis cordatis, superioribus alternis, pedunculis axillaribus bifloris. Hort. Cliff. 322.* Figwort with heart-shaped leaves, the upper of which are alternate, and foot-stalks proceeding from the wings of the stalks, bearing two flowers.

15. SCROPHULARIA *foliis pinnatis, foliolis incis, racemis simplicissimis terminalibus.* Figwort with winged leaves, whose lobes are cut, and a single thyse of flowers terminating the stalks.

16. SCROPHULARIA *foliis ovatis lanceolatis dentatis, racemis terminalibus.* Figwort with oval, indented, spear-shaped leaves, and a racemus of flowers terminating the stalks.

17. SCROPHULARIA *foliis cordatis serratis acutis basi rotundatis, caule obtusangulo. Hort. Upsal. 177.* Figwort with heart-shaped, acute, sawed leaves, which are rounded at their base, with obtuse angles to the stalks.

18. SCROPHULARIA *foliis ovatis acuminatis serratis, ternis caulem ambientibus, floribus corymbosis terminalibus.* Figwort with oval, acute-pointed, sawed leaves, placed by threes round the stalk, which is terminated by globular bunches of flowers.

The first sort grows naturally in woods and under hedges, in most parts of England, so is seldom admitted into gardens; but being a medicinal plant, it is here mentioned to introduce the others. This hath a spreading root, composed of many knobs, from which arise several four-cornered stalks three feet high, garnished with heart-shaped leaves, sawed on their edges; they are placed by pairs, are of a dark green, or brownish colour on their upper side, but pale on their under, having an odour of Elder. The flowers are produced in small clusters from the sides of the stalks opposite, forming a kind of loose spike to the top; they are of one petal, of a dark purple colour, shaped almost like a lip flower; the upper lip or crest being a little arched, the two side segments spread open, and the under segment is recurved. These are succeeded by roundish capsules, ending in acute points, having two cells, filled with small seeds.

The second sort grows naturally by the side of ditches and watery places in most parts of England. This has a fibrous root, sending out strong four-cornered stalks, which grow near four feet high, garnished with heart shaped leaves, rounded at their points, and crenated on their edges, somewhat like those of Betony, from whence it has been titled Water Betony. The flowers are larger than those of the former, and a little redder, but of the same shape. This sort is sometimes used in medicine, but as it grows wild in common, so it is seldom admitted into gardens. There is

a variety of this with variegated leaves, which is by some preserved in gardens.

The third sort grows naturally in *Italy* and *Spain*, by the side of rivers and other moist places. The stalks of this are stronger, taller, and greener than those of the former; the leaves have generally small appendages at their base; the flowers are greener, and grow thinner upon the stalks than those of the former. In these particulars consist their differences.

The fourth sort grows naturally in *Sicily*; this has a fibrous root. The stalks rise near four feet high, and have sharp angles; the leaves are arrow-pointed, heart-shaped, and are sharply sawed on their edges; the flowers terminate the stalks in loose panicles; they are in shape like those of the former, but of a dark red colour.

The fifth sort grows naturally in *Italy*; it has a perennial root. The stalks rise four feet high, branch out on their side, and are garnished with heart-shaped sawed leaves, which on the upper part of the stalk are placed alternate. The flowers are produced in loose panicles at the wings of the stalk, each foot-stalk supporting two flowers; they are small, and of a brown colour.

The sixth sort grows naturally in *Sicily*; this has a perennial root. The stalks rise four feet high, garnished with heart-shaped leaves, which are doubly sawed on their edges; the flowers are disposed in compound spikes, which sit upon long foot stalks, which arise from the wings of the stalks, and have generally two narrow leaves placed at their base, but the flowers terminate the stalks like the three first sorts.

The seventh sort grows naturally in *Spain*; this has a perennial root. The leaves at the bottom are irregularly cut, and have two appendages at their base; they are smooth, of a lucid green, and sawed on their edges. The stalks rise four feet high, four-cornered, smooth, and garnished with oval leaves, some of which are entire, and others have small lobes or appendages at their base. The flowers grow from the wings of the stalks in clusters, each standing upon a separate foot-stalk; they are of a bright red colour with greenish bottoms, and much larger than either of the former.

The eighth sort grows naturally in *Portugal*; this resembles the seventh, but the stalks are larger and rise higher. The leaves are much longer, have four appendages, and are irregularly sawed on their edges, running out into longer points; the whole plant is hairy; the flowers grow in compound bunches at the wings of the stalks; they are larger than those of the former sort, and have a greater mixture of green in them.

The ninth sort grows naturally in *Italy*; this has a root composed of a few thick fleshy fibres. The stalks are slender, four-cornered, and rise about two feet high; the lower leaves are composed of several pinnæ or lobes, which are sharply sawed, but those on the stalks are entire; on the lower part of the stalk they are placed opposite, but toward the top they are alternate and small. The flowers come out in bunches from the wings of the stalk; they are small, of a dark purple colour, with a mixture of green; the seed-vessels are small and roundish.

The tenth sort grows naturally in *Crete*; this hath a root, composed of fleshy fibres. The lower leaves are broad and jagged, not much unlike those of the *Indian Scabious*; the stalks rise three feet high, are four-cornered, green, and smooth, garnished with winged leaves, having very long foot stalks; they are composed of two or three pair of small lobes, terminated by a large one, acutely sawed on their edges, ending in sharp points. The stalks are terminated by slender bunches of small flowers, situated sparsely, of a purplish colour at their rims, edged with white; these

are succeeded by small roundish seed-vessels, filled with very small seeds.

The eleventh sort grows naturally in the kingdom of *Naples*, where it is frequently found upon rocks and old stone walls; this is a biennial plant, which perishes after it has produced ripe seeds. The stalks rise fifteen inches high; they are thick, smooth, and have scarce any corners; the leaves are winged, narrow, of a lucid green, succulent, and divided into many small lobes, which are again divided, and wing-pointed; the flowers are produced in loose panicles on the sides and at the top of the stalk; they are of a dark brown colour, with a mixture of green, and are succeeded by pretty large roundish capsules, filled with angular dark-coloured seeds.

The twelfth sort grows naturally in the *Levant*; this has a perennial creeping root. The stalks rise two feet and a half high; their lower parts are closely garnished with narrow spear-shaped leaves, sharply sawed, and cut at the bottom; the upper part of the stalk is garnished with compound panicles of small brown flowers, which are succeeded by small roundish capsules, filled with small seeds.

The thirteenth sort grows naturally in *Helvetia*; this is a biennial plant, which flowers and produces seeds the second year, and then decays. The lower leaves of this sort are long, heart-shaped, hairy, and of a pale green colour. The stalks rise three feet high, garnished with smaller leaves, of the same shape with those at bottom, placed by threes; the flowers stand upon pretty long foot-stalks; three of these come out at each joint, supporting clusters of pretty large flowers, of a pale yellow colour; these appear in *April*, and are succeeded by oval capsules, filled with small seeds.

The fourteenth sort is a biennial plant, which grows naturally in *Italy*. The leaves of this are heart-shaped, ending in acute points, sawed on their edges, of a lucid green, and on the upper part of the stalk are placed alternate; the foot-stalks of the flowers come out at the wings of the leaves, each sustaining two or three flowers, of a dark red or purple colour.

The fifteenth sort grows naturally in the *Levant*, and also upon *Gibraltar Hill*. The lower leaves of this are doubly winged, variously cut and indented; the stalk is slender, it rises three feet high, the lower part of which is garnished with smaller winged leaves, of a lucid green, indented, and sit close to the stalks; the upper part has very slender panicles of small flowers coming out of the side, and terminate the stalks. The flowers are thinly ranged on the foot-stalks, are very small, and of a purple colour with white borders.

The seeds of the sixteenth sort were sent me from *Zant*; this is also a biennial plant. The stalks are four-cornered, rise two feet high, sending out several small side branches; the leaves are oval, spear-shaped, rounded at both ends, indented on their edges, and stand upon pretty long foot-stalks. The upper part of the stalk is garnished with slender panicles of small flowers, of a bright purple colour.

The seventeenth sort grows naturally in *Maryland*; this hath a perennial fibrous root. The stalks are four-cornered; the leaves are heart-shaped, sharply sawed on their edges, and rounded at their base; the flowers are produced in panicles on the upper part of the stalk, and are like those of the first sort, but of an herbaceous colour.

The eighteenth sort was discovered by the late Dr. *Houfoun* growing naturally at *La Vera Cruz*; this is a biennial plant. The stalk rises two feet high, garnished with oval acute-pointed leaves, sawed on their edges, which sit close to the stalks; those at the bottom and top of the stalk are placed by pairs, but in the middle there are three leaves at each joint, of a pale green; at the top of the stalk the
flowers

flowers are produced in roundish bunches; they are about the size of those of the first sort, of a fine scarlet colour. This sort flowered in the *Chelsea* garden, but did not perfect its seeds.

These plants are propagated by seeds, which, if sown in the spring, the plants seldom rise the same season. Some of them may come up in autumn, and others the spring following, but, if they are sown in autumn, soon after they are ripe, the plants will come up the spring following. They may be sown in the place where the plants are to remain, for they are all of them hardy enough to bear the cold of our ordinary winters in the open air (except the last sort which is tender). When the plants come up, they will require no other care but to thin them where they are too close, and keep them clear from weeds. The second year the plants will flower and produce ripe seeds; after which those sorts which are biennial will die, but the others will continue some years.

The seventh and eighth sorts are ornamental plants, so may be allowed to have a place in the pleasure-garden, where, when the plants are strong, they will make a good appearance during their continuance in flower, which generally lasts two months, unless the season proves very hot and dry. The roots of these sorts will abide some years, unless by a very severe winter they are destroyed; but, as young plants flower stronger than the old ones, there should be a succession of them annually propagated by seeds.

The last sort is too tender to live through the winter in the open air in this country. The seeds should be sown in pots in autumn, which may be sheltered under a common frame in winter, and in the spring plunged into a moderate hot-bed, which will bring up the plants. When these are fit to remove, they should be planted into separate small pots, and plunged into a very moderate hot-bed, shading them from the sun till they have taken new root; after which they must be gradually hardened to bear the open air, into which they may be removed the latter end of *June*, placing them in a sheltered situation, where they may remain till *September*, when they should be removed into shelter before any morning frosts come on, and in winter they must be placed in a stove, kept moderately warm, where they will thrive and produce flowers the following summer.

SCUTELLARIA, *Lin. Gen. Plant.* 653. Skull-cap.

The Characters are,

The flower has a very short tubulous empalement, whose brim is entire, having an incumbent scaly operculum which seems closed; it is of the lip kind, with a very short crooked tube, long compressed chaps, and a concave trifid upper lip; the under lip is broad and indented; it has four stamina hid under the upper lip, two of which are longer than the other, terminated by small summits, and a four-pointed germen, supporting a slender style situated with the stamina, crowned by a single recurved stigma. The empalement afterward becomes a helmet-shaped capsule, including four seeds which are roundish.

The Species are,

1. SCUTELLARIA *foliis subcordatis serratis, spicis interruptis.* *Hort. Cliff.* 317. Skull-cap with almost heart-shaped sawed leaves, and interrupted spikes of flowers.

2. SCUTELLARIA *foliis cordatis obtusis obtusèque serratis, spicis foliosis.* *Prod. Leyd.* 311. Skull-cap with obtuse heart-shaped leaves, which are bluntly sawed, and leafy spikes of flowers.

3. SCUTELLARIA *foliis cordato-oblongis acuminatis serratis, spicis subnudis.* *Lin. Sp. Plant.* 600. Skull-cap, with oblong, acute pointed, heart-shaped, sawed leaves, and almost naked spikes of flowers.

4. SCUTELLARIA *foliis incisis, subtus tomentosis.* *Hort. Upsal.* 173. Skull-cap with cut leaves, which are woolly on their under side.

5. SCUTELLARIA *foliis ovatis sessilibus, interioribus obsolete serratis, superioribus integerrimis.* *Lin. Sp. Plant.* 599. Skull-cap with oval leaves sitting close to the stalks, the under of which are sometimes sawed, and the upper entire.

6. SCUTELLARIA *foliis inciso-serratis utrinque glabris, spicâ rotundato-tetragonâ.* *Hort. Upsal.* 173. Skull-cap with sawed cut leaves, which are smooth on both sides, and a roundish four-cornered spike of flowers.

The first sort grows naturally in *Italy*. Mr. Ray observed it about *Leghorn* and *Florence*, in the hedges and uncultivated places in plenty; this hath a perennial root; the stalk is four-cornered, hairy, and rises two feet high, garnished with heart shaped leaves placed opposite, sawed on their edges. The flowers grow in interrupted spikes at the top of the stalks, of a purple colour in some, and in others they are white.

The second sort grows naturally in *Crete*; this hath a ligneous stalk, which rises about two feet high, sending out slender side branches, garnished with obtuse heart-shaped leaves, bluntly sawed on their edges; they are hoary on their under side, and of a light green on their upper. The flowers are disposed in pretty long spikes at the top of the stalks; they are white, and have small leaves growing between them.

The third sort grows naturally in the *Levant*; this hath a perennial root. The stalks rise from three to four feet high, sending out a few slender branches from their sides, garnished with oblong heart-shaped leaves, ending in acute points, sawed on their edges. The flowers are disposed in naked spikes at the top of the stalks; they are purple, and have longer tubes than any of the other sorts.

The fourth sort grows naturally in the *Levant*; this is a perennial plant, with shrubby stalks which spread on the ground, garnished with cut leaves placed opposite, which are almost triangular, of a light green on their upper side, and downy on their under, standing upon slender foot-stalks. The flowers are disposed in short spikes at the end of the branches, of a bright yellow colour, and are succeeded by gray seeds which ripen in the empalement.

The fifth sort grows naturally in *North America*; it has a perennial root, from which come forth several four-cornered stalks, two feet high, sending out side branches. The lower leaves are heart-shaped, sawed on their edges, standing upon pretty long foot-stalks; the upper leaves are oval and entire. The flowers are disposed in very long loose spikes at the end of the branches, of a blue colour; these are succeeded by seeds which ripen in the empalement.

The sixth sort grows naturally on the *Alps* and *Apennines*; the stalks of this are shrubby, trailing on the ground, the leaves are smooth and cut on their edges; the flowers are disposed at the top of the stalks in roundish four-cornered spikes; in one they are white, and in another variety they are blue; they are larger than the flowers of any other known species, so make a pretty appearance in gardens.

These plants are all of them propagated by seeds; if these are sown in autumn, soon after they are ripe, they will more certainly succeed than when they are sown in the spring, for these sometimes miscarry, and, if they succeed, the plants seldom come up the same season. The seeds may either be sown where the plants are to remain, or in a border to be afterward removed; but, as the fourth sort does not bear transplanting well, unless they are removed young, the seeds of that had better be sown where the plants are to stand; this should be on a dry warm border of poor earth, where the plants will live much longer, and make a better appearance than on a rich soil. When the plants come up, they will require no other care but to thin them, and keep them clear from weeds.

When.

When the other sorts come up, and are fit to remove, they may be transplanted into a nursery-bed at five or six inches distance, where they may stand till autumn, but must be kept clean from weeds during that time; then they may be transplanted into the borders of the flower-garden where they are to remain.

As these plants are not of long duration, it will be proper to sow a succession of seeds every other year at least, to supply the places of those which decay.

SECALE. *Tourn. Inst. R. H.* 513. *tab.* 294. Rye.

The Characters are,

There are two flowers in each involucre; they have two leaves which are opposite, narrow, erect, and sharp-pointed. The petals have two leaves; the outer valve is rigid, bellied, acute-pointed, and compressed; the lower border is hairy, ending in a long awn, the inner is plain and spear-shaped; they have two oval erect nectariums, and three hair-like stamina, hanging without the flower, terminated by oblong forked summits, with a top-shaped germen supporting two reflexed hairy styles, crowned by a single stigma. The germen afterward becomes an oblong almost cylindrical seed which ripens in the empalement.

We have but one distinct Species of this genus which is cultivated in England, though it is often supposed the two varieties are essentially different; but, from several years cultivating them on the same land, I could find no real difference between them. Dr. *Linnaeus* titles this *Secale glumarum ciliis scabris*, *Hort. Upsal.* 22. Rye with rough hairs to the awns.

The farmers distinguish the two varieties by the titles of Winter and Spring Rye; but, when these are sown three or four years, at the same season, and on the same soil, it will be difficult to know them asunder; but, where Rye is sown upon a warm land, it will ripen much earlier than on cold stiff ground, and by continuing it two or three years, it will be forwarded so much, as to ripen a month earlier than the seeds which have long grown upon a strong cold soil; so those, who are obliged to sow Rye toward spring, generally provide themselves with this early seed.

There are several kinds of grass, which are now ranged under this generical title; but, as these do not merit cultivation, I shall not trouble the reader with the mention of them here.

Rye is so well known to every one who is the least acquainted with the different grains, as to need no description.

The winter Rye is what the generality of farmers propagate; it is usually sown in autumn at the same season with Wheat, and in many of the northern counties, as also in *Wales*, they are often mixed together, though I think it must be very bad husbandry, for the Rye will always ripen sooner than Wheat, so that, if the latter is permitted to be fully ripe, the former will shatter; nor can this be practised where the people are not accustomed to eat Rye bread; for although it is by some accounted good when mixed, yet being so very clammy, few people, who have been fed with Wheat, will ever care to eat the bread made of this.

It is generally sown on poor, dry, gravelly, or sandy land, where Wheat will not thrive, and in such places may answer very well; but on such land as will bear Wheat, it is not proper to sow Rye, as the value of it is greatly inferior to that of Wheat.

When Rye is sown, the ground should not be too wet; and if it should happen, that much rain falls before the Rye is come up, it often rots in the ground; but it is not long in coming up, it being much sooner out of the ground than Wheat.

The small Rye may be sown in the spring, about the same time with Oats, and is usually ripe as soon as the other sort; but if the season proves wet, it is apt to run much to straw;

and the grain is generally lighter than the other, so the only use of this sort is to sow upon such lands where the autumnal crop may have miscarried.

Rye is also sown in autumn to afford green feed for ewes and lambs in the spring, before there is plenty of grass. When this is intended, the Rye should be sown early in autumn that it may have strength to furnish early feed. The great use of this is to supply the want of Turneps in those places where they have failed, as also, after the Turneps are over, and before the grass is grown enough to supply green feed for the ewes; so that in those seasons, when the Turneps in general fail, it is very good husbandry to sow the land with Rye, especially where there are stocks of sheep, which cannot be well supported where green feed is wanting early in the spring; therefore those farmers, who have large live stocks, should have several methods of supplying themselves with sufficient feed, lest some should fail; for, as Turneps are a very precarious crop, some land should be sown with Cole seed, which will supply the want of Turneps in winter; and, if some of the ground, which was sown late with Turneps which had failed, was sown in autumn with Rye, that would be fit to supply the want of Cole seed afterward.

SECURIDACA. *Tourn. Inst. R. H.* 399. *tab.* 224. Hatchet-vetch.

The Characters are,

The empalement of the flower is short, compressed, and cut into two segments; the flower is of the butterfly kind; the standard is heart-shaped, reflexed on both sides, and scarce longer than the wings; these are oval, joining at the top, but open at the bottom, the keel is compressed and pointed. It hath ten stamina, nine joined, and one separate, terminated by small summits, and an oblong compressed germen, with a bristly style, crowned by an obtuse stigma. The germen afterward turns to a long, compressed, sword-shaped pod, with a thick border on one side, plain on the other, opening in two cells filled with square seeds.

We have but one Species of this genus at present, which is the

SECURIDACA *herbacea, leguminibus falcato-gladiatis.* Herbaceous Hatchet-vetch, with hooked sword-shaped pods.

This plant grows naturally in the Corn fields in *Spain* and *Italy*; it is annual, and hath trailing herbaceous stalks, which grow a foot and a half long, dividing into many branches, which spread on the ground, garnished with winged leaves, composed of seven or eight pair of oval obtuse lobes terminated by an odd one, of a deep green and smooth. From the wings of the leaves arise the foot-stalks of the flowers, by pairs at each joint, which are five or six inches long, sustaining at the top a large cluster of yellow flowers of the butterfly kind, succeeded by compressed pods near four inches long, ending in acute points, having a suture on each side, one plain and the other rising, joined at their base to the foot-stalk, but spread open like the rays of a star, and are divided by a longitudinal partition into two cells, each containing a row of square flat seeds of a reddish colour.

It is propagated by sowing the seeds in borders of light earth in the spring, in the places where the plants are to abide, for they seldom succeed well if they are transplanted; they should be allowed at least two feet distance, because their branches trail upon the ground. When the plants come up, they will require no other care, but to thin them where they are too close, and keep them clean from weeds. A few of these plants may be admitted into every good garden for variety, though there is no great beauty in their flowers.

SEDUM. *Lin. Gen. Plant.* 513. Houseleek.

The Characters are,

The empalement of the flower is permanent, and cut into five acute parts. The flower has five plain, spear shaped, acute-pointed petals, and five nectariums, with small single scales indented at the top, each being inserted at their base to the outside of the germen; it has ten awl-shaped stamina, the length of the petals, terminated by roundish summits, and five oblong germen ending in slender styles, crowned by obtuse stigmas. The germen afterward become five erect, spreading capsules, which are compressed, acute-pointed, opening from top to bottom, filled with small seeds.

The Species are,

1. *SEDUM foliis oblongis obtusis teretiusculis sessilibus patentibus, cymâ ramosâ.* Hort. Cliff. 177. Houseleek with oblong, obtuse, taper leaves, sitting close to the stalks, spreading open, and a branching stalk.
2. *SEDUM foliis oppositis ovatis obtusis carnosiss, caule infirmo, floribus sparsis.* Lin. Sp. Plant. 431. Houseleek with oval, fleshy, blunt leaves, which are placed opposite, a weak stalk, and flowers growing thinly.
3. *SEDUM foliis subulatis confertis basi membranaceâ solutis, floribus sinosis.* Hort. Cliff. 176. Houseleek with awl-shaped leaves growing in clusters, whose base has a loose membrane, and flowers growing from the top of the branches.
4. *SEDUM foliis subulatis carnosiss patentibus, caule dichotomo, cymis erectis.* Houseleek with fleshy, awl-shaped, spreading leaves, a stalk divided by pairs, and erect tops.
5. *SEDUM foliis subovatis adnato-sessilibus gibbis erectiusculis alternis, cymâ trifidâ.* Hort. Cliff. 177. Stone Crop with oval, gibbous, erect, alternate leaves sitting close to each other, and a trifid top; or Wall Pepper.
6. *SEDUM foliis subcylindricis obtusis alternis, cymâ semper erectâ.* Lin. Sp. Plant. 432. Houseleek with obtuse almost cylindrical leaves, which grow alternate, and the top always erect.
7. *SEDUM caule erecto solitario annuo, foliis ovatis sessilibus gibbis alternis, cymâ recurvâ.* Flor. Suec. 319. Houseleek with an erect, annual, single stalk, oval gibbous leaves, which are placed alternate, and a recurved top.
8. *SEDUM caulibus decumbentibus, foliis subulatis carnosiss patentibus, floribus paniculatis reflexis.* Stone Crop with trailing stalks, awl-shaped, fleshy, spreading leaves, and flowers growing in reflexed panicles.
9. *SEDUM foliis subovatis adnato-sessilibus gibbis erectiusculis sexfariâ imbricatis.* Flor. Suec. 390. Stone Crop with almost oval, gibbous, erect leaves growing close to each other, and imbricated six ways.
10. *SEDUM caule erecto, foliis planiusculis, pedunculisque subpilosis.* Lin. Sp. Plant. 432. Houseleek with an erect stalk, plain leaves, and foot-stalks which are somewhat hairy.
11. *SEDUM foliis planiusculis angulatis, floribus lateralibus subsessilibus solitariis.* Hort. Cliff. 176. Houseleek with plain angular leaves, and single flowers sitting close to the sides of the stalk.
12. *SEDUM foliis planis, caule ramoso, floribus paniculatis.* Hort. Cliff. 176. Houseleek with plain leaves, a branching stalk, and flowers growing in panicles.
13. *SEDUM foliis lanceolatis serratis planis, caule erecto, cymâ sessili terminali.* Lin. Sp. Plant. 430. Houseleek with plain, spear-shaped, sawed leaves, and an erect stalk, terminated by a head of flowers sitting close to it.
14. *SEDUM foliis oblongo-ovatis carinatis supernè serratis, corymbo terminali.* Houseleek with oblong, oval, keeled leaves, which are sawed on their upper part, and a stalk terminated by a corymbus of flowers; common Orpine, or Live-long.
15. *SEDUM foliis planiusculis serratis, corymbo folioso, caule erecto.* Lin. Sp. Plant. 430. Houseleek with plain sawed leaves, a leafy corymbus of flowers, and an erect stalk.

16. *SEDUM foliis ternis planiusculis serratis, caule erecto corymbo terminali.* Houseleek with plain sawed leaves growing by threes, and an erect stalk terminated by a corymbus.

17. *SEDUM foliis ovatis integerrimis, summis amplexicaulis, corymbo terminali.* Houseleek with oval entire leaves, which at the top embrace the stalk, and a corymbus of flowers terminating the branches.

18. *SEDUM foliis cuneiformibus integerrimis, caulibus decumbentibus, floribus corymbosis.* Lin. Sp. Plant. 430. Houseleek with wedge-shaped entire leaves, trailing stalks, and flowers growing in a corymbus.

The first sort grows naturally upon old walls in many parts of *England*, so is seldom planted in gardens, but, as it is a medicinal plant, I have placed it here. This hath slender trailing branches, garnished with taper succulent leaves about half an inch long, standing alternately round the branches. The flower-stalks rise four or five inches high; their lower part is garnished with leaves, which spread horizontally; the upper part of the stalk divides into small foot-stalks, supporting many white star-pointed flowers, gathered into a sort of umbel.

The second sort also grows upon old walls in many parts of *England*. The stalks of this are very slender and infirm; the leaves are very short, oval, and of a gray colour, placed opposite. The flowers are set thinly at the top of the stalks; they are small, white; their petals are obtuse; the summits upon the stamina are pretty large, and of a bright purple colour.

The third sort grows naturally upon *St. Vincent's Rock* near *Bristol*, and in several parts of *Wales*. This has slender purple stalks, which trail upon the ground, closely garnished with short awl-shaped leaves, placed round the stalks, having a short loose membrane at their base, which falls off on being touched; the leaves toward the top of the stalk fit close together; they are of a sea-green colour, and not very succulent. The flowers grow at the top of the stalks in roundish bunches, of a bright yellow colour. This plant, when it is once placed upon a wall, will propagate itself in plenty by its trailing branches, which put out roots from their joints.

The fourth sort grows naturally in *Spain*. This is an annual plant with upright stalks, which rise three or four inches high, garnished with fleshy awl-shaped leaves, of a gray colour. The top of the stalk divides into two slender erect branches, which have small, white, star-pointed flowers ranged above each other, and the top of the stalk at the division of the branches is terminated by two or three flowers sitting close. If the seeds are permitted to scatter, the plants will come up without care.

The fifth sort is the common Stone Crop or Wall Pepper, so called for the acrid biting quality of the leaves. This grows very common upon old walls and buildings in every part of *England*, and is so well known as to require no description. There are two varieties of this, one with a large, and the other a small yellow flower.

The sixth sort grows upon moist rocks in several parts of *France* and *Germany*, and is seldom seen in gardens. This rises with an erect stalk three inches high, garnished with obtuse, cylindrical, succulent leaves. The stalk divides upward into three or four branches, which sustain small purplish flowers, standing erect.

The seventh sort grows naturally on dry barren rocks in the north of *England*. This is an annual plant with an erect stalk, garnished with oval leaves, placed alternate. The stalk seldom rises above two or three inches high; the leaves sit close to the stalks, and are of a grayish colour; the flowers grow at the top of the stalk in a reflexed spike; they are small and white.

The eighth sort grows naturally upon old walls and buildings in most parts of *England*, and is by some called Prick-Madam. This has long trailing stalks, garnished with fleshy awl-shaped leaves, spreading out almost horizontally, of a gray colour, ending in acute points. The flowers grow in reflexed bunches at the top of the stalks; they are star-pointed, and of a bright yellow colour.

The ninth sort is less common than either of the former. I have found it growing upon the rocks in *Wales*. This hath the appearance of common Stone Crop, but the stalks and leaves are larger, and have no biting taste; the leaves are ranged in six rows, like the grains of the six-rowed Barley; the flowers are yellow, and larger than those of the common Stone Crop.

The tenth sort grows naturally upon moist rocks and boggy soils in several parts of the north of *England* and in *Wales*; this seldom rises more than two or three inches high. The stalks are garnished with a few plain hairy leaves, terminated by purple flowers growing thinly.

The eleventh sort grows naturally in *Italy* and *Germany*; this is a low annual plant. The leaves are plain and angular; the stalks rise three inches high, dividing at the top into two or three parts; the flowers come out singly from the side of the stalk; they are white, star-pointed, and are succeeded by star-pointed rough capsules.

The twelfth sort is an annual plant, which grows naturally in the south of *France* and in *Italy*; this hath plain succulent leaves. The stalks rise six or seven inches high, dividing into smaller branches, which sustain small white flowers, growing in large panicles; and if the seeds are permitted to scatter, the plants will come up without care. This loves a warm dry soil.

The thirteenth sort grows naturally in *Siberia*; this has a perennial root, from which come out several stalks near a foot high, garnished with spear-shaped, plain, thick leaves, placed alternately, slightly sawed on their edges. The stalk is terminated by a flat corymbus of flowers, of a bright yellow colour, fitting close on the top of the stalks.

The fourteenth sort is the common Orpine, which grows naturally in woods and shady places in many parts of *England*. Of this there are two varieties, one with white, the other with purple flowers. This has a perennial root, composed of many glandulous knobs, from which come out round succulent stalks two feet high, dividing toward the top into smaller branches, garnished with fleshy, oval, oblong leaves, a little keel-shaped, of a gray colour, and sawed toward their points. The stalk is terminated by a corymbus of flowers, which are star-pointed; in some they are white, and in others purple.

The fifteenth sort is not common in the *English* gardens; this hath roots like the former. The stalks grow more erect, of a purple colour; the leaves are flatter, and more sawed on their edges, of a dark green colour, and thicker substance; the flowers are purple.

The sixteenth sort has strong, succulent, erect stalks, which are purple, and rise higher than either of the former. The leaves are larger, of a dark green colour, sawed on their edges, and stand by threes round the stalk; the flowers are purple, collected into a large corymbus, terminating the stalk.

The seventeenth sort grows naturally in *Portugal*. There are two varieties of this, one with white, and the other with purple flowers. The roots of this are composed of many thick fleshy knobs; the stalks are thick, succulent, and round; they rise three feet high, garnished with oval succulent leaves, which are entire, placed by pairs; those on the upper part embrace the stalk with their base; they are of a pale herbaceous colour. The flowers are collected in large bunches, which terminate the stalks.

The eighteenth sort grows naturally in *Italy*. The roots

of this are fibrous; the stalks trail on the ground, garnished with wedge-shaped leaves, standing alternately round the stalks. The flowers are disposed in a compact corymbus, which fits close on the top of the stalks; they are star-shaped, of a purple colour, and appear in *July*.

All the sorts of Stone Crop are easily propagated by planting their trailing stalks either in spring or summer, which soon put out roots; but, as these thrive much better upon rocks, old walls, or buildings, than in the ground, they may be disposed upon rock-work in such a manner as to have a good effect. If the cuttings or roots of the perennial sort are planted in some soft mud laid upon the walls or buildings, they will soon take root, and then spread into every joint or crevice, and in a short time will cover the place, and, if the seeds of those annual sorts, which grow naturally in dry places, are sown soon after they are ripe on the top of walls, the plants will come up, and maintain themselves without farther care.

The several sorts of Orpine may be easily propagated by cuttings during the summer months, or by parting of their roots either in spring or autumn; these thrive best in a dry soil and a shady situation, but may also be planted for the same purposes as the other sorts, especially the eighteenth sort, which is ever-green. The stalks of this kind hang down, and have a very good effect in rock-work, and the plants require no care, for when they are fixed in the place, they will spread and propagate fast enough.

The stalks of the common Orpine are frequently cut in summer, and fastened to laths of the size of chimney-boards, which, being framed together, are used for screening the sight of the fire-grates in rooms; these stalks will shoot and spread over the frame, and, if the frames are taken out once a week, and the stalks watered over to refresh them, they will continue in verdure for two months.

SEED. The seed of a plant consists of an embryo, with its coat or cover. The embryo, which contains the whole plant in miniature, and which is called the germ or bud, is rooted in the placenta or cotyledon, which makes the coat or involucrum, and serves the same purposes as the secundines, *i. e.* the chorion and amnis in animals.

The placenta or cotyledon of a plant is always double, and in the middle and common center of the two is a point or speck, which is the embryo or plantule. This plantule, being acted on and moved by the warmth of the sun and the earth, begins to expand, and protrudes or shoots out its radicle or root both upward and downward. By this it absorbs the nutritious juice from the earth, and so grows and increases, and, the requisite heat continuing, the growth continues.

The two placentulæ or cotyledons of a seed are, as it were, a case to this little tender plantule or point, covering it up, sheltering it from injuries, and feeding it from their own proper substance; which the plantule receives and draws to itself, by an infinite number of little filaments or ramifications, called Funes Umbilicales, or Navel Strings, which it sends into the body of the placenta.

The cotyledons, for the most part, abound with a balsam, disposed in proper cells; and this seems to be oil brought to its greatest perfection, while it remains humid, and then lodged in these repositories; one part of the composition of this balsam is oily and tenacious, and serves to defend the embryo from any extraneous moisture, and, by its viscosity, to entangle and retain that fine, pure, volatile spirit, which is the ultimate production of the plant.

This oil is never observed to enter into the vessels of the embryo, which are too fine to admit so thick a fluid. The spirit, however, being quickened by an active power, may possibly breathe a vital principle into the juices that nourish the embryo, and stamp upon it the character that distinguishes

distinguishes the family; after which every thing is changed into the proper nature of that particular plant. That this spirit now is truly the efficacious part, is evident; for when that is gone off, the oil that remains is quite vapid and inactive. It is this that gives plants their fragrant smell and peculiar tastes, nor do their particular colours a little depend upon it.

Now when the seed is committed to the earth, the placenta still adheres to the embryo for some time, guards it from the access of noxious colds, &c. and even prepares and purifies the cruder juice the plant is to receive from the earth, by straining it, &c. through its own body.

This it continues to do, till the placentula being a little inured to its new element, and its root tolerably fixed in the ground, and fit to absorb the juice thereof, it then perishes, and the plant may be said to be delivered; so that nature observes the same method in plants contained in fruits, as in animals in the mother's womb.

It is very surprising, that many sorts of seeds will continue good for several years, and retain their growing faculty, whereas many other sorts will not grow when they are more than one year old; which is, in a great measure, owing to their abounding more or less with oil, as also the nature of the oil, whether it is of a cold or hot quality, and the texture of their outward covering. As for example; the seeds of Cucumbers, Melons, and Gourds, which have thick horny coverings, and the oil of this seed being of a cold nature, the seeds will continue good ten, fifteen, or twenty years; and Radish, Turnep, Rape, &c. with other oily seeds (whose coats, though they are not so hard and close as the others, yet) abounding with oil, which is of a warmer nature, the seeds will keep good three or four years; whereas the seeds of Parsley, Carrots, Parsneps, and most other umbelliferous plants, whose seeds are, for the most part, of a warm nature, lose their growing faculty often in one year, but seldom remain good longer than two years. Indeed all sorts of seeds are preserved best, if kept in the pods or husks wherein they grow; especially if they are not separated from the placenta, to which they are fastened by an umbilical cord, through which they received their nourishment in their embryo state; so that whoever would send seeds to a distant country, should always take care they are full ripe before they are gathered, and that they are preserved in their pods or husks; and when they are packed up for exportation, there should be great care taken, that they are not shut up too closely from the air, which is absolutely necessary to maintain the principle of vegetation in the seed (though in a less degree) as it is to nourish the plant when germinated, as I found by trying the following experiment, *viz.* Having saved a parcel of fresh seeds of several kinds, I took some of each kind, and put into glass phials; these I stopped down close, and sealed hermetically, then put them up in a trunk; the other parts of the same seeds I put into bags, and hung them up in a dry room, where the air had free admittance, in which place they remained a whole year; and the following spring I took out a part of each parcel of seeds from the phials, as also from the bags, and sowed them at the same time, and upon the same bed, where they had an equal advantage of the sun, air, &c. The result of this experiment was, that almost all the seeds which I took out of the bags, grew extremely well, but of those which were kept in the phials, not one come up; after which I sowed the remaining part of the seeds in the phials, but had not one single plant from the whole, whereas those preserved in the bags grew very well both the second and third years. And this experiment was afterward tried by one of my particular friends, with whom the effect was the same as with me. Some years after this, a gentleman of great eminence for his

knowledge of plants, being very desirous to procure seeds from every country, where the *British* nation had any commerce, gave his instructions to many of the agents abroad, to send him over all the sorts of seeds they could collect in their different countries, and to put them up in bottles, sealing the mouths of the bottles as close as possible, to exclude the air; which was done by several of his correspondents, who sent him great quantities of seeds, but not one of them grew when they were sown; so that those persons who send seeds to a distant country, should never be guilty of the like error.

How the vegetative life is so long preserved in seeds, when they are deeply immersed in the ground, is very difficult to explain; but as it is very notorious, that earth taken from the bottom of vaults, houses, and wells, and from the earth which has been taken at a very great depth in those places, there have been many plants produced, which were not inhabitants of the neighbouring soil; and this has been brought as a proof to support the doctrine of spontaneous productions, by some who have asserted, that plants are often produced without seed.

SELAGO. *Lin. Gen. Plant.* 687.

The Characters are,

The flower has a permanent empalement of one leaf, cut into four parts at the top. The flower is of one petal; it has a very small tube; the brim is spreading, and cut into five parts; the two upper segments are the least. It hath four hair-like stamina the length of the petal, to which they are inserted, two of which are longer than the other, terminated by single summits; and a roundish germen, supporting a single style, crowned by an acute stigma. The germen afterward becomes a single seed, wrapped up in the petal of the flower.

We have but one Species of this genus at present in the English gardens, *viz.*

SELAGO *corymbo multiplici.* *Lin. Sp. Plant.* 629. Selago with a multiplied corymbus.

This plant grows naturally at the *Cape of Good Hope*. It has slender ligneous stalks, which rise seven or eight feet high, but are so weak as to require support; they send out many slender branches, garnished with short, linear, hairy leaves, that come out in clusters from the same point. The flowers terminate the stalks in umbels, the general umbel being composed of a multiplicity of small umbels of white flowers, which appear in *July* and *August*, but are not succeeded by seeds in *England*.

This plant is preserved in gardens more for the sake of variety than for its beauty, for the branches grow very irregular, and hang downward; the leaves are small, so make little appearance, and the flowers are so small as not to be distinguished at any distance.

It is propagated by cuttings, which put out roots freely, if they are planted in any of the summer months; if these are planted in a bed of fresh earth, and covered close down with a bell or hand-glass, shading them from the sun, and refreshing them now and then with water, they will soon put out roots; then they must be gradually hardened, and afterward transplanted into small pots, placing them in the shade till they have taken new root; then they may be placed with other hardy green-house plants, where they may remain till the end of *October*, when they must be removed into shelter, for these plants will not live in the open air in *England*; but they only require protection from hard frost; so they should be treated in the same way as other of the hardiest kinds of green-house plants.

SELINUM. *Lin. Gen. Plant.* 300. Milky Parsley.

The Characters are,

It has an umbellated flower; the general umbel is plain and spreading; the particular umbels are the same; the involucrem is composed of many linear spear shaped leaves, which spread open; the umbel is uniform; the flowers have five inflexed heart-

shaped petals, which are unequal, and five hair-like stamina, terminated by roundish summits. The germen is situated under the flower, supporting two reflexed styles, crowned by single stigmas; it afterward becomes a plain compressed fruit, channelled on both sides, parting in two, containing two oblong elliptical plain-seeds, channelled in the middle, and have membranes on both sides.

The Species are,

1. SELINUM radice fusiformi multiplici. Milky Parsley with spindle-shaped roots.

2. SELINUM sublaetescens radice unica. Haller. Helv. 443. Selinum which is almost milky, having a single root.

The first sort grows by the sides of lakes and standing waters in several parts of Germany; this hath many spindle-shaped roots hanging by fibres, which spread and multiply in the ground. The stalks rise five or six feet high; they are streaked, and of a purple colour at bottom, sending out several branches toward the top; the leaves are finely divided like those of the Carrot, and when broken, there issues out a milky juice; the stalks are terminated by umbels of whitish flowers, which come out in June, and are succeeded by compressed bordered seeds, which ripen in August.

The second sort grows naturally in marshy places in Germany. The leaves of this are much longer and cut into narrower segments than those of the former; the stalks rise higher; the umbels are larger, as are also the seeds. The whole plant abounds with a caustick milky juice.

These plants are preserved in botanick gardens for variety, but are rarely cultivated any where else; they are easily propagated by seeds, which should be sown in autumn, and the plants afterward treated in the same way as Angelica.

A SEMINARY is a seed-plot, which is adapted or set apart for the sowing of seeds. These are of different natures and magnitudes, according to the several plants intended to be raised therein. If it be intended to raise forest or fruit-trees, it must be proportionably large to the quantity of trees designed, and the soil should be carefully adapted to the various sorts of trees. Without such a place as this every gentleman is obliged to buy, at every turn, whatever trees he may want to repair the losses he may sustain in his orchard, wilderness, or larger plantations, so that the necessity of such a spot of ground will easily be perceived by every one; but, as I have already given directions for preparing the soil, and sowing the seeds in such a seminary, under the article of NURSERY, I shall not repeat it in this place, but refer the reader to that article.

It is also as necessary for the support of a curious flower-garden, to have a spot of ground set apart for the sowing of all sorts of seeds of choice flowers, in order to obtain new varieties, which is the only method to have a fine collection of valuable flowers; as also for the sowing of all sorts of biennial plants, to succeed those which decay in the flower-garden; by which means the borders may be annually replenished, which, without such a seminary, could not be so well done.

This seminary should be situated at some distance from the house, and be entirely closed either with a hedge, wall, or pale, and kept under lock and key, that all vermin may be kept out, and that it may not be exposed to all comers and goers, who many times do mischief before they are aware of it. As to the situation, soil, and manner of preparing the ground, it has been already mentioned under the article of NURSERY, and the particular account of raising each sort of plant being directed under their proper heads, it would be needless to repeat it here.

SEMPERVIVUM. Lin. Gen. Plant. 538. Houseleek.

The Characters are,

The flower has a concave empalement, cut into many acute segments; it has ten oblong, spear-shaped, pointed petals, and twelve or more narrow awl-shaped stamina, terminated by roundish summits; it has twelve germen, placed circularly, sitting upon so many styles, which spread out, and are crowned by acute stigmas. The germen afterward becomes so many short compressed capsules, pointed on the outside, and open on the inside, filled with small seeds.

The Species are,

1. SEMPERVIVUM foliis ciliatis, propaginibus patentibus. Lin. Sp. Plant. 464. Houseleek with hairy-edged leaves, and spreading offsets; or common large Houseleek.

2. SEMPERVIVUM foliis ciliatis, propaginibus globosis. Lin. Sp. Plant. 464. Houseleek with hairy-edged leaves, whose offsets are globular.

3. SEMPERVIVUM foliis integerrimis, propaginibus patulis. Lin. Sp. Plant. 465. Houseleek with entire leaves and spreading offsets.

4. SEMPERVIVUM foliis pilis intertextis, propaginibus globosis. Lin. Sp. Plant. 465. Houseleek with threads from leaf to leaf, and globular offsets; commonly called Cobweb Sedum.

5. SEMPERVIVUM caule arborecente lævi ramoso. Lin. Sp. Plant. 464. Houseleek with a smooth, tree-like, branching stalk; or Tree Houseleek.

6. SEMPERVIVUM caule foliorum rudibus lacero, foliis retusis. Lin. Sp. Plant. 464. Houseleek with stalks torn by the rudiments of the leaves, and blunt-pointed leaves.

7. SEMPERVIVUM foliorum marginibus serrato-dentatis, propaginibus patulis. Houseleek with leaves, whose borders are indented like a saw, and spreading offsets.

The first sort is our common Houseleek, which is seen in every part of England growing on the tops of houses and walls, but is not a native of this country; it has many thick succulent leaves set together in a round form; they are convex on their outside and plain within, sharp-pointed, and their borders are set with short fine hairs. The leaves spread open, and lie close to the earth, sending out on every side offsets of the same form. From the center of these heads arise the flower-stalk, which is about a foot high, succulent and round, of a reddish colour, garnished at bottom with a few narrow leaves; the upper part of the stalk divides into two or three parts, each sustaining a spike or range of reflexed flowers, composed of several petals, which spread open, ending in acute points, of a red colour; in the center is situated the germen, which are placed circularly, and, after the petals are fallen off, they swell and become so many horned capsules, filled with small seeds.

This plant is easily propagated by offsets, which the plants put out in plenty. If these are planted in mud or strong earth placed on a building or old wall, they will thrive without farther care.

The second sort grows naturally in the northern parts of Europe. The leaves of this sort are much narrower, and the heads are furnished with a greater number of leaves than those of the former, which grow more compact, and are closely set on their edges with hairs. The offsets of this are globular, their leaves turning inward at the top, and lie close over each other; these are thrown off from between the larger heads, and falling on the ground take root, whereby it propagates very fast. The flower-stalks of this are smaller than those of the former, and the flowers are of a paler colour.

The third sort grows naturally upon the Helvetic mountains. This greatly resembles the first, but the leaves are smaller, and have no indentures on their edges; the offsets of this sort spread out from the side of the older heads, and their

their leaves are more open and expanded. Out of the center of the heads comes forth the flower stalk, which rises nine or ten inches high, garnished below with some narrow leaves; the upper part is divided into three or four branches, which are closely furnished with deep red flowers, composed of twelve star-pointed pointals, set round the circle of germen, which is attended by twenty-four stamina, terminated by purple summits.

The fourth sort grows naturally upon the *Alps* and *Helvetican* mountains; this hath much shorter and narrower leaves than either of the former. The heads are small and very compact; the leaves are gray, sharp-pointed, and have slender white threads crossing from one to the other, intersecting each other in various manners, so as in some measure to represent a spider's web. The flower-stalks rise about six inches, are succulent, round, and garnished with awl-shaped succulent leaves, placed alternately; the upper part of the stalk divides into two or three branches, upon each of which is a single row of flowers ranged on one side above each other, composed of eight spear-shaped petals, of a bright red colour, with a deep red line running longitudinally in the middle; these spread open in form of a star, and in the center is situated the germen, of an herbaceous colour, surrounded by sixteen purple stamina, which are erect, terminated by yellow summits.

All the above mentioned sorts are extremely hardy, and propagate very fast by offsets; they love a dry soil, so are very proper to plant in rock-work, where they will thrive better than in the full ground, as they want no care; for when they are once fixed, they will propagate and spread fast enough, so that the larger sorts may require to be annually reduced to keep them within proper compass. When any of these heads flower, they die soon after, but the offsets soon supply their place.

The fifth sort grows naturally at the *Cape of Good Hope*, and also in *Portugal*; the old walls about *Lisbon* are covered with this plant. This rises with a fleshy smooth stalk eight or ten feet high, dividing into many branches, terminated by round heads or clusters of leaves lying over each other like the petals of a double Rose; they are succulent, of a bright green, and have very small indentures on their edges like the teeth of a very fine saw. The stalks are marked with the vestiges of the fallen leaves, and have a light brown bark; the flowers rise from the center of the heads, forming a large pyramidal spike; they are of a bright yellow colour, and the petals spread open like the points of a star; the other parts are like those of the other species. This sort generally flowers in autumn or winter, and the flowers continue long in beauty, during which time they make a fine appearance.

There is a variety of this with variegated leaves, which is much esteemed by the curious; this was accidentally obtained by a branch which had been accidentally broken from a plant of the plain kind at *Badmington*, the seat of his Grace the Duke of *Beaufort*, which, after having laid some time, was planted, and when the young leaves pushed out, they were variegated. These plants are easily propagated by cutting off the branches, which, when planted, soon put out roots; these should be laid in a dry place for a week before they are planted, that the bottom may be healed over, otherwise they are apt to rot, especially if they have much wet. When the cuttings are planted in pots, they should be placed in a shady situation, and must have but little wet, and, if they are plunged in a shady border, they will require no water, for the moisture of the ground will be sufficient for them. Some years past these plants were tenderly treated; their cuttings were put into a hot-bed, to forward their putting out roots, and in winter the plants were kept in stoves, but later experience has taught

us that they will thrive better with hardier treatment; for, if they are protected from frost and wet in winter, and have a good share of air in mild weather, they will thrive better, and flower oftener than when they are tenderly nursed. I have frequently seen the branches of these plants, which have been accidentally broken off and fallen on the ground, put out roots as they have laid, and have made good plants. The sort with striped leaves is tenderer than the other, and more impatient of wet in winter.

The sixth sort grows naturally in the *Canary Islands*; this seldom rises high, unless the plants are drawn up by tender management. The stalk is thick and rugged, chiefly occasioned by the vestiges of the decayed leaves; it seldom rises above a foot and a half high, supporting at the top one very large crown of leaves, disposed circularly like a full-blown double Rose. The leaves are large, ending in obtuse points, are a little incurved, succulent, soft to the touch, and pliable. The flower-stalk comes out of the center, and rises two or three feet high, branching out from the bottom, so as to form a regular pyramid of flowers, which are of an herbaceous colour, shaped like those of the other species; they are succeeded by horned capsules, filled with small seeds, which ripen late in autumn or winter, and then the plant dies.

This is propagated by seeds, which should be sown soon after it is ripe, in pots filled with light sandy earth, covering them over very lightly with the same. These pots should be placed under a common frame to keep out the frost, but should be exposed to the open air at all times in mild weather; here the pots may remain till the spring, when the danger of hard frosts is over, when they should be removed to a situation where they may have only the morning sun, and in dry weather the earth should be watered gently. This will soon bring up the plants, which must be kept clean from weeds, and, when they are fit to remove, they should be planted in pots, filled with light earth, and placed in the shade till they have taken new root; then they may be placed with other hardy succulent plants in a sheltered situation for the summer, and in winter placed in a frame where they may be protected from hard frost, but enjoy the free air in mild weather, with which they will thrive better than with tender treatment.

The seventh sort grows naturally at the *Cape of Good Hope*. This is a very low plant, whose heads spread close on the ground; they are much smaller than those of the common Houseleek. The leaves have white edges, which are indented like the teeth of a saw; the flowers are produced in loose panicles upon naked foot stalks; they are small and white, so make but little appearance.

This is propagated by offsets, which are put out in plenty from the sides of the heads; they must be planted in pots, sheltered from the frost in winter, and in summer placed in the open air with other hardy succulent plants.

SENECIO. *Tern. Inf. R. H.* 456. *tab.* 260. Groundsel.

The Characters are,

The flower is composed of many hermaphrodite florets, which form the disk, and female half florets, which make the border or rays, included in one common cylindrical empalement, which is rough, scaly, and contracted above. The hermaphrodite florets are tubulous, funnel-shaped, cut into five parts at the brim, which are reflexed; they have five small hair-like stamina; terminated by cylindrical summits, and an oval germen, crowned with down, situated under the petal, supporting a slender style, crowned by two oblong revolving stigmas. The germen afterward turns to an oval seed, crowned with down, inclosed in the empalement. The female half florets, which form the rays, are stretched out like a tongue, and are indented in three parts at the top.

We shall not trouble the reader with mentioning those species of this genus, which are esteemed common

weeds, so are not cultivated in gardens, but confine ourselves to those which are the most valuable.

1. *SENECIO corollis nudis, foliis amplexicaulibus lacris, caule herbaceo erecto.* Hort. Upsal. 261. Groundsel with naked petals, torn leaves embracing the stalk, and an erect herbaceous stalk.

2. *SENECIO corollis nudis, scapo subnudo longissimo.* Flor. Leyd. Prod. 164. Groundsel with naked florets, and a very long foot-stalk, which is almost naked; called *China Root*.

3. *SENECIO corollis radiantibus, foliis crenatis, infimis cordatis petiolatis, superioribus pinnatifidis lyratis.* Flor. Virg. 98. Groundsel with radiated flowers, and crenated leaves, the lower ones of which are heart-shaped, and have foot-stalks, but the upper lyre-shaped and wing-pointed.

4. *SENECIO corollis radiantibus, petiolis amplexicaulibus, pedunculis folio triplo longioribus, foliis pinnato-sinuatis.* Flor. Leyd. Prod. 164. Groundsel with radiated flowers, foot-stalks embracing the stalks, with foot-stalks to the flowers three times the length of the leaves, and winged sinuated leaves.

5. *SENECIO corollis radiantibus, foliis pinnatifidis æqualibus patentissimis, rachi infernè angustatâ.* Hort. Cliff. 406. Groundsel with radiated flowers, wing-pointed leaves, which are equal, and the midrib below narrowed.

6. *SENECIO corollis radiantibus, foliis pinnato-multifidis linearibus.* Lin. Sp. Plant. 869. Groundsel with radiated flowers, and wing-pointed, multifid, linear leaves.

7. *SENECIO corollis radiantibus, foliis ensiformibus acutè serratis subtus subvillosis, caule striatò.* Lin. Sp. Plant. 870. Groundsel with radiated flowers, sword-shaped leaves, which are acutely sawed, a little hairy on their under side, and a close stalk.

8. *SENECIO corollis radiantibus, floribus corymbosis, foliis lanceolatis serratis glabriusculis.* Hort. Upsal. 266. Groundsel with radiated flowers growing in a corymbus, and spear-shaped, sawed, smooth leaves.

9. *SENECIO corollis radiantibus, floribus corymbosis, foliis lanceolatis serratis, semiamplexicaulibus.* Groundsel with radiated flowers growing in a corymbus, and spear-shaped sawed leaves half embracing the stalks.

10. *SENECIO corollis radiantibus, floribus corymbosis, foliis ensiformibus dentatis semiamplexicaulibus.* Groundsel with radiated flowers growing in a corymbus, and sword-shaped indented leaves, which half embrace the stalks.

11. *SENECIO corollis radiantibus, floribus corymbosis, foliis inferioribus oblongo-cordatis serratis, caulinis lanceolatis integerrimis amplexicaulibus.* Groundsel with radiated flowers growing in a corymbus, the lower leaves oblong, heart-shaped, sawed, and those on the stalks spear-shaped, entire, embracing the stalks.

12. *SENECIO corollis radiantibus, foliis utrinque tomentosis semipinnatis laciniis subdentatis, corymbo subrotundo.* Haller. Helv. 731. Groundsel with radiated flowers, half-winged leaves, which are downy on both sides, segments which are somewhat indented, and a roundish corymbus of flowers.

13. *SENECIO corollis radiantibus, foliis cordato-oblongis amplexicaulibus scabris acuminatis serratis, caule fruticoso.* Hort. Cliff. 406. Groundsel with radiated flowers, oblong, heart-shaped, rough-pointed, sawed leaves embracing the stalks, which are shrubby.

14. *SENECIO corollis radiantibus, foliis sagittatis amplexicaulibus dentatis, caule fruticoso.* Vir. Cliff. 84. Groundsel with radiated flowers, arrow-pointed indented leaves embracing the stalks, which are shrubby.

15. *SENECIO corollis radiantibus, foliis obovatis carnosissimis subdentatis, caule fruticoso.* Lin. Sp. Plant. 871. Groundsel with radiated flowers, oval fleshy leaves, which are somewhat indented, and a shrubby stalk.

15. *SENECIO corollis nudis, foliis linearibus hirsutis confertis, caule suffruticoso.* Groundsel with naked flowers, linear hairy leaves growing in clusters, and an under-shrub stalk.

The first sort grows naturally in *North America*; this is an annual plant. The stalk is round, channelled, and hairy; it rises three feet high, is garnished with torn leaves, which embrace the stalks with their base; the flowers are produced in a sort of umbel on the top of the stalks, composed of florets, having no rays; they are of a dirty white, and are succeeded by oblong seeds, crowned with a long down. This plant is preserved in some botanick gardens for the sake of variety, but has little beauty. The seeds of this must be sown upon a hot bed in the spring, and when the plants are come up fit to remove, they should be transplanted to another hot-bed to bring them forward, and afterward they may be planted in a warm border, where they will flower in *July*, and their seeds will ripen in autumn.

The second sort grows naturally at *Madras*; this has a perennial root, which has been supposed to be the *China Root*, but is now generally believed to be a spurious kind. The roots are composed of some thick fleshy tubers, sending out many fibres; the leaves are shaped like those of the Turnep, but are smooth. The flower stalk is slender, almost naked, and rises a foot and a half high, sustaining at the top a few yellow flowers, composed of several hermaphrodite florets, having no rays or borders; these are succeeded by oval seeds, crowned with down, but they rarely ripen in *England*.

This sort is tender, so will not thrive in this country, unless it is kept in a warm stove; it is propagated by parting of the roots in the spring. The offsets should be planted in pots, filled with light earth, and plunged into the tan-bed in the stove, and treated in the same way as other tender exoticks.

The third sort grows naturally in *North America*; this hath a perennial root, from which come out many roundish leaves upon long, slender, hairy foot-stalks, of a purplish colour on their under side, crenated on their edges. The stalks rise near two feet high, garnished with a few leaves, which are indented on each side in form of a lyre. The upper part of the stalk divides into several slender long foot-stalks, each sustaining one erect flower, composed of several hermaphrodite florets in the center, and a few female florets form the rays or border. They are yellow, and are succeeded by seeds, crowned with down. It is propagated by offsets, which come out in plenty from the root; these may be separated in autumn, and planted in an east border, allowing each plant two feet room to spread. When they have taken new root, they will require no other care, but to keep them clean from weeds.

The fourth sort grows naturally in *Africa*. This has an herbaceous perennial stalk, which rises about two feet and a half high, garnished at bottom with narrow leaves, which are situated on the sides so as to resemble winged leaves. The upper leaves are small, and embrace the stalks; they are very clammy, and stick to the fingers on being handled; the upper part of the stalk divides into several very long foot-stalks, each sustaining one yellow radiated flower. The plants continue in flower most part of the summer, and the seeds sometimes ripen in autumn.

This is propagated by cutting off the side shoots in any of the summer months, and planting them in a shady border, where in five or six weeks they will take root, and may then be taken up, and planted in pots, placing them in the shade till they have taken new root; then they may be removed to an open situation, and in autumn they must be placed under a frame, where they may be screened from hard frost, for they will not live abroad in winter here.

The fifth fort grows naturally at the *Cape of Good Hope*; it is an annual plant, which hath many herbaceous branching stalks that rise near three feet high, garnished with equal wing-pointed leaves. The flowers are produced in bunches on the top of the stalks; they are large and radiated, the border or rays being of a beautiful purple colour, and the middle or disk yellow. These plants flower from *July* till the frost stops them, and make a fine appearance. The seeds ripen in autumn, which, if permitted to scatter, there will be plenty of plants rise the spring following without care; they may be also sown upon a bed of earth in the spring, and when the plants are fit to remove, they may be transplanted about the borders of the flower-garden. If some of the plants are planted in pots, and housed in winter, they may be preserved till spring.

The sixth fort grows naturally on the *Alps* and *Pyrenees*; this has a perennial root and an annual stalk. The root is composed of a great number of long slender fibres; the stalks rise two feet high, and become a little lignous in autumn; they are garnished with very narrow wing-pointed leaves, resembling those of Hogs Fennel; the flowers are yellow, and are produced in bunches on the top of the stalks; they have rays or borders, resembling those of the other species. It is propagated by seeds, which should be sown upon a bed of loamy earth, where it is exposed only to the morning sun, where the plants will rise better than in a warmer situation. When the plants are fit to remove, they may be transplanted on a shady border, where they may remain till autumn, observing to keep them clear from weeds all the summer; then they should be transplanted to the places where they are to remain. The following summer the plants will flower and produce ripe seeds, and the roots will continue, if they are in a shady situation and a loamy soil.

The seventh fort grows naturally about *Paris*, by the sides of waters and in moist meadows. The root is perennial; the stalks rise three or four feet high, are close channelled, and garnished with sword-shaped leaves, which are hairy, and sharply sawed on their edges. The upper part of the stalk divides into several slender foot-stalks, sustaining yellow radiated flowers, which are succeeded by downy seeds in autumn, soon after which the stalks decay to the root.

The eighth fort grows naturally on the *Helvetian* mountains, and is sometimes found growing in low marshy places in the *Isle of Ely*. This hath a creeping root, by which it propagates and spreads where-ever it is once established. The stalks of this rise four feet high, garnished with smooth spear-shaped leaves, sawed on their edges, and placed alternate. The flowers are yellow, radiated, and are produced in a sort of corymbus on the top of the stalk, which are succeeded by seeds, having down.

The ninth fort grows naturally in *France*; this has some resemblance of the eighth, but the root does not creep like that. The leaves are shorter; the serratures on their edges are very small; they embrace the stalks with their base, and end in sharp points. The flowers are produced in larger and looser bunches on the top of the stalk, and are of a paler yellow colour than those of the former.

The tenth fort grows naturally in the *Levant*; this has a perennial root. The lower leaves are long, smooth, and somewhat shaped like a scymiter, the midrib being curved outward toward the point, and slightly indented on their edges. The stalk rises six feet high, garnished with leaves, growing smaller toward the top of the stalk. The flowers terminate the stalk in a compact corymbus; they are of a deep yellow, and have rays like those of the former forts.

These forts are easily propagated by seeds or parting of their roots; the latter is generally practised when the plant

is once obtained, as that is the most expeditious method, especially for the eighth fort, whose roots are apt to spread and increase too fast, where they are not confined. The best time to transplant and divide these roots is in autumn, when their stalks decay, that they may get good rooting before the spring. These plants are too large for small gardens, so are proper furniture for large borders in extensive gardens, or to plant on the sides of woods, where they may be allowed room, for they should have at least four feet allowed to each. When these are intermixed with other tall growing plants in such places, they will add to the variety.

The eleventh fort grows naturally in *North America*; this has a perennial root, from which come out smooth heart-shaped leaves, slightly indented on their edges, a little downy on their under side. The stalk rises three feet high, garnished with spear-shaped entire leaves embracing them; the flowers terminate the stalk in a close compact corymbus; they are of a deep yellow colour, and are succeeded by seeds, which ripen in autumn. This fort is propagated in the same manner as the former, and is equally hardy.

The twelfth fort grows naturally on the *Alps*; this is a perennial plant, of low growth. The stalks seldom rise a foot high; the whole plant is covered with a very white hoary down; the leaves are winged and indented; the flowers are collected into a close round corymbus on the top of the stalk, of a gold colour, and are radiated; they are rarely succeeded by good seeds in *England*. It is propagated by slipping off the heads in the autumn, and planting them in a bed of loamy earth in a shady situation, where they will put out roots, and may afterward be transplanted into an east border, where they may have the morning sun only, for this plant loves a gentle loamy soil, and a situation not too much exposed to the sun.

The thirteenth fort grows naturally at the *Cape of Good Hope*. This rises with a shrubby branching stalk six or seven feet high, closely garnished with rough leaves, whose base embrace the stalks; they are stiff, hairy, of a dark green colour, oblong, heart-shaped, and indented on their edges. The flowers are produced at the end of the branches, which are of a bright yellow colour, and are succeeded by seeds in autumn.

The fourteenth fort grows naturally at the *Cape of Good Hope*. This hath a very branching shrubby stalk, which rises four or five feet high, garnished with stiff leaves, whose base embraces the stalks; they are irregular in their figure, deeply cut on their edges, and of a gray colour on their under side. The flowers grow in loose bunches at the end of the branches, of a pale yellow colour. This fort flowers great part of summer, and the seeds ripen in autumn.

The fifteenth fort grows naturally at the *Cape of Good Hope*. This has a shrubby stalk, which rises seven or eight feet high, garnished with oblong oval leaves, indented on their edges. The flowers are produced in loose bunches at the extremity of the branches, almost in form of an umbel; they are of a pale yellow colour.

The sixteenth fort grows naturally at the *Cape of Good Hope*. This is a perennial plant, from whose roots arise several hairy herbaceous stalks four feet high, garnished with hairy linear leaves in clusters, which sit close to the branches; they are of a deep green on their upper side, and pale on their under. The flowers are produced at the end of the branches in close bunches, formed like umbels, of a gold colour, but have no rays or borders, only hermaphrodite florets, which are included in one common empalement.

The four forts last mentioned are too tender to live in the open air through the winter in *England*, but are so hardy as only to require protection from hard frost, so may be kept in

in pots, and placed either under a frame in winter, or in a common green-house with other hardy kinds of plants, which require a large share of air in mild weather. They are all easily propagated by seeds or cuttings, but the latter being the most expeditious method, is generally practised here. If the cuttings are planted in a shady border during any of the summer months, they will readily take root; then they should be taken up, and each planted in a separate pot, and placed in the shade till they have taken new root; then they may be removed to a more open situation, where they may remain till there is danger of sharp frost, when they should be removed into shelter, and treated in the same way as other hardy kinds of green-house plants.

SENNA. *Tern. Inst. R. H. 618. tab. 319.* Senna.

The Characters are,

The flower has an empalement of five leaves; it has five roundish concave petals, and ten declining stamina, terminated by oblong arched summits. The germen is roundish and compressed, supporting a short style, crowned by an obtuse stigma. The germen afterward becomes a plain, roundish, compressed pod, a little incurved, having two cells, divided by an intermediate partition, each containing one or two oblong pointed seeds.

The Species are,

1. SENNA *foliolis quadrijugatis lanceolatis acutis.* Senna with four pair of spear-shaped pointed lobes to the leaves.

2. SENNA *foliolis quinquejugatis cordatis obtusis.* Senna with five pair of lobes to the leaves, which are heart-shaped and obtuse.

The first sort grows naturally in *Egypt*; this is an annual plant, which rises with an upright branching stalk a foot high, garnished with winged leaves, composed of four pair of small spear shaped lobes, ending in acute points. The flowers terminate the stalks in loose bunches; they are yellow, composed of five roundish concave petals, with ten stamina in the center surrounding the style; after the flower is past, the germen turns to a roundish gibbous pod, having two cells, each containing one or two oblong seeds. The leaves of this sort are used in medicine, and are commonly known in the shops by the title of Senna; these are annually imported from *Alexandria*, which occasioned the title of *Alexandrina* being added to it. This plant is propagated by seeds, which should be sown early in the spring, upon a good hot-bed; and when the plants are come up, and are fit to remove, they should be each planted in a small pot, and plunged into a fresh hot-bed, shading them from the sun till they have taken new root, after which they must be treated in the same way as the most tender exoticks; for as this is an annual plant, unless they are brought forward in the spring, they will not flower in this country; therefore they must be constantly kept in the hot-bed all the summer, observing to admit plenty of air in warm weather; by which method I have frequently had these plants in flower, but it is very rare that they perfect their seeds in *England*.

The second sort grows naturally in *India*, from whence I have received the seeds; for although it is called *Italian*, yet the plant does not grow there naturally. This is also an annual plant, rising with a branching stalk a foot and a half high; the leaves are winged, each having five pair of heart-shaped lobes, which are inverted, the point joining the branches, and the obtuse part is upward; they are of a sea-green colour, and of a thick consistence. The flowers are produced at the end of the branches, shaped like those of the first sort, but are larger, and of a brighter yellow colour. If the plants are brought forward early in the spring, they will flower in *July*, and by so doing good seeds may be obtained here. This sort is propagated in the same way as the first, and the plants require the same treatment.

SENNA THE BLADDER. See *Colutea*.

SENNA THE SCORPION. See *Emerus*.

SENSIBLE PLANT. See *Mimosa*.

SERAPIAS. *Lin. Gen. Plant. 903.* Bastard Hellebore.

The Characters are,

It has a single stalk; the sheath of the flower is at a distance. The germen sustains the flower, which has no empalement, but has five oblong oval petals. The nectarium is the length of the petal, hollowed at the base, oval, and gibbous below, cut into three points. The flower has two short stamina sitting upon the point, terminated by erect summits, placed under the upper lip of the nectarium; and an oblong contorted germen, situated under the flower, the style growing to the upper lip of the nectarium, crowned by an obsolete stigma. The germen afterward becomes an oval, obtuse, three-cornered capsule, armed with three keels, opening with a valve under each, having one cell, filled with small seeds.

The Species are,

1. SERAPIAS *bulbis fibrosis, nectarii labio obtuso crenato petalis brevioribus.* *Act. Upsal. 1740.* Serapias with fibrous bulbs, and the lip of the nectarium obtuse, crenated, and shorter than the petal.

2. SERAPIAS *bulbis fibrosis, petalis nectario longioribus obtusis, foliis lanceolatis nervosis.* Serapias with fibrous bulbs, obtuse petals which are longer than the nectarium, and veined spear-shaped leaves.

3. SERAPIAS *bulbis fibrosis, petalis reflexis, nectarii labio obtuso, foliis ensiformibus nervosis.* Serapias with fibrous bulbs, reflexed petals, the lip of the nectarium obtuse, and sword-shaped veined leaves.

4. SERAPIAS *bulbis fibrosis, nectarii labio quinquesido clauso, foliis lanceolatis nervosis amplexicaulibus.* Serapias with fibrous bulbs, the lip of the nectarium cut into five parts, and spear-shaped veined leaves embracing the stalks.

There are some other species of this genus which grow naturally in *Great-Britain* and *Ireland*, but as I have not had the good fortune to meet with them, so I shall not trouble the reader with an imperfect account of them from books: there are also a greater number of them which grow naturally in the *West-Indies*, of which I have samples in my collection; but having never seen any growing plants of them, I shall not insert them here.

The first sort grows naturally in woods and shady places in many parts of *England*; the roots are composed of many thick fleshy fibres, from which arises a single jointed stalk a foot high, garnished at each joint with one veined leaf; those on the lower part of the stalk are oval, but those above are spear-shaped, ending in acute points, embracing the stalks at their base. The stalk is adorned with flowers toward the top, which have some resemblance to those of *Orchis*, composed of two whitish, and three herbaceous petals, which expand, and in the middle appears the nectarium, which has a resemblance of a disboweled body of a fly, of a purplish colour. Under the flower is situated a channelled oblong head, which after the flower is past, swells and becomes a seed-vessel, filled with very small seeds.

The second sort grows naturally in *Stoken-Church Woods* in *Oxfordshire*, and in several parts of *Westmoreland* and *Lancashire*. This has fleshy fibrous roots, not quite so thick as those of the former; the stalks rise more than a foot high, garnished with spear-shaped veined leaves, ending in acute points, of a lucid green, and sit close to the stalk. The flowers are white, disposed alternately on the upper part of the stalk; the three outer petals are large, and two smaller within; in the center is situated the gaping nectarium, which appears to have two wings.

The third sort grows naturally in marshy woods in many parts of *England*; this has a fleshy fibrous root, from which arise a single stalk a foot and a half high, garnished at bottom with sword-shaped veined leaves, embracing the stalk with

with their base, ending in acute points. The upper part of the stalk is garnished with faded purplish-coloured flowers, disposed in a loose spike; they have five petals, inclosing a large nectarium like the body of a fly, with a yellowish head, striped with purple and a white body; the lip which hangs down is white, and fringed on the edge.

The fourth sort was discovered first in *Hertfordshire*, but since it has been found growing in many other places. The root of this is composed of fleshy fibres; the stalks rise more than a foot high, garnished with spear-shaped veined leaves, which embrace the stalks with their base. The stalk is terminated by a loose spike of white flowers, composed of five petals, and a large five-pointed nectarium, which is shut; the germen is oblong and channelled: this afterward becomes a capsule of the same form, filled with small seeds.

These plants are rarely kept in gardens, being difficult to propagate; there are few who have attempted them. They may be taken up from the places where they naturally grow, when their leaves begin to decay, and planted in a shady moist place, where they will thrive and flower.

SERJANIA. See Paullinia.

SERPENTARIA. See Aristolochia.

SERPILLUM. See Thymus.

SERRATULA. Dillen. Nov. Gen. 8. Saw-wort.

The Characters are,

The flowers are composed of many hermaphrodite florets, contained in one common cylindrical empalement; the scales of which are spear-shaped, ending in acute points. The hermaphrodite florets are equal, funnel shaped, of one petal. The tube is inflexed, the brim is bellied, and cut into five points; they have each five short hair-like stamina, terminated by cylindrical summits; and an oval germen, supporting a slender style, crowned by two oblong reflexed stigmas. The germen afterward turns to a vertical, oval, single seed, crowned with down, which ripens in the empalement.

The Species are,

1. SERRATULA foliis pinnatifidis, pinnis terminali maxima. Hort. Cliff. 391. Saw-wort with wing-pointed leaves, whose end lobe is the largest; common Saw-wort.

2. SERRATULA foliis lanceolato-oblongis serratis subtus tomentosis. Saw-wort with oblong spear-shaped leaves, which are sawed, and downy on their under side.

3. SERRATULA foliis ovato-oblongis acuminatis serratis, floribus corymbosis, calycibus subrotundis. Flor. Virg. 92. Saw-wort with oblong, oval, acute-pointed, sawed leaves, and flowers in a corymbus, whose empalements are roundish.

4. SERRATULA foliis linearibus, calycibus squarrosis sessilibus acuminatis. Hort. Cliff. 392. Saw-wort with linear leaves and rough empalements, which sit close to the stalks, ending in acute points.

5. SERRATULA foliis lanceolatis integerrimis, calycibus squarrosis pedunculatis obtusis lateralibus. Lin. Sp. Plant. 818. Saw-wort with entire spear-shaped leaves, and rough empalements, having obtuse foot stalks proceeding from the side of the stalks.

6. SERRATULA foliis linearibus, floribus sessilibus lateralibus spicatis, caule simplici. Lin. Sp. Plant. 819. Saw-wort with linear leaves, flowers in spikes from the side of the stalks sitting close, and a single stalk.

7. SERRATULA foliis lanceolatis rigidis, acutè serratis, caule corymboso. Saw-wort with stiff spear-shaped leaves, sharply sawed, and stalks forming a corymbus.

8. SERRATULA foliis oblongo-lanceolatis, integerrimis subtus hirsutis. Saw-wort with oblong, spear-shaped, entire leaves, hairy on their under side.

9. SERRATULA foliis oblongo-ovatis obtusè-dentatis, caule ramoso patulo, calycibus subrotundis mollibus. Saw-wort with oblong oval leaves, bluntly indented, a branching spreading stalk, and soft roundish empalements.

10. SERRATULA calycibus subhirsutis ovatis. Lin. Sp. Plant. 816. Saw-wort with oval empalements, a little hairy.

The first sort grows naturally in moist woods and marshes in many parts of *England*, so is rarely admitted into gardens. There are two varieties of this, one with a white, and the other a purple flower. The root is perennial; the lower leaves are sometimes entire, and at others are cut almost to the midrib into many jags; they are smooth, of a deep green, and neatly sawed on their edges. The stalks rise two feet high, garnished with wing-pointed leaves, whose extreme lobe is much larger than the other; the upper part of the stalk divides into several foot-stalks, sustaining at the top oblong squamous heads or empalements, which include several hermaphrodite florets.

The second sort grows naturally in *North America*; this has a perennial root, sending out several channelled stalks seven or eight feet high, garnished with spear-shaped leaves, slightly sawed on their edges, which are downy on their under side, sitting close to the stalk; the upper part of the stalk divides into foot-stalks, which sustain purple flowers in scaly empalements.

The third sort is a native of *North America*; the root is perennial; the stalks rise six or seven feet high. The leaves are oblong, oval, stiff, sawed on their edges, and of a light green on both sides. The flowers grow in a loose corymbus at the top of the stalk; they are purple, and have roundish empalements.

The fourth sort grows naturally in *Carolina*. This has a tuberous root, sending out a single stalk three feet high, garnished with stiff linear leaves, which are entire, and rough to the touch, of a pale green on both sides. The upper part of the stalk is adorned with purple flowers, having oblong, rough, prickly empalements; these sit close to the side of the stalk alternately, and the stalk is terminated by one head, which is larger than the other.

The fifth sort grows naturally in most parts of *North America*; this has a large tuberous root, from which comes out one strong channelled stalk three or four feet high, closely garnished with narrow spear-shaped leaves, which are entire. The upper part of the stalk is adorned with loose spikes of purple flowers, which come out from the side upon pretty long blunt foot-stalks; they have large rough empalements, composed of wedge-shaped scales. The flowers on the top of the spike blow first, and are succeeded by the other downward, which is contrary to the usual order of the greatest number of plants, whose flowers are ranged in spikes.

The sixth sort is a native of *North America*; this has a tuberous root, from which comes forth a single stalk from two to three feet high, garnished with very narrow smooth leaves, sitting close to the stalk without any order. The upper part of the stalk is adorned with smaller purple flowers than those of the former, sitting very close to the stalk, forming a long loose spike.

The seventh sort is also a native of *North America*; this has a perennial fibrous root, from which arise several strong purple stalks upward of six feet high, garnished with stiff spear-shaped leaves, deeply sawed on their edges, of a pale green on their under side. The upper part of the stalk divides into small branches, forming a loose corymbus of purple flowers, which are irregular in height, some of the flowers standing upon shorter foot-stalks than the other; their empalements are round, and the scales terminate in bristly points.

The eighth sort grows naturally in *Carolina*; this has a fibrous perennial root; the stalk rises four feet high; the leaves are entire, hoary on their under side, sitting close to the stalk. The flowers grow in loose bunches at the end

of the branches; they have oval empalements, composed of a few scales, which terminate in bristles. The flowers are of a pale purple colour.

The ninth sort grows naturally in the northern parts of *China*. This is an annual plant, with an herbaceous stalk a foot and a half high, covered lightly with a white meal; the branches spread out almost horizontally, garnished with smooth, oblong, oval leaves, which have a few blunt indentures on their edges, of a light green colour. The flowers are produced in loose bunches at the extremity of the branches, having roundish soft empalements, whose scales end with hairy points, including hermaphrodite florets of a bluish purple colour.

The tenth sort grows naturally on the tops of mountains in *Wales* and the north of *England*, and is but seldom kept in gardens. The root is perennial, from which arise two or three stalks a foot and a half high, of a deep green colour, channelled, and garnished with deep green leaves. From the middle of the stalk upward, there are branches sent out from the side, which grow erect, and sustain at the top small bunches of purple flowers, which have oblong slender empalements a little hairy.

The eight sorts which are first mentioned, are hardy perennial plants, so will thrive in the open air in *England*. The first is rarely admitted into gardens, but the other are frequently preserved in the gardens of the curious. The fourth, fifth, and sixth sorts, have large knobbed roots, so are propagated only by seeds, which seldom ripen in *England*. These should be sown on an east-aspected border, for if they are exposed to the mid day sun, they seldom succeed well. The seeds will often grow the first summer, if they are sown early in the spring, but sometimes they will remain in the ground a year, before the plants appear; so that if they should not come up the first season, the ground should not be disturbed, but must be kept clean from weeds till the following spring, when, if the seeds were good, the plants will come up; when these appear, if they are too close, some of the plants should be carefully drawn out while they are young, and planted in another border of four inches asunder; in this place they may remain till autumn, when these, and also those in the seed-bed, should be carefully removed to the places where they are designed to remain; the following summer these plants will flower, and the roots will abide several years, if they are planted in a light loamy soil not over-wet.

The other perennial sorts may be propagated by parting of the roots; the best time for doing this is in autumn, when their stalks begin to decay; for when they are removed in the spring, if the season should prove dry, their roots will not be sufficiently established to flower well the same year. These plants should not be removed or parted oftener than every third year, if they are expected to grow strong; nor should they be parted into small heads, for those will make no figure the first year. As these plants grow tall, so they should be planted in the middle of large borders, or with other tall plants; they may be planted in spaces between shrubs, or on the borders of woods, where they will have a good effect, during their continuance in flower, as they require no other culture than to dig the ground between them every spring.

The tenth sort is a perennial plant, which may be propagated by its creeping roots, and may be planted in a shady border, where it will thrive, and annually produce flowers.

The ninth sort is an annual plant; the seeds of this should be sown upon a moderate hot-bed the beginning of *April*, and, when the plants come up, and are fit to remove, they should be transplanted to a fresh hot-bed to bring them forward; afterward they should be treated in the same way as other hardy annual plants.

SESAMUM. *Lin. Gen. Plant.* 700. Oily Grain.

The Characters are,

The flower has an erect permanent empalement, cut at the top into five very short equal parts. The flower has one ringent petal, with a roundish tube the length of the empalement; the chaps are swollen, bell-shaped; the brim is cut into five points, four of which are almost equal; the other is twice their length. It has four stamina rising from the tube, which are shorter than the petal, the two inner being shorter than the other, terminated by erect summits; and an oval hairy germen, supporting a slender style longer than the stamina, crowned by a spear-shaped stigma, divided in two parts. The germen afterward becomes an oblong almost four-cornered capsule, having four cells, filled with oval compressed seeds.

The Species are,

1. SESAMUM foliis ovato-oblongis integris. *Hort. Cliff.* 318. Sesamum with oblong, oval, entire leaves.
2. SESAMUM foliis inferioribus trifidis. *Prod. Leyd.* 292. Sesamum with trifid lower leaves.
3. SESAMUM foliis omnibus trifidis. Sesamum with all the leaves trifid.

The first sort is cultivated in great plenty in the *Levant*, but is supposed to have been brought there from *India*. It is an annual plant, rising with an herbaceous four-cornered stalk two feet high, sending out a few short side branches; the leaves are oblong, oval, a little hairy, and stand opposite. The flowers terminate the stalks in loose spikes; they are small, of a dirty white colour, shaped somewhat like those of the Foxglove. After the flowers are past, the germen turns to an oval acute-pointed capsule with four cells, filled with oval compressed seeds, which ripen in autumn.

The second sort grows naturally in *India*; this is also an annual plant; the stalk rises taller than that of the former; the lower leaves are cut into three parts, which is the only difference between them.

The third sort grows naturally in *Africa*. This is also an annual plant, with a taller and more branched stalk than either of the former, in which it differs from both the other.

The first sort is frequently cultivated in all the eastern countries, and also in *Africa*, as a pulse; and of late years the seeds have been introduced into *Carolina* by the *African* negroes, where they succeed extremely well. The inhabitants of that country make an oil from the seed, which will keep good many years, without having any rancid smell or taste, but in two years becomes quite mild; so that when the warm taste of the seed, which is in the oil when first drawn, is worn off, they use it as a salad oil, and for all the purposes of sweet oil.

The seeds of this plant are also used by the negroes for food, which seeds they parch over the fire, and then mix them with water, and stew other ingredients with them, which makes an hearty food. Sometimes a sort of pudding is made of these seeds, in the same manner as with Millet or Rice, and is by some persons esteemed, and is rarely used for these purposes in *Europe*. This is called Benny, or Bonny, in *Carolina*.

In *England* these plants are preserved in botanick gardens as curiosities. Their seeds must be sown in the spring upon a hot-bed, and when the plants are come up, they must be transplanted into a fresh hot-bed to bring them forward. After they have acquired a tolerable degree of strength, they should be planted into pots, and plunged into another hot-bed, managing them as hath been directed for Amaranthuses, to which I shall refer the reader, to avoid repetition; for if these plants are not thus brought forward in the former part of the summer, they will not produce good seeds in this country.

The seed of the first sort is mentioned in the list of *Officinal Simples* in the *College Dispensatory*, but is rarely used in medicine in *England*. From nine pounds of this seed which came from *Carolina*, there were upwards of two quarts of oil drawn, which is as great a quantity as hath been obtained from any vegetable whatever. This, I suppose, might occasion its being called *Oily Grain*.

SESELI. *Boerb. Ind. alt.* 1. p. 50. Wild Spignel.

The Characters are,

It has an umbellated flower; the particular umbels are very short, multiplex, and almost globular. The principal umbel has no involucre; the particular ones have a many narrow-leaved involucre, which is as long as the umbel; the principal umbel is uniform. The flowers have five inflexed heart-shaped petals, which are unequal; they have each five awl-shaped stamina, terminated by single summits. The germen is situated under the flower, supporting two reflexed styles, crowned by obtuse stigmas. The germen afterward turns to a small, oval, channelled fruit, dividing in two parts, each containing one oval streaked seed, flat on one side, and convex on the other.

The Species are,

1. SESELI *petiolis ramiferis membranaceis ventricosus emarginatis. Hort. Cliff.* 103. Sefeli with bellied, membranaceous, branching foot-stalks, which are indented at the top.

2. SESELI *foliis bipinnatis sublinearibus, petiolis basi membranaceis, seminibus ovalibus. Lin. Sp. Plant.* 360. Sefeli with double-winged leaves almost linear, with a membranaceous base to the foot-stalks, and oval seeds.

3. SESELI *petiolis ramiferis membranaceis oblongis integris, foliis singularibus binatisque. Guett.* 64. Sefeli with branching, oblong, entire, membranaceous foot-stalks, the small leaves single and by pairs.

4. SESELI *petiolis ramiferis membranaceis oblongis integris, foliis caulinis angustissimis. Hort. Cliff.* 102. Sefeli with oblong, entire, membranaceous, branching foot-stalks, and very narrow leaves on the stalks.

5. SESELI *caule alto rigido, foliis linearibus fasciculatis. Lin. Sp. Plant.* 260. Sefeli with a tall stiff stalk, and very narrow leaves in clusters.

6. SESELI *petiolis membrana destitutis. Flor. Leyd. Prod.* 112. Sefeli with foot-stalks without membranes.

The first sort grows naturally in *France* amongst the Corn; this rises with an erect stalk two feet high, garnished with short leaves, divided into small segments like *Hogs Fennel*. At the foot-stalk of each branch or leaf is a bellied membrane, which embraces it. The stalk is terminated by an umbel of white flowers, and the seeds ripen in *August*.

The second sort grows naturally in *Germany*; this hath a perennial root. The leaves are long, made up of eight or nine pair of winged lobes, which are cut like those of *Parsley*; the stalk rises two feet and a half high, branching out into several divisions; at each of these there is a membrane embracing the base, and one small leaf, composed of a few linear lobes. The stalks are terminated by compound umbels of yellow flowers, which are succeeded by seeds.

The third sort grows naturally in uncultivated places in the south of *France* and *Italy*; this has a perennial root, sending out slender smooth stalks two feet high. The leaves are long and narrow, composed of seven or eight pair of wings, whose lobes are sometimes single, and at others are divided into two parts; they have a membrane embracing their foot-stalks, and are of a gray colour. The stalks are terminated by umbels of flowers, which are purple on their outside, and white within.

The fourth sort grows naturally on the dry hills in many parts of *France* and *Italy*; this has a perennial root, from which come out leaves like those of *Spignel*, but the segments are broader and of a gray colour. The stalks rise a foot high, garnished with a few very narrow leaves, whose

foot-stalks are embraced by a long entire membrane, and are terminated by umbels of white flowers.

The fifth sort grows naturally in the south of *France*, in *Italy*, and *Spain*; this has a thick ligneous root, from which arise stiff stalks four feet high, crooked at their joints, and garnished with narrow leaves coming out in bunches. The stalks divide into slender branches, which have small umbels of flowers coming out of their sides, and are terminated by larger. The flowers are small and yellow.

The sixth sort is an annual plant, which grows naturally in *Portugal*. The leaves of this are like those of *Spignel*, but much smaller, and have a very acrid biting taste. The stalks rise four inches high, sustaining a small umbel of flowers.

These plants are preserved in the gardens of botanists for the sake of variety, but at present their virtues are unknown, and, as they have little beauty to recommend them, they are rarely admitted into other gardens.

They may be propagated by sowing their seeds in autumn, for when they are sown in the spring, they frequently lie in the ground a year before the plants will appear; whereas those which are sown in autumn, always rise the following spring. They should be sown in drills about eighteen inches asunder, in a bed of fresh earth, where they are designed to remain, and in the spring, when the plants come up, they should be thinned where they are too close, leaving them about six inches distance in the rows; after this the plants will require no farther care, but to keep them constantly clear from weeds; the second season they will produce flowers and seeds. The perennial roots, which are permitted to remain after they have seeded, should have the ground gently dug every spring between the rows to loosen the earth, but there should be care taken not to injure their roots with the spade.

SHERARDIA. *Dillen. Gen. Nov.* 3. Little Field-Madder.

The Characters are,

The flower has a small permanent empalement sitting upon the germen; it has one long tubulous petal, cut into four plain acute parts at the brim; it has four stamina, situated on the top of the tube, terminated by single summits, and an oblong twin germen below the flower, supporting a slender bifid style, crowned by two headed stigmas. The germen afterward becomes an oblong fruit, containing two oblong seeds, which are separated.

The Species are,

1. SHERARDIA *foliis omnibus verticillatis, floribus terminalibus. Lin. Sp. Plant.* 102. Sherardia with all the leaves placed in whorls, and flowers terminating the stalks.

2. SHERARDIA *foliis foralibus binis oppositis binis floribus. Lin. Sp. Plant.* 103. Sherardia with leaves among the flowers by pairs opposite, and two flowers at a place.

The first sort grows naturally amongst the Corn in many parts of *England*; it is an annual plant, with trailing stalks which spread on the ground, garnished with short acute-pointed leaves growing in whorls, some of which have four, others five and six, and some have eight leaves in each whorl. The flowers terminate the stalk; there are generally five or six flowers in each bunch; they are blue, have pretty long tubes, and are cut into four segments at the top, spreading open. Their seeds ripen in autumn.

The second sort is an annual plant, which grows naturally on walls and dry places in *Italy*. The stalks of this are short; the leaves grow by pairs; the flowers are yellow, and placed by pairs. The seeds of these plants scatter, and come up without care.

SHERARDIA. *Vaill. See Verbena.*

SICYOS. *Lin. Gen. Plant.* 971. Single-seeded Cucumber.

The Characters are,

It hath male and female flowers on the same plant; the male flowers have a bell-shaped empalement of one leaf, with five indentures. The petal is bell-shaped, growing on the empalement; they have each three stamina, which are united above, terminated by summits, joined in a head. The female flowers are like the male, and sit upon the germen; they have no stamina, but the germen supports a cylindrical style, crowned by a thick three-pointed stigma. The germen afterward becomes an oval fruit set with bristly hairs, having one cell, containing a single seed of the same shape.

The Species are,

1. *SICYOS foliis angulatis*. Hort. Cliff. 452. Sicyos with angular leaves.

2. *SICYOS foliis laciniatis*. Lin. Sp. Plant. 1013. Sicyos with cut leaves.

3. *SICYOS foliis ternatis incis.* Flor. Leyd. Prod. 265. Sicyos with trifoliate cut leaves.

The first sort grows naturally in North America; this is an annual plant, which rises with two large seed-leaves like those of the Cucumber. The stalk is trailing, and has tendrils, by which it fastens itself to the neighbouring plants, where, if it has support, will rise fifteen or sixteen feet high, dividing into many branches, garnished with angular leaves like those of the Cucumber. The flowers come out upon long foot-stalks from the side of the branches, standing in clusters, some of which are male or barren flowers, others are female fruitful flowers; they are of a pale sulphur colour; the female flowers are succeeded by prickly oval fruit, containing one seed. If the seeds are permitted to scatter, the plants will come up in the spring better than when sown by hand, and require no other care, but to keep them clean from weeds. These plants ramble, and take up too much room for small gardens, therefore should be allowed a place near a hedge, upon which they may climb; they do not bear transplanting well, unless when they first come up.

The second sort grows naturally in the West-Indies; this is also an annual plant, with trailing stalks like the former, but the leaves of this are cut into several segments. The flowers are larger, and of a deeper colour; the fruit are not quite so large, nor so closely armed with prickly hairs, in which consists their difference.

This sort is not so hardy as the first, therefore whoever has a mind to cultivate it, must sow the seeds upon a hot-bed in the spring, and treat the plants in the same way as Cucumbers and Melons, keeping them under frames, otherwise the seeds will not ripen here; the plants will require more room than either of the former, so that one or two plants will be enough for curiosity, as they have no great beauty or use.

The third sort grows naturally in Jamaica; this is a perennial plant, with thick, jointed, fleshy stalks, which by age become ligneous; they send out branches, which have tendrils or clasps, by which they fasten themselves to any neighbouring support, and rise seven or eight feet high, garnished with trifoliate leaves, standing upon pretty long foot-stalks, which are thick, succulent, of a gray colour, cut on their edges, having a sharp acid taste. The flowers come out in clusters from the side of the branches, like those of the Vine; they are small, and of an herbaceous colour. This plant has flowered in the Chelsea garden, but has not produced fruit in England.

It is propagated by seeds, which should be sown in small pots, and plunged into a hot-bed of tanners bark, where the pots should remain till the plants come up, for the seeds sometimes lie long in the ground. When the plants are fit to remove, they should be each planted into a small pot, and plunged into a new hot-bed, shading them from the sun till they have taken new root; after which they must

be treated in the same way as other tender plants from the same country, keeping them always in the tan-bed in the stove; in winter they should have but little water. This plant is preserved for the sake of variety in the gardens of the curious.

SIDA. Lin. Gen. Plant. 747. Indian Mallow.

The Characters are,

The empalement of the flower is single, permanent, angular, and five-pointed. The flower is of one petal, cut into five broad segments, which are joined at their base, and are indented at their points; it has many stamina, which are joined in a column at bottom, but spread open above, terminated by roundish summits, and an orbicular germen, supporting a short multifid style, crowned by headed stigmas. The germen afterward becomes a five-cornered capsule, having five cells, each containing an angular roundish seed.

The Species are,

1. *SIDA foliis ovato-lanceolatis serratis, floribus solitariis axillaribus, semine rostrato bidente*. Indian Mallow with oval, spear-shaped, sawed leaves, single flowers on the side of the stalk, and seeds with two horns.

2. *SIDA caule ramoso hirsuto, foliis lanceolatis serratis floribus confertis axillaribus, semine rostrato simplici*. Sida with a branching hairy stalk, spear-shaped sawed leaves, flowers in clusters from the wings of the stalk, and seeds with a single horn or tooth.

3. *SIDA caule erecto ramoso, foliis lineari-lanceolatis dentatis subtus villosis, pedunculis axillaribus unifloris*. Sida with an erect branching stalk, linear spear-shaped leaves, hairy on their under side, and foot-stalks with one flower at the wings of the stalks.

4. *SIDA foliis cordatis serratis, pedunculis unifloris axillaribus, semine rostrato bidente*. Sida with heart-shaped sawed leaves, foot-stalks with one flower from the wings of the stalk, and seeds with two horns.

5. *SIDA foliis ovato-lanceolatis inæqualiter serratis, floribus axillaribus sessilibus, semine tridente*. Sida with oval spear-shaped leaves, which are unequally sawed, flowers sitting close at the wings of the stalks, and seeds with three teeth.

6. *SIDA caule erecto hirsuto, foliis subcordatis sessilibus serratis subvillosis, floribus confertis axillaribus sessilibus*. Sida with a hairy stalk, leaves almost heart-shaped, sitting close to the stalk, which are a little woolly, and flowers in clusters sitting close at the wings of the stalk.

7. *SIDA foliis orbiculatis plicatis serratis*. Hort. Cliff. 346. Sida with orbicular plaited leaves, which are sawed.

8. *SIDA foliis cordatis subangulatis serratis villosis*. Lin. Sp. Plant. 684. Sida with heart-shaped leaves almost angular, which are woolly and sawed.

9. *SIDA foliis orbiculato-cordatis crenatis, caule petiolisque hirsutis, pedunculis longis axillaribus unifloris*. Sida with orbicular, heart-shaped, crenated leaves, the stalks and foot-stalks of the leaves hairy, and long foot-stalks from the wings of the stalk with one flower.

10. *SIDA capitulis pedunculatis triphyllis septemfloris*. Lin. Aët. Upsal. 1743. p. 137. Sida with heads on foot-stalks, which have three leaves and seven flowers.

11. *SIDA foliis lanceolatis serratis villosis, caule erecto piloso, pedunculis axillaribus unifloris*. Sida with spear-shaped, woolly, sawed leaves, an erect hairy stalk, and foot-stalks from the wings of the stalk with one flower.

12. *SIDA foliis cordatis crenatis acuminatis villosis, caule petiolisque pilosis, pedunculis axillaribus unifloris*. Sida with heart-shaped, pointed, crenated, woolly leaves, the stalks and foot-stalks hairy, and foot-stalks with one flower at the wings of the stalk.

13. *SIDA caulibus procumbentibus, foliis oblongo-ovatis serratis hirsutis, floribus sessilibus terminalibus*. Sida with trailing stalks, oblong, oval, hairy, sawed leaves, and flowers sitting close at the end of the branches.

14. SIDA

14. *SIDA foliis cordatis serratis acuminatis glabris, caule ramoso, pedunculis axillaribus unifloris.* Sida with heart-shaped, sawed, acute-pointed, smooth leaves, a branching stalk, and foot-stalks from the wings of the stalks with one flower.

15. *SIDA caulibus procumbentibus, foliis ovatis serratis tomentosis nitidis, floribus solitariis axillaribus sessilibus.* Sida with trailing stalks, neat, oval, sawed, woolly leaves, and single flowers sitting close to the wings of the stalk.

16. *SIDA foliis subcordatis crenatis subtus tomentosis, floribus aggregatis axillaribus sessilibus.* Sida with almost heart-shaped leaves, which are crenated, woolly on their under side, and flowers in clusters sitting close at the wings of the stalk.

17. *SIDA foliis subovatis serratis nervosis subtus tomentosis, caule piloso, pedunculis axillaribus multifloris.* Sida with veined sawed leaves almost oval, woolly on their under side, a hairy stalk, and foot-stalks with many flowers at the wings of the stalks.

18. *SIDA foliis lanceolatis inaequaliter serratis acuminatis, floribus capitatis terminalibus, caule fruticoso.* Sida with spear-shaped acute-pointed leaves unequally sawed, flowers collected in heads at the end of the branches, and a shrubby stalk.

19. *SIDA foliis cordatis acuminatis serratis nervosis, floribus aggregatis axillaribus sessilibus.* Sida with acute-pointed, heart-shaped, sawed, veined leaves, and flowers in clusters sitting close to the wings of the stalk.

20. *SIDA caule erecto suffruticoso, foliis cordatis crenatis tomentosis, pedunculis axillaribus unifloris.* Sida with an erect under-shrub stalk, heart-shaped, woolly, crenated leaves, and foot-stalks, with one flower from the wings of the stalk.

These plants grow naturally in the *West-Indies*, from whence I have received the seeds of three or four species by the title of Broom-weed; and I have been informed that the inhabitants cut these plants in the same manner as we do Heath, and make it up into brooms for sweeping. Sometimes I have received seeds of others by the title of *West-India Thea*, so that I suppose the leaves of some of these plants are sometimes used as the *Thea*. There are certainly more species of this genus than are here mentioned, which have escaped the notice of those who have been in the *West-Indies* in search of plants, for we frequently have new sorts come up in the earth, which is brought from thence with other plants. Those here enumerated are undoubtedly distinct species, for I have cultivated them several years, and have never observed either of them change, when raised from seeds.

The first sort grows as far north as *Virginia*, from whence I have several times received the seeds; this has an upright branching stalk three feet high, garnished with oval spear-shaped leaves, sawed on their edges, and sit close to the branches. The flowers come out singly from the wings of the stalks, standing upon very short foot-stalks; they are small, of a pale copper colour, of one petal, which is cut into five parts almost to the bottom, where they are joined. In the center arises a small column, composed of several stamens, and the style, which are connected together at bottom, but are separated above. The germen turns to a capsule with five cells, inclosed by the empalement; in each cell is contained one angular seed, gibbous on one side, having two horns or teeth at the point.

The second sort has hairy branching stalks three feet high. The branches of this come out from the bottom, and form a pyramidal bush; the leaves are longer and narrower; the saw on the edges deeper, of a brighter green than those of the former, and stand upon short foot-stalks.

The third sort rises with a slender ligneous stalk two feet high, sending out erect branches, garnished with narrow spear-shaped leaves, indented on their edges, ending in acute points, having pretty long slender foot-stalks. The

flowers come out singly from the wings of the stalks; they are small, of a pale yellow colour.

The fourth sort has very slender stalks, which seldom rise more than a foot high, sending out a few slender branches, garnished with small heart shaped leaves, sawed on their edges, a little hoary on their under side, standing upon pretty long foot-stalks. The flowers are small, of a pale yellowish colour, and come out singly from the wings of the stalk.

The fifth sort has a hairy stalk, covered with a dark brown bark three feet high, sending out many branches from the side, garnished with oval spear-shaped leaves, standing upon long foot-stalks, ending in an obtuse point, and are deeply sawed on their edges. The flowers come out by pairs at the foot-stalk of each leaf, sitting close to the stalk; they are larger than those of the former sorts, and of a deeper yellow colour; the seeds of this are larger, and have three teeth.

The sixth sort rises with a ligneous hairy stalk four feet high, sending out a few slender branches toward the top. The leaves are heart-shaped, a little woolly, and sit close to the stalk; they are veined, and sawed on their edges. The flowers come out in clusters on the side of the branches, to which they sit very close; they are small, of a pale yellow colour, and the seeds have two teeth.

The seventh sort has a slender ligneous stalk, which rises two feet high, sending out several slender branches, garnished with roundish leaves, having long foot-stalks, hairy on their under side. The flowers come out at the foot-stalks of the leaves, sometimes singly, and at others there are two or three; they are of a pale copper colour.

The eighth sort rises with an herbaceous stalk three feet high, sending out several erect branches, garnished with heart-shaped leaves, sawed on their edges, of a light green colour, soft to the touch, and stand upon very long hairy foot-stalks. The flowers stand upon long foot-stalks, which come out from the wings of the stalk; they are small, and of a sulphur colour.

The ninth sort has very slender stiff stalks, covered with fine hairs, sending out a few side branches, garnished with roundish heart-shaped leaves; they are of a light green colour, crenated on their edges, and stand upon long, slender, hairy foot-stalks. The flowers come out upon long foot-stalks from the wings of the stalks singly; they are small and white.

The tenth sort rises with an herbaceous prickly stalk near four feet high, sending out several branches, garnished with rough hairy leaves, standing upon long foot-stalks. These are of different forms, some are divided into five obtuse lobes, others into three, some are hollowed on the sides in shape of a fiddle; they are indented on their edges, and are of a pale green colour. The flowers are collected in heads, which stand upon very long hairy foot-stalks, arising from the wings of the stalks. Under each head are placed three obtuse small leaves, upon which rest seven small pale yellow flowers, which are almost hid by their empalements; these are succeeded by seeds, having acute spines.

The eleventh sort rises with a ligneous stalk three feet high, covered with yellowish hairs very closely garnished, with spear-shaped hairy leaves, sitting close to the stalks, sawed on their edges, of a pale green on their under side. The flowers come out singly from the wings of the stalk, standing upon short foot-stalks; they are small and white.

The twelfth sort rises with very slender infirm stalks three feet high, covered with long white hairs, garnished with soft, woolly, heart-shaped leaves, sitting upon long, slender, hairy foot-stalks, crenated on their edges. The flowers stand upon long slender foot-stalks, which arise from the

wings of the stalk, two of them generally coming out at each leaf; they are of a pale yellow colour.

The thirteenth sort has many trailing stalks, which divide into slender branches, covered with a light brown bark, garnished with small, oblong, oval leaves, sawed on their edges, hairy on their under side, standing upon short foot-stalks. The flowers are produced in small clusters, sitting close at the end of the branches; they are of a bright scarlet colour, and are succeeded by seeds, having two stiff bristly teeth.

The fourteenth sort hath smooth round stalks, which rise three feet high, sending out long slender branches. The leaves are smooth, heart-shaped, of a light green colour, and stand upon long foot-stalks, sawed on their edges, ending in acute points. The flowers stand upon very long foot-stalks, arising from the wings of the stalks singly; they are small, and of a whitish yellow colour.

The fifteenth sort sends out several stalks from the root, which spread flat on the ground, garnished with oval fatty leaves, sawed on their edges, having short foot-stalks; the flowers come out singly at the wings of the stalks, sitting very close thereto; they are small, of a yellow colour, and are succeeded by seeds which have no teeth.

The sixteenth sort has a ligneous stalk two feet high, with a purplish bark, sending out several branches from the lower part. The leaves are veined pretty thick, and almost heart-shaped, ending with obtuse points, crenated on their edges, and woolly on their under side, standing upon pretty long foot-stalks. The flowers are of a pale yellow colour, gathered in clusters, sitting close at the wings of the stalk; the seeds have two teeth at their points.

The seventeenth sort has a ligneous stalk four feet high, covered with brown hairs, sending out a few long slender branches, the lower parts of which are garnished with oval veined leaves, slightly sawed on their edges, and are downy on their under side. The upper part of the branches are destitute of leaves more than a foot in length; from the side come out foot-stalks two inches long, sustaining several small yellow flowers in clusters, having hairy empalements.

The eighteenth sort grows naturally at *La Vera Cruz* in *New-Spain*; this rises with a strong shrubby branching stalk six or seven feet high, covered with a rough brown bark, garnished with spear-shaped leaves, standing on pretty long foot-stalks, ending in acute points, and are unequally sawed on their edges. The upper surface of the leaves are of a dark green; their under is of a pale or light green colour. The flowers are collected in heads, standing upon long naked foot-stalks, which terminate the branches; each of these heads contain seven or eight flowers, whose petals extend much beyond their empalements. They are of a pale sulphur colour when they first open, but afterward fade to an almost white; the seed have three sharp teeth, which are burry, and stick to the clothes of those who rub against them when ripe.

The nineteenth sort grows naturally in *Jamaica*; this rises with a shrubby branching stalk seven or eight feet high, garnished at each joint by one large heart-shaped leaf, standing upon a pretty long foot-stalk, sawed on their edges, and run out to a long sharp point, of a light green on their upper surface, and pale on their under. The flowers grow in clusters at the wings of the stalks; those on the lower part of the branches are formed in close obtuse spikes; the branches are terminated by one of these spikes; the flowers are small, and when first open are white, but afterward they fade to a brownish colour.

The twentieth sort rises with ligneous stalks, covered with a soft woolly bark; garnished with heart-shaped woolly leaves, standing upon pretty long foot-stalks; they are veined, and crenated on their edges. The flowers stand

upon short foot-stalks, which arise from the wings of the stalk singly; their empalements are woolly and obtuse; the flowers are yellow, and are succeeded by seeds which have two teeth.

These plants are most of them annual in *England*, but some of them are of longer duration in their native countries, and might be so here, if they were placed in a warm stove in winter; but, as they perfect their seeds the same year, if the plants are brought forward in the spring, so few persons have room in their stoves to receive these plants, as there are so many perennial exotic plants at present in the *English* gardens, which require a warm stove to preserve them.

These plants are propagated by seeds, which should be sown upon a moderate hot-bed the beginning of *April*, and when the plants are fit to remove, they should be transplanted to another hot-bed four inches distance every way; they must be shaded from the sun till they have taken new root, and must have a large share of free air admitted to them, when the weather is mild, to prevent their drawing up weak. If the plants thrive well, they will have strength enough to be transplanted in the open air, for which purpose they should be gradually hardened, and taken up with balls of earth to their roots, and planted in a sheltered part of the garden, observing to shade and water them until they have taken new root; after which they will require no other care; but to keep them clean from weeds.

The eighteenth species will not flower the first year, so the plants must be placed in a warm stove in autumn, and during the winter they must be treated in the same way as other tender plants from the same country. The following summer they will flower and produce ripe seeds, but the plants are not of long duration, so that there should be a succession of young plants raised from seeds.

SIDERITIS. *Tourn. Inst. R. H.* 191. tab. 90. Ironwort.

The Characters are,

The flower has an oblong tubulous empalement, cut into five segments at the top. It is of the lip kind, of one petal, almost equal; the tube is cylindrical, the chaps oblong and taper. The upper lip is erect, and cut into two acute segments, the under lip is cut into three; the two side segments are acute, the middle is round and crenated. It has four stamina within the tube, two of which are as long as the tube, the other are shorter; and a four-pointed germen, supporting a slender style a little longer than the stamina, crowned by two stigmas; the upper is cylindrical, concave, and torn; the lower is short and membranaceous. The germen afterward turns to four seeds, which ripen in the empalement.

The Species are,

1. SIDERITIS *caulibus hirsutis procumbentibus, foliis oblongo-ovatis crenatis villosis, verticillis remotis.* Ironwort with hairy trailing stalks, oblong, oval, hairy, crenated leaves, and the whorls of flowers far asunder.

2. SIDERITIS *herbacea decumbens, calycibus spinosis, labio superiore indiviso.* *Lin. Sp. Plant.* 575. Declining herbaceous Ironwort with prickly empalements, and the upper lip of the flower undivided.

3. SIDERITIS *herbacea hispido-pilosa foliis superioribus amplexicaulibus.* *Lin. Sp. Plant.* 575. Herbaceous, hairy, stinging Ironwort, whose upper leaves embrace the stalk.

4. SIDERITIS *tomentosa, foliis linearilanceolatis sessilibus, calycibus spinosis.* Woolly Ironwort with narrow spear-shaped leaves sitting close to the stalks, and prickly empalements to the flowers.

5. SIDERITIS *foliis lanceolatis subdentatis, bracteis cordatis dentato-spinosis, calycibus æqualibus.* *Lin. Sp. Plant.* 575. Ironwort with spear-shaped leaves slightly indented, heart-shaped, prickly, indented bractæ, and the empalements of the flower equal.

6. *SIDERITIS fruticosa tomentoso-lanata, foliis cuneiformibus sessilibus, calycibus inermibus.* Shrubby, downy, woolly Ironwort, with wedge-shaped leaves sitting close to the stalks, and unarmed empalements.

7. *SIDERITIS fruticosa, foliis lanceolatis integerrimis, floribus spicatis terminalibus, calycibus spinosis.* Shrubby Ironwort with spear-shaped entire leaves, and spiked flowers terminating the stalks, having prickly empalements.

8. *SIDERITIS foliis lanceolatis glabris integerrimis, bracteis cordatis dentato-spinosis, calycibus aequalibus.* Lin. Sp. Plant. 575. Ironwort with smooth, entire, spear-shaped leaves, prickly, heart-shaped, indented bractæ, and equal empalements.

9. *SIDERITIS fruticosa tomentosa, foliis cordatis, pedunculis ante florescentiam nutantibus.* Lin. Sp. Plant. 574. Shrubby woolly Ironwort with heart-shaped leaves, and the foot-stalks nod before they flower.

The first sort grows naturally in *France, Spain, and Italy*; the root is perennial; the stalks are herbaceous, hairy, and trail upon the ground, sending out branches, garnished with oblong, oval, crenated, hairy leaves; the upper part of the stalk is furnished with whorls of purplish flowers, placed pretty far asunder. It is a plant of no great beauty or use, so is seldom kept in gardens.

The second sort is an annual plant with trailing stalks; the leaves are small, spear-shaped, and sit close to the stalks. The flowers grow in whorled spikes at the end of the branches; they are yellow. It grows in all the southern parts of *Europe*, and is seldom admitted into gardens.

The third sort grows naturally in the *Levant*. The roots of this sort seldom continue longer than two years in *England*; the lower leaves are oblong, entire, and hairy; the stalks are smooth, hoary, and rise near four feet high, sending out several long slender branches, garnished with hoary acute-pointed leaves, furnished with whitish flowers in whorls, which are placed far asunder; the empalements of the flowers are prickly, and the flowers are small.

The fourth sort grows naturally in *Crete*; this is a low shrubby plant, whose stalks rise a foot high, and are ligneous, sending out branches, garnished with narrow, spear-shaped, downy leaves; the upper part of the stalk is furnished with whorls of whitish yellow flowers, having prickly empalements.

The fifth sort grows naturally in the south of *France and Italy*; this hath a perennial root; the stalks rise a foot high, garnished with spear-shaped leaves, which are deeply crenated on their edges, and have short heart-shaped bractæ, which are prickly. The flowers grow in whorled spikes toward the end of the stalks; they are yellow, and have prickly empalements, which are equal.

The sixth sort grows naturally in *Crete*; this has a short ligneous stalk, from which is sent out a few branches, garnished with thick, wedge-shaped, downy leaves. The flowers are produced in whorls toward the end of the branches; they are yellow, and have smooth downy empalements.

The seventh sort grows naturally in *Spain and Italy*; this has a low shrubby stalk, sending out several hairy branches a foot long, garnished with hairy spear-shaped leaves. The flowers grow in close whorled spikes at the end of the branches; they are of a sulphur colour, and have very prickly empalements.

The eighth sort grows naturally on the mountains of *Valentia*; this has a short ligneous stalk, sending out branches a foot and a half long, garnished with narrow smooth leaves, of a strong scent when bruised. The flowers are yellow, and grow in large spiked whorls at the end of the branches.

The ninth sort grows naturally in the *Canary Islands*; it rises with a soft shrubby stalk five or six feet high, sending

out ligneous branches, covered with a soft down, garnished with heart-shaped leaves, having long foot-stalks. These differ greatly in size, according to the age and vigour of the plants; they are very woolly, especially on their under side, which is white, but their upper surface is of a dark yellowish green. The flowers grow in thick whorled spikes at the end of the branches; they are of a dirty white, shaped like those of the other sorts.

These plants are preserved in botanick gardens for the sake of variety. The five sorts first mentioned, and also the eighth, are hardy enough to thrive in the open air in *England*; they are propagated by seeds, which, if sown in autumn, will succeed better than those which are sown in spring. When the plants come up, they must be kept clean from weeds; and when the plants are fit to remove, part of each sort may be drawn out, and planted in a bed; this will give those which are left in the seed-bed room to grow. The plants which are removed should be shaded and watered until they have taken new root; after which they will require no other care, but to keep them clean from weeds. The fourth sort should have a dry soil and a warm situation, but neither of the sorts should be planted in rich ground, for that will cause them to grow so luxuriant in summer, that the frost or much wet will destroy them in winter.

The annual sort should not be removed, but the plants thinned and left in the place where they are sown, keeping them clean from weeds.

The sixth and seventh sorts will often live through the winter in the open air, especially if their seeds are sown upon dry rubbish; for when either of these happen to grow in the joints of old walls, they will endure the greatest cold of this country, therefore their seeds should be sown in such places. The sixth sort does not produce good seeds in *England*, so this is propagated by slipping off the heads, planting them in a shady border during the spring or summer months, which will readily take root; some of these may then be taken up and put into pots, that they may be screened under a frame in winter. The other may be removed in autumn, and planted close to warm walls in rubbish, where they will abide some years.

The ninth sort is generally kept in green-houses in *England*, but in moderate winters I have had the plants live abroad without cover in a warm dry border: however, if they are screened from hard frost under a common frame, where they may be exposed to the open air at all times when the weather is mild, and protected from hard frosts, they will thrive better than with more tender treatment. It is propagated by seeds, which should be sown in autumn, for those which are sown in the spring seldom succeed, or if they do, the plants rarely come up the first year.

SIDEROXYLUM, Iron-wood.

The Characters are,

The empalement of the flower is permanent, and is cut into five segments. The flower is bell-shaped, divided into five parts at the brim. It has five awl-shaped stamina the length of the petal, terminated by single summits, and a round germen, supporting an awl-shaped style, crowned by a single stigma. The germen afterward becomes a roundish berry, having one cell, containing four seeds.

The Species are,

1. *SIDEROXYLUM inerme.* Lin. Hort. Cliff. 69. Smooth Iron-wood.

2. *SIDEROXYLUM foliis lanceolatis ex adverso sitis.* Iron-wood with spear-shaped leaves growing opposite.

These plants grow naturally at the *Cape of Good Hope*.

The first sort hath large oval leaves, shaped somewhat like those of the Bay-tree, but smoother and blunter at the end. These are placed on the branches without order, as the branches also are produced. The stalks are shrubby, and

and rise five or six feet high, sending out many branches, covered with a dark brown bark.

The second sort grows more upright and regular; the leaves, which are smaller, and more pointed than those of the first, are placed opposite on the branches, and these continue green through the year.

The wood of these trees being very close and solid, has given occasion for this name being applied to them, it being so heavy as to sink in water; and the title of Iron-wood having been applied to the wood, by the inhabitants of the countries where it grows, has occasioned the botanists to constitute a genus by this name. But as the characters of the plants have not been so well examined as could be wished, occasioned by their seldom flowering in Europe, it is very probable, that the plants which have been ranged under this genus, do not properly belong to it; for Dr. Plukenet has figured a plant under the title of *Ebenus Jamaicensis*, whose characters are very different from those assigned to this genus: and the *Jamaica Iron-wood* is totally different from both in its characters, for this has male and female flowers on different trees; the male flowers have no petals, as appears by dried samples in my collection.

These plants are natives of warm countries, so cannot be preserved in England, unless they are placed in a warm stove. They are propagated by seeds, when these can be procured from abroad. These must be sown in pots, and plunged into a good hot-bed in the spring, in order to get the plants forward early in the season. When the plants are fit to transplant, they should be each put into a separate small pot, and plunged into a fresh hot-bed. In the winter they must be plunged into the tan-bed in the stove, and treated in the same manner as hath been directed for several tender plants from the same countries. As the plants obtain strength, they may be treated more hardily, by placing them in a dry airy glass-case in the winter, giving them free air in mild weather, but in summer they should be placed abroad in a sheltered situation.

I have propagated them by layers, but these were two years before they had made good roots; and sometimes they will take from cuttings, but this is a very uncertain method of propagating them; nor do the plants so raised, ever grow so vigorously as those which come from seeds; so that when those can be procured, it is the best method.

SIGESBECKIA. *Lin. Sp. Plant.* 873.

The Characters are,

The proper involucre of the flower is composed of five linear, taper, obtuse leaves, which open beyond the petal, and is permanent. The common cover is five-leaved, sitting close; the leaves are oval, concave, equal, and disposed in several series; and between each leaf is contained a floret. The flower is composed of hermaphrodite florets in the disk, and the border or ray is made up of female half florets, which are tongue-shaped. The hermaphrodite florets are funnel-shaped, cut in five parts at the brim; these have five short stamina, with tubulous summits joined together, and an oblong incurved germen as large as the empalement, supporting a slender style, crowned by a bifid stigma. The germen afterward turns to an oblong, four-cornered, blunt seed; the female half florets have a short, broad, tongue-shaped petal, indented in three parts; these have a germen, style, and stigma, like the hermaphrodite florets, but have no stamina, and are succeeded by single seeds like the other.

We have but one Species of this genus, viz.

SIGESBECKIA. *Lin. Hort. Cliff.* Sigesbeckia.

This plant is annual, perishing at the approach of winter. The seeds of it were brought from the *Eaji-Indies*, where it is a troublesome weed; in England it is raised on a hot-bed, and brought forward in the spring; then the plants may be planted out in warm borders, and if they are kept dry with water in dry weather, they will grow four or

five feet high, and send out many branches. The flowers are produced at the extremity of the shoots, which are small, and of a yellow colour, so make no great appearance; therefore it is only preserved in the gardens of those persons, who are curious in the study of plants.

SILAUM. See Peucedanum.

SILENE. *Lin. Gen. Plant.* 503. Viscous Campion, or Lychnis.

The Characters are,

The flower has a permanent empalement, which is indented at the top in five parts. It has five plain obtuse petals, indented at their points, and a nectarium, compounded of two small indentures in the neck of each petal, constituting a crown to the chaps; and ten awl shaped stamina, inserted alternately to the tail of the petals above each other, terminated by oblong summits. In the center is situated a cylindrical germen, supporting three styles, which are longer than the stamina, crowned by stigmas that are reflexed against the sun. The germen afterward becomes a close cylindrical capsule with three cells, opening at the top five ways, inclosing many kidney-shaped seeds.

The Species are,

1. SILENE *petalis integerrimis subrotundis, fructibus erectis alternis.* *Hort. Cliff.* 171. Silene with entire roundish petals to the flower, and erect fruit alternate; commonly called Dwarf Lychnis.

2. SILENE *floribus spicatis alternis secundis sessilibus, petalis bifidis.* *Lin. Sp. Plant.* 416. Silene with fertile spikes of flowers sitting close, and the petals bifid.

3. SILENE *petalis bifidis, floribus lateralibus secundis cernuis, caule recurvato.* *Lin. Sp. Plant.* 417. Silene with bifid petals, nodding flowers growing from the side of the stalks, and a recurved stalk.

4. SILENE *petalis bifidis, caule fruticoso, foliis lato lanceolatis, panicula trichotoma.* *Lin. Sp. Plant.* 417. Silene with bifid petals, a shrubby stalk, broad spear-shaped leaves, and panicles divided three ways.

5. SILENE *foliis radicalibus cochleariformibus obtusissimis, caule subverticillato.* *Lin. Sp. Plant.* 418. Silene with the bluntest, spoon-shaped, lower leaves, and those upon the stalks almost in whorls.

6. SILENE *calycibus fructus globosis acuminatis striis triginta, foliis glabris.* *Hort. Upsal.* 110. Silene with globular acute-pointed capsules to the fruit, and smooth leaves.

7. SILENE *calycibus fructus pendulis inflatis, angulis decem scabris.* *Hort. Upsal.* 109. Silene with pendulous swollen empalements to the fruit, with ten rough angles.

8. SILENE *calycibus decem angularibus, dentibus tubum æquantibus.* *Lin. Sp. Plant.* 419. Silene with empalements having ten angles, and the indentures as long as the tube.

9. SILENE *calycibus fructus pyramidatis striatis, caulibus hirsutis, foliis acuminatis glabris.* Silene with pyramidal striped empalements to the fruit, a hairy stalk, and smooth acute-pointed leaves.

10. SILENE *calycibus conicis striis hirsutis, fructibus erectioribus, caule erecto hirsuto, foliis nervosis.* Silene with conical empalements, having hairy stripes, erect fruit, a hairy upright stalk, and veined leaves.

11. SILENE *petalis bifidis, caule dichotomo, floribus axillaribus sessilibus, foliis glabris.* *Lin. Sp. Plant.* 420. Silene with bifid petals, a stalk divided by pairs, flowers sitting close to the wings of the stalk, and smooth leaves.

12. SILENE *floribus fasciculatis fastigiatis, foliis superioribus cordatis glabris.* *Hort. Upsal.* 110. Silene with flowers gathered into bunches, whose upper leaves are smooth and heart-shaped; commonly called *Lobel's Catchfly*.

13. SILENE *foliis radicalibus obtusis, caulibus lanceolatis oppositis, floribus axillaribus erectis, pedunculis subtrifloris.* Silene with obtuse lower leaves, those upon the stalks spear-shaped and opposite, erect flowers at the wings of the

the stalks, and foot-stalks for the most part with three flowers.

14. *SILENE caule folioso herbaceo, foliis lanceolatis acutis glabris, calycibus erectis.* Hort. Cliff. 171. Silene with an herbaceous leafy stalk, spear-shaped, acute-pointed, smooth leaves, and erect empalements.

There are several other species of this genus, whose flowers have no beauty, so are seldom cultivated but in botanick gardens for the sake of variety, therefore I have not enumerated them, which would swell the work too much.

The first sort grows naturally in *Portugal*; in *England* it is well known by the title of Dwarf Lychnis. The seeds of this were formerly sown in drills on the edges of borders, as were several other low annual plants, for edgings of borders; but as they are of short duration, so they soon were rejected for this purpose; after which the seeds were usually sown in patches in the borders, where they made a better appearance than in the former way; but in both these methods the plants were generally left so close as to spoil their growth, for as their stalks were drawn up weak, and had not room to branch out, so their flowers were small, and made little appearance; but to have this plant in beauty, the seeds should be sown thin in autumn, and in the spring the plants should be thinned to the distance of four inches, and afterward kept clean from weeds. When they are so managed, the plants will rise a foot high, with hairy channelled stalks, and divide into many branches, garnished with oval, spear-shaped, hairy leaves, placed opposite. The flowers grow in short spikes at the end of the branches; they are placed alternately, and are of a bright purple colour, edged with white.

The second sort grows naturally in *Sicily*, and also at the *Cape of Good Hope*. This is an annual plant, with a low branching stalk, which seldom rises more than eight or nine inches high; the stalks are smooth; the leaves are very narrow and smooth, placed by pairs; the stalks are terminated by spikes of dark purple flowers standing alternate, whose petals are bifid; they open in the evening, but are closely shut in the day. If the seeds of this plant are sown in autumn upon a warm border, the plants will live through the winter, so good seeds may be obtained; but when the seeds are sown in the spring, they often fail.

The third sort is a perennial plant, which grows naturally on the *Alps*; the lower leaves of this are smooth and spear-shaped; the stalk rises near two feet high, garnished with two narrow leaves, placed opposite at each joint, and immediately below them; the stalk is very clammy. The flowers come out on short foot-stalks from the wings of the leaves, each foot-stalk for the most part sustaining three flowers, with long, white, bifid petals. This plant rises easily from seeds if they are sown in autumn, and the only culture the plants require, is to keep them clean from weeds, and allow them room to spread.

The fourth sort grows naturally in *Sicily*; this has a low shrubby stalk, which divides into several short shrubby branches, garnished with broad, smooth, spear-shaped leaves, ending in acute points. The flower-stalks rise about a foot high, and divide into spreading panicles by twos and threes. The flowers are of an herbaceous white colour, and are succeeded by oval smooth capsules, having thick covers, filled with small seeds, which ripen in autumn. This sort rises easily from seeds as the former; if the plants are planted in a warm border of dry earth, they will live several years, and require no shelter, but in moist ground they frequently rot in winter.

The fifth sort grows naturally in *Portugal*; this has a perennial root; the lower leaves are roundish, and hollowed like a spoon; those upon the stalks are obtuse, and stand sometimes by pairs, at others by threes or fours round the

stalks; they are of a deep green, smooth, and sit close to the stalks; the stalks are round, smooth, and rise from two to three feet high. The flowers grow in loose spikes at the top, and are of a green colour. This rises easily from seeds sown in autumn, or if the seeds are permitted to scatter, the plants will come up, and require no other culture but to keep them clean from weeds.

The sixth sort grows naturally among Corn in *France*, *Spain*, and *Italy*. It is an annual plant, with an upright branching stalk a foot and a half high, having swelling viscid joints, garnished with narrow, acute-pointed, smooth leaves, sitting close to the stalks. The flowers are small, of a red colour, and produced at the end of the branches; these are succeeded by globular capsules, ending in acute points, whose empalements are striped. The seeds of this should be sown in autumn, and in the spring the plants should be thinned and kept clean from weeds, which is all the culture they require.

The seventh sort grows naturally in *Sicily* and *Crete*; this is an annual plant, from whose root comes out several branching stalks a foot and a half long, which trail upon the ground, garnished with oval acute-pointed leaves, placed opposite. The flowers come out singly from the wings of the stalk upon short foot-stalks; they are large, of a bright red colour, resembling those of the common wild red Campion. These are succeeded by large capsules, included in inflated empalements, having ten rough angles, containing many large roundish seeds, whose weight causes the capsules to hang downward. If the seeds of this are permitted to scatter, the plants will come up without care, and require no more but to keep them clean from weeds.

The eighth sort is an annual plant, which is found naturally in *England* growing among Corn. It rises with a thick clammy stalk nine inches or a foot high, garnished with small oblong leaves by pairs, whose base embrace the stalks; the top of the stalk sustains one or two small red flowers, which open only in the night. The seeds ripen in *August*, which, if permitted to scatter, the plants will come up without farther trouble.

The ninth sort grows naturally in the *Archipelago*; this rises with a hairy stalk a foot and a half high, garnished with narrow spear-shaped leaves, placed by pairs, which are smooth, and sit close to the stalks. The flowers are disposed loosely at the top of the stalks; they are red, and have long pyramidal striped empalements. If the seeds of this sort are sown in autumn, and the plants afterward treated in the same way as the first, they will thrive and flower early in summer.

The tenth sort grows naturally in the *Levant*; this is an annual plant, with a strong, erect, hairy, branching stalk two feet high. The branches grow erect, as do also the flowers, which are red, and have large, conical, striped empalements, whose stripes are hairy, and of a brownish colour. This must be treated in the same way as the first sort.

The eleventh sort grows naturally in the south of *France*, *Spain*, and *Italy*; this is biennial. The stalk is round, clammy, and rises a foot and a half high, having swelling joints; the leaves grow round the stalks in clusters; they are narrow and smooth. The upper part of the stalk divides into spreading branches by pairs, adorned by red flowers, coming out singly from the wings of the leaves, sitting close to the stalks.

This sort is easily propagated by seeds, which, if sown in autumn, will succeed much better than in the spring. When the plants come up and are fit to remove, they should be transplanted at six inches distance, shading them from the sun, and watering them until they have taken new root; after which they must be kept clean from weeds till autumn, when they should be transplanted to the places where they are

are designed to remain for flowering. When the seeds of this plant happen to scatter upon a wall, and the plants arise there, they will continue much longer than in the ground.

The twelfth sort is an annual plant, which grows naturally in the south of *France* and *Italy*. The seeds of this have spread out upon walls and buildings so far, as to induce some to believe it a native of *England*.

There are three varieties of this, which generally retain their differences; one has a bright purple flower, the other a pale red, and the third a white flower; these do not differ in any other respect, so cannot be reckoned as different species.

These seeds should be sown in autumn, for those which are sown in the spring often fail; and if the plants do come up, they never grow so large, or make so good appearance, as the autumnal plants.

The thirteenth sort is biennial; this grows naturally in *Sicily* and *Crete*; the lower leaves of this plant are obtuse, and are gathered in circular heads like some of the *House-leeks*, or those of the *Auricula*; they are smooth, of a pretty thick consistence. The stalks rise five or six feet high, and are very viscous, garnished with spear-shaped leaves, placed opposite. The flowers come out upon short foot-stalks from the wings of the stalks, each foot-stalk sustaining three or four greenish flowers, which are succeeded by oval capsules, spreading open at the top, filled with angular seeds.

If the seeds of this plant are sown in autumn upon a warm border, they will more certainly succeed than those sown in the spring. When the plants come up and are fit to remove, they should be planted on a dry soil and in a warm situation, where they will live through the winter, and the following summer they will flower, ripen their seeds, and then decay.

The fourteenth sort grows naturally in the *Levant*; this has a perennial root; the lower leaves are narrow, spear-shaped, and smooth; they are gathered in clustered heads, from the middle of which arises an erect clammy stalk a foot and a half high, garnished with very narrow leaves. The flowers come out from the wings of the leaves toward the top of the stalk; their foot-stalks are short, each sustains two white flowers, having long tubes, standing erect; the flowers are closed in the day, and expand at night.

As the seeds seldom ripen here, so it is difficult to propagate it: the only way is to slip off the heads in *June*, and plant them under a glass; these will take root, if they are shaded from the sun and duly watered.

SILER. *Dod. Ligusticum. Tourn. Inst. R. H. 323.* Ser-mountain.

The Characters are,

It is a plant with an umbellated flower. The principal umbel is composed of many smaller. The involucre of the general umbel is composed of many short, broad, obtuse leaves, those of the particular umbels are composed of eight acute-pointed leaves; the principal umbel is uniform. The flowers have five petals, whose points are inflexed, heart-shaped, and equal. They have five slender stamina the length of the petal, terminated by single summits, and an oblong germen situated under the flower, supporting two styles, crowned by obtuse stigmas. The germen afterward becomes an oblong fruit with eight narrow membranaceous wings, and is divided into two parts, containing two oblong seeds, which are half cylindrical, plain on one side, but have two membranaceous borders on the other.

The Species are,

1. SILER *foliis duplicato pinnatis, foliolis ternis lanceolatis integerrimis sessilibus.* Siler with doubly-winged leaves, the lobes by threes, which are spear-shaped; entire, and sit close to the stalks.

2. SILER *foliis duplicato pinnatis, foliis ternis quiniseve, lanceolatis integerrimis, umbellis minoribus.* Siler with doubly-

winged leaves, whose lobes are placed by threes and fives; are spear-shaped, entire, and the umbels are smaller.

3. SILER *foliis duplicato pinnatis, foliolis quinis lineari-lanceolatis integerrimis, umbella maxima.* Siler with doubly-winged leaves, the lobes placed by fives, which are linear, spear-shaped, entire, and the largest umbel.

The first sort is used in medicine, by the direction of the College of Physicians. The seeds of this sort are the *Semen Seseleos* of the shops, which enters in compositions; and the green herb also is used, for which some of the people who supply the shops, often impose on their customers the *Mountain Oser*, which, by translating Siler an Oser, may afford them some pretence.

This sort grows naturally upon the mountains *Jura* and *Saleva* near *Geneva*, and in many parts of the *Alps*. The root is perennial, composed of many thick, rugged, fleshy fibres. The stalks rise four feet high, branching out upward into many foot-stalks, each being terminated by a large umbel of white flowers. The leaves stand upon very long foot-stalks, whose base embrace the stalks, and divide first into three smaller, and the middle foot-stalk divides again into three smaller, and these are again divided into small foot-stalks, which sustain three spear-shaped entire lobes; the middle one is the largest, of a gray colour, and sit close to the foot-stalks. The principal umbel of flowers is composed of thirty-four small umbels; the involucre of the great umbel is composed of ten short blunt leaves, which are alternately larger; the particular umbels have long foot-stalks, which spread out from one center in rays, and are nearly equal, so that the principal umbel is uniform. The flowers have five heart-shaped petals, which are a little inflexed; these are succeeded by oblong channelled fruit, having five narrow membranaceous borders, which divide into two seeds, which are plain on the sides which join, but are channelled on the other.

The second sort grows naturally in *Austria* and *Bohemia*; the root of this is like the former; the stalks are not so thick, but grow almost as tall; the foot-stalks of the leaves divide into three as the former, and the middle one is again divided into three smaller, which divide into small foot-stalks. The lobes are of a brighter gray than those of the other, and not so stiff. The umbels are composed of about twelve or fourteen small umbels, which are all of them much less than those of the former.

This sort never alters to the first; for I have many years raised both from seeds, and have not observed either to change.

The third sort grows naturally on the *Pyrenean* mountains; this has a strong perennial root like the two former; the stalks rise five or six feet high, and sustain very large umbels of flowers. The leaves are very large, being composed of many divisions of the foot-stalks, which are again divided into smaller; these sustain five narrower lobes than either of the former.

These plants are propagated by seeds, which should be sown in autumn soon after they are ripe, on a border of fresh undunged earth; in the spring, when the plants will appear, they should be kept constantly clear from weeds, and in very dry weather should be watered, which will greatly promote their growth. Where the plants come up too close together, they should be thinned, so as to leave them three or four inches apart, which will be sufficient room for them the first season; and at *Michaelmas* when their leaves decay, some of the plants may be carefully taken up, so as not to cut or break their roots, and transplanted into a moist shady border about three feet asunder, where they may remain for continuance. If these plants thrive well, they will produce seeds the second season, otherwise it will be the third summer before they flower and seed; after

after which the roots will abide many years, and greatly increase in their size, and will produce seeds every year.

The culture which these plants require, is only to keep them clear from weeds; and every spring, just before the plants put out their leaves, to dig the ground between them gently, so as not to injure their roots; and when their flower-stems are advanced, to place some sticks down by them, to which their stems should be fastened, to support them from being broken down by winds; for as their stems rise to the height of four or five feet, so when their umbels of seeds are formed, which are generally pretty large and heavy, they often occasion their stems falling to the ground, where they are not supported.

SILYQUA. See Ceratonia.

SILYQUASTRUM. See Cercis.

SILPHIUM. *Lin. Gen. Plant.* 882. Bastard Chrysanthemum.

The Characters are,

The common empalement of the flower is oval, imbricated, and permanent; the scales are oval, prominent, and reflexed in the middle. The disk of the flower is composed of hermaphrodite florets, which are tubulous, indented in five parts at the top. These have five short hair-like stamina, terminated by cylindrical summits, and a slender taper germen, supporting a long hairy style, crowned by a single stigma; these are barren. The rays of the flower are composed of a few female half florets, which are long, spear-shaped, and for the most part have three indentures at their points; these have a heart-shaped germen with a short single style, having two bristly stigmas of the same length, and are succeeded by single heart-shaped seeds with a membranaceous border, indented at the top, each point ending with a horn or tooth, and are separated by linear chaff, ripening in the empalement.

The Species are,

1. SILPHIUM *foliis binis, ternis quaternisque*. Silphium with leaves by pairs, threes and fours at a joint.

2. SILPHIUM *foliis indivisis sessilibus oppositis, inferioribus alternis*. *Lin. Sp. Plant.* 920. Silphium with undivided leaves set opposite close to the stalks, whose lower leaves are alternate.

3. SILPHIUM *foliis oppositis petiolatis serratis*. *Flor. Virg.* 181. Silphium with sawed leaves, having foot-stalks, which grow opposite.

4. SILPHIUM *foliis lanceolatis alternis scabris, obsolete serratis, caule fruticoso*. Silphium with rough spear-shaped leaves placed alternate, which have slight sawed edges, and a shrubby stalk.

The first sort grows naturally in many parts of North America; the root is perennial and ligneous; the stalks are annual; these rise six feet high or more in good land; they are of a purplish colour, and branch toward the top. The leaves are oblong, rough, and have some sharp teeth on their edges; toward the bottom of the stalk they stand by fours at each joint; higher up they are by threes, and at the top by pairs, sitting close to the stalks. The foot-stalks are pretty long, each sustaining one flower, whose empalement is composed of three orders of leaves placed imbricatum, like the scales of fish, the outer order being the smallest. The ray or border of the flower is composed of thirteen female half florets, which are yellow, tongue-shaped, and indented in three points at the end. The disk or middle of the flower is made up of hermaphrodite tubulous flowers, which are slightly cut into five parts at the top; these have five stamina and a style connected together, which are longer than the tube of the floret.

It is propagated by parting of the roots, in the same way as it is practised for the perennial Sunflowers; the best time for this is in autumn, when their stalks begin to decay, and the plants may afterward be treated in the same way as the perennial Sunflower.

The second sort grows naturally in Carolina; the root of this is perennial, the stalk is thick, solid, and set with prickly hairs; it rises near three feet high, has many purple spots; the leaves on the lower part of the stalk are placed alternate, but upward they are opposite, and sit close to the stalk; they are rough, having a few slight indentures on their edges. The upper part of the stalk divides into five or six small branches, which are terminated by yellow radiated flowers, like those of the perennial Sunflower, but smaller, having generally nine female half florets which compose the border or ray, the other parts are like those of the former sort. This sort is propagated by parting the roots in the same way as the former, but as this is not quite so hardy, it should be planted in a sheltered situation.

The third sort grows naturally in many parts of North America; this is a perennial plant, whose stalks rise near three feet high, garnished with oblong sawed leaves placed by pairs, upon short foot-stalks. The flowers are loosely disposed at the top of the stalks, they are yellow, and have their half florets which compose the ray, indented in three parts at the end. It may be propagated in the same way as the former, and the plants require the same treatment.

The fourth sort was discovered by the late Dr. William Houstoun, growing naturally at La Vera Cruz in New Spain. This rises with a shrubby stalk to the height of eight or ten feet, sending out ligneous branches, garnished with spear-shaped leaves placed alternately; their surface is rough, and their edges slightly sawed. The flowers are produced at the end of the branches, some of them singly on slender foot-stalks, others have two or three; they are unequal in height, and have short scaly empalements. They are of a deep yellow colour, but are not succeeded by seeds in England.

This sort is with difficulty propagated here, for unless the seeds are procured from the country where the plants grow naturally, they cannot be obtained that way, and the cuttings are not apt to take root. The only method of getting them to grow, is to slip off the young shoots in July, and plant them in a pot, and plunge it into a gentle hot-bed, covering the pot closely with a bell or hand-glass, and shade them from the sun. When the cuttings are rooted, they should be each planted in a separate pot, and during the warm months, they may be placed in the open air in a warm situation, but in winter they should be kept in a moderate stove.

SINAPIS. *Lin. Gen. Plant.* 735. Mustard.

The Characters are,

The empalement of the flower is composed of four narrow leaves placed in form of a cross, which fall off. The flower has four roundish petals in form of a cross, and four oval nectariums, one on each side of the stamina and the pointal. It has six awl-shaped erect stamina, two of which are opposite and as long as the empalement, the other four are longer. In the center is placed a taper germen, with a style the length of it, crowned by a headed stigma. The germen afterwards turns to an oblong pod, which is very rough at bottom, having two cells, opening with two valves, whose intermediate partition is large, compressed, and almost twice the length of the valves, the seeds are globular.

The Species are,

1. SINAPIS *filiquis hispida, rostro obliquo longissimo*. *Hort. Cliff.* 338. Mustard with prickly pods, and a very long oblique beak; commonly called White Mustard.

2. SINAPIS *filiquis glabris tetragonis*. *Hort. Cliff.* 338. Mustard with a smooth four-cornered pod; or common Mustard.

3. SINAPIS *filiquis multangulis toroso-turgidis, rostro longioribus*. *Hort. Cliff.* 338. Mustard with many angled rough swelling pods, having a longer beak.

4. SINAPIS *filiquis teretibus glabris obtusis*. Mustard with taper, obtuse, smooth pods.

5. *SINAPIS ramis fasciculatis, foliis summis lanceolatis integerrimis. Hort. Upsal. 191.* Mustard with bundled branches, and the upper leaves spear-shaped and entire.

6. *SINAPIS foliis duplicato-pinnatis, laciniis linearibus. Hort. Cliff. 338.* Mustard with double winged leaves, having linear segments.

The first sort is the common White Mustard, which is generally cultivated as a salad herb for winter and spring use. This rises with a branched hairy stalk two feet high, the leaves are deeply jagged on their edges and rough. The flowers are disposed in loose spikes at the end of the branches, standing upon horizontal foot-stalks; they have four yellow petals in form of a cross, which are succeeded by hairy pods that end with long, compressed, oblique beaks; the pods generally contain four white seeds.

The second sort is the common Mustard, which is frequently found growing naturally in many parts of *England*, but is also cultivated in fields for the seed, of which the sauce called Mustard is made. This rises with a branching stalk four or five feet high; the lower leaves are large, rough, and very like those of Turnep; the upper leaves are smaller, and less jagged. The flowers are small, yellow, and grow in spiked clusters at the end of the branches; they have four petals placed in form of a cross, these are succeeded by smooth four-cornered pods.

The third sort grows naturally on arable land, in many parts of *England*. The seed of this is commonly sold under the title of *Durham Mustard seed*; of this there are two varieties, if not distinct species; one with cut, the other has entire leaves. The stalks rise two feet high; the leaves are rough, and in one they are jagged like Turnep leaves, the other are long and entire. The flowers are yellow, the pods are turgid, angular, and have long beaks.

The fourth sort grows naturally in *Spain*; this seldom rises more than eight or nine inches high; the leaves are smooth and much jagged; the stalk branches toward the top, and is terminated by a loose spike of white flowers, which are succeeded by smooth, taper, blunt pods, filled with small brown seeds.

The fifth sort grows naturally in *China*. The plant is used as a boiled salad by the *Chinese*, where it may prove acceptable to those who have not better herbs for that purpose, but in *England* it is not regarded. The stalks of this rise three feet high, toward the bottom are garnished with broad, smooth, jagged leaves, but those at the top are entire. The flowers are yellow like those of the first sort, and the pods are smooth and turgid.

The first sort is chiefly cultivated in gardens, for a salad herb in the winter season. The seeds of this are commonly sown very thick in drills, either upon a warm border, or in very cold weather upon a moderate hot-bed, with Cresses and other small salad herbs, which are commonly fit for use in ten days or a fortnight from the time of sowing; for if they are large and have rough leaves, they are too strong to put into salads. In order to save the seeds of this plant, a spot of ground must be sown with it in the spring, and when the plants have four leaves, the ground should be hoed in the same manner as for Turneps, to cut down the weeds, and thin the plants where they are too close; this should be done in dry weather, for then the weeds will soon die after they are cut. If this is well performed, the ground will remain clean for a month, by which time young weeds will spring up again; therefore the ground should be again hoed over, and the plants now left about eight or nine inches asunder, which will be sufficient room for this sort to grow; if this is well performed in dry weather, the ground will remain clean till the seeds are ripe. As soon as the pods change brown, the plants should be cut off, and spread upon cloths two or three days to dry, and then threshed out for use.

The second sort is cultivated only for the seeds; these should be sown in the same way as those of the first, and the plants treated in the same manner, with this difference of allowing the plants twice as much room, because they grow much larger, so these should be hoed out to the distance of eighteen inches; and as the seeds will not ripen so soon as the other, so the ground may require to be hoed three times over, but that may be easily seen by the growth of the weeds.

The seeds of these two first species are ordered for medicinal use.

The third sort is a pretty common weed on arable lands, in most parts of *England*; this comes up early in the spring amongst the Corn, so flowers and seeds in *May*; therefore where it is not weeded out, the seeds will scatter long before the Corn is ripe, and the ground will be stocked with the weed.

The other three sorts are preserved in botanick gardens for variety, but are never cultivated for use; these may be treated in the same way as the two first species.

SINAPISTRUM. See Cleome.

SISARUM. See Sium.

SISON. *Lin. Gen. Plant. 311.* Bastard Stone Parsley.

The Characters are,

It has an umbellated flower; the general umbel is composed of six thin rays or small umbels, which are unequal, as are also the smaller, which have ten. The involucres of both are four-leaved and unequal; the empalement of the flower is scarce discernible. The outer petals of the general umbel are uniform; the flowers have five equal petals, which are spear-shaped and inflexed. They have five hair-like stamina the length of the petals, terminated by single summits. The oval germen is situated under the flower, supporting two reflexed styles, crowned by obtuse stigmas. The germen afterward becomes an oval streaked fruit, dividing in two parts, each containing one oval streaked seed, convex on one side, and plain on the other.

The Species are,

1. *SISON foliis pinnatis, umbellis erectis. Prod. Leyd. 105.* Sison with winged leaves and erect umbels.

2. *SISON foliis pinnatis, umbellis cernuis. Prod. Leyd. 105.* Sison with winged leaves and nodding umbels.

3. *SISON foliolis verticillatis capillaribus. Lin. Sp. Plant. 253.* Sison with hair-like small leaves in whorls.

The first sort grows on the side of ditches, and moist shady banks, in many parts of *England*; it is a biennial plant, which perishes soon after the seeds are ripe. The root is taper; the lower leaves are winged, composed of four pair of lobes, terminated by an odd one, regularly indented on both sides, and the indentures are sawed; they are of a lucid green, and have an aromattick odour. The stalks rise three feet high, and are garnished with leaves of the same form with those below, but smaller; at the end of the branches the white flowers are produced in small umbels, which are succeeded by striated seeds of a hot pleasant aromattick sinell and taste, which ripen in *August*.

This plant is found growing so plentifully wild, as that it is rarely kept in gardens; but whoever is willing to propagate it, should sow the seeds in autumn, in a moist shady spot of ground, where the plants will come up, and require no farther care than to keep them clean from weeds; and if the seeds are permitted to scatter, the plants will rise without care. The seed of this plant is put into *Venice Treacle*, for a succedaneum to the true Amomum.

The second sort grows naturally among Corn on moist land, in several parts of *England*. This is also a biennial plant, which decays soon after the seeds are ripe; it rises with an upright stalk about a foot high, which rarely divides into branches; the leaves stand upon pretty long foot-stalks; they are winged, but the lobes are smaller and finer cut

cut than those of the former; the umbels of flowers are more compact, and nod on one side. The plant may be cultivated in the same way as the first.

The third sort grows naturally on the *Alps* and *Apennines*; this rises with a swelling jointed stalk two feet high, garnished with very fine slender leaves, standing in whorls like those of the Water Milfoil; it branches out toward the top, each branch being terminated by a pretty large umbel of flowers, which are purplish on their outside, but white within; these are succeeded by seeds, which ripen the end of *July*. The roots of this plant are composed of thick fleshy knots, somewhat like those of the King's Spear.

The last mentioned sort may be cultivated by seeds, which should be sown in autumn, for those which are sown in the spring, seldom grow the first year. The plants require no other culture than to thin them where they are too close, and keep them clean from weeds.

SISYMBRIUM. *Tourn. Inst. R. H. 225. tab. 109.* Water Cresses.

The Characters are,

The flower has a spreading empalement, composed of four linear, spear-shaped, coloured leaves, which fall off; it has four oblong spreading petals, placed in form of a cross, and six stamina, four of which are longer than the empalement; the other two, which are opposite, are shorter, terminated by single summits; it has an oblong slender germen, with scarce any style, crowned by an obtuse stigma. The germen afterward becomes a taper, oblong, incurved pod, having two cells, opening with two valves, which are shorter than the intermediate partition, filled with small seeds.

The Species are,

1. **SISYMBRIUM** *filiquis declinatis, foliis pinnatis, foliolis subcordatis.* *Hort. Cliff. 336.* Sisymbrium with declining pods, and winged leaves, whose lobes are almost heart-shaped; or Water Cress.

2. **SISYMBRIUM** *filiquis declinatis, foliis pinnatis, foliolis lanceolatis serratis.* *Hort. Cliff. 336.* Sisymbrium with declining pods, and winged leaves having spear-shaped sawed lobes.

3. **SISYMBRIUM** *filiquis declinatis, oblongo-ovatis, foliis pinnatifidis serratis.* *Lin. Sp. Plant. 657.* Sisymbrium with oblong, oval, declining pods, and wing-pointed sawed leaves.

4. **SISYMBRIUM** *foliis simplicibus dentatis serratis.* *Hort. Cliff. 336.* Sisymbrium with single, indented, sawed leaves.

5. **SISYMBRIUM** *filiquis axillaribus sessilibus subulatis aggregatis, foliis repando-dentatis.* *Hort. Upsal. 193.* Sisymbrium with awl-shaped pods in clusters sitting close to the stalks, and indented leaves which turn backward.

6. **SISYMBRIUM** *petalis calyce minoribus, foliis decomposito-pinnatis.* *Flor. Succ.* Sisymbrium with petals smaller than the empalement, and decomposed winged leaves; called Flixweed.

7. **SISYMBRIUM** *foliis pinnato-hastatis flaccidis, foliolis sub-linearibus integerrimis, pedunculis laxis.* *Hort. Upsal. 193.* Sisymbrium with spear, wing-pointed, flaccid leaves, having linear entire lobes with loose foot-stalks.

8. **SISYMBRIUM** *foliis pinnato-hastatis dentatis, filiquis erectis.* *Lin. Sp. Plant. 659.* Sisymbrium with spear-shaped, winged, indented leaves, and erect pods.

9. **SISYMBRIUM** *foliis lanceolatis dentato-serratis caulinis.* *Hort. Cliff. 337.* Sisymbrium with spear-shaped, winged, indented leaves on the stalks.

The first sort is the common Water Cress, which grows naturally in ditches and rills of water in most parts of *England*. The roots of this plant are composed of a great number of long fibres, which fasten themselves to the mud at the bottom of the ditches, from which arise several stalks, garnished with winged leaves, composed of five or six pair of roundish lobes, terminated by an odd one; these stand

almost alternate along the midrib. The stalks rise a foot and a half high; they are channelled, and divide at the top into two or three branches, which are terminated by loose spikes of small white flowers, composed of four petals, placed in form of a cross, and are succeeded by taper pods, filled with small brown seeds.

This plant has of late years been generally used as a salad herb in the spring of the year, and is by many preferred to all other sorts of salads for the agreeable warm bitter taste, and, being accounted an excellent remedy for the scurvy, and to cleanse the blood, as also a good diuretick, it has greatly obtained a preference to most other herbs for winter and spring use with many people. This is generally gathered in the ditches, and in other standing waters near *London*, to supply the markets; but whoever has a mind to cultivate it may easily do it, by taking some of the plants from the places of their natural growth, early in the spring, being careful to preserve their roots as entire as possible, and plant them into mud, and then let the water in upon them by degrees. When they have taken root, they will soon flourish, and spread over a large compass of water; they should not be cut the first season, but suffered to run to seed, which will fall into the water, and furnish a sufficient supply of plants afterward.

But where the water is so deep, that it will not be easy to plant them, the best method will be to get a quantity of the plants just as their seeds are ripening, and throw them on the surface of the water where they are designed to grow, and their seeds will ripen, and fall to the bottom, where they will take root, and produce a supply of these plants.

Some of those people who gather this herb for use, either through ignorance or some worse design, have frequently taken the creeping Water Parsnep, and sold it for Water Cress, whereby many persons have suffered who have eaten it, therefore those who make use of Water Cress, should be careful to have the right plant; they may be easily distinguished by the shape of their leaves, those of the Water Cress having roundish almost heart-shaped small leaves or lobes, with a few indentures on their edges, and are of a dark green colour; but those of the Water Parsnep have oblong lobes, ending in points, which are of a light green, sawed on their edges.

The second sort grows naturally on the borders of the river *Thames*, and in some other parts of *England*. The leaves of this sort are longer than those of the first; the lobes are much narrower, and are sawed on their edges; the flowers stand upon longer foot-stalks, and are much smaller. This spreads and multiplies in the same manner as the first.

The third and fourth sorts grow naturally on the banks of the *Thames*, and in ditches in many parts of *England*, so are not admitted into gardens.

The fifth sort grows naturally in the south of *France* and *Italy*; it is an annual plant, whose stalks spread and decline toward the ground; they grow a foot long, and divide into many branches, garnished with smooth leaves, shaped like the point of a halberd, deeply sinuated on their borders; the indentures turn backward. The flowers come out in clusters at the wings of the stalk; they are small, yellow, and are succeeded by slender crooked pods, standing in clusters. The seeds ripen in autumn.

The sixth sort grows naturally in uncultivated places, and also by the side of footways, in many parts of *England*. The leaves of this are divided into many very narrow segments; the stalks rise a foot and a half high, garnished with winged leaves, whose lobes are finely cut, resembling those of the true *Roman* Wormwood. The flowers are produced in loose spikes at the top of the stalk; they are

small, yellow, and composed of four petals, set in form of a cross, and are succeeded by slender pods, filled with small roundish seeds, which ripen in *August*, and then the plant dies. The seeds of this plant are used in medicine, and are by some greatly recommended for the gravel and stoppage of urine.

The seventh sort grows naturally in *France* and *Italy*. The lower leaves of this are flaccid, cut in form of winged leaves, ending in arrow-pointed lobes. The stalk rises three feet high, garnished with linear wing-pointed leaves; it branches out greatly; the flowers grow sparsely toward the end of the branches, which are succeeded by very long, slender, smooth pods, filled with small yellowish seeds. The seeds ripen in autumn, and the plant dies soon after.

The two last are preserved in botanick gardens for the sake of variety. If their seeds are permitted to scatter, the plants will come up in plenty, and require no other care but to thin them, and keep them clean from weeds; or if their seeds are sown in autumn, they will succeed better than in the spring.

The eighth sort grows naturally in many parts of *England*, so is seldom admitted into gardens; this is an annual plant, which sows itself, and comes up without care. It was remarked, after the great fire of *London*, that this plant came up in great plenty on the ruins.

The ninth sort grows naturally on the *Helvetian* mountains; this hath a perennial root, from which arise several branching stalks three feet high, garnished with spear-shaped leaves, sawed on their edges, of a deep green, standing alternately on the stalks. The flowers grow in loose spikes at the top of the stalks; they are small, yellow, composed of four petals, placed in form of a cross, and are succeeded by taper pods, filled with small seeds, which ripen in *August*.

This is preserved in some gardens for the sake of variety, but has no great beauty; it is propagated by seeds, which succeed best when sown in autumn, for those which are sown in the spring, seldom come up the same year. The plants require no care, but to thin them, and keep them clean from weeds; they love a cool shady situation.

SISYRINCHIUM. *Lin. Gen. Plant.* 908.

The Characters are,

The sheath, which incloses the flowers, faces both ways, and is composed of two compressed keel-shaped leaves. The flower has six oblong petals, and three very short stamina, terminated by bifid summits, which are fixed to the base of the style, with an oval germen situated under the flower, supporting an awl-shaped style, crowned by a trifid reflexed stigma. The germen afterward turns to an oval three-cornered capsule with three cells, filled with roundish seeds.

The Species are,

1. SISYRINCHIUM *foliis gladiolatis amplexicaulibus, pedunculis brevioribus.* Sisyrinchium with sword shaped leaves embracing the stalks, and shorter foot-stalks to the flower.

2. SISYRINCHIUM *foliis lineari-gladiolatis, pedunculis longioribus.* Sisyrinchium with linear sword-shaped leaves, and longer foot-stalks to the flower.

3. SISYRINCHIUM *foliis plicatis, spatha biflora.* Sisyrinchium with a plaited leaf, and two flowers in a sheath.

The first sort grows naturally in *Bermuda*, from whence it had the title of *Bermudiana* given it by *Tournefort*; this has a fibrous root, from which arise stiff, sword-shaped, entire leaves, of a dark green colour; between these come out the foot-stalks, which rises six inches high, compressed, with two borders or wings running the whole length, having three or four sword-shaped leaves, which embrace it; these grow erect, and are hollowed like the keel of a boat. The stalk is terminated by a cluster of six or seven flowers, standing upon short foot-stalks, inclosed by a two-leaved keel-shaped sheath before they open; the flowers are of a

deep blue colour with yellow bottoms, composed of six oval petals, ending in acute points. In the center is situated an upright style, at the bottom of which are three stamina, whose summits sit close to it; the stigma is cut into three parts, which are reflexed back to the style; these are of a gold colour. The germen, which was situated under the flower, turns to an oval obtuse capsule with three cells, filled with roundish seeds.

The second sort grows naturally in *Virginia*; this has a perennial fibrous root, from which arise many very narrow, spear-shaped, entire leaves, of a light green colour. The stalks rise about three inches high; they are very slender, compressed and bordered like those of the first, and have short, narrow, sword-shaped leaves, whose base embrace them; they are terminated by two small, pale, blue flowers, inclosed in a two-leaved sheath, standing upon longer foot-stalks than those of the other.

These plants are propagated by seeds, and also by parting of their roots; if they are raised from seeds, these should be sown in autumn, soon after they are ripe, upon an east-aspected border, where they may have only the morning sun. In the spring the plants will appear, when their leaves will have much resemblance to Grass, therefore care should be taken that they are not pulled up as weeds by those who clean the ground. During the first summer, they will require no other care but to keep them clean from weeds, unless the plants should come up so close as not to have room to grow; in which case, part of them should be drawn out to give room to the others; these may be planted in a shady border at three inches distance, where they may remain till autumn, when they should be transplanted to the places where they are to remain; the following summer they will flower. These plants love a shady situation and a soft, loamy, undunged soil.

The time for transplanting and flipping of the old roots, is early in autumn, that they may get good root before winter. They are both so hardy as to thrive in the open air in *England*, and are very rarely injured by cold.

The third sort grows naturally in the *West-Indies*; this has a small, oval, bulbous root, covered with a bright red skin, from which come out the leaves very like the first leaves of Palm-trees, but of a thinner substance; they have five or six longitudinal plaits, and are of a light green, ending with points; between these arise the foot-stalk of the flower four inches high, terminated by two or three small blue flowers, inclosed in a spatha or sheath, composed of six petals, which expand like those of the other sorts, but do not continue open longer than three or four hours in the morning; when they are expanded, their petals are so small as to make but little appearance. This sort flowers commonly in the middle of summer, but does not keep any particular month; they are never succeeded by seeds in *England*.

This is propagated by offsets from the roots, which are sent out in plenty; these should be taken off when the roots are transplanted: the time for doing of this is soon after the leaves decay, or before the roots begin to shoot again. They must be planted in small pots, and plunged into the tan-bed in the stove, where they should constantly remain, for they are too tender to thrive in this country, unless they are thus treated. Their after management is the same as for other bulbous-rooted plants from the same countries.

SIUM. *Tourn. Inst. R. H.* 308. *tab.* 162. *Lin. Gen. Plant.* 310. Water Parsnep, and Skirret.

The Characters are,

It hath an umbellated flower; the general umbel is various in different species; the small ones are plain and spreading. The general involucre is composed of several short, spear-shaped, reflexed leaves; those of the smaller are of very small narrow leaves. The general umbel is uniform; the flowers have five inflexed.

inflexed petals, which are equal; they have five stamina, terminated by single summits, and a small germen situated under the flower, supporting two reflexed styles, crowned by obtuse stigmas. The germen afterward becomes a roundish, oval, streaked fruit splitting in two, each part containing one streaked seed, plain on one side, and convex on the other.

The Species are,

1. *Sium foliis pinnatis, umbella terminali.* Hort. Cliff. 98. Sium with winged leaves, and the stalk terminated by an umbel; or the great Water Parsnep.

2. *Sium foliis pinnatis serratis, umbella terminali.* Sium with winged sawed leaves, and umbels terminating the stalks.

3. *Sium foliis pinnatis, umbellis axillaribus sessilibus.* Hort. Cliff. 98. Sium with winged leaves, and umbels of flowers sitting close to the wings of the stalks.

4. *Sium foliis pinnatis, floralibus ternatis.* Hort. Cliff. 98. Sium with winged lower leaves, but those under the flowers trifoliate; called Skirrets.

5. *Sium foliis linearibus decurrentibus connatis.* Hort. Cliff. 98. Sium with linear small leaves, having running membranes, joining at their base round the stalk.

6. *Sium foliis radicalibus ternatis, caulinis bipinnatis.* Prod. Leyd. 105. Sium with trifoliate bottom leaves, and those on the stalks doubly winged.

The first sort is the great Water Parsnep, which grows naturally in deep standing waters in several parts of *England*; it rises with upright stalks five or six feet high, garnished with large winged leaves, shaped like those of the common Parsnep; the stalk is terminated by large umbels of pale yellow flowers.

The second sort is the common upright Parsnep, which grows naturally in ditches in most parts of *England*; this rises with an upright branching stalk three feet high, garnished with winged leaves, composed of three or four pair of oblong sawed lobes, terminated by an odd one. The stalk is terminated by an umbel of white flowers, which are succeeded by seeds, which ripen in autumn; this is rarely cultivated, as it is a common weed in ditches and standing waters. Both these plants have been recommended by ancient physicians for their virtues in medicine, but at present they are seldom used.

The third sort is very common upon standing waters in most parts of *England*. The stalks spread over the surface, and produce umbels of white flowers at their joints. This is the plant which is frequently gathered and sold for Water Cress, as is before mentioned under the article *SISYMBRIUM*.

The fourth sort is the common Skirret, which was formerly more cultivated in the *English* gardens than at present. The roots are the only part used, and although it is mentioned in most Dispensaries as a medicinal plant, yet it is rarely used as such, being better adapted for the kitchen. It is esteemed a wholesome root, affording good nourishment, but has a flatulency, and its very sweet taste is disagreeable to many palates.

The root of this plant is composed of several fleshy fibres, as large as a man's little finger, which join together in one head. The lower leaves are winged, having two or three pair of oblong lobes, terminated by an odd one; the stalks rise a foot high, terminated by an umbel of white flowers, which are succeeded by striated seeds like those of Parsley, which ripen in autumn.

This plant is cultivated two ways, first by seeds, and afterward by slips from the root: the former method I think the more eligible, because the roots which are raised from seeds, generally grow larger than those raised by slips, and are less subject to be sticky. The seeds should be sown the latter end of *March*, or the beginning of *April*, either in broad cast or in drills; the ground should be light and moist,

for in dry land the roots are generally small, unless the season proves very moist. If the seeds are good, the plants will appear in five or six weeks after they are sown, and, when they have put out their leaves so as to be well distinguished from the weeds, the ground should be hoed over to destroy the weeds in the same manner as is practised for Carrots; and where the seeds are sown in broad cast, the plants should be cut up, leaving them two or three inches asunder. Those sown in the drills should also be thinned to the same distance, and the ground hoed over to destroy the weeds. This should be repeated three times, as is usually done for Carrots, which, if well performed in dry weather, will keep the ground clean all the first part of the summer, so that, unless there should be much rain about *Midsummer*, there will be scarce any necessity for farther cleaning of the plants, for their leaves will spread, and prevent the growth of weeds afterward. In autumn, when the leaves begin to decay, the roots will be fit for use, and may be continued all the winter till they begin to shoot in the spring, when they will become sticky, as will also any of those which run up to seed the first summer, so that all such should be pulled up and thrown away.

The time for propagating this plant by offsets is in the spring, before they begin to shoot, at which time the old roots should be dug up, and the side roots should be slipped off, preserving an eye or bud to each; these should be planted in rows one foot asunder, and four inches distant in the rows. If the ground is light, this may be performed with a dibble, but for stiff land it will be best to make a trench with a spade, in the same manner as for Asparagus, laying the roots therein at a proper distance. The ground must be kept clean by hoeing it in the same manner as before directed, and at the same season the roots will be fit for use.

The fifth sort is a perennial plant, which grows naturally in *Germany*. The roots of this plant creep and spread very far under ground; the least part of them will grow, so that when it is once brought into a garden, it will soon multiply; they are thick, fleshy, and taste like those of Eryngo. The leaves are divided into linear segments, and their base embrace the stalks, which rise two feet high, and are terminated by large flat umbels of white flowers, but their seeds do not often ripen here.

The sixth sort grows naturally in *Sicily*, and is preserved in botanick gardens for the sake of variety. The lower leaves are pretty broad, trifoliate, and of a lucid green; the stalks rise two feet high, terminated by an umbel of yellow flowers; the leaves on the stalks are doubly winged, and the seeds ripen in autumn, which should be sown soon after they are ripe.

SMALLAGE. See Apium.

SMILAX. Town. Inst. R. H. 654. tab. 421. Rough Bindweed.

The Characters are,

It is male and female in different plants. The male flowers have a six-leaved bell-shaped empalement, but no petals; they have six stamina, terminated by oblong summits. The female flowers have the like empalement, but they fall off; they have no petals or stamina, but have an oval germen, supporting three very small styles, crowned by oblong reflexed stigmas. The germen afterward turns to a globular berry with two cells, containing two globular seeds.

The Species are,

1. *SMILAX caule aculeato angulato, foliis dentato-aculeatis cordatis.* Lin. Sp. Plant. 1028. Smilax with an angular prickly stalk, and heart shaped, prickly, indented leaves.

2. *SMILAX caule aculeato angulato, foliis cordatis inermibus.* Smilax with an angular prickly stalk, and smooth heart-shaped leaves.

3. *SMILAX caule aculeato angulato, foliis inermibus retusocordatis.* Smilax with an angular prickly stalk, and retuse, heart-shaped, unarmed leaves.

4. *SMILAX caule aculeato tereti, foliis inermibus cordatis oblongis multinerviis.* Lin. Sp. Plant. 1030. Smilax with a taper prickly stalk, and oblong, heart-shaped, unarmed leaves, with many veins.

5. *SMILAX caule aculeato teretiufculo, foliis inermibus ovato-cordatis.* Lin. Sp. Plant. 1029. Smilax with a taper prickly stalk, and oval, heart-shaped, unarmed leaves.

6. *SMILAX caule subaculeato tereti, foliis inermibus cordatis trinerviis.* Smilax with a taper stalk, having a few small thorns, and unarmed heart-shaped leaves, with three veins.

7. *SMILAX caule aculeato tereti, foliis inermibus sagittatis obtusiusculis trinerviis.* Smilax with a prickly taper stalk, and very blunt, halberd-pointed, unarmed leaves.

8. *SMILAX caule aculeato tereti, foliis ovato-lanceolatis nervis foliorum infernè aculeatis.* Smilax with a taper prickly stalk, and oval spear-shaped leaves, whose veins on the under side are prickly.

9. *SMILAX caule aculeato angulato, foliis lanceolatis inermibus, acuminatis.* Smilax with an angular prickly stalk, and spear-shaped, acute-pointed, unarmed leaves.

10. *SMILAX caule inermi tereti, foliis inermibus ovato-cordatis quinquenerviis floribus corymbosis.* Rough Bindweed with a taper unarmed stalk, oval, heart-shaped, unarmed leaves, and flowers in a corymbus.

11. *SMILAX caule inermi tereti, foliis inermibus ovatis trinerviis.* Smilax with an unarmed taper stalk, and oval unarmed leaves with three veins.

12. *SMILAX caule inermi tereti, foliis inermibus oblongo-cordatis trinerviis.* Smilax with a taper unarmed stalk, and oblong, heart-shaped, unarmed leaves with three veins.

13. *SMILAX caule inermi tereti, foliis inermibus ovato-cordatis trinerviis, floribus corymbosis.* Smilax with a taper unarmed stalk, oval, heart-shaped, unarmed leaves, and flowers in a corymbus.

14. *SMILAX caule inermi tereti, foliis inermibus cordato-oblongis trinerviis cum acumine.* Smilax with a taper unarmed stalk, and heart shaped oblong leaves, having three veins, ending with acute points.

15. *SMILAX caule inermi tereti, foliis inermibus, caulinis cordatis, racemis ovato-oblongis.* Lin. Sp. Plant. 1031. Smilax with an unarmed taper stalk, unarmed heart-shaped leaves on the stalks, and oval oblong bunches of flowers.

16. *SMILAX caule inermi tereti, foliis inermibus lanceolatis.* Smilax with a taper unarmed stalk, and spear-shaped unarmed leaves.

The first sort grows naturally under hedges and in woods in *Italy* and *Spain*. The roots are composed of many thick fleshy fibres, from which come out several slender stalks which are angular, armed with short crooked spines, and have clasps on their sides, by which they fasten themselves to any neighbouring plant for support, and rise six or eight feet high. The leaves are stiff, heart-shaped, and acute-pointed, eared at their base; they are of a dark green, and have five longitudinal veins; their edges are set with a few short reddish spines. The flowers come out from the wings of the stalk in short bunches, which are small and whitish, having no petals. Those on the female plants are succeeded by red berries, which ripen in autumn.

The second sort grows naturally in *Syria*. The roots of this are like those of the former; the stalks are four-cornered and prickly; these fasten themselves to the trees near them by their clasps, and mount to their tops. The leaves are heart shaped; they have no spines on their edges, but have five veins running lengthways. The flowers and fruit are like those of the first sort.

The third sort grows naturally in *Virginia*. The roots of

this are like those of the former; the stalks are angular and prickly; the leaves are heart-shaped, turning backward, and unarmed; the flowers are small, in long loose bunches at the wings of the stalks: the berries are small and red.

The fourth sort grows naturally in *Carolina*. The roots are like the former; the stalks are taper and prickly; the leaves are oblong, heart-shaped, having no spines, but longitudinal veins; the flowers come out in long loose bunches from the side of the stalks, and the berries are black.

The fifth sort grows naturally at *Carthagen* in *New Spain*: The stalks are taper, very strong, and armed with short stiff spines; they fasten themselves by their clasps to the neighbouring trees, and rise twenty feet high. The leaves are of a thick substance, and have no spines; they are oval, heart-shaped, ending in an obtuse point, and have three longitudinal veins. The flowers are like those of the other species, but grow in close bunches; the berries are red. This is the same with a plant which I received from *China* by the title of *China Root*.

The sixth sort grows naturally at *Carthagen* in *New Spain*. This has very strong taper stalks, armed with a very few short spines. The leaves are thick, unarmed, and heart-shaped, their base ending with acute points. This sort climbs on the neighbouring trees, and rises thirty feet high.

The seventh sort grows naturally at *La Vera Cruz* in *New Spain*; this hath a thick, taper, prickly stalk, which climbs up the neighbouring trees to the height of thirty or forty feet. The leaves are thick, stiff, unarmed, and have two round ears at their base; they have three longitudinal veins, and stand on short foot-stalks.

The eighth sort grows naturally at *La Vera Cruz*; this has slender, taper, prickly stalks, which fasten themselves to any neighbouring support by their clasps, and rise eight or ten feet high. The leaves are oval, spear-shaped; they have no spines on their edges, but their midrib and veins on the under side are armed with short reddish spines.

The ninth sort grows naturally in *Jamaica*. The stalks of this are slender, angular, and prickly; the leaves are spear-shaped, ending in acute points, having no spines; their base is a little rounded, but have no ears.

The tenth sort grows naturally at *La Vera Cruz* in *New Spain*. The stalks of this are taper and unarmed; the leaves are oval, heart-shaped, having five longitudinal veins; they have no spines, and stand on short foot-stalks. The flowers come out from the wings of the stalk in round bunches, which are succeeded by red berries.

The eleventh sort grows naturally in *Jamaica*; this has thick, fleshy, creeping roots. The stalks are taper and unarmed; these climb up the neighbouring trees and bushes to the height of ten or twelve feet. The leaves are oval, ending in acute points, and have three longitudinal veins, but no spines.

The twelfth sort grows naturally in *Jamaica*. The stalks of this are very slender and taper, having no thorns; these branch out greatly, and rise over the neighbouring bushes, having very long clasps, which twine about their branches. The leaves are oblong, heart-shaped, with three longitudinal veins, ending in acute points, of a lucid green, and pretty thick consistence.

The thirteenth sort grows naturally in *Carolina*; this has taper unarmed stalks, which rise three or four feet high. The leaves are oval, heart-shaped, and have three longitudinal veins. The flowers come out from the wings of the stalk at every joint, standing upon short foot-stalks, formed in a round bunch; these are succeeded by roundish red berries.

The fourteenth sort grows naturally in *Jamaica*. The stalks of this are taper, branching, and unarmed; the leaves are heart-shaped, oblong, and have three longitudinal

nal veins, ending with acute points, of a lucid green, and stand upon short foot-stalks.

The fifteenth sort grows naturally in *Jamaica*, and also in *Maryland*. The stalks of this are ligneous, taper, unarmed, and have very long clasps, by which they fasten to any neighbouring support, and rise twenty feet high. The leaves are some oval, and others are heart-shaped. The flowers come out from the wings of the stalk in oblong bunches, which are succeeded by red berries.

The sixteenth sort grows naturally in *Carolina*; this has a thick, taper, unarmed stalk, which rises by the help of neighbouring bushes and trees ten or twelve feet high. The leaves are thick, spear-shaped, and unarmed. The flowers come out from the wings of the stalk in round bunches, which are succeeded by black berries.

These plants are many of them preserved in the gardens of the curious for the sake of variety, but some of them may be disposed as to make them ornamental, especially those sorts which grow naturally in *North America*, and also the two first sorts, which are so hardy as to thrive in the open air in *England*; and, as they retain their verdure all the year, so if the plants are placed on the borders of woods or groves in gardens, and their branches properly supported, they will screen the nakedness of the ground under the trees from sight, and in winter, when their leaves are in beauty, they will make a pleasing variety, when they are properly intermixed with other ever-greens; and, as some of the sorts will rise five or six feet high, they will shut up from view any disagreeable objects.

Those sorts which require a stove to protect them in winter, are little esteemed, because they require much room; and, as their flowers have no beauty to recommend them, few persons care to be at the trouble of preserving them for that of their leaves, because there are many other plants whose leaves make as good an appearance, and the plants do not require so much room, so these are rather proper furniture of botanick gardens than those of pleasure.

They are all propagated by seeds. Those sorts which have been brought from *North America*, frequently produce flowers in *England*, but the summers here are neither warm enough, nor of duration to ripen their seeds, so that these are propagated by parting of their roots; for when the roots have obtained strength, they may be greatly increased, by parting of them early in autumn, that the offsets or young plants may have time to get good roots before the frosts come on; and if after they are planted, the cold should come on earlier, or be more severe than ordinary, if the surface about their roots is covered with some old tanners bark or mulch to keep the frost out of the ground, it will preserve them; but these roots should not be parted oftener than every third or fourth year, for unless the roots are large, there will be few stalks to each, and therefore will make but little appearance.

The tender sorts must be kept in pots, and plunged into the tan-bed of the bark-stove, to have them strong; for although they will live in a moderate warmth in winter, they will make but little progress, and their stalks will be short, their leaves small, and the plants weak, so will make but a poor appearance; therefore, unless they can be allowed room in the warm stove, and constantly kept in the tan-bed, they will not be worth preserving.

As all the sorts grow naturally under hedges, and in woods, they should be disposed in such a manner, as to imitate their places of growth, and not place them in the open sun, where they will not thrive; therefore the hardy kinds should be planted under the shade of trees, and the tender ones may be placed between the pots which contain tall plants, whose branches may screen them from the sun.

When the seeds of these plants are obtained from abroad, they should be sown in pots, and plunged into a moderate hot-bed; these generally remain in the ground a whole year before they grow, so that when the plants do not come up the first season, the pots in which the hardy sorts are sown, should be in winter sheltered from frost under a common frame, and the tender ones plunged into the bark-bed in the stove: the following spring they must be again plunged into the hot-bed, which will bring the plants up very soon. When they are come up, they must be inured to the open air by degrees, and in *June* the hardy sorts may be removed out of the bed, and placed abroad in a sheltered situation, where they should remain till the frost comes on in autumn, when they must be removed into shelter. If the pots are plunged into an old tan-bed under a frame where they may be protected from the frost, and in mild weather be exposed to the open air, they will thrive much better than with more tender treatment.

The tender sorts should be plunged between the other pots in the bark-bed of the stove, where they should remain all the winter. These plants should remain untransplanted in the seed-pots till the following spring, when they should be turned out of the pots, carefully separated, and each planted in a pot; and if the hardy sorts are plunged into a very temperate hot-bed, it will cause them to take new root very soon, so will greatly strengthen the plants; but the tender sorts should be plunged into a good hot-bed of tanners bark to bring the plants forward, that they may get strength before winter, when they must be treated in the manner before directed.

The hardy sorts should be kept in pots for two years, that they may be sheltered in winter, by which time they will have strength enough to bear the cold in the open air, so in the spring they may be turned out of the pots, and planted where they are designed to remain, observing, if the spring should prove dry, to refresh them now and then with water.

SMYRNIUM. *Tourn. Inst. R. H. 315. tab. 168. Alexanders, or Alifanders.*

The Characters are,

It has an umbellated flower; the principal umbel is unequal, the small ones are erect; they have no involucre, and the empalement of the flowers are scarce discernible. The flowers have five spear-shaped petals, which are a little inflexed, and five stamina the length of the petals, terminated by single summits. The germen is situated under the flower, supporting two styles, crowned by beaded stigmas. The germen afterwards turns to an almost globular fruit, which is streaked and splits in two, each containing one moon-shaped seed, convex on one side, marked with three streaks, and plain on the other.

The Species are,

1. SMYRNIUM *foliis caulinis ternatis petiolatis serratis. Hort. Cliff. 105.* Smyrniium with trifoliate leaves on the stalks, which are sawed and have foot-stalks; or common Alexanders, or Alifanders.
2. SMYRNIUM *foliis caulinis orbiculatis integerrimis amplexicaulibus.* Smyrniium with orbicular leaves on the stalks, which embrace them.
3. SMYRNIUM *foliis caulinis cordato-ovatis dentatis amplexicaulibus.* Alexanders with heart-shaped oval leaves, which are indented, embracing the stalks.
4. SMYRNIUM *foliis caulinis ternatis serratis, summis oppositis sessilibus.* Alexanders with leaves by threes, which are sawed, and those at the top by pairs, sitting close to the stalks.
5. SMYRNIUM *foliis caulinis duplicato ternatis integerrimis. Lin. Sp. Plant. 263.* Alexanders with double trifoliate leaves on the stalks, which are entire.

The first sort grows naturally on the rocks by the sea-shore in *Wales*, the north of *England*, and in *Scotland*. It is also found growing wild in many places near *London*, but here it may be supposed to have been thrown out of gardens; for as it was formerly cultivated in gardens for the table, so the seeds may have been scattered, which will grow where-ever they alight.

The lower leaves of this plant resemble those of Smal-lage, but they are much larger; the lobes are rounder, and are sawed on their edges. The stalk rises from three to four feet high, furrowed, and branch into many divisions, garnished with trifoliate leaves of the same shape and form with the lower, but are smaller. The branches are terminated by large umbels of white flowers, which are succeeded by large roundish fruit, containing two moon-shaped seeds.

The second sort grows naturally in *Sicily* and *Crete*; the lower leaves of this sort are decomposed of small leaves, which divide by threes; their lobes are oval and indented on their edges; the stalk is smooth, hollow, and rises three feet high, dividing toward the top into two or three branches; at each joint is placed one large orbicular leaf, whose base embrace the stalk; these are of a yellow green colour, and their edges are entire; the branches are terminated by small umbels of yellowish flowers, whose smaller umbels or rays are of unequal lengths. The seeds are black, and shaped like those of the former, but are smaller.

The third sort grows naturally in *Crete*; the lower leaves of this are larger than those of the former, but are composed of several winged divisions. The stalk does not rise so high as that of the last mentioned, but is angular, and not so hollow; the leaves upon the stalks are much larger; they are of the heart-shaped oval kind, are indented on their edges, and embrace the stalks with their base; their colour is nearly the same with the former, but they are of a thinner texture. The umbels of flowers are smaller, as are also the seeds.

These two sorts have been frequently blended together by botanists, who have supposed they were but one species; but I have cultivated both many years, and have not found either of them alter.

The fourth sort grows naturally in *Crete*; the lower leaves of this are smaller than those of the first sort, and are more like those of Smal-lage; the stalk rises higher, and grows more erect than those of the first; the leaves on the lower part of the stalk are large, and sawed on their edges; they stand by threes round the stalk at the joints, their base set close, having no foot-stalks; the upper part of the stalk and branches are garnished with leaves of the same form, which stand by pairs. The umbels of flowers are much smaller, and the seeds are less.

The first of these sorts is that ordered by the College for medicinal use, but is seldom now prescribed; and at present is seldom cultivated in gardens, though formerly it was greatly used in the kitchen, before Celery was so much cultivated, which hath taken place of Alexanders, and entirely supplanted it. The other sorts are preserved in botanick gardens for variety. The second sort is much preferable to the first for blanching, as I have tried, and will be tenderer, and not quite so strong.

All these plants may be propagated by sowing their seeds upon an open spot of ground in *August*, as soon as they are ripe; for if they are sown in spring, they often miscarry, or at least do not come up until the second year; whereas those sown in autumn, rarely fail of coming up soon after *Christmas*, and will make much stronger plants than the other.

The common sort when cultivated for the table, should be treated in the following manner:

In the spring the plants should be hoed out, so as to leave

them ten inches or a foot apart each way; and, during the following summer, they must be constantly cleared from weeds. In *February* following the plants will shoot up again vigorously, at which time the earth must be drawn up to each plant, to blanch them, and in three weeks after they will be fit for use; when they may be dug up, and the white part preserved, which may be stewed and eaten as Celery.

SNAP-DRAGON. See *Antirrhinum*.

SNEEZ-WORT. See *Achillea*.

SNOW is defined to be a meteor formed in the middle region of the air, of vapour raised by the action of the sun, or subterraneous fire, there congealed, its parts constricted, its specific gravity increased, and thus returned to the earth in the form of little villi or flakes.

The snow we receive may properly enough be ascribed to the coldness of the atmosphere through which it falls; when the atmosphere is warm enough to dissolve the snow before it arrives at us, we call it rain; if it preserves itself undissolved, we call it snow.

Snow is very useful; it fructifies the ground; it guards Corn, or other vegetables, from the intenser cold of the air, especially the cold piercing winds.

It is supposed to abound with salific and fertile particles, as much or more than rain; however, it is accounted more ponderous, and by that means sinks deeper in the ground than rain does, and therefore is in some cases of more benefit to planting; for which reason, some lay heaps of snow round the feet of the forest trees, especially in hot burning lands.

SNOWDROP. See *Galanthus*.

SOIL. See *Earth*.

SOLANOIDES. See *Piercea*.

SOLANUM. *Tourn. Inst. R. H. 148. tab. 62.* Nightshade.

The Characters are,

The impalement of the flower is permanent, of one leaf. The flower has one wheel-shaped petal, having a very short tube; the brim is large, spreading, and five-pointed. It has five oval-shaped stamina, terminated by oblong summits, which stand together, and a roundish germen, supporting a slender style longer than the stamina, crowned by an obtuse stigma. The germen afterward turns to a roundish berry with two cells, having a convex fleshy receptacle, filled with roundish compressed seeds.

The Species are,

1. SOLANUM caule inermit herbaceo, foliis ovatis acuminatis glabris, umbellis nutantibus. Nightshade with an herbaceous unarmed stalk, smooth oval-pointed leaves, and nodding umbels; common Nightshade with black fruit.

2. SOLANUM caule inermit herbaceo, foliis ovatis dentato-angulatis, umbellis nutantibus. Nightshade with an herbaceous unarmed stalk, oval, angular, indented leaves, and nodding umbels; Nightshade with red fruit.

3. SOLANUM caule inermit herbaceo, foliis ovato-lanceolatis acuminatis tomentosis, umbellis nutantibus. Nightshade with an herbaceous unarmed stalk, oval, spear-shaped, acute-pointed, indented, woolly leaves, and nodding umbels; Nightshade with yellow berries.

4. SOLANUM caule inermit herbaceo glabro, foliis oblongo-ovatis acuminatis, dentatis glabris, umbellis nutantibus. Nightshade with an herbaceous, unarmed, smooth stalk, oblong, oval, acute-pointed, indented, smooth leaves, and nodding umbels.

5. SOLANUM caule inermit herbaceo, foliis ovatis acuminatis glabris, umbellis erectis. Nightshade with an herbaceous unarmed stalk, oval, acute-pointed, smooth leaves, and erect umbels.

6. SOLANUM caule herbaceo subaculeato, foliis ovatis obtusis integerrimis, petiolis longissimis, umbellis nutantibus. Nightshade

shade with an herbaceous prickly stalk, oval, obtuse, entire leaves on very long foot-stalks, and nodding umbels.

7. SOLANUM caule inermi herbaceo, foliis oblongo-ovatis acuminatis glabris subdentatis, umbellis nutantibus. Nightshade with an herbaceous unarmed stalk, oblong, oval, acute-pointed, smooth leaves, a little indented, and nodding umbels.

8. SOLANUM caule inermi frutescente flexuoso, foliis superioribus hastatis, racemis cymosis. Hort. Cliff. 60. Nightshade with a shrubby, flexible, unarmed stalk, the upper leaves spear-shaped, and bunches of flowers at the top of the stalk; commonly called Bitter-sweet.

9. SOLANUM caule inermi fruticoso, foliis lanceolatis repandis, umbellis sessilibus. Lin. Sp. Plant. 184. Nightshade with a shrubby unarmed stalk, spear-shaped leaves turning inward, and the umbels fitting close to the stalks; commonly called Amomum Plinii.

10. SOLANUM caule aculeato fruticoso, foliis lanceolatis anguloso-dentatis. Hort. Cliff. 61. Nightshade with a shrubby prickly stalk, and spear-shaped leaves, which are angularly indented.

11. SOLANUM caule aculeato fruticoso, foliis ovatis dentato-angulatis utrinque tomentosis, pedunculis spinosis. Nightshade with a shrubby prickly stalk, oval, angular, indented leaves, woolly on every side, and prickly foot-stalks to the flowers.

12. SOLANUM caule aculeato fruticoso, foliis pinnato-lacinatis obtusis utrinque aculeatis. Nightshade with a shrubby prickly stalk, wing-cut leaves, which are obtuse, and have spines on both sides; commonly called Pomum Amoris.

13. SOLANUM caule aculeis recurvis, foliis sinuatis subtus tomentosis, utrinque aculeatis, pedunculis aculeatis. Lin. Flor. Zeyl. 95. Nightshade with recurved thorns on the stalks, and sinuated leaves, downy on their under side, armed with prickles on both sides, and the foot-stalks of the flowers are prickly.

14. SOLANUM caule aculeato, foliis pinnato-sinuatis, fructu racemoso. Nightshade with prickly stalks, leaves cut into wing-points, and the fruit disposed in oblong bunches.

15. SOLANUM caule aculeato herbaceo, foliis sinuatis glabris, utrinque aculeatis, umbellis erectis, calycibus echinatis. Nightshade with a prickly herbaceous stalk, smooth sinuated leaves armed with spines on both sides, upright umbels, and very prickly empalements.

16. SOLANUM caule aculeato fruticoso, foliis pinnato-lacinatis tomentosis, utrinque aculeatis, pedunculis axillaribus bifloris. Nightshade with a prickly shrubby stalk, wing-cut leaves which are woolly, prickly on both sides, and foot-stalks with two flowers at the wings of the stalk.

17. SOLANUM caule aculeato fruticoso, foliis oblongis sinuato-pinnatis, aculeatis, umbellis sessilibus. Nightshade with a prickly shrubby stalk, oblong, wing-sinuated, prickly leaves, and umbels fitting close to the stalks.

18. SOLANUM caule aculeato fruticoso, foliis ovatis tomentosis, anguloso-sinuatis subaculeatis, umbellis sessilibus. Nightshade with a prickly shrubby stalk, oval, woolly, angular, sinuated leaves a little prickly, and umbels fitting close to the stalks.

19. SOLANUM caule aculeato fruticoso, foliis lanceolatis subdentatis glabris, racemis longioribus axillaribus. Nightshade with a prickly shrubby stalk, smooth spear-shaped leaves a little indented, and longer bunches of flowers from the wings of the stalk.

20. SOLANUM caule aculeato fruticoso, foliis ovato-oblongis acuminatis tomentosis, umbellis erectis axillaribus. Nightshade with a shrubby stalk armed with a few spines, oval, oblong, woolly leaves, and erect umbels from the wings of the stalk.

21. SOLANUM caule inermi frutescente flexuoso, foliis ovatis subtus tomentosis, floribus solitariis alaribus. Nightshade with a shrubby, bending, unarmed stalk, oval leaves which are woolly on their under side, and flowers growing singly from the wings of the stalk.

22. SOLANUM caule inermi fruticoso, foliis ovatis acuminatis integerrimis, subtus tomentosis, umbellis erectis alaribus & terminalibus. Nightshade with a shrubby unarmed stalk, oval, acute-pointed, entire leaves, which are woolly on their under side, and erect umbels from the wings and the top of the branches.

23. SOLANUM caule aculeato fruticoso, foliis ovatis sinuato-dentatis subtus tomentosis, aculeis utrinque rectis, umbellis sessilibus terminalibus. Nightshade with a prickly shrubby stalk, oval, sinuated, indented leaves, which are woolly on their under side, the spines every way strait, and umbels sitting close at the end of the branches.

24. SOLANUM caule inermi fruticoso, foliis ovato lanceolatis integerrimis subtus tomentosis, umbellis erectis pedunculis longissimis. Nightshade with a shrubby unarmed stalk, oval, spear-shaped, entire leaves, which are woolly on their under side, and erect umbels having very long foot-stalks.

25. SOLANUM caule frutescente subinermi, foliis cuneiformibus sinuato-repandis. Lin. Sp. Plant. 185. Nightshade with a shrubby almost unarmed stalk, and wedge-shaped leaves which are sinuated, and turn backward.

26. SOLANUM caule frutescente inermi, foliis lanceolatis sinuato-dentatis glabris, umbellis erectis. Nightshade with a shrubby unarmed stalk, spear-shaped, sinuated, indented, smooth leaves, and erect umbels.

27. SOLANUM caule inermi fruticoso, foliis ovatis integerrimis, pedunculis lateralibus filiformibus. Lin. Sp. Plant. 185. Nightshade with a shrubby unarmed stalk, oval entire leaves, and thread-like foot-stalks to the flowers, proceeding from the side of the branches.

28. SOLANUM caule inermi frutescente flexuoso, foliis ovatis subdentatis crassis. Nightshade with a shrubby, flexible, unarmed stalk, and oval thick leaves somewhat indented.

29. SOLANUM caule frutescente inermi, foliis lanceolatis integerrimis subtus pilosis, umbellis erectis terminalibus. Nightshade with a shrubby unarmed stalk, spear-shaped entire leaves, which are hairy on their under side, and erect umbels terminating the branches.

30. SOLANUM caule inermi fruticoso, foliis ovatis integerrimis, subtus tomentosis, umbellis erectis terminalibus, calycibus obtusis lanuginosis. Nightshade with a shrubby unarmed stalk, oval entire leaves, which are woolly on their under side, erect umbels terminating the branches, and downy obtuse empalements.

31. SOLANUM caule aculeato, foliis oblongo-ovatis; dentato-sinuatis, subtus pilosis, umbellis lateralibus. Nightshade with a shrubby prickly stalk, oblong oval leaves, with sinuated indentures, hairy on their under side, and umbels on the side of the branches.

32. SOLANUM caule aculeato fruticoso, foliis sinuato-dentatis, racemis lateralibus, aculeis utrinque incurvis. Nightshade with a prickly shrubby stalk, leaves with sinuated indentures, bunches of flowers on the side of the branches, and the spines every where recurved.

33. SOLANUM caule aculeato fruticoso, foliis sinuatis obtusis, utrinque tomentosis, floribus racemosis terminalibus. Nightshade with a shrubby prickly stalk, obtuse sinuated leaves, which are woolly on both sides, and flowers in loose bunches terminating the branches.

34. SOLANUM caule aculeato herbaceo, foliis laciniatis dentatis tomentosis, utrinque aculeatis, calycibus tomentosis. Nightshade with a prickly herbaceous stalk, cut leaves which are indented, woolly, and armed with spines on both sides, and woolly empalements.

35. SOLANUM caule aculeato herbaceo, foliis cordatis quinquelobis, utrinque villosis aculeatis. Vir. Cliff. 15. Nightshade with a prickly herbaceous stalk, and heart-shaped leaves with five lobes, which are hairy and prickly on both sides.

36. SOLANUM caule herbaceo erecto inermi, foliis ovato lanceolatis anguloso-dentatis floribus lateralibus. Nightshade with an herbaceous, erect, unarmed stalk, oval spear-shaped leaves angularly indented, and flowers on the side of the stalks.

The first sort is now very common upon dunghills, and on rich cultivated soils, in many parts of *England*, where it often becomes a very troublesome weed. This is the sort which the College of Physicians have directed to be used in medicine, under the title of *Solanum hortense*: and although it is now become a very troublesome weed in many gardens near *London*, yet it is not a native of this country, but is supposed to have been brought originally from *America*, from whence the greater part of the species of this genus have been introduced into *Europe*.

There are two varieties of this, which are found growing naturally in *England*. The most common sort is an upright plant with oval, acute-pointed, smooth leaves, and black berries. The other is a low branching plant with indented leaves, and greenish yellow berries, but whether these are only varieties, or distinct species, I cannot say, though I have sown their seeds separately, and have found them keep their difference, but do not know if they will continue it always.

The second sort rises with an erect branching stalk three feet high; the leaves are oval, angular, indented, and smooth; the flowers are white, produced in roundish bunches, in form of umbels, having five star-pointed petals, which are reflexed; in the center are five stamina, which are terminated by oblong yellow summits standing close together; after the flowers are past, the germen will swell to round pulpy berries of a deep red colour, standing in nodding umbels on the side of the branches.

The third sort rises with hairy branching stalks two feet high; the leaves are woolly, oval, spear-shaped, acute-pointed, and indented on their edges; the flowers are like those of the former sort; the berries are smaller, and of a dirty yellow colour. The seeds of this came from *America*.

The seeds of the fourth sort came from the *West-Indies*; this hath taller and smoother stalks than either of the former; the leaves are of a dark green, smooth, oval, acute-pointed, and indented on their edges in angular indentures; the flowers are produced in umbels on the side of the branches, which are succeeded by smooth red berries.

The fifth sort grows naturally in *Virginia*; the stalks of this are angular, and rise upward of three feet high, dividing into a few slender spreading branches, garnished with oval, acute-pointed, smooth leaves, of a deep green colour, with a few indentures on their edges; the flowers are very small, and but few in each umbel; they have narrow acute-pointed petals, white on the inside, and purplish without, and are succeeded by small black berries, which ripen late in autumn.

The sixth sort grows naturally in *North America*. The stalks of this sort rise three feet high, and divide into spreading angular branches, having a few short spines; the leaves are oval and entire, of a dark green colour, and have long foot-stalks; the flowers come out from the side of the branches in small umbels, which nod on one side; they are star-pointed, and are succeeded by small black berries, which ripen late in the autumn.

The seventh sort grows naturally in *Guinea*. This rises with a strong, thick, angular, herbaceous stalk two feet high, dividing into short thick branches, garnished with oblong, oval, smooth, indented leaves, standing upon pretty long foot-stalks. The flowers are produced in nodding umbels from the side of the stalk; they are like those of the first sort, but are larger. These are succeeded by large black berries the size of the common black Cherry, which ripen in autumn.

These seven sorts are annual, so their seeds should be sown in the spring, on a bed of rich earth, where the plants are designed to remain; and when they come up, they must be thinned, leaving them at least two feet distance, that they may have room to grow; after this they will require no farther care, but to keep them clean from weeds; in *July* and *August* they will flower, and the seeds will ripen in autumn. Some people plant one or two plants of each sort in pots, whose stalks they train up to sticks, to make them strait; and in autumn they remove the pots into the green-house, where they may be preserved till the spring, and during the winter, their fruit being ripe, will make a pretty appearance.

The eighth sort is a climbing woody plant, which grows in the hedges in divers parts of *England*, and is by some planted in gardens to cover arbours, or shady walls, in *London*, and other close places, where few other plants will thrive. The cuttings or stalks of this are put into glasses of water, and placed in rooms, where they will put out branches and leaves, and continue a long time green. This plant is also used in medicine, for some particular preparations; but the herb folks in the markets often sell this instead of the Garden Nightshade, which is a cooling plant, but this a hot acrid one, which renders it contrary to the intention of the ointment, wherein Nightshade is one of the ingredients.

There is a sort of this with white flowers, which is supposed to be a variety of the former, but the leaves are woolly, in which it differs from the other, and this is constant. There is also one with variegated leaves, which is preserved by those who are very curious in collecting the various kinds of striped-leaved plants.

These may be easily propagated by planting their cuttings in the spring upon a moist soil, where they will soon take root, and may afterward be transplanted where they are to remain.

The ninth sort grows naturally at the *Madeiras*; this rises with a strong woody stalk four or five feet high, dividing into many slender stiff branches, garnished with spear-shaped leaves, turning backward; the flowers grow in small umbels, or singly on the side of the branches, to which they sit close. These are succeeded by berries as large as small Cherries, which ripen in winter, when they make a good appearance in the green-house. There are two varieties of this, one with a red, and the other has a yellowish fruit.

This plant may be propagated by sowing its seeds in a pot of rich earth in the spring, placing it upon a moderate hot bed, which will greatly facilitate their growth. When the plants are come up, you should make a gentle hot-bed, covered with rich earth about six inches thick; in this they should be planted about six inches distance each way, and the bed arched over with hoops, &c. and covered with mats, to shade them from the sun and cold, observing frequently to water them.

When the plants have acquired strength, and the season becomes favourable, you must inure them to bear the open air by degrees, to which they should be fully exposed in summer, when they should be taken up, with a ball of earth to the root, and placed separately in pots, filled with rich earth, and set in a shady situation, until they have taken new root; after which they may be removed into a more open exposure, and placed among other exotic plants; but they require a great plenty of water in dry weather, without which they seldom produce much fruit.

In winter they must be removed into the green-house, and placed in the coldest part of the house, where they may have as much free air as possible in mild weather; being so hardy, as many times to endure the cold of our ordinary winters abroad, when planted in a warm situation;

tion; so that they only require to be sheltered from severe frost.

The tenth sort grows naturally in the *West-Indies*; this rises with a shrubby stalk three feet high, dividing at the top into several branches, closely armed with strait gold coloured spines on every side. The leaves are angularly indented; their midrib is armed with a row of the like spines as those upon the stalks, which stand erect. The flowers are produced in oblong bunches from the side of the stalks, which are succeeded by red berries almost as large as the small black Cherry.

The tenth sort is much tenderer than either of the former, being brought from the warm parts of *America*. This is propagated by seeds, which must be sown upon a good hot-bed; and when the plants are come up, they should be each transplanted into a separate small pot, and plunged into a fresh hot-bed again, observing to water and shade them until they have taken root; after which they should have air and water in proportion to the heat of the season.

In *July* these plants may be inured to bear the open air by degrees, into which they may be removed, if the season be warm, otherwise they must be preserved either under glasses, or in the stove; if they are placed in the open air, they should not remain there longer than the middle or latter end of *August*, lest the nights growing cold, should hurt them. During the winter season they must be preserved in the stove, observing to refresh them frequently with water; but they must not have too much each time, especially in cold weather. The second year they will produce flowers and fruit.

The eleventh sort has a shrubby stalk, which rises two feet high, dividing into several woody branches, armed with sharp thorns, garnished with oval woolly leaves, which have angular indentures on their edges. The flowers are produced in small loose bunches from the wings of the stalks; they are blue, and larger than those of the former sorts; these are succeeded by round berries as large as common Cherries, of a gold colour, which turn black when ripe.

The twelfth sort grows naturally at the *Cape of Good Hope*. This hath a strong, thick, shrubby stalk, which rises from two to three feet high, sending out many short thick branches, closely armed with short, strong, yellow spines on every side; the leaves are cut almost to their midrib in obtuse segments, which are opposite, regular, and formed like winged leaves; these segments have several obtuse indentures on their edges; they are of a dark green colour, and armed with the same sort of spines, as those on the stalks on both sides. The flowers come out in small bunches on the side of the branches; they are blue, and larger than those of the former sort, and are succeeded by round yellow berries as large as Walnuts, which ripen in winter.

The eleventh and twelfth sorts are not so tender as the last, but require an open airy glass-case, or a warm greenhouse in winter, but in summer may be exposed in the open air with other exotic plants. These may be propagated by sowing their seeds on a hot-bed as the former, and should be managed as hath been directed for them, with this difference, that they may be much sooner exposed to the air, and should not be treated so tenderly.

The thirteenth sort grows naturally at the *Cape of Good Hope*; this hath a shrubby stalk four or five feet high, covered with a white meally down, dividing into a few straggling branches, armed with short, thick, dark, brown, recurved spines, with yellowish points. The leaves are sinuated, of a bright green on their upper side, but woolly on their under. This sort has not as yet produced any flowers in *England*, though there are large plants of it in the *Chelsea* garden, where they were raised from seeds, which came from the *Cape of Good Hope*.

This may be propagated by seeds: in the same way as the two former, and the plants must be treated in the same way, but they are not so hardy as the two former, so should be placed in a warm stove in winter, and should not have much water in cold weather.

The fourteenth sort has a shrubby stalk, which rises two feet high, sending out several ligneous branches, armed with short, strong, yellowish spines; the leaves are regularly indented, armed with spines on both sides. The flowers come out in longish bunches from the side of the stalks, and are succeeded by round red berries, as large as middling Cherries, which ripen in winter.

The fifteenth sort was discovered by the late Dr. *Houssoun* at *La Vera Cruz*. This rises with a prickly herbaceous stalk two feet high, dividing into two or three branches, closely armed with slender yellow spines of unequal lengths. The leaves are of a bright green colour, deeply sinuated; the veins of the leaves are armed with yellow erect spines on both sides. The umbels of flowers stand erect at the end of the branches; the flowers are very large, of a fine blue colour, and are succeeded by round berries as large as common Cherries, which are marbled with white and green. The empalement of the flower is armed with spines like a hedgehog. The fruit ripens late in the autumn, so that unless the plants are brought forward in the spring, they will not produce ripe seeds in *England*.

The sixteenth sort grows naturally at *La Vera Cruz*; this hath shrubby trailing stalks two feet long; armed with long yellow spines, covered with a gray bark; the leaves are woolly, very finely cut in form of winged leaves almost to their midrib, and armed with long, slender, yellowish spines on their veins on both sides. The foot-stalks of the flowers arise from the wings of the stalks; they are three inches long, for the most part sustaining two large yellow flowers, having very prickly empalements, and are succeeded by small round berries the size of gray Peas, which are marbled with green and white.

The seventeenth sort grows at *La Vera Cruz*; this rises with a shrubby stalk five or six feet high, armed with short recurved spines, covered with a smooth brownish bark, garnished with oblong leaves, which are regularly sinuated on both edges in form of winged leaves, armed with a few short spines along their midrib on both sides. The flowers come out in small loose bunches from the side of the branches, to which they fit close; they have five white star-pointed petals, and are succeeded by small berries about the size of those of Juniper, which, when ripe, are red.

The eighteenth sort grows naturally in *Jamaica*; this rises with a shrubby woolly stalk five or six feet high, armed with short recurved thorns, garnished with oval woolly leaves, angularly sinuated, and have a very few short crooked spines upon the midrib on the under side. The flowers are in small umbels sitting close to the side of the branches; they are yellow, and are succeeded by small round berries, of a Saffron colour when ripe.

The nineteenth sort grows naturally in *Jamaica*; this rises with shrubby stalks three or four feet high, dividing into several irregular branches, which have a gray bark, armed on every side with slender erect spines of a gray colour. The leaves are spear-shaped, smooth, and a little indented or waved on their edges. The flowers come out in long bunches from the side of the stalk, standing upon long foot stalks, of a fine blue colour, and are succeeded by Saffron-coloured berries the size of Peas.

The twentieth sort grows naturally at *La Vera Cruz*; this has a strong shrubby stalk five feet high, covered with a brown woolly bark, armed with a few short spines, sending out several ligneous branches, garnished with oblong, oval, acute-pointed leaves, covered with a brown woolly down.

on both sides. The flowers are large, white, and grow in erect umbels from the side of the branches, and have thick woolly empalements; these are succeeded by yellow berries as large as middling Cherries.

The twenty-first sort grows naturally at *La Vera Cruz*; this has a shrubby climbing stalk ten or twelve feet high, covered with a smooth brown bark, divided into several branches. The leaves are oval, woolly on their under side, but of a dark green on their upper. The flowers come out singly from the wings of the stalk; they are large, of a fine blue colour, and the petal is not divided into segments like those of the other species, but have five angles, each ending in a point; these are succeeded by round berries, about the size of gray Peas, which are red when ripe.

The twenty-second sort grows naturally at *Campeachy*; this hath a smooth shrubby stalk six or seven feet high, sending out ligneous branches, garnished with oval acute-pointed leaves, which are entire, woolly on their under side. The flowers are collected into umbels, which stand erect; these come out from the side and at the end of the branches; they are of a light blue colour, and are succeeded by round berries the size of small black Cherries, which are yellow when ripe.

The twenty-third sort grows naturally at *La Vera Cruz*; this has a shrubby stalk four feet high, with a white downy bark, armed on every side with strait brown spines. The leaves are oval, and have sinuated indentures, woolly on their under side, and have prickly foot-stalks. Their mid-rib is armed with two or three small spines, sometimes on both sides, and at others but on one. The spines are all erect; the flowers are disposed in an umbel sitting close at the end of the branches; they are large, of a fine blue colour, and have woolly empalements; these are succeeded by round berries the size of large Peas, which are red when ripe.

The twenty-fourth sort grows naturally at *Campeachy*; this rises with a woody stalk eight or ten feet high, sending out several ligneous furrowed branches, covered with a gray down. The leaves are sometimes placed alternately on the branches, and at others they are opposite, standing upon pretty long foot-stalks; their edges are entire, end in acute points, and woolly on their under side. The flowers terminate the branches in large erect umbels, standing upon long foot-stalks; they are large, white, and have woolly empalements; these are succeeded by berries the size of Cherries, which turn yellow.

The twelve last mentioned sorts are propagated by seeds in the same manner as the former, but these, being natives of a warm country, must be raised on a hot-bed early in the spring, and when the plants are fit to remove, they must be each planted in a separate small pot, and plunged into a moderate hot-bed of tanners bark, observing to shade them from the sun until they have taken new root; after which they should have a large share of air admitted to them in warm weather, and must be frequently watered. Toward the latter end of *June* it will be proper to harden the plants gradually, and soon after they should be removed into the stove, where they must have as much free air as possible in warm weather, but as the cold approaches in autumn, they must be carefully protected therefrom, and in winter they should be kept in a moderate temperature of warmth, otherwise they will not live in this country.

Some of these sorts will bear to be exposed in the open air in the heat of summer, provided they are placed in a warm situation, but if the season should prove cold, they will not thrive abroad; wherefore it will be better to let them remain in the stove, and open the glasses in front, and at the top of the stove, every day, to admit as much air as possible in hot weather, with which management they will thrive much better than in the open air.

The twenty-fifth sort grows naturally at *Buenos Ayres*; this rises with a woody stalk ten or twelve feet high, covered with a purplish bark, almost smooth. At the top it divides into several erect branches, garnished with wedge-shaped leaves, which are sinuated. The flowers are produced in umbels at the end of the branches; they are large, white, and the petal is angular, but not divided at the brim; these are often succeeded by berries, which change yellow when they are ripe.

The twenty-sixth sort grows naturally in the *Babama Islands*; this rises with a smooth shrubby stalk six or eight feet high, covered with a brown bark, dividing into many branches, garnished with spear-shaped leaves, sinuated on their edges, ending in acute points; they are smooth, of a light green colour. The flowers are produced in small umbels from the side of the stalks, standing erect; they are large, white, and have their petals cut into five star-pointed segments; these are very rarely succeeded by seeds in *England*.

The two last mentioned sorts are not so tender as the twelve former, so may be treated in the same way as the eleventh and twelfth, by housing them in winter with Oranges and other green-house plants, and in summer place them abroad in a sheltered situation; they may be propagated by cuttings, which, if planted in a shady border during any of the summer months, will take root pretty freely, and may then be taken up and potted, placing them in the shade till they have taken new root, and then they may be treated in the same way as the old plants.

The twenty-seventh sort grows naturally on the coast of *Guinea*; this has a shrubby stalk, which rises seven or eight feet high, dividing into many branches. The lower leaves are oblong, oval, smooth, of a dark green colour, and stand upon short foot-stalks; the flowers come out from the side of the branches in small bunches, standing upon very slender foot-stalks; they are of the same shape and colour with those of the *Amomum Plinii*, but smaller, and are sometimes succeeded by berries about the size of small black Cherries, which are yellow when ripe.

This sort requires a stove in winter, and must not be exposed abroad longer than ten or twelve weeks in the warmest part of summer; it may be propagated by cuttings, which, when planted, must be closely covered with a bell or hand-glass, and shaded from the sun, treating them in the same manner as other cuttings of exotick plants.

The twenty-eighth sort grows naturally at the *Cape of Good Hope*; this has shrubby flexible stalks, requiring support like our common woody Nightshade, to which the plant has great resemblance, but the leaves are shorter, thicker, and are more indented on their edges. This sort very rarely flowers in *England*.

It may be easily propagated by cuttings during any of the summer months, and may be preserved in a green-house in winter, treating it in the same way as the *Amomum Plinii*.

The twenty-ninth sort grows naturally at *Campeachy*; this rises with a woody stalk ten or twelve feet high, sending out many branches, having a light gray bark. The leaves are spear-shaped, of a deep green on their upper side, but hoary on their under. The flowers are produced in large umbels at the end of the branches; they are small, star-pointed, and white; their summits, which fill up the mouth of the tube, are purple; these are succeeded by small berries the size of middling Peas, which are yellow when ripe.

The thirtieth sort grows naturally at *Carthagena*; this rises with a shrubby stalk, having a light brown bark, which divides into several irregular ligneous branches, garnished with oval leaves, of a dark green on their upper side, but woolly

woolly on their under. The flowers are produced in large erect umbels at the end of the branches, which are white, and are succeeded by round berries the size of small Cherries, fitting in the blunt woolly empalement of the flower, which turn yellow when ripe.

The thirty-first sort grows naturally at *Carthage*; this rises with a strong shrubby stalk twelve or fourteen feet high. The branches are woody, of a dark brown colour, armed with a few short recurved spines; the leaves are oblong, oval, sinuated on their edges, smooth, of a dark green on their upper side, but their under sides are hairy, of a light green. The flowers come out from the side of the stalk in small umbels; they are white, and the petal is cut into five acute segments almost to the bottom. This has not produced fruit here.

The thirty-second sort grows in the *West-Indies*, and also at the *Cape of Good Hope*. The stalk is shrubby, and rises three feet high, dividing into many ligneous branches, closely armed with short, strong, yellow, recurved spines. The leaves are sinuated, and armed with short crooked spines along their midrib. The flowers are produced in long loose bunches from the side of the stalks; they are white, star-pointed, and are succeeded by berries the size of small black Cherries, of a gold colour when ripe. This sort is propagated by seeds, and may be kept in a warm green-house in winter, and in summer placed in the open air.

The thirty-third sort grows naturally at *Carthage*; this has a shrubby stalk, which rises five or six feet high, sending out many branches, armed with a few short recurved spines. The leaves are deeply sinuated, and covered on both sides with a brown woolly down, which is a little lighter-coloured on the under side. The flowers are produced in pretty large bunches at the end of the branches; they are large, of a bright purple colour. The fruit is yellow when ripe, the size of gray Peas. I have also received the seeds of this from *Bermuda*.

These sorts are propagated by seeds, and require the same treatment as the tender sorts before mentioned.

The thirty-fourth sort grows naturally in the *West-Indies*; this hath an herbaceous stalk two feet high; it is very woolly, closely armed on every side with slender, strait, yellow spines, which renders it very troublesome to handle. The leaves are very woolly on both sides, and cut on their edges; they are armed all over their surface on both sides with the like strait spines. The flowers come out in small loose bunches from the side of the stalks; they are large, of a pale blue colour, and have very woolly empalements; these are succeeded by berries the size of gray Peas, which are of a pale yellow colour when ripe.

The thirty-fifth sort is very common in the islands of the *West-Indies*, where it is titled Bachelors Pear; this has a prickly herbaceous stalk three or four feet high, dividing into a few branches, closely covered with a hairy down, and armed with short, recurved, brown spines. The leaves are divided into lobes, covered with soft hairs, and armed on both sides with crooked spines. The flowers come out from the side of the branches in small bunches; they are large, of a pale blue colour, and are succeeded by fruit about the size and shape of a Catherine Pear, but the stalk is fixed to the large end, so the fruit seems inverted. This is of a gold colour when ripe.

These are plants which require to be raised early in the spring upon a hot-bed, and should be treated in the same way as the fifteenth and sixteenth sorts.

The thirty-sixth sort was sent me from *New England*; this is an annual plant, with an upright herbaceous stalk two feet and a half high, having a smooth purple bark. The leaves have angular indentures, of a deep green co-

lour with purple veins. The flowers come out from the side of the stalks, sometimes singly, and at others there are three or four in a cluster; they are small, white within, and purple on their outside; these are succeeded by berries the size of common Cherries, which are red when ripe.

This is propagated by seeds, which should be sown upon a hot-bed in the spring, and when the plants come up fit to remove, they must be planted upon a fresh hot-bed to bring them forward, and afterward treated in the way as the Capsicums, planting them into a warm border in *June*, where they will flower in *August*, and if the season proves favourable, the seeds will ripen in autumn, soon after which the plants decay.

SOLDANELLA. *Tourn. Inst. R. H. 82. tab. 16.* Soldanel.

The Characters are,

The flower has an erect permanent empalement, cut into five parts; it has one bell-shaped petal. The brim is cut into acute segments; it has five awl-shaped stamina, terminated by single summits, and a roundish germen, supporting a slender style the length of the petal, which is permanent, crowned by an obtuse stigma. The germen afterward turns to an oblong taper capsule of one cell, obliquely streaked, opening at the top with ten indentures, filled with small acute-pointed seeds.

We have but one Species of this genus, viz.

SOLDANELLA. *Hort. Cliff. 49.* Soldanel.

This plant grows naturally on the *Alps*, and other mountains in *Germany*. The root is fibrous and perennial; the leaves are almost kidney-shaped, of a dark green colour, and stand upon long foot-stalks. Between these arise the foot-stalk of the flower, which is naked, about four inches long, sustaining at the top two small, open, bell-shaped flowers, whose brim is cut into many fine segments like a fringe; the most frequent colour of the flower is blue, but it is sometimes found with a snow-white flower. After the flower is past, the germen becomes an oval capsule, with the style coming out at the top, filled with very small acute-pointed seeds.

There is another variety of this, whose leaves are less round.

The best method to propagate these plants is by parting of their roots, because their seeds do not succeed, unless they are perfectly ripe, and well nourished; and this rarely happens in *England*. Nor do the seeds, which are brought from abroad, succeed, for they seldom grow unless they are sown soon after they are ripe.

The season for transplanting and parting these roots is in *September*, that they may have time to make good roots before winter; for if they are removed in the spring, they never flower very strong.

The soil in which these plants thrive best, is a strong, cool loam; they must have a shady situation, for if they are exposed to the sun, they will not live, nor will they thrive in a warm light soil. In dry weather these plants should be frequently watered, which will cause them to flower strongly, and make a good increase.

SOLIDAGO. *Lin. Gen. Plant. 859.* Golden-rod, or Woundwort.

The Characters are,

It has a compound flower made up of hermaphrodite florets, and female half florets inclosed in one oblong imbricated empalement. The hermaphrodite flowers, which compose the disk, are funnel-shaped, cut into five points at the brim; they have very short hair-like stamina, terminated by cylindrical summits, and a crowned germen, supporting a slender style as long as the stamina, crowned by a bifid open stigma. The germen afterward turns to a single seed, crowned with hairy down. The female half florets are tongue shaped, indented in three parts; these have a crowned germen with a slender style, crowned by two revolving stigmas,

figmas, and are succeeded by a single seed like the hermaphrodite florets.

The Species are,

1. SOLIDAGO caule erecto angulato, racemis paniculatis erectis confertis, foliis inferioribus lanceolatis serratis. Golden-rod with an erect angular stalk, flowers in clusters upon upright panicles, and the lower leaves spear-shaped.
2. SOLIDAGO caule erecto paniculato, foliis infimis dentato-serratis caulinis sub-integerrimis. Golden-rod with an erect paniced stalk, the lower leaves indented like saws, but those on the stalks almost entire.
3. SOLIDAGO foliis caulinis lineari-lanceolatis subintegerrimis, floribus confertis alaribus sessilibus. Golden-rod with narrow spear-shaped leaves on the stalk almost entire, and flowers in clusters sitting close to the stalks.
4. SOLIDAGO foliis lineari-lanceolatis subserratis, incanis panicula corymbosa terminali. Flor. Angl. Welsh Golden-rod with narrow, spear-shaped, hoary leaves, and the stalk terminated by a corymbus of flowers.
5. SOLIDAGO caule erecto, foliis lanceolatis acute serratis caule corymboso. Golden-rod with an erect stalk, spear-shaped leaves sharply sawed, and flowers in a corymbus.
6. SOLIDAGO paniculato-corymbosa racemus recurvatis floribus adscendentibus, foliis trinerviis subserratis scabris. Hort. Upsal. 259. Golden-rod with a paniced corymbus, a recurved racemus, and rough sawed leaves with three veins.
7. SOLIDAGO foliis lanceolatis subserratis acuminatis, pedunculis lateralibus unifloris. Golden-rod with spear-shaped, sharp-pointed, sawed leaves, and lateral foot-stalks with one flower.
8. SOLIDAGO paniculato-corymbosa, racemis recurvatis, floribus adscendentibus, foliis enerviis subintegerrimis. Hort. Upsal. 259. Golden-rod with a paniced corymbus, a recurved racemus, and leaves almost entire, without veins.
9. SOLIDAGO paniculato-corymbosa, racemus recurvatis, floribus adscendentibus, foliis nervosis scabris integerrimis. Golden-rod with a paniced corymbus, a recurved racemus, and rough veined leaves.
10. SOLIDAGO caule flexuoso, foliis ovatis acuminatis serratis, racemis lateralibus simplicibus. Flor. Leyd. Prod. 161. Golden-rod with a flexible stalk, oval, sharp pointed, sawed leaves, and simple racemus on the sides of the stalk.
11. SOLIDAGO foliis linearibus integerrimis, corymbo simplici. Hort. Cliff. 410. Golden-rod with linear entire leaves, and a simple corymbus.
12. SOLIDAGO caule flexuosa, foliis ovato-lanceolatis serratis, racemis erectis corymbosis. Golden-rod with a flexible stalk, oval, spear-shaped, sawed leaves, and upright spikes of flowers.
13. SOLIDAGO caule erecto glabro, foliis ovato-lanceolatis serratis, racemis lateralibus simplicibus sessilibus. Golden-rod with an erect smooth stalk, oval, spear-shaped, sawed leaves, and simple spikes of flowers on the side of the stalk.
14. SOLIDAGO paniculato-corymbosa, racemis recurvatis, caule hirsuto, foliis lanceolatis serratis trinerviis subtus tomentosiss. Golden-rod with a paniced corymbus, recurved spikes of flowers, a hairy stalk, and spear-shaped sawed leaves, hoary on their under side.
15. SOLIDAGO paniculato-corymbosa, racemis recurvatis, floribus adscendentibus, foliis lanceolatis subdentatis sessilibus. Golden-rod with a paniced corymbus, recurved spikes of flowers, and spear-shaped indented leaves sitting close to the stalk.
16. SOLIDAGO foliis caulinis ovatis scabris, ramis alternis fastigiatis corymbis terminalibus. Lin. Sp. Plant. 878. Golden-rod with oval rough leaves on the stalk, alternate branches, and bundled spikes of flowers terminating the branches.
17. SOLIDAGO caule obliquo, pedunculis erectis foliatis ramosis, foliis lanceolatis integerrimis. Hort. Cliff. Golden-rod

with an oblique stalk, erect foot-stalks to the flowers, and entire spear-shaped leaves.

18. SOLIDAGO panicula erecta corymbosa, caule glabro, foliis longissimis integerrimis glabris. Golden-rod with an erect paniced corymbus, a smooth stalk, and very long, entire, smooth leaves.

19. SOLIDAGO foliis lanceolatis subcarnosis glaberrimis margine scabriusculis, panicula corymbosa. Lin. Sp. Plant. 878. Golden-rod with spear-shaped, fleshy, very smooth leaves, with rough edges, and a paniced corymbus of flowers.

20. SOLIDAGO caule diffuso glabro, foliis caulinis linearibus glabris sessilibus, racemis erectis simplicibus. Golden-rod with an erect smooth stalk, garnished with narrow smooth leaves sitting close, and simple erect spikes of flowers.

21. SOLIDAGO caule paniculato, racemis lateralibus simplicibus, foliis ovato-lanceolatis scabris integerrimis. Golden-rod with a paniced stalk, single lateral spikes of flowers, and rough, entire, spear-shaped leaves.

22. SOLIDAGO panicula corymbosa, racemis supra densifloribus, caule glabro laevi. Lin. Sp. Pl. 879. Golden-rod with a paniced corymbus, the upper part of the spikes closer set with flowers, and a smooth stalk.

23. SOLIDAGO panicula corymbosa, racemis recurvis adscendentibus, caule inferne ramoso floriferoque. Lin. Sp. Plant. 879. Golden-rod with a paniced corymbus, recurved spikes of flowers, and the lower part of the stalk branching and flowering.

24. SOLIDAGO caule paniculato, racemis confertis, foliis inferioribus lanceolatis, petiolatis caulinis sessilibus glabris. Golden-rod with a paniced stalk, clustered spikes of flowers, lower leaves spear-shaped upon foot-stalks, and those upon the stalks smooth, sitting close.

25. SOLIDAGO paniculato-corymbosa, racemis longissimis recurvatis, foliis lanceolatis scabris. Golden-rod with a paniced corymbus, very long recurved spikes of flowers, and rough spear-shaped leaves.

26. SOLIDAGO caule paniculato, pedunculis erectis, foliis linearibus glabris integerrimis sessilibus. Golden-rod with a paniced stalk, erect foot-stalks to the flowers, and smooth, narrow, entire leaves.

27. SOLIDAGO caule paniculato, racemis erectis, floribus confertis, foliis lanceolatis serratis scabris. Golden-rod with a paniced stalk, erect spikes with flowers in clusters, and spear-shaped, rough, sawed leaves.

28. SOLIDAGO caule paniculato, racemis sparsis, pedunculis erectis, foliis inferioribus lanceolatis serratis caulinis obtusis integerrimis sessilibus. Golden-rod with a paniced stalk, the spikes of flowers thinly disposed, the foot-stalks erect, the lower leaves spear-shaped and sawed, but those on the stalks obtuse, entire, sitting close.

The three first sorts grow naturally in *England*, yet have not been well distinguished by any botanick writer, for in all the books which treat of the *English* plants, they are put down as one sort, to which they have applied a title of *Caspar Bauhin*, viz. *Virga aurea latifolia serrata*, which is a very different plant from either of our *English* sorts. But the third sort here mentioned, I believe to be what *Caspar Bauhin* has titled *Virga aurea angustifolia minus serrata*. As neither of these three *English* sorts, nor the *Welsh* sort, are propagated in gardens, so it is needless to trouble the reader with their description.

The sixth sort was first brought from *Canada*, but has been since found growing naturally in many other parts of *North America*. The stalks of this rise three feet high, garnished with narrow, acute-pointed, entire leaves, a little rough on their surface, sitting close to the stalk, which is terminated by a close panicle of yellow flowers, making a goodly appearance.

The seventh fort grows naturally on the *Alps*. The stalks seldom rise more than four or five inches high, garnished with small spear-shaped leaves, sitting close; and at their base the foot-stalk of the flower comes out, which is an inch long, sustaining one yellow flower at the top, so makes but little appearance. This is kept for variety in botanick gardens.

The eighth fort grows naturally in several parts of *North America*. The stalks of this rise higher than those of the sixth fort; the leaves are broader, without veins, and stand closer upon the stalks; the racemi of the panicles are much longer and more reflexed. The flowers are specious, and come later in the year.

The ninth fort has pretty strong smooth stalks about three feet high, closely garnished with rough, veined, entire leaves, without foot-stalks. The panicle of flowers is very compact, and the racemi are short.

The tenth fort has flexible stalks about two feet high, garnished with oval acute-pointed leaves, deeply sawed on their edges, standing on short foot-stalks. The racemi of flowers, which are for the most part simple, are produced from the wings of the stalk, which is also terminated by a thick spike.

The eleventh fort grows naturally in the south of *France* and in *Italy*. The stalks are near two feet high, garnished with narrow, spear-shaped, entire leaves; and most part of the stalk is adorned with flowers, standing on long foot-stalks, which proceed from the wings. The whole plant is very clammy, and seldom lives more than two or three years. It is propagated by seeds, and will thrive in the full ground, if it has a light dry soil and a sheltered situation.

The twelfth fort has a great resemblance of the tenth, but the leaves of the twelfth are smoother, more unequally sawed, and their foot-stalks are a little longer. The racemi of flowers are longer, and grow more erect than those of the tenth.

The thirteenth fort has smooth erect stalks three or four feet high, garnished with smooth, oval, spear-shaped leaves, sawed on their edges. The racemi of flowers are short, and come out on the side of the stalk.

The fourteenth fort has hairy stalks four feet high, closely garnished with long spear-shaped leaves, sawed on their edges, and downy on their under side. The stalks are terminated by a corymbus of flowers, composed of several reflexed racemi.

The fifteenth fort has rough hairy stalks two feet high, closely garnished with long spear-shaped leaves, a little indented on their edges; the stalks are terminated by a large corymbus of flowers, composed of many long reflexed racemi.

The sixteenth fort has rough channelled stalks from two to three feet high, garnished with large, rough, oval leaves, and are terminated by bunches of yellow flowers, forming almost an umbel. The bottom leaves of this fort are long and spear shaped, so differ much from those on the stalk.

The seventeenth fort was brought from *Mexico*, where it grows naturally. The stalks of this are smooth, one foot and a half high, garnished with smooth, spear-shaped, entire leaves: the flowers come out on one side of the stalk, forming a small corymbus at the end of the foot-stalk. This is not so hardy as the other sorts, so should be planted in a warmer situation.

The eighteenth fort has hairy stalks six or seven feet high, closely garnished with smooth spear-shaped leaves, sitting close, and terminated by a compact corymbus of flowers, ranged on short racemi. The lower leaves are very long and smooth.

The nineteenth fort rises with thick, succulent, smooth

stalks five feet high, garnished with fleshy, smooth, pear-shaped leaves, whose edges are rough; the flowers terminate the stalk in a corymbus; the racemi, which compose it, are erect, and below the flowers are closely garnished with linear smooth leaves. The lower leaves of this fort are very long, smooth, and fleshy.

The twentieth fort hath smooth diffused stalks three feet high, garnished with very narrow smooth leaves; the upper part sends out many long side branches, disposed closely, which are terminated by simple racemi of small yellow flowers, standing erect.

The twenty-first fort sends out many slender hairy stalks three feet high, garnished with oval, spear-shaped, rough leaves, which are entire. The upper part of the stalk sends out on each side single racemi of bright yellow flowers. This fort flowers very late in the year.

The twenty-second fort has slender smooth stalks, rising from two to three feet high, thinly garnished with smooth spear-shaped leaves, a little notched on their edges. The stalk is terminated by a paniced corymbus of yellow flowers, whose racemi are very closely adorned with flowers toward their ends.

The twenty-third fort sends out at the bottom large oval leaves, sawed on their edges, whose foot-stalks are bordered by the appendix of the leaf; the stalks are slender, stiff, and of a purplish colour, branching out in loose racemi of flowers, which are recurved, garnished with smooth, spear-shaped, entire leaves.

The twenty-fourth fort has smooth erect stalks two feet high, which are closely garnished with small, spear-shaped, smooth leaves, sitting close to the stalks, and are entire. The flowers terminate the stalk in a clustered corymbus, whose foot-stalks are erect. The lower leaves of this are long, spear-shaped, smooth, and have foot-stalks.

The twenty-fifth fort sends out strong smooth stalks two feet high, garnished with rough spear-shaped leaves, indented on their edges; the upper part of the stalk divides into many slender branches, which are garnished with very small leaves, and are terminated by recurved racemi of bright yellow flowers.

The twenty-sixth fort sends out smooth paniced stalks two feet high, garnished with linear, smooth, obtuse leaves, which are entire, and sit close the stalk. The flowers terminate the stalk in loose panicles, standing erect.

The twenty-seventh fort hath purplish stalks, which rise three feet high, and are closely garnished with rough spear-shaped leaves, slightly sawed on their edges, ending in acute points. The stalks are terminated by erect racemi of flowers, growing in clusters, of a bright yellow colour.

The twenty-eighth fort has smooth, pale, green stalks, which rise four feet high, and are thinly garnished with oblong, entire, smooth, blunt-pointed leaves, sitting very close. The lower leaves are large, spear-shaped, oblique, and sawed on their edges. The stalks are terminated by simple racemi, which are thinly disposed in a corymbus, but their foot-stalks are erect.

There are several other varieties (if not distinct species) of this genus; but it is very difficult to settle the specific differences of those now growing in the *English* gardens, for of late years there has been a great number of these and also of *Asters* raised from seeds, which have been sent from *North America*, from whence most of the sorts here mentioned originally came. But as the seeds have been gathered by persons little acquainted with the science of botany, so they have generally been sent mixed together, which, when sown, the plants have risen promiscuously.

So that in order to ascertain the species, their seeds should be saved very carefully and distinctly sown, to see if the plants arising from each do retain their difference.

These plants are hardy, so will thrive in almost any situation in this country; and as they flower in autumn, when there is a scarcity of other sorts, so they are proper furniture for large gardens; for they do most of them propagate and spread so much at their roots, as to require more room than can well be spared in small gardens. But as they do not require much care in their cultivation, so they are fit for wood-walks, and to intermix with shrubs, where, when they are properly disposed, they will be very ornamental.

Some of the sorts begin to flower in the middle of July, which are succeeded by others till the end of November; and in favourable seasons there are two or three sorts, which frequently continue in flower till Christmas, so that for near five months these plants will, in succession, adorn the garden.

They are easily propagated by parting of their roots; the best time for doing this is soon after the flowers decay; for those which are parted in the spring, will not be well established in the ground before they begin to put out their stalks, so will not flower strong, unless the summer is wet, or the plants are duly watered, which is difficult to perform in large plantations.

When the roots of these sorts are well fixed in the ground, they may remain five or six years without transplanting; for if the ground about them is dug every winter, and such of the sorts as spread much at their root are reduced so as to keep them within proper limits, they will require no other culture. But in five or six years it will be proper to take up the roots, because in that time the middle of the bunch of roots will begin to decay; so the offsets should be taken off for to plant, and the old decayed roots thrown away.

The plants may also be propagated by seed; but these should be sown soon after they are ripe, for then they will more certainly grow than if sown in the spring, and the plants will come up the following spring; whereas those which are sown in the spring, generally remain a year in the ground before the plants appear.

When the plants come up, and have strength enough to be removed, they may be planted in a shady border at six inches distance, where they should remain till the following autumn, when they should be transplanted to the places where they are designed to remain, and the summer following they will flower.

SONCHUS, Sowthistle.

These are many of them weeds in England, so are not planted in gardens; for if their seeds are once permitted to scatter upon the ground, they will soon stock it with plants; for which reason they should always be extirpated, not only those in the garden, but also those in the parts near it; because their seeds being furnished with down, are waisted in the air to a considerable distance, where falling on the ground, they soon come up, and prove troublesome weeds.

SOPHORA. Lin. Gen. Plant. 456.

The Characters are,

The flower hath a short bell-shaped empalement, cut at the brim into five obtuse segments. The flower is of the butterfly kind; the standard is oblong, broad, and reflexed on the sides. It has two oblong wings with appendages to their base; the keel is of two leaves, like those of the wings, whose lower borders join like the keel of a boat. It has ten distinct stamina, which are awl-shaped, parallel, and the length of the petals hid in the keel, terminated by small summits, and a taper oblong germen, supporting a style the length of the stamina, crowned by an obtuse stigma. The germen afterward turns to a long slender pod, with swellings where each seed is posited.

The Species are,

1. SOPHORA foliis pinnatis, foliolis numerosis villosis oblongis. Lin. Sp. Plant. 373. Sophora with winged leaves, having a great number of oblong hairy lobes.

2. SOPHORA foliis pinnatis, foliolis numerosis subrotundis.

Lin. Sp. Plant. 373. Sophora with winged leaves, composed of many roundish lobes.

3. SOPHORA foliis ternatis subsessilibus, foliolis subrotundis glabris. Lin. Sp. Plant. 373. Sophora with trifoliate leaves fitting almost close to the stalks, whose lobes are roundish and smooth.

The first sort grows naturally in the *Levant*; this has a perennial creeping root, from which arise several erect stalks from three to four feet high, garnished with winged leaves, composed of a great number of oblong hairy lobes, ranged by pairs along the midrib, terminated by an odd one. The flowers come out from the wings of the stalk in long spikes, which stand erect close to the stalk; they are of a pale blue colour, and small. These appear in July, but are rarely succeeded by pods in England.

It propagates fast enough by its creeping root, in the same manner as Liquorice, when the plant is once obtained, and is very hardy, so should be planted in some corner of the garden, at a distance from other plants, because the roots of this plant will spread, and mix with those of the neighbouring plants, and soon over-bear them. It will thrive in almost any soil or situation, for I have frequently seen the roots spread into the middle of gravel-walks, and send up stalks.

The second sort grows naturally in the island of *Ceylon*, and also in the *West-Indies*, but particularly at *Jamaica*, where the inhabitants call it Sea-side Pigeon Pea; this rises with a downy stalk to the height of six or seven feet, garnished with winged leaves, composed of five or six pair of roundish woolly lobes, terminated by an odd one. The flowers come out in short loose spikes from the wings of the stalks; they are large and yellow, not much unlike those of *Spanish Broom*, but have no scent; these are succeeded by taper woolly pods five or six inches long, having four or five large swellings, in each of which is contained one roundish brown seed as large as Peas.

This plant is tender, so will not thrive in England out of a stove; it is propagated by seeds, which may be easily procured from the *West-Indies*, for the plants do not perfect them in England; these should be sown in pots, and plunged into a good hot-bed, where, if the seeds are good, the plants will appear in a month or six weeks. When these are fit to remove, they should be each transplanted into a separate pot, and plunged again into a hot bed of tanners bark, observing to shade them from the sun, till they have taken new root; after which they must be treated in the same way as other tender plants from the same countries, always keeping them in the bark-bed in the stove, and in the winter they should have but little water.

The third sort grows naturally in *Virginia* and *Philadelphia*; from both these places I have received the seeds; from this plant there was formerly a coarse sort of Indigo made in *America*, as there was from some other plants, before the true Indigo plants were introduced there: this has a perennial root, from which arise several stalks about a foot high, sending out from the bottom a great number of small branches, garnished with leaves, composed of three oval smooth lobes, joined together at the foot-stalk like other trifoliate leaves; they fit close to the branches. The flowers come out toward the end of the branches in short spikes; they are of the butterfly kind, yellow, and appear in July; they are often succeeded by short swelling pods, which in warm seasons come to maturity in England. The stalks of this decay to the root in autumn.

This is propagated by seeds, which should be sown on a warm border the beginning of April. The best way is to sow them in shallow drills for the more conveniently keeping the plants clean, for they must not be removed till the stalks decay in autumn, when they should be carefully taken

taken up, and planted in a warm border, where they are designed to remain.

SORBUS. *Tourn. Inst. R. H. 633.* The Service-tree.

The Characters are,

The flower has a spreading, concave, permanent empalement, indented in five parts; it has five roundish concave petals, which are inserted in the empalement, and about twenty awl shaped stamina, which are also inserted in the empalement, terminated by roundish summits. The germen is situated under the flower, supporting three slender styles, crowned by erect beaded stigmas; it afterward becomes a soft umbilicated fruit, inclosing three or four oblong cartilaginous seeds.

The Species are,

1. SORBUS *foliis pinnatis, utrinque glabris.* Hall. *Helv.* 250. Service-tree with winged leaves, which are smooth on both sides; called Quickbeam, Mountain Ash, and in the north Roan-tree.

2. SORBUS *foliis pinnatis, subtus tomentosus.* Hall. *Helv.* 351. Service-tree with winged leaves, which are woolly on their under side; the cultivated Service.

The first sort grows naturally in many parts of *England*, but in the southern counties they are seldom seen of any great magnitude, for the trees are commonly cut down, and reduced to underwood; but in the north of *England* and *Wales*, where they are permitted to grow, there are trees of a very large size. The stems are covered with a smooth gray bark; the branches while young have a purplish brown bark; the leaves are winged; they are composed of eight or nine pair of long narrow lobes, terminated by an odd one; they are sharply sawed on their edges; the leaves on the young trees in the spring are hoary on their under side, which about *Midsummer* goes off, and those upon the older branches have very little at any season. The flowers are produced in large bunches almost in form of umbels at the end of the branches; they are composed of five spreading concave petals, shaped like those of the Pear-tree, but smaller; these appear in *May*, and are succeeded by roundish berries, growing in large bunches, which have a depressed navel on the top, and turn red in autumn when they ripen.

This tree is cultivated in the nursery-gardens, and sold as a flowering shrub; if they were permitted to grow, they would rise to a great height, and have large stems. The leaves of this tree make a pretty variety when they are mixed with others, during the time of their flowering, and also in autumn. When their fruit is ripe, they make a pretty appearance, but the blackbirds and thrushes are so fond of this fruit, as to devour it as soon as it ripens; so that in those places where there is a plenty of these birds, there will not be any of the fruit left to be perfectly ripe; however, as it is good food for these songsters, where people have a desire of drawing a number of these birds about their habitations, they should plant a quantity of these trees for that purpose.

The second sort grows naturally in the warmer parts of *Europe*, where it rises to a great height, and becomes a large tree, but in *England* there are few of any large size. In the south of *France* and in *Italy*, the fruit is served up to the table in their deserts, but in *England* they have not been much esteemed, which has occasioned their being so little cultivated here. There are several varieties of this fruit, which differ from each other in size and shape, as Apples and Pears do; some of these are shaped like Catherine Pears, and are nearly as large; others are depressed at both ends, and shaped like Apples; but both these sorts will arise from seeds of the same tree, so that those, who are desirous of having the largest and best kinds, should propagate them by grafting or budding from those trees whose fruit are the fairest and best flavoured, as is practised for other fruits; these may be grafted or budded upon Pear-

stocks, which agree better with this tree than any other except their own, for they will not take upon Apple-stocks, nor do they thrive upon the Hawthorn or Medlar near so well, though the fruit of this tree approaches nearer to those than any other, and are not fit for the table till they are in a state of decay.

The several varieties of this tree differ in the number of their seeds, in the same manner as Pears, Apples, Quinces, and Medlars, some of them having but three seeds in each fruit, and others have four or five; so that, although one of the characters of this genus is, that the fruit has but three seeds, yet that must be understood to be of the wild sort, in which there are seldom more, but those of the cultivated kind are as uncertain as the fruit of Apples and Pears.

In *Italy* these trees are very common, where they have a great variety of sorts, which have been obtained from seeds; but I have not observed in the *English* gardens more than three, and those are yet but scarce, for there are at present but few large trees of the true Service in *England*, one of which was lately growing in the gardens formerly belonging to *John Tradescant* at *South-Lambeth*, near *Vauxhall* in *Surry*, who was a very curious collector of rare plants in king *Charles* the Second's time; which tree was near forty feet high, and produced a great quantity of fruit annually, which were shaped like Pears; and there are indeed some trees of middling growth in the gardens of *Henry Marsh*, Esq; at *Hammer-smith*, which produce fruit of the Apple shape (from whence several young plants have been raised of late in the nurseries near *London*); but these are small, compared to that in *John Tradescant's* garden.

There are great numbers of large trees of this Service growing wild about *Aubigny* in *France*, from whence his grace the late duke of *Richmond* brought a great quantity of the fruit, and from the seeds raised a great number of young plants in his garden at *Goodwood* in *Suffex*.

The leaves of this tree differ from those of the first, in their lobes being broader, and not so much sawed; they are also much more downy on their under side, and the young shoots of the tree are covered with a white down. The flowers are produced in larger and more diffused bunches, and are a little larger; but there are seldom more than two or three fruit produced upon each bunch. The stamina of the flowers are also longer than those of the wild sort, which are the only differences I can observe between them.

Both these sorts may be propagated by sowing their seeds in pots soon after the fruit is ripe, sheltering them under a common frame in winter, and plunging the pots into a moderate hot-bed in the spring, which will soon bring up the plants; when they are come up, they should be carefully kept clear from weeds, and in dry weather watered; but they should be soon exposed to the open air, for the only reason of putting them in a hot-bed, is to forward the growth of the seeds; but if, when the plants are come up, the bed is kept covered, it will draw the plants, and spoil them. In this bed the plants should remain until the middle of *October*, at which time their leaves will decay, when there should be a warm light spot of ground prepared to receive them, into which they should be planted in rows two feet asunder, and a foot distant in the rows, observing to take them up carefully, and to plant them as soon as possible, that their roots may not dry.

During the summer, the ground should be kept constantly clear from weeds, and in winter there should be a little mulch laid upon the surface of the ground about their roots, to protect them from being injured by frost, but in the spring the ground between them should be dug, burying the mulch therein; in doing of which you

must be careful not to cut or injure the roots of the plants.

In this nursery they may continue three or four years, according to their growth, when it will be proper to transplant them out where they are to remain; the best season for which is in *October*, or in the spring, just before they begin to shoot. The soil should be warm in which they are planted, and the situation defended from cold winds, in which place they will thrive, and produce fruit in a few years.

Those who raise many of these trees from seeds, will procure some varieties of the fruit, from which the best may be selected, and propagated for the table, and the others may be planted for variety in wildernesses or wood-walks, or may be used for stocks to graft the better kinds upon.

The wood of the wild Service-tree is much commended by the wheelwright for being all heart; and it is of great use for husbandmens tools, goads, &c. It is very white and smooth, so will polish pretty well.

There is a sort of this with variegated leaves, which is preserved by such as are curious in collecting the several sorts of striped plants, but there is no great beauty in it; it may be propagated by layers, or by being budded on the plain sort; but they become plain on a very rich soil.

These trees should have a moist strong soil, but will grow in the most exposed places, being extremely hardy, which renders them worthy of care, since they will thrive where few other trees will succeed.

SORREL. See *Acetosa*.

SOUTHERNWOOD. See *Abrotanum*.

SOWBREAD. See *Cyclamen*.

SPARTIUM. *Lin. Gen. Plant.* 765. The Broom-tree.

The Characters are,

The empalement of the flower is heart-shaped. The flower is of the butterfly kind; the standard is almost heart-shaped, large, and wholly reflexed; the wings are oblong, shorter than the standard, and annexed to the stamina; the keel is oblong, longer than the wings; the borders are hairy, and connected together, to which the stamina are inserted. It has ten unequal stamina, nine of which are joined together, and the under stands apart, with an oblong hairy germen, supporting a rising awl-shaped style, to which is fastened an oblong, hairy, inflexed stigma. The germen afterward becomes a long cylindrical obtuse pod, of one cell, opening with two valves, including several globular kidney shaped seeds.

The Species are,

1. SPARTIUM ramis oppositis teretibus apice floriferis, foliis lanceolatis. *Hort. Cliff.* 356. Commonly called Spanish Broom.

2. SPARTIUM ramis oppositis angulatis, foliis oppositis subulatis. *Lin. Sp. Plant.* 708. Radiated or starry Broom.

3. SPARTIUM ramis angulatis, racemis lateralibus, foliis lanceolatis. *Hort. Cliff.* 356. Broom with angular branches, flowers in bunches from the side, and spear-shaped leaves.

4. SPARTIUM ramis subteretibus, racemis lateralibus, foliis lineari-lanceolatis. Commonly called white Spanish Broom.

5. SPARTIUM foliis ternatis solitariisque, ramis inermibus angulosis. *Hort. Cliff.* 356. Common green Broom with a yellow flower.

6. SPARTIUM foliis ternatis, foliolis cuneiformibus, ramis inermibus angulatis. Portugal Broom with a large flower.

7. SPARTIUM foliis ternatis petiolatis, foliolis lineari-lanceolatis bisectis, ramis inermibus angulatis. Broom with trifoliolate leaves upon foot-stalks, linear spear-shaped lobes, which are hairy, and angular armed branches.

8. SPARTIUM foliis ternatis glabris sessilibus, ramis inermibus angulatis, leguminibus glabris. Broom with trifoliolate smooth leaves sitting close to the branches, which are angular and unarmed, and smooth pods.

9. SPARTIUM foliis solitariis ternatisque, ramis sexangula-

ribus apice floriferis. *Lin. Sp. Plant.* 709. Eastern Broom with round, smooth, compressed pods.

10. SPARTIUM foliis ternatis, ramis angulatis spinosis. *Hort. Cliff.* 356. Broom with trifoliolate leaves, and angular prickly branches; commonly called prickly Cytifus.

11. SPARTIUM caule arborecente ramofo aculeato, foliis cuneiformibus confertis, floribus solitariis alaribus. Prickly Broom with Purslain leaves; or Ebony of the *West-Indies*.

The first sort is the common Spanish Broom, which has been long cultivated in the English gardens for the sweetness of its flowers: of this there are two varieties, if not distinct species, which grow naturally in *Spain* and *Portugal*. The first, which is the common sort in *England*, has larger branches, and broader leaves than the other. The flowers are also larger, of a deeper yellow colour, and appear earlier than those of the other, which has been of late years introduced from *Portugal*.

Both these sorts have smooth flexible branches, which rise eight or ten feet high. The lower part of the branches are garnished with small, spear-shaped, smooth leaves; the flowers are disposed in a loose spike, terminating the branches; they are large, yellow, of the butterfly kind, have a strong agreeable odour, appear in *July*, and in cool seasons there is frequently a succession of flowers till *September*, which are succeeded by compressed pods, containing one row of kidney-shaped seeds, which ripen in autumn.

These plants are easily propagated by seeds, which should be sown in the spring upon a bed of common earth in a shady situation, where the plants will rise very freely; these must be kept clean from weeds the following summer, and in autumn they may be taken up and transplanted in a nursery, which should be chosen in a warm sheltered situation. In the taking up of the plants, there should be care taken not to tear the roots, for these send their roots deep into the ground, and are very apt to be torn if they are not raised out of the ground with a spade; they should be planted in rows three feet asunder, and at one foot distance in the rows. In this nursery they may remain a year or two to get strength, and then may be planted where they are to remain, for they do not succeed if they are removed large.

If the seeds of these sorts are permitted to scatter in autumn, the plants will come up in plenty in the spring without care, which may be transplanted the following autumn, and treated in the same way as those before mentioned. These shrubs are very ornamental to large wood-walks in gardens, but hares and rabbits are very fond of them; so that, unless they are screened from these animals, they will devour them in winter when they have a scarcity of other food.

The second sort grows naturally in *India*; this is a shrub of low growth, seldom rising more than three feet high, but divides into many spreading branches, so as to form a large bush. The branches are small, angular, and come out opposite; the leaves are very narrow, awl-shaped, and are placed round the stalk, spreading out like the points of a star; the flowers are disposed in small clusters at the end of the branches; they are yellow, but not more than half the size of those of the former, and have no scent; they are succeeded by short hairy pods, containing two or three small kidney-shaped seeds in each. This shrub makes a pretty appearance during the time of its continuing in flower, and, as it is hardy, deserves a place in gardens.

It is propagated by seeds, which should be sown in autumn, for those which are sown in the spring, seldom grow the same year; these may be sown in a bed of common earth in rows, for the more conveniently keeping the plants clean from weeds. The plants should remain in the seed-bed till the following autumn, when they may be either trans-

transplanted to the places where they are to remain, or in a nursery to grow a year or two to get strength, before they are planted out for good; but these plants will not bear transplanting when they are large, so should be removed while they are young.

The third sort rises with slender flexible stalks six or seven feet high, sending out slender Rush-like branches, which are angular, and toward the bottom are garnished with a few small spear-shaped leaves. The flowers are produced in small bunches, which come out from the side of the branches; they are very small, of the butterfly kind, and of a deep yellow colour; these are succeeded by short, oval, swelling pods, containing one large kidney-shaped seed; but unless the season is warm, the seeds do not ripen in *England*.

The fourth sort has a thick stalk, covered with a rugged bark when old; it rises eight or nine feet high, sending out many slender Rush-like branches of a silvery colour, almost taper, which have a few narrow spear-shaped leaves. The flowers are produced in very short spikes or clusters on the side of the branches; they are small, white, and are succeeded by large oval pods, containing one kidney-shaped seed.

These two sorts grow plentifully in *Spain* and *Portugal*, from both which countries the seeds may be easily procured. The seeds should be sown in the middle of *April* upon a bed of fresh light earth; but the best way will be to sow them in drills about half an inch deep. The drills should not be less than one foot asunder, and the seeds may be laid in the drills at about three inches distance, which will allow room for the plants to grow the first summer, for it will not be safe to remove them till the spring following. Although I have here directed the sowing of these seeds in *April*, yet it must be understood, if the season proves favourable, otherwise it will be better to defer it longer, for these seeds are as subject to perish in the ground by cold or wet, as are the Kidney-beans; therefore, when the season is favourable for sowing them, the seeds of the Broom may be safely sown.

But at *Michaëmas* some of the plants of each kind may be taken up and potted, to be sheltered in winter, for while they are young, they are in danger of suffering by frost; so these should be placed under a common hot-bed frame, to screen them from cold, but in mild weather they must be exposed daily to the open air.

Those plants which are left in the seed-bed, may be sheltered with mats, and some mulch laid about their roots to prevent the frost penetrating the ground; in the spring these may be transplanted in a warm situation, where they will do very well; but it is always necessary to have a plant or two of each sort in pots, that they may be sheltered in winter to preserve the sorts.

The fifth sort is the common Broom, which grows naturally in *England*, so is not often admitted into gardens, though, when it is in flower, it makes a much better appearance than many others which are costly; this rises with a flexible stalk four or five feet high, sending out many Rush-like angular branches. The lower part of the branches are garnished with trifoliate leaves, but upward they are single. The flowers come out upon short foot-stalks singly on the side of the branches toward the top; these are large, of the butterfly kind, and of a bright yellow colour. The flowers and branches of this sort are used in medicine.

The sixth sort grows naturally in *Portugal* and *Spain*; this has stronger stalks than our common Broom. The branches grow more erect, and have deeper angles; the leaves are all trifoliate, and much larger than those of the fifth, and the lobes are wedge-shaped; the flowers are lar-

ger, of a deeper yellow colour, and have longer foot-stalks. This is not so hardy as the last.

The seventh sort grows naturally in *Portugal*; this rises with a strong stalk like the former. The branches are angular, and grow erect; they are better furnished with leaves than either of the other sorts, which stand upon pretty long foot-stalks; the lobes are small, very narrow, and hairy; the flowers grow closer together, are larger, and of a deep yellow colour.

The eighth sort was brought from *Portugal*. The stalks and branches of this are slender, angular, and smooth, and are fully garnished with very narrow, trifoliate, smooth leaves, fitting close to the stalks. The flowers come out in long loose spikes at the end of the branches; they are large, of a bright yellow colour, and are succeeded by short compressed pods, which are smooth, containing small kidney-shaped seeds. This is by *Tournefort* made a *Cytisus*.

The ninth sort grows naturally in the *Levant*; this has slender stalks and branches, garnished with a few trifoliate and single leaves toward the bottom. The branches have six angles or furrows; the flowers are small, of a pale yellow colour, and are produced in loose spikes at the end of the branches, but are rarely succeeded by seeds in *England*.

The tenth sort grows naturally in *Italy* and *Spain* near the sea coast. The stalks rise five or six feet high, sending out many angular flexible branches, armed with long spines, upon which grow trifoliate leaves; the flowers are produced at the end of the branches in clusters, each standing upon a long foot-stalk; they are of a bright yellow colour, and are succeeded by short ligneous pods, with a thick border on their upper edges, containing three or four kidney-shaped seeds. This plant will not live abroad in *England*, unless it has a very warm situation.

These plants are raised from seeds in the same way as the first sort, and may be treated in the same manner.

The eleventh sort is very common in *Jamaica*, and several other places in the *West-Indies*, where the wood is cut, and sent to *England* under the title of Ebony, though it is not the true Ebony, which is a native of the eastern country, and is a plant of a very different genus. The wood of this *American* Ebony is of a fine greenish brown colour, and polishes very well, so is much coveted by the instrument makers, and is used for several purposes, being of a very hard durable nature.

This tree has a pretty thick stem, which rises twelve or fourteen feet high, covered with a rugged brown bark, dividing into spreading branches, which grow almost horizontal, and are armed with short, brown, crooked spines. The leaves are small, stiff, and wedge-shaped, coming out in clusters, and sit close to the branches. The flowers come out upon slender foot-stalks from the side of the branches singly; they are of the butterfly kind, of a bright yellow colour, and are succeeded by compressed moon-shaped pods, which inclose one kidney-shaped seed.

This plant is propagated by seeds, which must be procured from the countries of its natural growth. These should be sown in pots, filled with light fresh earth, early in the spring, and plunged into a good hot-bed of tanners bark. In about six weeks after the plants will appear, when they must be carefully treated (being very tender while young); they must have fresh air admitted to them every day, when the weather is warm, and should be frequently refreshed with water, when the earth in the pots appears dry. In about five or six weeks after the plants appear, they will be fit to transplant, when they should be carefully shaken out of the pots, and separated, planting each into a small pot, and plunged into the hot-bed again, being careful to shade them from the sun every day until they have taken root; after which time they must be treated

in the same manner as other tender exotick plants, by giving them air every day in warm weather, and watering them once in two or three days gently, and when the nights are cold, to cover the glasses. In this hot-bed the plants may remain till autumn, when they must be removed into the stove, and plunged into the bark-bed. Those of them whose roots have filled the pots, should be carefully shifted into pots one size larger, before they are plunged; but as these plants are not of quick growth while young, they do not require to be often shifted out of the pots. During the winter season these plants must be kept warm (especially the first year), and must have but little water; and in cold weather it must be given to them in small quantities. As these plants are very tender, they will not live in the open air in this country, even in the warmest part of the year; therefore they must be constantly kept in the stove, and should be plunged in the bark-bed, observing in the summer season, when the weather is warm, to admit a large share of fresh air to the plants. With this management the plants will thrive very well, and in a few years will produce their flowers, when they will make a pretty appearance in the stove.

SPERGULA. *Dillen. Gen. Nov. 7. Lin. Gen. Plant. 519.* Spurrey.

The Characters are,

The flower has a spreading permanent empalement. It has five oval, concave, spreading petals, which are larger than the empalement, and ten awl-shaped stamina shorter than the petals, terminated by roundish summits. It has an oval germen, supporting five slender, erect, reflexed styles, crowned by thick stigmas. The germen afterward turns to an oval close capsule with one cell, opening with five valves, inclosing many depressed, globular, bordered seeds.

The Species are,

1. SPERGULA *foliis verticillatis, floribus decandris.* Hort. Cliff. 173. Spurrey with leaves in whorls, and flowers with ten stamina.

2. SPERGULA *foliis verticillatis, floribus pentandris.* Lin. Sp. Plant. 440. Spurrey with whorled leaves, and flowers with five stamina.

3. SPERGULA *foliis oppositis subulatis lævibus, caulibus simplicibus.* Lin. Sp. Plant. 440. Spurrey with awl-shaped smooth leaves placed opposite, and single stalks.

There are some other species of this genus, which grow naturally as weeds in England, so are not worthy notice here; nor should I have mentioned these, were they not sometimes cultivated.

The first and second sorts are cultivated in Holland and Flanders for feeding their cattle; the usual time of sowing the seed is in July or August, that the plants may acquire strength before the winter's cold. The use that is made of this is to feed sheep, and other cattle, in winter and spring, when the common Grass fails. This plant seldom rises above six inches high, so will not afford a very great quantity of food; but as it will grow on the poorest land, it may be cultivated in many places to good advantage, where no other Grass will thrive so well, and by feeding it off the ground, the dung of the cattle will improve the land. This pasture, it is affirmed, will make excellent butter, and the mutton fed on it is said to be well tasted, so is by many preferred to that fed on Turneps. Hens will greedily eat this herb, and it makes them lay more eggs.

This plant being annual, must be sown every year; and whoever is willing to save the seeds, should sow it in April, that the plants may flower the beginning of July, and the seeds will ripen in August; when it must be cut before the heads are quite brown, otherwise the seeds will soon scatter.

The seeds being very small, about twelve pounds will be sufficient to sow an acre of land. The ground should be well harrowed before the seeds are sown, for if the larger clods are not broken, there will be an uneven crop of Grass. People in the low country sow this seed after a crop of Corn is taken off the land. The second sort is now much cultivated in Flanders, though it is a much lower plant than the common sort; but they esteem it a much better Grass. The seeds of this kind are smaller and flatter than those of the common sort, and have a white border round each.

SPERMACOCE. *Dill. Hort. Elth. 277. Lin. Gen. Plant. 111.* Button-weed.

The Characters are,

The flower has a permanent empalement, indented in four parts, sitting on the germen. It has one cylindrical petal, whose tube is longer than the empalement, and the brim indented in four parts. It has four awl-shaped stamina shorter than the petal, terminated by single summits; and a roundish compressed germen, situated under the flower, supporting a single style, divided in two parts at the top, crowned by obtuse stigmas. The germen afterward turns to two oblong seeds, which are joined, having two horns, and are convexed on one side, and plain on the other.

The Species are,

1. SPERMACOCE *glabro, staminibus inclusis.* Lin. Sp. Plant. 102. Smooth Spermacoce with stamina included in the flower.

2. SPERMACOCE *glabra, staminibus extantibus.* Lin. Sp. Plant. 102. Smooth Spermacoce with stamina standing out of the flowers.

The first sort grows to the height of two feet and a half; the stalks are stiff, a little angular, and covered with a brown bark; the branches and leaves come out by pairs; the leaves are smooth, and have one strong vein or midrib. The flowers grow in slender whorls toward the top of the stalks; they are small, white, and sit close to the stalks, having a whorl of small leaves close under them; these are succeeded by two oblong seeds, having small horns, which ripen in the empalement.

The second sort rises with a shrubby stalk three or four feet high, sending out a few slender branches, which are garnished with narrow leaves not so long as those of the former; they are smooth, of a light green, and stand in a kind of whorls round the stalk. The flowers grow in thick globular whorls toward the top of the stalk, one of which terminates the stalk; they are small, very white, and funnel-shaped. The brim is cut into four obtuse segments, which spread open, and the stamina stand out above the tube of the flower. After the flowers are past, the germen turns to two seeds, shaped like those of the former sort.

These plants grow naturally in moist places in Jamaica; the inhabitants call the second sort Button-weed. They are both propagated by seeds, which must be sown upon a hot-bed; and when the plants come up, they must be transplanted on a fresh hot-bed to bring them forward, and afterward treated in the same way as other tender plants, and, if they are placed in a stove, they will live through the winter, and produce good seeds the following year.

SPHÆRANTHUS. *Vaill. Aët. Par. 1719.* Globe-flower.

The Characters are,

The flowers are composed of hermaphrodite florets, and female half florets, which are included in one globular scaly empalement, garnished with them on every side the receptacle. There are several of these florets included in each partial empalement. The hermaphrodite florets are placed in the center; they are funnel shaped, and cut into five parts at the brim, having five very short hair-like stamina, terminated by cylindrical summits, and a germen supporting a thick style, having a single stigma; these are barren. The female half florets are situated round the border, and have scarce any petals,

but

but an oblong germen supporting a bristly style, crowned by a double stigma; these have one oblong naked seed.

The Species are,

1. SPHÆRANTHUS *pedunculis lateralibus unifloris*. Globe-flower with foot-stalks on the side with one flower.
2. SPHÆRANTHUS *pedunculis ramosis terminalibus*. Globe-flower with branching foot-stalks terminating the branches.

The first sort grows naturally in *India*; this rises with an herbaceous stalk about a foot high, which rarely branches out, garnished with spear-shaped leaves, whose base fits close to the stalk, and from them is extended a leafy border or wing along the stalk; they are sawed on their edges, and are of a deep green, standing alternate. The foot-stalks of the flowers come out from the side of the stalk, opposite to the leaf; they are about two inches long, and sustain one globular head of flowers at the top, of a purplish red colour; these are succeeded by oblong seeds, situated on the margin, which are naked.

The second sort grows naturally at *Madras*, and also at *La Vera Cruz*, in *New Spain*, where it was discovered by the late Dr. *Houssoun*. This rises with an herbaceous winged stalk about ten inches high, garnished with oval, spear-shaped, sawed leaves, placed alternately. The upper part of the stalk branches out into small divisions, which are terminated by foot stalks, sustaining three or four globular flowers, of a pale yellow colour.

These are both annual plants, which require a hot bed to bring them forward in the spring; and if the summer proves cold, they must be kept in a glass case, otherwise they will not ripen seeds here.

SPHONDYLIIUM. *Tourn. Inst. R. H. 219. tab. 170.* Cow Parsnep.

The Characters are,

It has an umbellated flower. The principal umbel is composed of many smaller, which are flat; the involucre of the general umbel has many leaves which decay; the particular ones have from three to seven leaves; the general umbel is difformed. The flowers in the middle or disk have five equal, crooked, inflexed petals. Those of the rays are unequal. They have five stamina, which are longer than the petals, terminated by small summits, and an oval germen, situated under the flower, supporting two short styles, crowned by single stigmas. The germen afterward turns to an elliptical compressed fruit, furrowed on each side, containing two compressed leafy seeds.

The Species are,

1. SPHONDYLIIUM *foliolis latioribus pinnatifidis, radiis umbellis maximarum*. Common hairy Cow Parsnep.
2. SPHONDYLIIUM *foliolis angustioribus pinnatifidis serratis, radiis umbellarum minoribus*. Hairy Cow Parsnep with narrower leaves.
3. SPHONDYLIIUM *foliolis pinnatifidis obtusis, petiolis bipidis, radiis umbellarum inæqualibus*. Greatest eastern Cow Parsnep.
4. SPHONDYLIIUM *foliis pinnatis utrinque scabris, floribus radiatis*. Small Alpine Cow Parsnep.
5. SPHONDYLIIUM *foliis simplicibus glabris floribus radiatis*. Smooth Alpine Cow Parsnep.

The first sort grows naturally by the side of brooks, ditches, and in moist meadows in many parts of *England*. The root of this plant is taper, fleshy, and shoots deep in the ground. The lower leaves are large and winged, composed of three pair of large lobes, placed along the midrib, terminated by an odd one; the lobes are also cut into two or three pair of wings almost to the midrib, terminated by an odd one. The foot-stalks of the leaves are very hairy; the leaves are of a deep green on their upper side, but are pale on their under, and are rough to the touch; the stalks are garnished at each joint with one leaf, of the same shape with those at bottom, but smaller, whose base embrace the

stalks. The flowers terminate the stalks in large umbels, which are composed of about twenty-two partial umbels, every third having longer foot-stalks than the others. The partial umbels have many large flowers, which are barren, and compose the rays; those of the disk or middle are smaller and fruitful, and are each succeeded by two flat bordered seeds.

The second sort grows naturally in moist meadows near *Battersea* in *Surry*, and in other parts of *England*; this has been supposed only a feminal variety of the first, but I have cultivated it in the garden near thirty years, and have always found the plants which were raised from seeds, kept their difference. The leaves of this sort are composed of two or three pair of narrow lobes, terminated by an odd one; the wings of the lobes are very narrow, acute-pointed, and are cut almost to the midrib; they are hairy, and of a lighter green than those of the former; the umbels are much smaller, as are also the flowers and seeds, in which it greatly differs from the former.

The third sort grows naturally in the *Levant*, and also in *Siberia*. The leaves of this are very broad; their foot-stalks are armed with prickly hairs, and are deeply channelled on their upper side; they are composed of two or three pair of very broad, smooth, obtuse lobes, terminated by an odd one, of a yellowish green colour. The stalks rise eight or ten feet high; they are channelled, and sustain umbels of flowers at the top, which are smaller than those of either of the two former sorts, and the flowers are yellow.

The fourth sort grows naturally on the *Alps*. The stalks of this do not rise more than one foot and a half high; the leaves are divided to the midrib; the lobes are a little cut on their edges, are of a deep green, and rough on both sides; the umbels of flowers are small and white.

The fifth sort grows naturally on the *Alps* and *Apennines*. The stalks of this rise almost three feet high; the leaves of this are smooth, divided into three lobes, but not very deep, and are indented about the edges. The stalks are terminated by small umbels of white flowers, which are succeeded by small, compressed, bordered seeds.

These are all very hardy plants, which may be propagated by seeds; the best time for sowing them is in autumn, soon after they are ripe. They should be sown where the plants are designed to remain, because they send forth tap-roots somewhat like those of the Parsnep, therefore do not thrive so well when transplanted, as if suffered to remain where they are sown. The plants grow very large, therefore the seeds should be sown in drills, at two feet and a half, or three feet distance; and in the spring, when the plants appear, they should be thinned, so as to leave them at least eighteen inches asunder in the rows; after which they will require no farther care, but to keep them clear from weeds; and when the plants have obtained strength, they will not easily be injured by weeds, for they will overbear them, and prevent their getting up. The second year these plants will produce flowers and seeds, and their roots soon after die; if their seeds are permitted to scatter, they will fill the neighbouring ground, and become troublesome weeds.

SPIGELIA. *Lin. Gen. Plant. 192.* Arapabaca. *Plum. Nov. Gen. 10. tab. 31.* Worm-grass.

The Characters are,

The flower has a permanent empalement of one leaf, which is cut into five acute points; it has one funnel-shaped petal, whose tube is longer than the empalement, cut into five points at the brim, which spread open. It has five stamina, terminated by single summits, and a germen, composed of two globular lobes, supporting one awl-shaped style the length of the tube, crowned by a single stigma. The germen afterward becomes two globular seed-vessels, which are joined, sitting in the empalement.

The Species are,

1. SPIGELIA *caule erecto, foliis quaternis sessilibus, spicis terminalibus.* Worm-seed with an erect stalk, and leaves growing by fours sitting close to the stalks, which are terminated by spikes of flowers.

2. SPIGELIA *foliis oppositis ovato-oblongis acuminatis sessilibus, spicis terminalibus.* Worm-grass with oblong acute-pointed leaves growing opposite, sitting close to the stalks, which are terminated by spikes of flowers.

The first sort grows naturally in moist places in most of the islands of the *West-Indies*. It is an annual plant with a fibrous root, from which arises a strong, erect, herbaceous stalk near a foot and a half high, which is channelled, and sends out two side branches opposite near the bottom, and a little above the middle is garnished with four oblong, oval, acute-pointed leaves, placed in form of a cross round the stalk; and at the same joint comes out two small side branches opposite; these, and also the principal stalk, have four smaller leaves near the top, sitting round in the same manner as the other; and from these arise short spikes of herbaceous flowers, ranged on one side the foot-stalk. These are succeeded by roundish twin capsules, which contain the seeds.

This plant is esteemed the most efficacious medicine for the worms yet known, and has been long used by the inhabitants of the *Brazils* as such, and also by the negroes, who taught the inhabitants of the *British* islands in *America* the use of it, where it has had great success; and from thence had the appellation of Worm-grass given to it.

It is too tender to thrive in the open air in *England*, so the seeds should be sown in pots, filled with soft loamy earth in the autumn, and plunged into the bark-bed in the stove, where they should remain till the spring, when they should be plunged into a fresh hot-bed, which will bring up the plants; these must be afterward planted into separate pots, and plunged into another hot-bed, and shaded till they have taken new root; after which they must be treated in the same way as other tender annual plants from the same countries, keeping them constantly in the hot bed under cover, otherwise they will not perfect their seeds in *England*.

The second sort grows naturally in *Carolina*, where the inhabitants call it *Indian Pink*. This has a perennial fibrous root, from which arise two or three erect herbaceous stalks about seven or eight inches high, garnished with three or four pair of oval, oblong, acute-pointed, smooth leaves, placed opposite, sitting pretty close to the stalk. The stalk is terminated by a short spike of flowers, which are ranged on one side; they have short empalements, which are cut into five acute segments. The tube of the flower is long, narrow at the bottom, swelling upward much larger, and is cut at the brim into five acute segments, which spread open flat; the outside of the flower is of a bright red, and the inside of a deep Orange colour. The seeds of this sort never ripen here.

This plant is used in *Carolina* for the same purposes as the other in the *West-Indies*, and is esteemed the best medicine there known for the worms. A particular account of the virtues of this plant is mentioned in the first volume of the *Philosophical Essays*, printed at *Edinburgh*, communicated by Dr. *Garden* of *Carolina*.

This is not easily propagated in *England*, for the roots make but slow increase, so that the plant is not very common in the *English* gardens at present; for although it is so hardy as to endure the cold of our ordinary winters in the open air, yet, as it does not ripen seeds, the only way of propagating it is by parting of the roots; and as these do not make much increase by offsets, so the plants are scarce. It delights in a moist soil, and must not be often transplanted.

SPINA ALBA. See *Mespilus*.

SPINACIA. *Tourn. Inst. R. H. 533. tab. 308.* Spinach; or Spinage.

The Characters are,

It is male and female in different plants; the male flowers have an empalement cut into five oblong, obtuse, concave segments, but no petals, with five hair-like stamina longer than the empalement, terminated by oblong twin summits; these are barren. The female flowers have permanent empalements of one leaf, cut into four points, two of which are very small; they have no petals, but a compressed roundish germen, supporting four hair-like styles, crowned by single stigmas. The germen afterward turns to a roundish seed, which is stout up in the empalement; in some species they are almost smooth, and in others they have two or three sharp thorns.

The Species are,

1. SPINACIA *foliis sagittatis seminibus aculeatis.* Spinach with arrow pointed leaves and prickly seeds; or common prickly Spinach.

2. SPINACIA *foliis oblongo-ovatis, seminibus glabris.* Spinach with oblong oval leaves, and smooth seeds.

The first sort was formerly more cultivated in the *English* gardens than at present, because it is much hardier, so not in much danger from cold, therefore is generally cultivated for use in winter. The leaves of this are triangular, and shaped like the point of an arrow; the stalks are hollow, branching, and herbaceous; they rise about two feet high. The male flowers are produced in long spikes; they are herbaceous, having no petals, but each has five slender stamina, terminated by oblong twin summits, filled with a yellowish farina, which, when ripe, flies out on the plants being shaken, and spreads all round; these plants, after their farina is shed, soon decay. The female flowers which are upon separate plants, sit in clusters close to the stalks at every joint; they are small, herbaceous, and have neither stamina or petals, but have roundish compressed germen, which afterward turns to roundish seeds, armed with short acute spines.

There are two or three varieties of this now cultivated in the kitchen-gardens, which differ in the size and shape of their leaves, and their seeds being more or less prickly.

The seeds of the first kind should be sown upon an open spot of ground in *August*, observing, if possible, to do it when there is an appearance of rain; for, if the season should prove dry for a long time after the seed is sown, the plants will not come up regularly; part of them may come up soon, and a great part of them may remain till rain falls; before they come up, which, if that should not happen in a little time after, many times there will not be half a crop. When the Spinach is come up pretty strong, the ground should be hoed to destroy the weeds, and also to cut up the plants where they are too close, leaving the remaining plants about three or four inches asunder; but this should always be done in dry weather, that the weeds may be destroyed soon after they are cut.

About a month or five weeks after the first hoeing, the weeds will begin to grow again; therefore the ground should be then hoed the second time, observing, as before, to do it in dry weather. But if the season should prove moist, it will be proper to gather the weeds up after they are cut, and carry them off the ground; for if the Spinach is not cleaned from weeds before winter, they will grow up, and stifle it so, that in wet weather the Spinach will rot away.

In the end of *October* the Spinach will be fit for use, when you should only crop off the largest outer leaves, leaving those in the center of the plants to grow bigger; and thus you may continue cropping it all the winter and spring, until the young Spinach, sowed in the spring, is large enough for use,

use, which is commonly in *April*; at which time the spring advancing, the winter Spinach will run up to seed; so that it should be all cut up, leaving only a small parcel to produce seeds if wanted.

But the ground in which this winter Spinach is sown, being commonly planted with early Cabbages, it is not proper to let any of the Spinach remain there for seed; therefore it should be cleared off as soon as ever the Spring Spinach is fit for use, that the Cabbages may be earthed up, and laid clear, which is of great service to them; wherefore you should sow a small spot of ground with this sort of Spinach, on purpose to stand for seed, where there should be no other plants among it.

The second sort differs from the first in having oval thick leaves, which are not angular at their base; the seeds are smooth, having no spines, and the stalks and leaves are much more fleshy and succulent. Of this there are two or three varieties, which differ in the thickness and size of their leaves, which in one are much rounder and thicker than the other.

These are sown in the spring upon an open spot of ground by themselves, or else mixed with Radish-seed, as is the common practice of the *London* gardeners, who always endeavour to have as many crops from their land in a season as possible; but where land is cheap in the country, it will be the better method to sow it alone without any other sort of seed mixed with it; and when the plants are come up, the ground should be hoed to destroy the weeds, and cut out the plants where they are too close, leaving the remaining about three inches asunder; and when they are grown so large as to meet, you may then cut out a part of it for use, thinning the plants, that they may have room to spread; and this thinning may be twice performed, as there is occasion for the herb; at the last of which the roots should be left eight or ten inches asunder; and if then you hoe the ground over again to destroy the weeds, it will be of great service to the Spinach, for if the land is good upon which it is sown, the sort with broad thick leaves, commonly called Plantain Spinach, will, with this management, many times produce leaves as large as the broad-leaved Dock, and be extremely fine.

But in order to have a succession of Spinach through the season, it will be proper to sow the seed at several different times in the spring, the first in *January*, which must be on a dry soil; the second the beginning of *February*, upon a moister soil; the third the beginning of *March*, which should be on a moist soil; and the fourth the beginning of *April*; another in *May*; but these late sowings should be hoed out thinner at the first time than either of the former, for there will be no necessity to leave it for cutting out thin for use, because the former sowings will be sufficient to supply the table till these are full grown; besides, by leaving it thin at first, it will not be apt to run up to seed so soon as it would, if the plants were close.

These sowings here mentioned are such as are practised by the kitchen-gardeners near *London*; but, as this herb is much used in soups, &c. for great tables, there should be some seeds sown every three weeks, during the summer season, to supply the kitchen; but these late sowings should be on moist strong ground, otherwise, if the season proves hot and dry, the Spinach will run to seed before the plants are fit for use, especially if the plants do not stand thin.

In order to save seeds of either of these kinds, you should sow an open rich spot of ground, with the sort you intend, in *February*, after the danger of frost is over; and when the plants are come up, they should be hoed out to six or eight inches distance, observing to cut down the weeds at the same time; and when the plants have grown about three weeks or a month longer, they

should be hoed a second time, when they should be left twelve or fourteen inches asunder at least, for when they have shot out their side branches, they will sufficiently spread over the ground.

You must also observe to keep them clear from weeds, which, if suffered to grow amongst the Spinach, will cause it to run up weak, and greatly injure it. When the plants have run up to flower, you will easily perceive two sorts amongst them, *viz.* male and female. The male will produce spikes of staminate flowers, which contain the farina, and are absolutely necessary to impregnate the embryos of the female plants, in order to render the seeds prolific. These male plants are, by the gardeners, commonly called She Spinach, and are often by the ignorant pulled up as soon as they can be distinguished from the female, in order, as they pretend, to give room for the seed bearing to spread; but, from several experiments which I made on these plants, I find, where-ever the male plants are entirely removed before the farina is shed over the female plants, the seed will not grow which they produce, so that it is absolutely necessary to leave a few of them in every part of the spot, though there may be a great many drawn out where they are too thick, for a small quantity of male plants (if rightly situated) will be sufficient to impregnate a great number of female, because they greatly abound with the farina, which, when ripe, will spread to a considerable distance, when the plants are shaken by the wind.

When the seeds are ripe (which may be known by their changing their colour, and beginning to shatter), the plants should be drawn up, and spread abroad for a few days to dry, observing to turn them every other day, that the seeds on both sides may dry equally; you must also guard the seeds from birds, otherwise they will devour them. When it is dry, the seeds should be threshed out, cleaned from the dirt, and laid up for use, where mice cannot come to them, for they are extremely fond of this seed.

SPIRÆA. *Tourn. Inst. R. H.* 618. *tab.* 389. Spiræa Frutex.

The Characters are,

The flower has a permanent empalement of one leaf, plain at the base, and cut into five acute segments at the top; it has five roundish oblong petals inserted in the empalement, and twenty or more slender stamina, which are shorter than the petals, and are inserted in the empalement, terminated by roundish summits, and five or more germen, supporting as many slender styles, which are longer than the stamina, crowned by beaded stigmas. The germen afterward turns to an oblong, acute-pointed, compressed capsule, opening with two valves, containing a few small acute-pointed seeds.

The Species are,

1. SPIRÆA foliis lanceolatis obtusis serratis nudis, floribus duplicato racemosis. *Hort. Cliff.* 191. Common Spiræa Frutex.
2. SPIRÆA foliis lobatis serratis, corymbis terminalibus. *Lin. Sp. Plant.* 489. Spiræa with lobated sawed leaves, and flowers growing in a corymbus, terminating the stalks; commonly called *Virginia Gelder Rose* with a *Currant leaf*.
3. SPIRÆA foliis integerrimis, umbellis sessilibus. *Hort. Ups.* 131. Spiræa with entire leaves, and umbels of flowers sitting close to the branches; commonly called *Hypericum Frutex*.
4. SPIRÆA foliis oblongiusculis apice serratis, corymbis lateralibus. *Lin. Sp. Plant.* 489. Spiræa with oblong leaves, whose points are sawed, and flowers growing in a corymbus on the sides of the branches.
5. SPIRÆA foliis lanceolatis inæqualiter serratis subtus tomentosis, floribus duplicato-racemosis. *Lin. Sp. Plant.* 480. Spiræa with spear-shaped leaves, which are unequally sawed, and woolly on their under side, and flowers growing in doubly-branching bunches; or *Red Spiræa*.

6. *SPIRÆA foliis pinnatis, foliolis uniformibus serratis, caule fruticoso, floribus paniculatis.* Lin. Sp. Plant. 490. Spiræa with winged leaves, whose lobes are uniformly sawed, a shrubby stalk, and flowers growing in panicles.

7. *SPIRÆA foliis lanceolatis supernè serratis nervosis, subtus incanis, floribus racemosis, caule fruticoso.* Spiræa with spear-shaped veined leaves, which are sawed toward their points, and hoary on their under side, flowers growing in long bunches, and a shrubby stalk.

8. *SPIRÆA foliis lanceolatis acutè serratis, floribus paniculatis, caule fruticoso.* Spiræa with spear-shaped leaves, which are sharply sawed, flowers growing in panicles, and a shrubby stalk.

9. *SPIRÆA foliis ternatis serratis subæqualibus, floribus subpaniculatis.* Lin. Sp. Plant. 490. Spiræa with trifoliate sawed leaves, which are almost equal, and flowers growing in a kind of panicle.

10. *SPIRÆA foliis pinnatis, foliolis uniformibus serratis, caule herbaceo, floribus cymosis.* Lin. Sp. Plant. 480. Spiræa with winged leaves, having uniform sawed lobes, an herbaceous stalk, and flowers growing on slender foot-stalks at the top; the common Dropwort.

11. *SPIRÆA foliis pinnatis, impari majore lobato, floribus cymosis.* Flor. Lapp. 201. Spiræa with winged leaves, whose outer lobe is greater, and divided into lobes, and flowers growing in bunches on weak foot-stalks; Meadow-sweet, or Queen of the Meadows.

12. *SPIRÆA foliis supra decompositis, spicis paniculatis, floribus divisis.* Lin. Sp. Plant. 490. Spiræa with more than decomposed leaves, paniculated spikes, and male and female flowers.

The first sort has been long cultivated in the *English* gardens, but from what country it originally came, is not very certain; it is generally sold by the nursery-gardeners with other flowering shrubs; it rises with several shrubby stalks, which are very taper, and rough toward the top, covered with a reddish bark. The leaves are spear-shaped, bluntly sawed on their edges, and of a bright green colour. In rich moist ground the stalks will rise six or eight feet high, but in moderate land from four to five. The branches are terminated by spikes of pale red flowers; the lower part of the spikes are branched out into small spikes, but the upper parts are close and obtuse. Each flower is composed of five petals, which spread open, of a pale red or flesh colour, and have a great number of stamina, some of which stand out much beyond the petals, but others are not so long, terminated by brown headed summits; and in the center are situated five styles, which are terminated by headed stigmas. After the flowers are past, the germen turns to pointed capsules, but they rarely come to perfection here.

This is propagated from suckers, which are sent forth in plenty from the stems of the old plants, or by laying down the tender branches, which, when rooted, should be transplanted out in rows at three feet distance, and the plants a foot asunder in the rows. In this nursery they may remain two years, observing to keep the ground clear from weeds, and in the spring to dig up the ground between the rows, so that the roots may the more easily extend themselves; but, if they put out suckers from their roots, those should be taken off to keep the shrubs within bounds, and afterwards they may be transplanted where they are to remain, either in small wilderness quarters, or in clumps of flowering shrubs, observing to place them amongst other sorts of equal growth; the young shoots of this shrub, being very tough and pliable, are often used for the tops of fishing rods.

The second sort grows naturally in *North America*, but is now as common in the *English* gardens as the first; this rises with many shrubby branching stalks sometimes eight

or ten feet high in good ground, but generally five or six feet high, covered with a loose brown bark, which falls off, and are garnished with lobed leaves, about the size and shape of those of the common Currant Bush, ending in acute points, sawed on their edges. The flowers are produced in roundish bunches at the end of the branches; they are white, with some spots of a pale red. This is commonly known in the nurseries by the title of *Virginia Gelder Rose* with a Currant leaf. It may be propagated and managed in the same manner as the former, and is equally hardy.

The third sort came originally from *Canada*, but is now as common in the nursery-gardens as either of the former, where it is known by the title of *Hypericum Frutex*, but has no affinity to *St. Johnswort*, and is only so called from the resemblance of their leaves; this rises with several slender shrubby stalks five or six feet high, covered with a dark brown bark, sending out small side branches, garnished with small, wedge shaped, entire leaves, which have many punctures on their surface like *St. Johnswort*. The flowers are disposed in small umbels, which sit close to the stalks, each flower standing upon a long slender foot-stalk; they are white, composed of five roundish petals, which spread open, and in the center have a great number of stamina, almost equal in length with the petals. The shrubs make a good appearance during the time of their flowering.

This may be propagated by laying down the under branches, which will take root in the compass of one year, when they may be taken off, and planted in a nursery for two or three years (as hath been directed for the former); after which they may be transplanted out where they are designed to remain, placing them with the two former, being nearly of the same growth, where they will add to the variety.

The fourth sort grows naturally in *Spain*; this is not very common at present in the *English* gardens. The whole appearance of the shrub is so like the third, as not to be distinguished at a small distance; the only difference being, that the leaves of this are broader at the point, where they have two or three indentures. The flowers are like those of the former. This may be propagated in the same way as the other.

The fifth sort grows naturally in *Philadelphia*; this is a shrub of lower stature than the former. The stalks are slender, and branch out near the ground; they have a purple bark, covered with a gray mealy down. The leaves are spear-shaped, but smaller than those of the first sort, and are unequally sawed; they are downy, and veined on their under side, but are of a bright green above. The branches are terminated by a thick racemus of flowers, which are branched toward the bottom into small spikes; the flowers are very small, of a beautiful red colour, and the spikes of this are longer than those of the first.

The sixth sort grows naturally in *Siberia* upon moist land; this is a shrub of humble growth in this country, seldom rising more than two feet high, putting out some side branches, which are covered with a purple bark, and garnished with winged leaves, composed of three or four pair of oblong, oval, thin lobes, sawed on their edges. The flowers are produced in panicles at the end of the branches; they are small, white, and of the same construction with the former.

The seventh sort grows naturally in *North America*; this has a shrubby stalk, which rises five or six feet high, covered with a brown bark, dividing into many strong branches, which are closely garnished toward their end with spear-shaped veined leaves, hoary on their under side, and are sawed on their edges toward their points. The flowers are white, and disposed in a racemus.

The eighth sort grows naturally in *North America*; this rises with shrubby stalks like the first, but sends out horizontal branches which are slender, and covered with a brown bark. The leaves are spear-shaped, of a thin texture, and of a bright green colour on both sides; they are slightly sawed on their edges, but the saws are acute. The flowers are disposed in panicles at the end of the branches; they are small, white, and of the same construction of the former.

These sorts are propagated in the same way as the first, but, as some of them do not put out suckers from their roots here in any plenty, their branches should be laid down in autumn, which in one year will take root, and may then be planted where they are designed to remain, or into a nursery, where they may stand one or two years to get strength, before they are planted out for good.

The ninth sort grows naturally in *North America*; this has a perennial root, but the stalks are annual, and rise about a foot high, sending out branches from the side their whole length; these are garnished with leaves, which for the most part are trifoliate, but are sometimes single, and at others by pairs, sharply sawed on their edges, of a bright green on their upper side, and pale on their under. The flowers are disposed in loose panicles at the top of the stalks, standing upon slender foot-stalks; they have five long spear-shaped petals, which spread open, and a great many stamina, which are no longer than the tube of the flower.

It is propagated by seeds, which should be sown on a shady border soon after they are ripe, for if they are sown in the spring, the plants will not come up till the year after, and many times fail. When the plants appear, they must be constantly kept clean from weeds; but they should not be removed till autumn, when their leaves begin to decay; then they may be either transplanted where they are designed to remain, or into a nursery border, where they may grow a year or two to get strength, before they are planted out for good. This plant loves a shady situation and a moist light soil.

The tenth sort is the common Dropwort, which grows plentifully upon chalky grounds in many parts of *England*. The roots of this consist of a great number of oval knobs or glandules, which are fastened together by slender fibres, from whence it had the title of Dropwort; the leaves are winged, and composed of many sawed lobes, which are almost placed alternately along the midrib; those near the base are the smallest, the others increase in size to the middle, afterward decrease again to the point. The flower-stalk rises a foot or more in height, and has seldom more than one leaf upon it; the top is garnished with loose bunches of small white flowers, standing upon slender foot-stalks, which are succeeded by several capsules, ranged circularly. The roots of these plants are used in medicine, and are accounted diuretick. It is rarely kept in gardens, but there is a variety of this with double flowers, which was found growing naturally in the north of *England*, that is kept in gardens for the sake of variety.

The eleventh sort grows naturally on the sides of waters, and in low moist meadows, in most parts of *England*. The stalks are angular, red, and rise three or four feet high, garnished with winged leaves, composed of two or three pair of large indented lobes, terminated by an odd one, which is much larger than the other, and divided into three lobes; they are of a dark green on their upper side, but hoary on their under. The stalks are terminated by large loose bunches of white flowers, which have an agreeable scent, and are succeeded by roundish capsules, twisted like a screw, filled with small seeds.

The leaves and tops of this plant are used in medicine, but the plants are rarely kept in gardens. There is a va-

riety of it with double flowers, which is kept in some gardens, and one with variegated leaves.

The twelfth sort grows naturally upon the mountains in *Austria*; this has a perennial root and an annual stalk, which rises from three to four feet high, garnished with decomposed winged leaves, composed of several doubly-winged leaves, each having three or four pair of oblong lobes, terminated by an odd one, sawed on their edges, and ending in acute points. The flowers are disposed in loose spikes, which are formed into loose panicles at the top of the stalks; they are small, white, and of two sexes in the same spike. The seeds rarely ripen here.

This plant is kept in gardens for the sake of variety; it may be propagated by parting of the root in autumn; it loves a moist soil and a shady situation.

SPIRÆA OF AFRICA. See Diosma.

SPONDIAS. The *Jamaica Plum*.

The Characters are,

The flower has five oblong spear-shaped petals, and a small permanent coloured empalement, with ten scaly obtuse nectariums, situated between the petals, and ten bristly stamina shorter than the petals, with oblong summits; the oblong germen, which is immersed in the receptacle, supports five short parallel styles, joined in a five cornered column, crowned by a simple stigma; and afterward becomes an oblong fleshy berry, inclosing a hard oblong nut, covered with fibres, having five cells.

We have but one Species of this genus at present in the *English gardens*, viz.

SPONDIAS foliis pinnatis, pinnis acuminatis serratis. The yellow, or *Jamaica Plum*.

This tree is of humble stature, seldom rising more than twelve or fourteen feet high in the *West-Indies*, but in *England* is rarely more than half that height; the bark is brown, the leaves are very long, composed of a great number of pinnæ, placed alternate along the midrib, terminated by an odd one; these are sawed on their edges, and end in acute points. The flowers terminate the branches in a racemus, and are of a whitish yellow colour, some of which are succeeded by oblong fleshy berries, of a pale yellow colour, covered with a mealy farina; the flesh of which is but thin, of a luscious sweet taste. The nut inclosed appears as if composed of many ligneous fibres.

The fruit of this sort is esteemed by some of the inhabitants of the islands in the *West-Indies*; but as the flesh is very thin, so a great number of the Plums will afford but little meat: however, the wild hogs are very fond of them, and it is their principal food during the season of their ripening.

The trees are easily propagated in *America*, by planting some of the branches which readily take root in the rainy seasons. The cuttings will also grow in *England*, if properly managed; but here they are generally raised from the fruit, which are frequently brought from some of the islands in *America*, which, when fresh, come up very readily. The *Leeward Islands* generally furnish the best, as their passage is not so long as from *Jamaica*. The nuts should be planted as soon as they arrive in pots, which should be plunged into a hot-bed of tan, where, if the bed is of a good temperature of heat, the plants will appear in a month or five weeks after. When the plants have obtained strength enough to be removed, they should be shaken out of the pots, and carefully parted, planting them in separate small pots, and plunging them into a fresh hot-bed of tan, shading them daily from the sun until they have taken new root; after which they should have air, and be supplied with water in proportion to the warmth of the season; but they are too tender to thrive in the open air in *England* in the warmest season, therefore should be constantly kept in the bark-stove, and, if carefully managed, will ripen their fruit here. The

plants generally drop their leaves in spring, and often remain naked two or three months.

SQUASHES. See Pepo.

SQUILLS. See Scilla.

STACHYS. *Tourn. Inst. R. H. 186. tab. 86.* Base Horehound.

The Characters are,

The flower has a tubulous permanent empalement, cut into five acute parts at the top; it has one lip-shaped petal with a short tube, having oblong chaps. The upper lip is erect, hooked, and a little indented at the point, and cut into three parts. It has four awl-shaped stamina, two of which are longer, and inclined to the upper lip; the other two are shorter, terminated by single summits, and a four-pointed germen, supporting a slender style the length of the stamina, crowned by a bifid acute stigma. The germen afterward turns to four oblong angular seeds, which ripen in the empalement.

The Species are,

1. STACHYS caule erecto sulcato tomentoso, foliis ovato-lanceolatis tomentosis crenatis, verticillis piloso-tomentosis. Base Horehound with an erect, furrowed, woolly stalk, oval, spear-shaped, woolly leaves, which are crenated, and woolly whorls of flowers.

2. STACHYS verticillis triginta floris, calycibus pungentibus. *Hort. Upsal. 170.* Base Horehound with thirty flowers in the whorls, and prickly empalements.

3. STACHYS foliis lineari-lanceolatis tomentosis subcrenatis, petiolis longissimis, caule fruticoso tomentoso. Base Horehound with narrow, spear-shaped, woolly leaves, which are somewhat crenated, with very long foot-stalks, and have a shrubby woolly stalk.

4. STACHYS foliis oblongo ovatis crenatis pilosis, calycibus pungentibus, labii superiore piloso. Base Horehound with oblong, oval, crenated, hairy leaves, prickly empalements to the flowers, and the upper lip hairy.

5. STACHYS foliis cordatis obtusè serratis, verticillis minoribus lanuginosis, calycibus acutis. Base Horehound with heart-shaped, obtuse, sawed leaves, smaller whorls of flowers, which are woolly, and acute empalements to the flowers.

6. STACHYS foliis inferioribus ovato-oblongis subcrenatis subtus tomentosis, caulibus cordatis acutis sessilibus, calycibus spinosis. Base Horehound with oval, oblong, lower leaves, which are slightly crenated, and woolly on their under side, those on the stalks being heart-shaped, acute-pointed, and fitting close to the stalks, and prickly empalements to the flowers.

7. STACHYS ramis ramosissimis, foliis lanceolatis glabris. *Hort. Cliff. 310.* Base Horehound with very spreading branches, and smooth spear-shaped leaves.

8. STACHYS verticillis sexfloris, foliis lineari lanceolatis semiamplexicaulis. *Flor. Suec. 490.* Base Horehound with whorls of six flowers, and narrow spear-shaped leaves, which half embrace the stalk.

The first and last sort here mentioned, grow naturally in England; the first only in a few particular places, but the latter is common by the side of ditches and waters every where, and is here only mentioned, because it is a dispensary plant, and has been supposed a good vulnerary herb. Of this there is another species, which was found by Mr. Stonestreet growing wild, with narrow leaves, shorter stalks, longer and closer spikes of flowers, and the leaves stand distinct upon short foot-stalks: this has constantly retained its difference in the garden. Both these sorts have creeping roots, so will soon spread over a large spot of ground where they have liberty.

The seventh sort grows naturally in Crete; this is a low plant with an herbaceous stalk, which is very branchy from the bottom. The stalks are slender, four-cornered, and

smooth, garnished with a few small spear-shaped leaves: the whole plant is very clammy, and smells like bitumen. The flowers are small, of a dirty white colour, and stand in small whorls round the stalks; these appear in July, and are succeeded by roundish seeds, which ripen in autumn. This is propagated by seeds, and requires to be sheltered under a frame in winter, being too tender to live in the open air here.

The other sorts are kept in botanick gardens for the sake of variety, but are not cultivated in other places, so it will be needless to give a particular description of them here.

They are all propagated by seeds, which should be sown in March upon a bed of light fresh earth; and when the plants are come up, they may be planted out into other beds about six inches asunder, observing to water them until they have taken root; after which they will require no farther care, but to keep them clear from weeds till Michaelmas, when they should be transplanted where they are to remain, which must be in an open situation, and upon a dry light soil, not rich, in which they will endure the winter much better than in good ground. The summer following these plants will flower, and in August their seeds will ripen, when they may be gathered and preserved till spring for sowing.

STÆHELINA. *Lin. Gen. Plant. 844.*

The Characters are,

The common empalement of the flower is oblong, cylindrical, and imbricated; the scales are reflexed; the flower is composed of several uniform funnel-shaped florets, of one petal. The brim is cut into five equal acute points; they have each five hair-like stamina, terminated by cylindrical summits, and a short crowned germen, supporting a slender style, crowned by a double oblong stigma. The germen afterward becomes a short four-cornered seed, crowned with a feathery down, which ripens in the empalement.

The Species are,

1. STÆHELINA foliis tomentosis, squamis calycinis lanceolatis. *Lin. Sp. Plant. 840.* Stæhelina with woolly leaves, and spear-shaped scales to the empalement.

2. STÆHELINA foliis subtrigonis, squamis calycinis crenatis. *Lin. Sp. Plant. 840.* Stæhelina with leaves which are almost three-cornered, and crenated stalks to the empalement.

The first sort grows naturally at the Cape of Good Hope, from whence it was introduced into the Dutch gardens; this rises with a shrubby stalk about three feet high, which divides into several branches, garnished with long taper woolly leaves, set thinly. The flowers are produced at the end of the branches in single heads, which are pretty large, and have scaly empalements; these terminate in spines, and are recurved; they are composed of several florets, which are tubulous, hermaphrodite, and of a yellow colour, each of which is succeeded by a single four-cornered seed, crowned with a feathery down, ripening in the empalement, each being separated by a chaffy scale.

The second sort is a native of the same country; this is a low shrub, seldom rising more than two feet high, sending out many slender branches, which are garnished with leaves placed alternate; there is a small knob or angle just under that part where the leaf is inserted to the branch; the leaves are narrow, and have three blunt angles or corners. The branches are terminated by a single flower, whose empalement is oval, and like those of the flowers of Knapweed, being imbricated. The scales are oblong, oval, and their points are rounded; some of them have a large membranaceous border, whose edge is crenated, and spread open; the florets are yellow and equal, of the same length as the empalement; they are all hermaphrodite, and have a bifid stigma, and the seeds have a little hairy down on their top.

As these plants do not always ripen their seeds in *England*, so they are generally propagated by cuttings, which, if planted in any of the summer months, and covered close with a bell or hand-glass, will take root pretty freely. When these have made good roots, they should be taken up carefully, and planted in pots, filled with fresh light earth, not too rich, and placed in the shade until they have taken new root; then they should be removed to a sheltered situation, where they may be intermixed with other exotic plants till the autumn, when they must be removed into shelter, and treated in the same way as other plants from the same country. These plants do not require any artificial heat in winter, but should have a dry air, for their tender shoots are very subject to rot with damp; therefore they will thrive better in a glass-case than a green-house in winter.

STAPELIA. *Lin. Gen. Plant.* 271. Swallow-wort, or *Fritillaria crassa*.

The Characters are,

The flower has a permanent empalement of one leaf, cut into five acute segments; it has one large plain petal, cut into five acute segments above the middle, and a plain five-pointed starry nectarium, with linear segments, whose torn points surround the parts of generation; it has five plain, broad, erect stamina, with linear summits fastened on each side the stamina, and two oval plain germen, having no style, crowned by a blunt stigma. The germen afterward turns to two oblong taper pods, filled with compressed seeds, crowned with a feathery down, lying over each other like the scales of fish.

The Species are,

1. STAPELIA *denticulis ramorum patentibus*. *Vir. Cliff.* 20. Stapelia with spreading indentures to the branches; commonly called *Fritillaria crassa*.

2. STAPELIA *denticulis ramorum erectis*. *Hort. Cliff.* 77. Stapelia with erect indentures to the branches.

There is another species of this genus, which has been lately introduced into the *English* gardens, whose branches are larger, more erect, and the indentures are not so erect as those of the second sort; but, as it has not produced flowers in this country, nor is described in books, so I cannot say more of it, only that it is not so hardy as either of the former, therefore requires a stove in winter to preserve it in *England*.

There is also a variety of the first sort mentioned in some books, with flat crested branches, and is by some gardeners titled *Coxcomb Fritillary*; but this is no other than an exuberance of branches joined together, which become flat, so will return back to its original again, therefore is not worthy notice.

The first sort hath many succulent branches arising from the root, which are five or six inches long, having several protuberant indentures on their sides, spreading open horizontally, ending in acute points; the branches which spread on the ground, emit roots from their joints; so where they have room will extend very wide. The branches abound with a viscous juice of a nauseous taste. From the side of the branches toward their bottom comes out the foot-stalk of the flower at one of the sinuses, and sustains one flower, having a large thick petal cut half way into five points like a star, which spreads open flat, greenish on the outside, but yellow within, having a circle of purple round the nectarii; and the whole petal is finely spotted with purple, resembling the belly of a frog. In the center are the five compressed nectarii which are prominent, of a livid colour, which include the genital parts. The flower when blown has a very foetid odour, like that of carrion, so like, as that the common flesh fly deposit their eggs on it, which frequently are hatched, but wanting proper food, die soon after; for I have many years watched the progress of these, to see if

the maggots produced from these eggs ever eat any part of the flower, or lived any time; but could never observe either, nor have ever heard that any other person of credit has ever discovered any thing like it, though it has been asserted, by persons of more assurance than knowledge, that they have devoured great part of the petal, and come to maturity, changing afterward into their last state of flies. After the flowers are past, the double germen changes into two taper pods, joined at their base, which are near a span long, and almost as thick as a man's little finger, which are filled with flat seeds, crowned with a feathery down, lying over each other like the scales of fish; but these pods are seldom formed in *England*, unless the pots in which they grow are plunged in tanners bark; for in upward of forty years which I have cultivated these plants, I never saw them produce their pods but three times, and those were plunged into the tan-bed in the stove.

The branches of the second sort are much larger than those of the first, and stand more erect, but spread and emit roots in the same way; they have four longitudinal furrows, which divide them into four angles, which have protuberant indentures on their edges, whose points are erect; they are nearly of the same colour as those of the first, being of a dark green in summer, but inclining to purple in autumn. The flowers come out upon short foot-stalks from the side of the branches; these are of the form with those of the former, but are larger; the petal is of a thicker substance, and on the inside covered with fine purplish soft hairs; the ground of the flower is an herbaceous yellow, streaked and chequered with purplish lines. This sort produces its flowers in much greater plenty than the first sort, so that in summer and autumn they are seldom long destitute of flowers; but I have never seen any of the pods of this sort produced in *England*.

Both these plants grow naturally upon the rocks near the *Cape of Good Hope*, where they strike their roots into the crevices of the rocks and spread themselves greatly. They are propagated here very easily, by taking off any of the side branches, during any of the summer months, which, when planted, put out roots very freely. The branches should be slipped off from the plants to the bottom, where they are joined by a small ligature, so will not occasion a great wound, the joints at the place where they are connected being almost closed round; for if they are cut through the branch, the wound will be so great as to occasion their rotting when planted; these should be laid in a dry place under cover for eight or ten days, that the wounded part may dry and heal over, before they are planted, otherwise they will rot; then they should be planted in pots, filled with earth, composed of fresh sandy earth, mixed with lime rubbish and sea sand; and if the pots are plunged into a very moderate hot-bed, it will promote their taking root; they should be now and then sprinkled with water, but it must be given them sparingly, and as soon as they have taken root, they must be inured to the open air. If these plants are kept in a very moderate stove in winter, and in summer placed in an airy glass-case, where they may enjoy much free air, but screened from wet and cold, they will thrive and flower very well, for although they will live in the open air in summer, and may be kept through the winter in a good green-house, yet these plants will not flower so well as those managed in the other way. These plants must have little water given them, especially in winter.

STAPHYLÆA. *Lin. Gen. Plant.* 336. Bladder Nut.

The Characters are,

The empalement is concave, coloured, and so large as to inclose the flower, which has five oblong erect petals, and a pitcher-shaped concave nectarium at the bottom of the flower, with five oblong erect styles, terminated by single summits, and a thick germen, divided

divided in three parts, supporting three styles, to which there are obtuse stigmas contiguous. The germen afterward becomes two hard almost globular seeds, included in three bladders, joined by a longitudinal seam, with an acute point opening within.

The Species are,

1. STAPHYLÆA foliis pinnatis. Hort. Cliff. 112. Bladder Nut with winged leaves.

2. STAPHYLÆA foliis ternatis. Hort. Cliff. 112. Bladder Nut with trifoliate leaves; or three-leaved *Virginian* Bladder Nut.

The first sort grows naturally in woods in several parts of *England*, but is cultivated as a flowering shrub in the nursery-gardens. This hath several shrubby stalks arising from the same root, which grow ten or twelve feet high, covered with a smooth bark, and divide into several branches, which are pithy, garnished with winged leaves, composed of two pair of oval lobes, terminated by an odd one; these differ greatly in size according to the strength and vigour of the shrubs. They are smooth, entire, and of a light green colour, standing upon pretty long foot-stalks. The flowers come out upon long slender foot-stalks, which hang downward; these spring from the wings of the stalks near their extremity, and are disposed in oblong bunches; they have each five oblong white petals, which expand in form of a Rose; these are succeeded by inflated capsules or bladders, composed of three cells, one or two of which have a roundish, smooth, hard seed, and the other are barren.

This shrub makes a variety when intermixed with others, though their flowers are not very beautiful. The nuts of this tree being hard and smooth, are strung for beads by the Roman Catholicks in some countries; and the children of the poor inhabitants eat the nuts, though they have a disagreeable taste.

The second sort grows naturally in *North America*, but is now become as common in the nursery-gardens about *London* as the other. This hath a more substantial stalk than the first; the bark of the older branches and stalks is smooth, and of a gray colour; that of the young is of a light green and very smooth; the leaves are by threes on each foot-stalk; the lobes are oval, ending in a point, and their edges are sawed; they are of different sizes, according to the age and strength of the plants; they are smooth, and of a light green colour. The flowers are produced from the side of branches, in longer bunches than those of the former sort, but their foot-stalks are much shorter; the flowers are of a cleaner white, and their petals are somewhat larger than those of the first, as are also the Bladder capsules; the seeds are larger, and ripen better than those of the common sort.

Both these sorts are usually propagated by suckers, from the root which the first sort sends out in plenty; these should be taken from the old plants in autumn, and their roots trimmed, then planted in a nursery, in rows at three feet distance, and one foot asunder in the rows. In this nursery the plants should stand one or two years, according to their strength, and then be transplanted to the places where they are to remain.

The plants which are propagated in this manner from suckers, are very subject to put out suckers in greater plenty from their roots than those which are raised from seeds, or propagated by layers or cuttings, so are not to be chosen when the other can be had; therefore those who propagate them for their own use, should prefer the other methods. If they are propagated by layers, the young branches should be laid down in autumn, in the same manner as is practised for other trees and shrubs; these will have put out roots the following autumn, when they may be taken from the old plants, and planted in a nursery, where they may grow one or two years to get strength, and then may be removed to the places where they are to stand.

When these are propagated by cuttings, it should be the shoots of the former year, and if they have a small piece of the two years wood at the bottom, they will more certainly succeed; for as the young shoots are soft and pithy, so they are very subject to rot, when they have no part of the old wood to them. They should be planted in autumn on a shady border, but must not have too much wet.

They may also be propagated by sowing their seeds early in autumn, in beds of light fresh earth; and when the plants are come up, they must be carefully kept clear from weeds, and, in very dry weather, if they are now and then refreshed with water, it will greatly promote their growth; in these beds they may remain until *October* following, at which time they should be carefully taken up, and planted in a nursery, placing them in rows three feet asunder, and the plants one foot distance in the rows; and, if the following spring should prove very dry, it will be convenient to give them a little water, to encourage their taking root; after which they will require no farther care, but to keep the ground clear from weeds in summer, and every spring to prune off irregular branches, and dig the ground between the rows, to loosen the earth, that their roots may the more easily extend. In this nursery they may remain two years, by which time it will be proper to transplant them out where they are to remain, either in wilderness quarters, or in clumps of various trees, where they will add to the diversity. The best season for transplanting these trees is in autumn, with other deciduous trees. When these seeds are sown in the spring, the plants seldom come up till the following year.

AFRICAN BLADDER NUT. See *Royena*.

LAUREL-LEAVED AMERICAN BLADDER NUT. See *Ptelea*.

STAR-FLOWER. See *Ornithogalum*.

STARWORT. See *Aster*.

STATICE. *Journ. Inst. R. H.* 341. tab. 177. Thrift, or Sea Pink.

The Characters are,

The flowers are collected in a roundish head, surrounded by a common scaly empalement; each flower has also a funnel shaped empalement of one leaf; the flowers are funnel-shaped; the base of the petals are narrow, their points broad, and spread open; they have five stamina which are shorter than the petals, terminated by prostrate summits; and a small germen, supporting five styles, which stand apart, crowned by acute stigmas. The germen afterward turns to one small roundish seed, inclosed in the empalement.

The Species are,

1. STATICE foliis lanceolato-linearibus, squamis calycinis inferioribus acutis. Thrift with spear-shaped linear leaves, and the lower scales of the empalement acute-pointed.

2. STATICE foliis linearibus subulatis, squamis calycinis obtusis. Thrift with linear awl-shaped leaves, and obtuse scales to the empalement.

3. STATICE foliis linearibus planis, squamis calycinis obtusis. Thrift with plain linear leaves, and obtuse scales to the empalement; or Sea Pink.

The first sort grows naturally on the *Alps*, and other cold mountains in several parts of *Europe*. This has a perennial fibrous root, from which come out many narrow, smooth, spear-shaped leaves, of a dark green colour, sitting close over each other at their base. The foot-stalks of the flowers are naked, and rise about a foot high, terminated by one globular head, containing several small, pale, red flowers, which are included in one common scaly empalement; immediately under the flower is placed five narrow leaves, which afterward fall off. The flowers are succeeded by oblong seeds, which are closely wrapped up in the particular empalement of the flower. There are two varieties

of this, one with white flowers, and the other a bright red.

The second sort is also a native of the *Alps*, and other cold mountains, where it seldom rises more than two inches high, but when it is planted in gardens, it becomes much larger. The roots of this are fibrous and perennial; they divide into heads, which have a great number of narrow Grass-like leaves, fitting close round the heads, whose base embrace the stems, and lie over each other. The stalks are naked, and rise about six inches high, sustaining on their tops heads of pale purplish flowers, inclosed in one common scaly empalement, whose scales are broad, and rounded at their points.

The third sort grows naturally in salt marshes, where the sea flows over them frequently, in many parts of *England*, so is very rarely admitted into gardens. The leaves of this sort are very narrow, short, and plain; the stalks seldom rise more than three or four inches high; the heads of flowers are small, and the flowers are of a very pale flesh colour, so make but little appearance.

There was some years past another species of this genus in the *English* gardens, which came from *Portugal*, with a thick perennial stalk, which by age became shrubby, and rose a foot and a half in height; the leaves like those of the first sort, but much larger; the foot-stalks of the flowers were a foot and a half long, naked, and terminated by one large globular head of flowers, of a pale red colour; but all the plants of this kind which were in *England*, the severe frost in the beginning of the year 1740 destroyed, since which time I have not seen one plant.

The second sort was formerly planted in gardens, to make edgings on the sides of borders in the flower-gardens; for which purpose they were then in great esteem, but of late they have been very justly rejected, because there was a necessity of transplanting these edgings every year, otherwise they could not be kept within due bounds; besides, wherever a plant failed, which was no extraordinary thing, there always appeared a large unsightly gap; however, though they are not in use at present for that purpose, yet a few plants of the first and second should have a place in some part of the flower-garden for variety, especially the variety with red flowers; they will grow in almost any soil or situation, and their flowers will continue a long time in beauty, especially in a shady situation.

All these sorts may be propagated by parting their roots; the best time for which is in autumn, that they may take root before the frost, for these will flower much stronger than those transplanted in the spring; and the plants will not be in so much danger of miscarrying, especially when the spring happens to prove dry. After these plants have taken root, they will require no farther care, but to keep them clear from weeds, and to transplant and part their roots annually, for if they are permitted to stand longer unremoved, they are very subject to rot and decay, especially when they are planted in good ground.

STEWARTIA. *Lin. Gen. Plant.* 758.

The Characters are,

The flower has a permanent empalement, cut into five oval concave segments; it has five large oval petals, which spread open, and a great number of slender stamina, joined in a cylinder at bottom, and are shorter than the petals, to which they are connected at their base, terminated by roundish prostrate summits, with a roundish hairy germen, supporting five styles the length of the stamina, crowned by obtuse stigmas. The germen afterward turns to a five-cornered capsule with five cells, opening with five valves, whose cells are closed, each containing one oval compressed seed.

We have but one Species of this genus, viz.

STEWARTIA. *Art. Upsal.* 1741. *Stewartia.*

This shrub grows naturally in *Virginia*, where it rises with strong ligneous stalks to the height of ten or twelve feet, covered with a brown bark, and garnished with oval spear-shaped leaves, sawed on their edges, and pretty much veined, standing alternately. The flowers are produced from the wings of the stalk; their empalements are of one leaf, cut into five obtuse segments almost to the bottom. The flower is of one petal (according to *Ray* and *Tournefort*) which is cut into five parts almost to the bottom, but their base are connected together, and fall off united; the segments are narrow at their base, but spread open, are broad, and obtuse at their points, and hollowed like a spoon in the middle; they are white, but one of the segments in each flower is stained with an herbaceous yellow colour. In the center of the flower arise five styles, which are surrounded by a circle of purple stamina, terminated by roundish blue summits. The stamina are inserted to the base of the petals, so form at their base one body, being there connected together. The fruit of this is a conical, dry, ligneous capsule, having five sharp angles, and five cells, which open at the top with five valves, each cell containing one oblong smooth seed.

This shrub is at present very rare in the *English* gardens. The seeds are seldom brought to *England*, and those frequently fail, either by their not having been properly impregnated, or duly ripened, for I have examined several which have been hollow, having only a shell; and the plants which do come up, are very difficult to maintain while young, for if they are exposed to too much sun, they will soon be destroyed, nor do they thrive when exposed to the open air. The only way in which I have seen the young plants succeed was, when they were sown under glasses, and the surface of the ground between the plants was covered with moss to keep the ground moist, and the glasses were constantly shaded every day when the sun was bright. With this management the plants seemed in good health, but made little progress in their growth.

STOCK GILLIFLOWER. See *Cheiranthus*.

STOEBE. *Lin. Gen. Plant.* 839.

The Characters are,

The flower is composed of many hermaphrodite florets, included in one common empalement, whose scales are awl-shaped and permanent; between each scale is situated one floret, whose empalement is composed of five narrow acute leaves, which are equal and erect. The florets are funnel-shaped, of one petal, cut into five points at the brim; they have five short hair-like stamina, terminated by cylindrical summits, and an oblong germen, supporting a slender style, crowned by a bifid acute stigma. The germen afterward becomes a single seed, crowned with a long feathery down, sitting in the common empalement.

We have but one Species of this genus, viz.

STOEBE. *Hort. Cliff.* 390. *Stoebe.*

This plant grows naturally at the *Cape of Good Hope*; it is perennial, having a ligneous stalk, which rises two or three feet high, sending out slender branches from the sides, garnished with short linear leaves, that are for the most part hooked, of a grayish colour, and placed irregularly round the branches. The flowers are produced in single heads at the end of the branches; they are of a pale yellow colour, and are composed of several hermaphrodite florets, included in one common empalement, whose scales lie over each other like those of fish. The florets are single, and peep out between the scales of the empalement.

It is propagated by cuttings or slips, which should be planted in *July* upon a bed of soft loam, and covered close down either with a bell or hand-glass, shading them every day from the sun till they have taken root; then they must be gradually inured to the open air, and afterward taken up, and planted in pots, placing them in the shade till they

they have taken new root; then they may be placed in a sheltered situation with other tender exotic plants, and in autumn they must be removed into shelter, for they are too tender to live through the winter in the open air in *England*.

STOECHAS. *Tourn. Inst. R. H. 201. tab. 95.* Cassidony, *French* Lavender, or Stickadore.

The Characters are,

The flower has an oval permanent empalement, whose brim has some obscure indentures; it is of the lip kind, having a cylindrical tube longer than the empalement, whose brim spreads open. The upper lip is large, bifid, and open; the under lip is cut into three roundish almost equal segments. It has four stamina within the tube, which are turned aside, two of which are shorter than the other, terminated by small summits, and a quadrifid germen, supporting a slender style the length of the tube, crowned by an obtuse indented stigma. The germen afterward turns to four almost oval seeds, which ripen in the empalement. To which the following notes must be added: the flowers are ranged in several series, and the spikes are terminated by tufts of leaves.

The Species are,

1. STOECHAS foliis lanceolato-linearibus, pedunculis brevioribus. Stoechas with spear-shaped linear leaves, and shorter foot-stalks to the flowers.

2. STOECHAS foliis lanceolato-linearibus, pedunculis longissimis. Stoechas with spear-shaped linear leaves, and the longest foot-stalks to the flowers.

3. STOECHAS foliis pinnato-dentatis. Stoechas with wing-indented leaves.

The first sort grows naturally in the south of *France* and *Spain*, from whence the tops or heads of flowers are imported to *England* for medicinal use; this has a low, thick, shrubby stalk, which rises about two feet high, sending out ligneous branches the whole length, which are garnished with spear-shaped linear leaves about an inch long, which are hoary and pointed, of a strong aromattick scent, and stand opposite on the branches at each joint, with smaller leaves of the same shape, coming out at the same places. The branches are terminated with scaly spikes of purple flowers about an inch in length; the spikes are four-cornered; the scales lie over each other like those of fish; out of each scale peeps one lip flower, whose tube is the length of the scale, so the two lips only appear; the under is spread open, and the upper stands erect. The spike of flowers is terminated by a small tuft of purple leaves like the Clary of *Matthiolus*; the flowers are succeeded by oval seeds, which ripen in autumn. The whole plant has a very strong, aromattick, agreeable odour.

The heads of flowers of this kind are used in some of the capital medicines directed by the College of Physicians, which are commonly brought from the south of *France*, where the plants are in great plenty; but, as these are seldom imported, and very little care taken in the drying and packing them, they are very apt to take a mouldiness in their passage, and are not near so good for use as those which are gathered fresh in *England*, where the plants may be cultivated to great advantage.

The second sort grows naturally in *Spain*. The difference between this and the first consists in the foot-stalks, which sustains the spikes of flowers, being three times the length of those of the first sort, and naked, having no leaves. The spikes of flowers are longer, and not so thick, and have more coloured leaves on their tops, which are longer, and of a brighter purple colour. These differences are not accidental, for I have many years propagated this plant by seeds, and have always found the plants produced were the same. Of both these there are some plants which vary in the colour of their flowers, some producing white, and others purplish flowers, but the most common colour is blue.

These plants may be cultivated by sowing their seeds upon a bed of light dry soil in *March*, and when they come up, they should be carefully cleared from weeds until they are two inches high, at which time they should be removed; therefore there must be a spot of light dry ground prepared, and laid level, which must be trodden out in beds, into which the plants should be planted at about five or six inches distance each way, observing to water and shade them until they have taken root; after which they will require no further care, but to keep them clear from weeds the following summer; but, if the winter should prove severe, it will be proper to cover them with mats, Peas haulm, or some other light covering, to guard them against the frost, which otherwise would be apt to injure them while they are so young; but in *March*, or the beginning of *April*, the following spring, they must be removed into the places where they are to remain, observing, if possible, to transplant them in a warm moist season, and not to let them remain long above ground, for if their roots are dried, they seldom grow well after. The soil in which these are planted, should be a dry warm sand or gravel, and the poorer the soil is in which they are planted, the better they will endure the cold of the winter, provided the ground be dry, though indeed the plants will thrive better in summer upon a rich moist ground; but then they will not produce so many flowers, nor will the heads or spikes have near so strong an aromattick scent, as is the case with most sorts of aromattick plants.

These plants may also be propagated by planting slips or cuttings of any of the kinds in the spring, observing to refresh them with water until they have taken root; after which they may be managed as hath been directed for the seedling plants; but, as those plants raised from seeds are much better than these, it is hardly worth while to propagate them this way, especially since their seeds ripen so well in this country.

The heads of the first sorts may be gathered for use when the flowers are in full perfection, and spread to dry in a shady place, after which they may be put up for use.

The third sort grows naturally in *Andalusia* in *Spain*, and also about *Murcia*; this has a ligneous stalk, which rises two or three feet high, furnished with branches on every side, which are four-cornered, and garnished with leaves, placed opposite by pairs, indented regularly on both sides, almost to the midrib, in form of winged leaves; they are of a grayish colour, have a pleasant aromattick odour and biting warm taste. The flowers are produced in scaly spikes at the end of the branches, standing upon long naked foot-stalks; they are four-cornered, hairy, and about an inch long, terminated by a few purplish leaves in the like manner as the other sorts, which inclined me to keep it joined to them. It flowers great part of summer, but the seeds very rarely ripen in *England*.

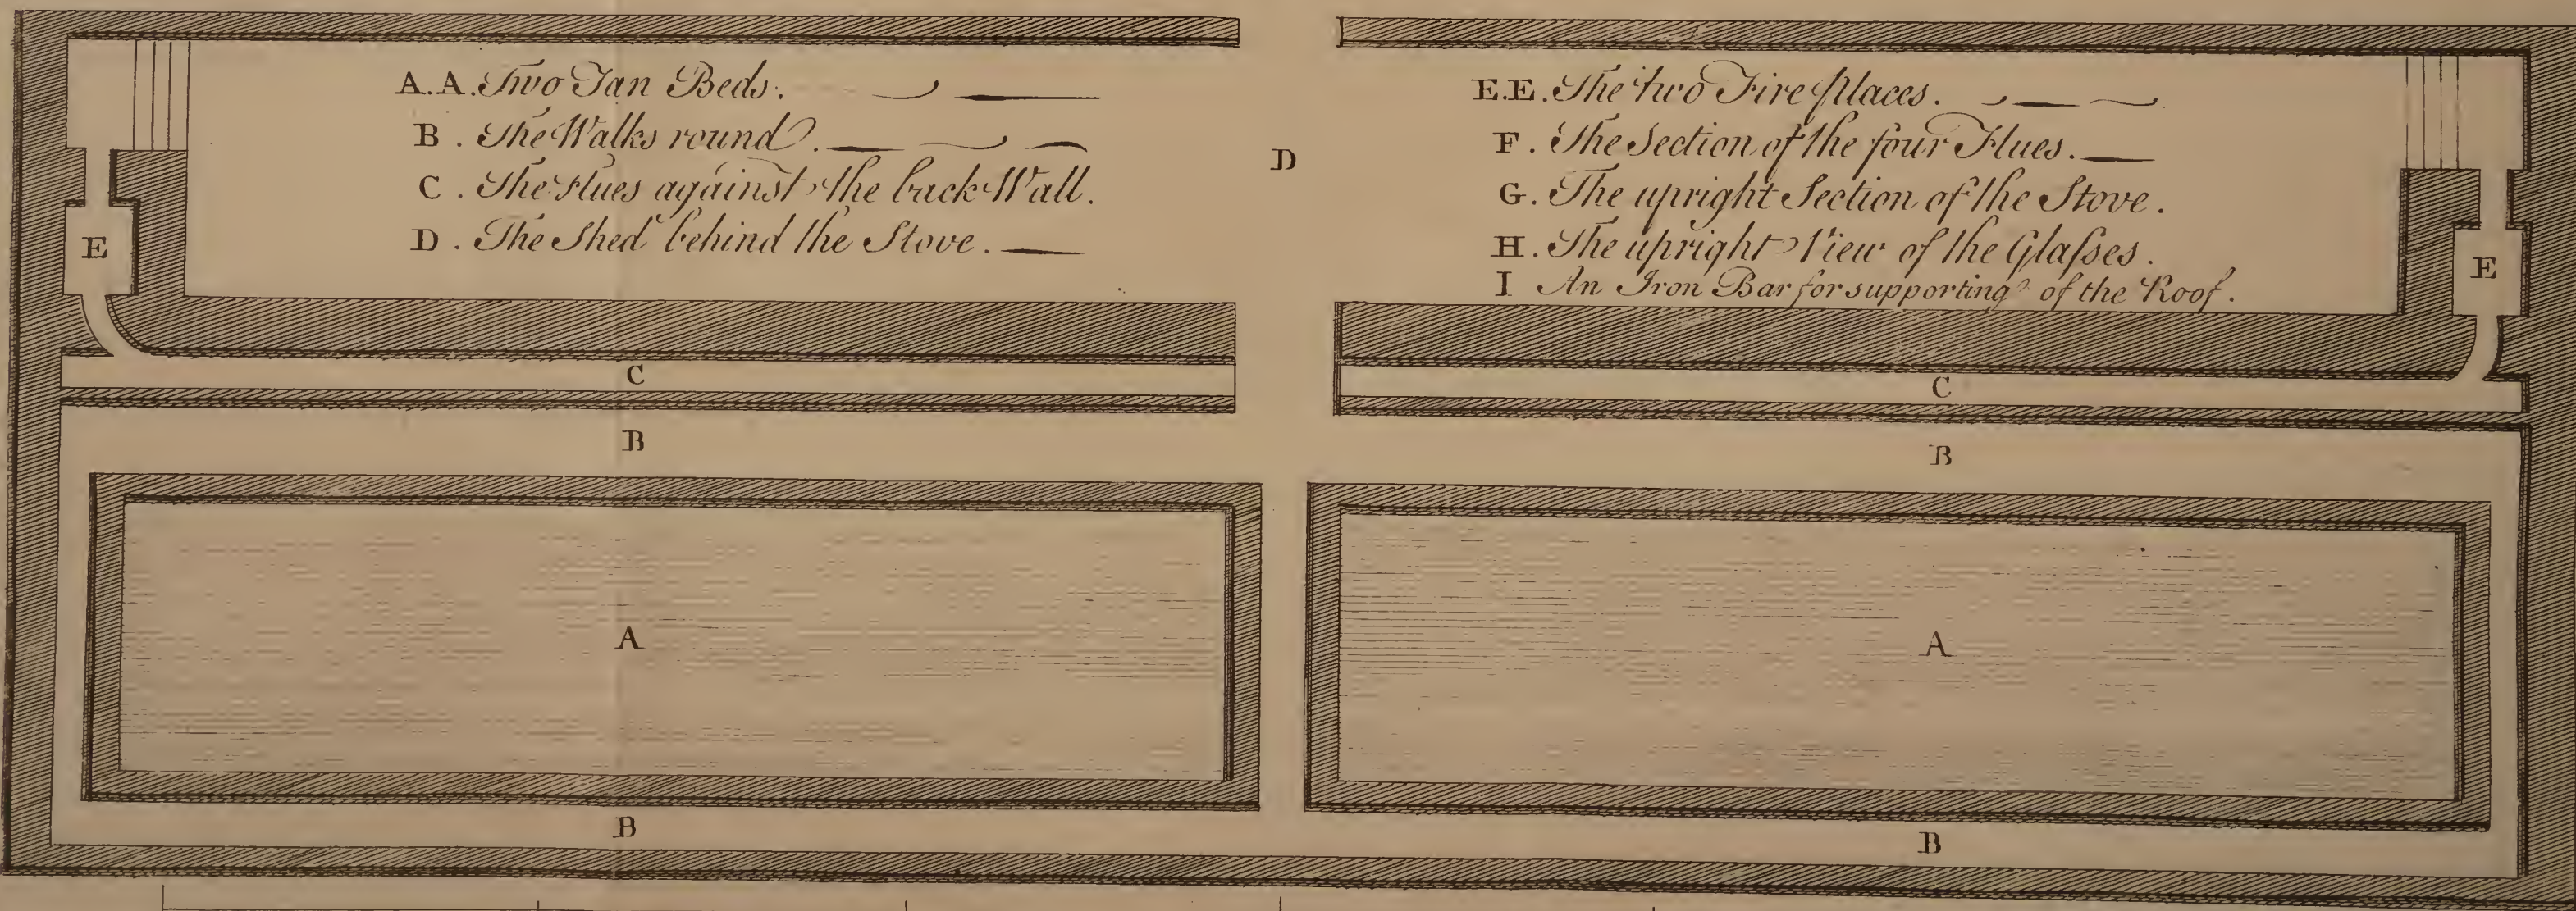

As this plant seldom produces seeds in *England*, it is propagated by slips or cuttings, which, if planted in *April*, and treated in the same way as those of the two other sorts, will take root very freely; but these plants, when rooted, must be planted in pots, that they may be sheltered from severe frost in winter, because they are too tender to live in the open air through the winter in *England*, especially while they are young; but, when they have obtained strength, some of them may be turned out of the pots, and planted in a warm situation, upon a dry rubbishy soil, where they will be stinted from growing too vigorously, so will endure the cold much better than if they were growing in better ground.

tries without artificial warmth in winter. These are built in different methods, according to the ingenuity of the artist, or the different purposes for which they are intended, but in *England* they are at present reducible to two or three.

The first is called a dry stove, being so contrived, that the flues through which the smoke passes, are either carried under the pavement of the floor, or else are erected in the back part of the house, over each other, and are returned six or eight times the whole length of the building, according to the height. In these stoves the plants are placed on shelves of boards laid on a scaffold, rising above each other like the seats in a theatre, for the greater advantage of their standing in sight, and enjoying an equal share of light and air. In these stoves are commonly placed the tender sorts of Aloes, Cereuses, Euphorbiums, Tithymals, and other succulent plants, which are impatient of moisture in winter, and therefore require for the most part to be kept in a separate stove, and not placed among trees, or herbaceous plants, which perspire freely, and thereby often cause a damp air in the house, which is imbibed by the succulent plants to their no small prejudice. These stoves should be regulated by a thermometer, so as not to over-heat them, nor to let the plants suffer by cold; in order to which, all such plants as require nearly the same degree of heat, should be placed by themselves in a separate house; for if in the same stove there are plants placed of many different countries, which require as many different heats, by making the house warm enough for some plants, others, by having too much heat, are drawn and spoiled.

The other sort of stoves are commonly called bark-stoves, to distinguish them from the dry stoves already mentioned. These have a large pit, nearly the length of the house, three feet deep, and six or seven feet wide, according to the breadth of the house; which pit is filled with fresh tanners bark to make a hot-bed, and in this bed the pots of the most tender exotick trees, and herbaceous plants, are plunged. The heat of this bed being moderate, the roots of the plants are always kept in action, and the moisture, detained by the bark, keeps the fibres of their roots in a ductile state, which in the dry stove, where they are placed on shelves, are subject to dry too fast, to the great injury of the plants. In these stoves, if they are rightly contrived, may be preserved the most tender exotick trees and plants, which, before the use of the bark was introduced, were thought impossible to be kept in *England*; but, as there is some skill required in the structure of both these stoves, I shall not only describe them as intelligibly as possible, but also annex plans of both stoves hereto, by which it is hoped every curious person will be capable of directing his workmen in their structure.

The dimension of these stoves should be proportioned to the number of plants intended to be preserved, or the particular fancy of the owner; but their length should not exceed forty feet, unless there are two fire places, and in that case it will be proper to make a partition of glass in the middle, and to have two tan-pits, that there may be two different degrees of heat for plants from different countries (for the reasons before given in the account of dry stoves); and were I to erect a range of stoves, they should be all built in one, and only divided with glass partitions, at least the half way toward the front, which will be of great advantage to the plants, because they may have the air in each division shifted by sliding the glasses of the partitions, or by opening the glass door, which should be made between each division, for the more easy passage from one to the other.

These stoves should be raised above the level of the ground, in proportion to the dryness of the place; for if they are built on a moist situation, the whole should be

placed upon the top of the ground, so that the brick-work in front must be raised three feet above the surface, which is the depth of the bark-bed, whereby none of the bark will be in danger of lying in water, but, if the soil be dry, the brick-work in front need not be more than one foot above ground, and the pit may be sunk two feet below the surface. Upon the top of this brick-work in front must be laid the plate of timber, into which the wood-work of the frame is to be mortised; this should be of sound Oak without sap, the dimension ten inches wide, and six deep, and the upright timbers in front must be placed four feet asunder, or somewhat more, which is the proportion of the width of the glass-doors or sashes; these should be about eight or nine feet long; their dimension should be ten inches by six, of yellow Fir; from the top of these should be sloping glasses, which should reach within three feet of the back of the stove, where there should be a strong crown piece of timber placed, in which there should be a groove made for the glasses to slide into; the dimension of the sloping timbers should be one foot by nine inches, of yellow Fir, and the crown-plate one foot by nine or ten inches of the same timber. The wall in the back part of the stove should be at least eighteen or twenty-two inches, which is two bricks, or two bricks and a half; for the greater thickness there is in the back wall, the more heat will be thrown to the front, whereby the air of the stove will be better warmed, and the building will be so much stronger, for to this back wall the flues, through which the smoke is to pass, must be joined. This back wall should be carried up about sixteen feet high or more for tall stoves, that they may be of a proper height to support the timbers of the back roof, which covers the shed behind the stove. This roof is fastened into the crown-piece before mentioned, which in tall stoves should be about thirty feet above the surface of the tan-bed, which will give a sufficient declivity to the sloping glasses to carry off the wet, and be of a reasonable height for containing many tall plants. The back roof may be slated, covered with lead, or tiled, according to the fancy of the owner; but the manner of the outside building is better expressed by the annexed plan, than is possible to be described in words.

In the front of the house, before the tan-bed, there should be a walk about two feet wide, for the conveniency of walking; next to which the bark-pit must be placed, which should be in width proportionable to the breadth of the house. If the house is fifteen feet wide, which is a due proportion, the pit may be nine feet wide, and behind the pit should be a walk two feet wide to pass, in order to water the plants, &c. then there will be two feet left next the back wall to erect the flues, which must be all raised above the level of the bark-bed. These flues ought to be one foot wide in the clear, that they may not be too soon stopped with the soot, as also for the more conveniently cleaning them; the lower flue, into which the smoke first enters from the fire, should be two feet and a half deep in the clear; this should be covered with broad tiles, which should be a foot and a half square, that they may be wide enough to extend over the wall in front of the flues, and to take sufficient hold of the back wall; over this the second flue must be returned back again, which may be twenty inches deep, and covered on the top as before, and so in like manner the flues may be returned over each other six or eight times, that the heat may be spent before the smoke passes off. The thickness of the wall in front of these flues need not be more than four inches, but it must be well-jointed with mortar, and pargetered within side to prevent the smoke from getting into the house, and the outside should be faced with mortar, and covered with a coarse cloth, to keep the mortar from cracking, as is practised in setting up coppers.

If this be carefully done, there will be no danger of the smoke entering the house, which cannot be too carefully guarded against; for there is nothing more injurious to plants than smoke, which will cause them to drop their leaves, and, if it continue long in the house, will entirely destroy them.

The fire place must be made at one end, where there is but one; but, if the stove is so long as to require two, they should be placed at each end of the shed, which must be made the length of the stove, that the fires and the back of the flues may not suffer from the outer air, for it will be impossible to make the fires burn equally, where the wind has full ingress to them; and it will be troublesome to attend the fires in wet weather, where they are exposed to the rain.

The contrivance of the furnace must be according to the fuel which is designed to burn, but as turf is the cheapest firing for stoves, where it can be had, many prefer it, because it lasts longer than any other sort of fuel, so requires less attendance. I shall describe a proper sort of furnace for that purpose.

The whole of this furnace should be erected within the house, which will be a great addition to the heat, and the front wall on the outside of the fire place, next the shed, should be three bricks thick, the better to prevent the heat from coming out that way. The door of the furnace, at which the fuel is put in, must be as small as conveniently may be to admit of the fuel; and this door should be placed near the upper part of the furnace, and made to shut as close as possible, so that there may be but little of the heat pass off through it. This furnace should be about twenty inches deep, and sixteen inches square at bottom, but may be sloped off on every side, so as to be two feet square at the top; and under this furnace should be a place for the ashes to fall into, which should be about a foot deep, and as wide as the bottom of the furnace; this should also have an iron door to shut as close as possible, but just over the ash-hole, above the bars which support the fuel, should be a square hole about four or six inches wide to let in air to make the fire burn; this must also have an iron frame, and a door to shut close when the fire is perfectly lighted, which will make the fuel last longer, and the heat will be more moderate.

The top of this furnace should be nearly equal to the top of the bark-bed, that the lowest flue may be above the fire, so that there may be a greater draught for the smoke, and the furnace should be arched over with bricks. The best materials for this purpose are what the bricklayers call *Windfor Bricks*, which should be laid in loam of the same kind as that the bricks are made with; and this, when burnt by fire, will cement the whole together, and become like one brick; but you should be very careful, wherever the fire is placed, that it be not too near the bark-bed, for the heat of the fire will, by its long continuance, dry the bark, so that it will lose its virtue, and be in danger of taking fire; to prevent which, it will be the best method to continue a hollow, between the brick-work of the fire and that of the pit, about eight inches wide, which will effectually prevent any damage arising from the heat of the fire; nor should there be any wood-work placed near the flues, or the fire place, because the continual heat of the stove may in time dry it so much, as to cause it to take fire, which ought to be very carefully guarded against.

The entrance into this stove should be either from a green-house, the dry stove, or else through the shed where the fire is made, because in cold weather the front glasses must not be opened. The inside of the house should be clean white-washed, because the whiter the back part of the house is, the better it will reflect the light, which is of

great consequence to plants, especially in winter, when the stove is obliged to be shut up close.

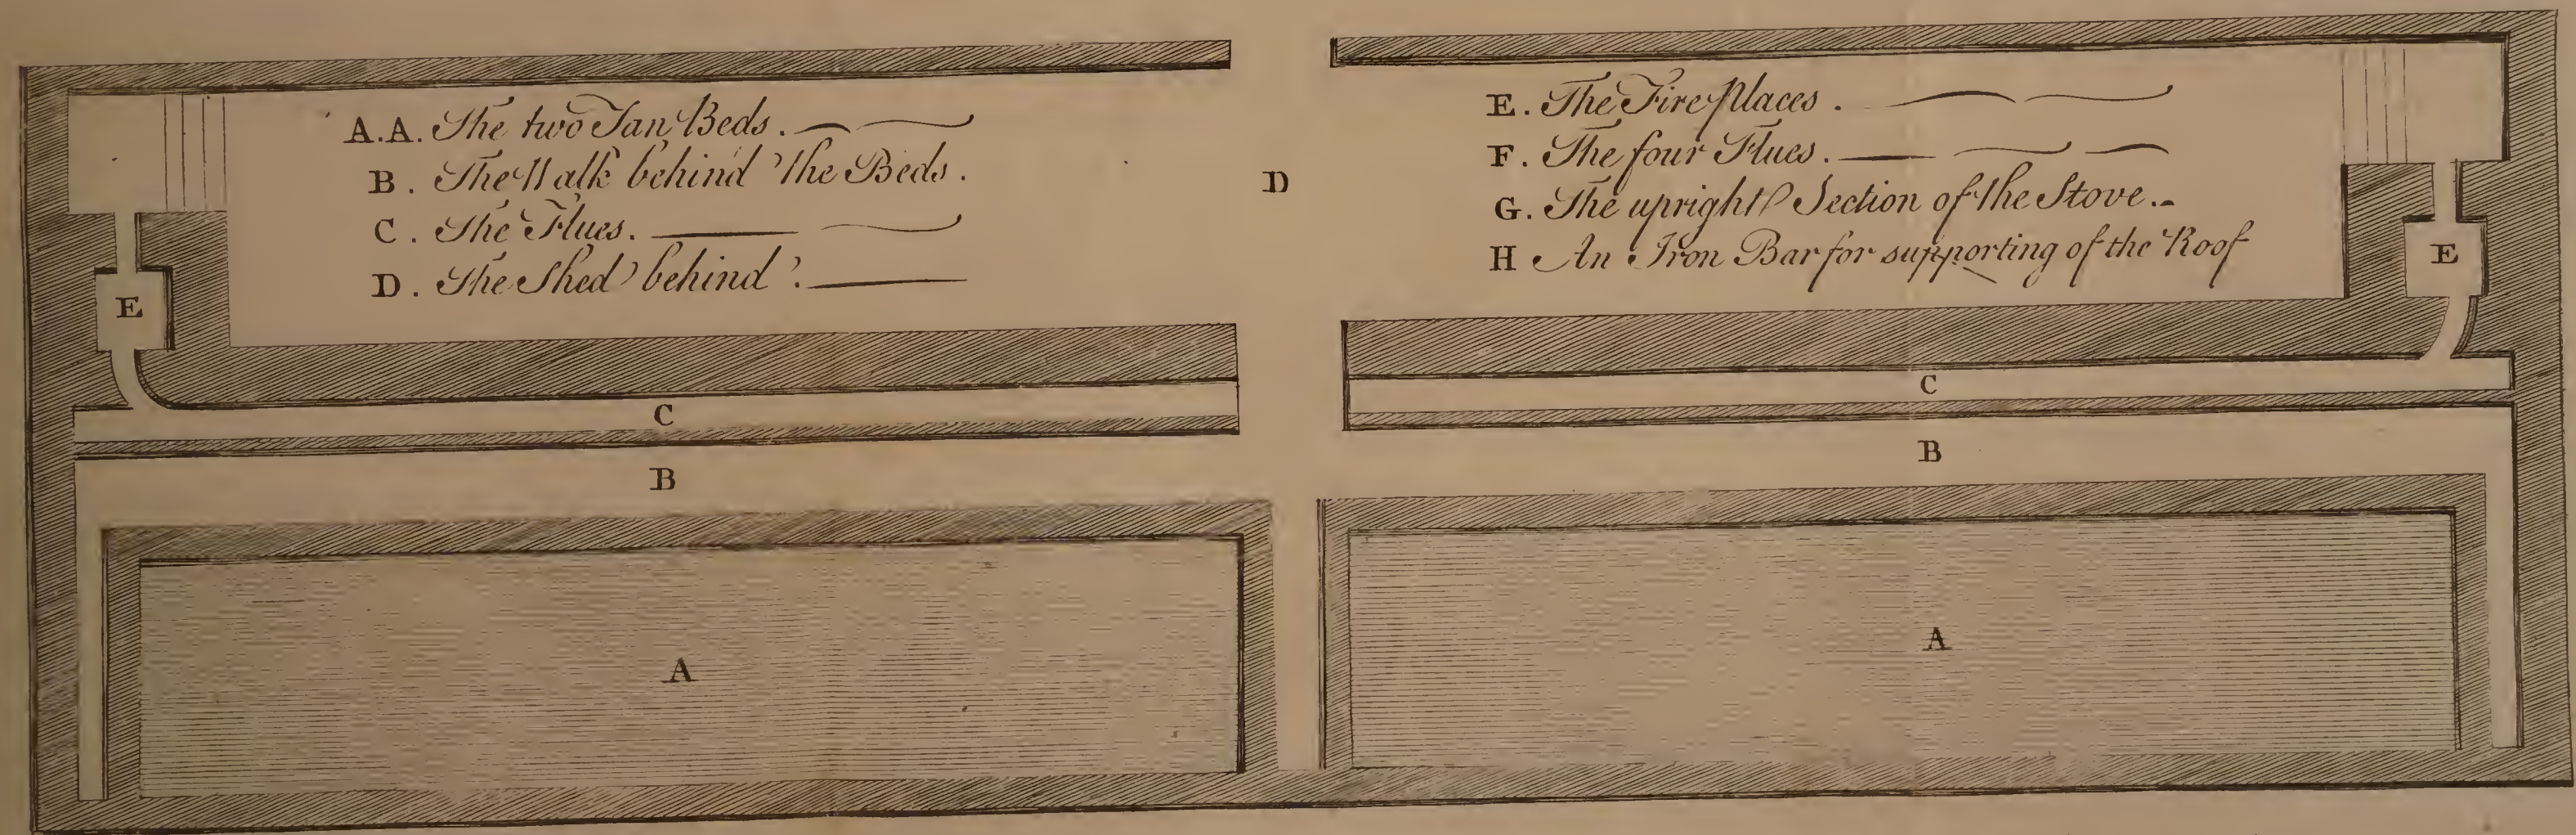

Over the top sliding glasses there should be either wooden shutters, or tarpaulins fixed in frames, to cover them in bad weather, to prevent the wet from getting through the glasses, and to secure them from being broken by storms and hail; and these outer coverings will be very serviceable to keep out the frost; and if in very severe cold there is a tarpaulin hung before the upright glasses in the front, it will be of great service to the stove, and much less fire will preserve a heat in the house.

As in this stove will be placed the plants of the hottest parts of the *East and West-Indies*, the heat should be kept up equal to that marked Anana upon the botanical thermometers, and should never be suffered to be above eight or ten degrees cooler at most; nor should the spirit be raised above ten degrees higher in the thermometer during the winter season, both which extremes will be equally injurious to the plants.

But in order to judge more exactly of the temper of the air in the stove, the thermometer should be hung at a good distance from the fire, nor should the tube be exposed to the sun; but, on the contrary, as much in shade as possible, because, whenever the sun shines upon the ball of the thermometer but one single hour, it will raise the liquor in the tube considerably, when perhaps the air of the house is not near so warm, which many times deceives those who are not aware of this.

In the management of the plants placed in the bark-bed, there must be a particular regard had to the temper of the bark, and the air of the house, that neither be too violent; as also to water them frequently, but sparingly, in cold weather, because when they are in continual warmth, which will cause them to perspire freely, if they have not a proper supply to answer their discharge, their leaves will decay, and soon fall off. As to the farther directions concerning the culture of the particular plants, the reader is desired to turn to their several articles, where they are distinctly treated of.

The other sort of stove, which is commonly called the dry stove, as was before said, may be either built, with upright and sloping glasses at the top, in the same manner, and after the same model of the bark-stove, which is the most convenient; or else the front glasses, which should run from the floor of the ceiling, may be laid sloping, to an angle of 45 degrees, the better to admit the rays of the sun in spring and autumn. The latter method has been chiefly followed by most persons who have built these sorts of stoves; but were I to have the contrivance of a stove of this kind, I would have it built after the model of the bark-stove, with upright glasses in front, and sloping glasses over them, because this will more easily admit the sun at all the different seasons; for in summer, when the sun is high, the top glasses will admit the rays to shine almost all over the house, and in winter, when the sun is low, the front glasses will admit its rays; whereas, when the glasses are laid to any declivity in one direction, the rays of the sun will not fall directly thereon above a fortnight in autumn; and about the same time in spring, and during the other parts of the year, they will fall obliquely thereon, and in summer, when the sun is high, the rays will not reach above five or six feet from the glasses. Besides, the plants placed toward the back part of the house, will not thrive in the summer season for want of air; whereas, when there are sloping glasses at the top, which run within four feet of the back of the house, these, by being drawn down in hot weather, will let in perpendicular air to all the plants; and of how much service this is to all sorts of plants, every one who has had opportunity of observing the growth of plants

in a stove, will easily judge, for when plants are placed under cover of a ceiling, they always turn themselves toward the air and light, and thereby grow crooked; and if, in order to preserve them strait, they are turned every week, they will nevertheless grow weak, and look pale and sickly; for which reasons, I am sure, whoever has made trial of both sorts of stoves, will readily join with me to recommend the model of the bark-stove for every purpose.

As to the farther contrivance of this stove, it will be necessary to observe the temper of the place, whether the situation be dry or wet; if it be dry, then the floor need not be raised above two feet above the level of the ground; but if it be wet, it will be proper to raise it three feet, especially if these flues are to be carried under the floor; for when they are erected close upon the surface of the ground, they will raise a damp, which will prevent the flues drawing so well as when they are more elevated. The furnace of this stove must be placed at one end of the house, according to the directions before given. This must be made according to the fuel intended to burn, which, if for coals or wood, may be made according to the common method for coppers, but only much larger; because, as the fire is to be continued in the night chiefly, if there is not room to contain a proper quantity of fuel, it will occasion a great deal of trouble in tending upon the fire in the night, which should be avoided as much as possible; because, whenever the trouble is made very great or difficult, and the person who is intrusted with the care of it, has not a very great affection for the thing, and is withal not very careful, there will be great hazard of the fire being neglected, which in a little time may be of dangerous consequence to the plants; but, if the fuel intended be turf, then the contrivance of the furnace may be the same as for the bark-stove already mentioned. The flues of this stove, if they are carried under the pavement, may be turned after the following manner,

which will cause them to draw better than if strait; and by this method of disposing them, they may be so much turned as to reach from the back to the front of the house.

The depth of them should not be less than eighteen inches, and the width nearly equal, which will prevent their being choked up with soot, as is often the case when the flues are made too small. The spaces between the flues should be filled up either with dry brick rubbish, lime, or sand, from which there will little moisture arise, and the flues should be closely plastered with loam both within and without, and the upper part of them covered with a coarse cloth under the floor, to prevent the smoke from getting into the house.

When the flue is carried from the furnace to the end of the house, it may be returned in the back above the floor twice in strait lines, which may be contrived to appear like a step or two; by which means the smoke will be continued in the house until all its heat is spent, which will consequently warm the air of the house the better; and the chimneys, through which the smoke is to pass off, may be either at both ends, or in the middle, carried up in the thickness of the brick-work of the flues, so as not to appear in sight in the house. The flues should be first covered with broad tiles, and then a bed of sand laid over them about two inches thick, upon which the plain tiles should be laid to correspond with the rest of the floor. This thickness of cover will be full enough to prevent the too sudden rise of the heat from the flues.

But if the furnace is placed under the floor, the thickness of sand between the brick arch which covers it and the

floor, should not be less than four or six inches, so that the bottom of the furnace should be sunk the lower; and if from the fire-place to the end of the house, the flues are laid a little rising, it will cause them to draw the better; but this rise must be allowed in the placing them lower under the floor next the fire, because the floor must be laid perfectly level, otherwise it will appear unsightly.

In this stove there should be a stand or scaffold erected for placing shelves above each other, in the manner annexed, that the plants may be disposed above each other, so as to make a handsome appearance in the house; but these shelves should be made moveable, so as to be raised or sunk, according to the various heights of the plants, otherwise it will be very troublesome to raise or sink every particular plant, according to their heights, or every year as they advance in their growth.

In placing the feet of this stand, you must be careful not to set them too near the fire, nor directly upon the top of the flue, especially that end next the fire, lest by the constant heat of the tiles the wood should take fire, which cannot be too much guarded against, since such an accident would go near to destroy all the plants, if the house escaped being burnt. This stand or scaffold should be placed in the middle of the house, leaving a passage about two feet and a half in the front, and another of the same width in the back, for the more conveniently passing round the plants to water them, and that the air may freely circulate about them. In disposing the plants, the tallest should be placed backward, and the smallest in front, so that there will not be occasion for more than four shelves in height at most; but the scaffold should be so contrived, that there may be two or three shelves in breadth laid upon every rise whenever there may be occasion for it, which will save a deal of trouble in disposing of the plants.

In the erection of these stoves, it will be of great service to join them all together with only glass partitions between them, as was before observed; and where several of these stoves and green-houses are required in one garden, then it will be very proper to have the green-house in the middle, and the stoves at each end, either in the manner directed in the plan of the green-house exhibited in that article, or carried on in one strait front.

By this contrivance in the structure of these houses, a person may pass from one to the other of them, without going to the open air, which, besides the pleasure to the owner, is also of great use, because there will be no occasion of making a back-way into each of them, which otherwise must be, since the front glasses of the stove should not be opened in cold weather, if it can possibly be avoided on any account, otherwise the cold air rushing in, will greatly prejudice the very tender plants.

But besides the stoves here described, and the green-house, it will be very necessary to have a glass case or two, wherever there are great collections of plants. These may be built exactly in the manner already described for the stoves, with upright glasses in front, and sloping glasses over the top of them, which should run within three feet of the back of the house. The height, depth, and other dimensions, should be conformable to that of the stoves, which will make a regularity in the building. These may be placed at the end of the range on each hand beyond the stoves; and if there be a flue carried along round each of these, with an oven to make a fire in very cold weather, it will save a great deal of labour, and prevent the frost from ever entering the house, be the winter ever so severe; but the upper glasses of these houses should have either shutters of wood, or tarpawlin in frames, to cover them in frosty weather; and if there is a contrivance to cover the upright glasses

glasses in frost, either with mats, shutters, or tarpawlins, it will be of great use in winter, otherwise the flue must be used when the frost comes on, which should not be done, but upon extraordinary occasions; because the design of these houses is, to keep such plants as require only to be preserved from frost, and need no additional warmth, but at the same time require more air than can conveniently be given them in a green-house. In one of these houses may be placed all the sorts of *African Sedums*, *Cotyledons*, and other succulent plants from the *Cape of Good Hope*. In the other may be placed the several kinds of *Arctotis*, *Osteospermum*, *Royena*, *Lotus*, and other woody or herbaceous plants from the same country, or any other in the same latitude.

Thus by contriving the green-house in the middle, and one stove and a glass-case at each end, there will be a conveniency to keep plants from all the different parts of the world, which can be no otherwise maintained but by placing them in different degrees of heat, according to the places of their native growth.

The stoves before described are such as are usually built to maintain exotick plants, which will not live in *England*, unless they enjoy a temperature of air, approaching to that of the several countries from whence they are brought; therefore, whoever is inclinable to preserve a large collection of plants from different countries, must contrive to have two or three of these stoves, each of which should be kept in a different temperature of warmth; and the plants should be also adapted to the several degrees of heat, as they shall require, to preserve them. But as the far greatest number of stoves, which have been erected in *England*, are designed for the culture of the *Ananas* only, so I shall add a description and plans of two sorts of stoves, of the least expence in building for this purpose; so that whoever is inclinable to erect a stove for ripening of the *Ananas*, may, by attending to the plans and descriptions, direct the building and contriving such stoves as they are desirous to have, or according to the number of fruit proposed to be ripened annually.

The first sort of stove is that which is designed for the plants which produce the fruit the same year; for as the plants do not generally fruit, until the second year from their being taken from the old plants, whether they are suckers from the side of the plants, or crowns taken from the fruit, if they fruit the succeeding year, the fruit will be small; therefore, when they are properly managed, they will not produce their fruit until the second year; by which time they will have obtained strength to produce large fruit, in which their greatest value consists; for although there are several varieties of this fruit, which differ in degrees of goodness, as in most other fruits, yet they may all of them be improved in their size, without diminishing of their excellence in taste; though I know there are some persons of a contrary opinion, and who believe, that the small fruit are always better flavoured than the large; but from long experience I can assert, that the larger and better nourished this fruit is, the higher will be its flavour, supposing the sorts are the same; therefore every person who cultivates this fruit, should endeavour to have it improved to the greatest perfection; in order to which it will be proper to have a small stove, in which the young plants may be placed to bring them forward for fruiting, and the following autumn they should be removed into the larger stove for ripening: but I shall return to the description of the larger stove. The length of this must be proportionable to the quantity of fruit desired in one season; for as to their width, that should not be much varied; the tan-bed should never be narrower than six, nor should it be more than eight feet wide, for when it is more, there will be difficulty

in reaching those plants which are in the middle of the bed, to water or clean them; and if there is room enough on each side of the bed for a walk a foot and a half broad, it will be sufficient for persons to water and do every thing which is necessary to the plants; and as these places are not designed for walking in, so it is to no purpose to have broad walks, which will take up too much space; for the fires must be larger, in proportion to the space of the house; otherwise the air cannot be kept in a proper temperature of warmth. If the stove is made thirty-six feet long in the clear, then the tan-bed may be thirty-three feet long, and a walk left at each end a foot and a half wide, which will be sufficient to walk round the bed to water and attend the plants, and such a tan-bed will contain eighty fruiting plants very well; and this stove may be very well warmed with one fire; but if the stove is built much larger, there must be two fire-places contrived, one at each end, otherwise the air of the house cannot be kept in a proper temperature of heat. The quantity of fuel which will be wanting for a stove of thirty-six feet long in the clear, is about three chaldron and a half of coals, or in such proportion for any other sort of fuel; when coals can be had reasonable it is the best kind of fuel; and the pit or *Scotch* coal is preferable to the *Newcastle* coal, because the latter is very subject to melt or run into clinkers, when the oven is very hot, which the pit coal never does, but always burns away with a white ash, making but little soot; so that the flues will not require to be so often cleaned, as when the other coal is used. The next best fuel for stoves is Peat, where it can be procured good; but the scent of this fuel is disagreeable to many people. There are some persons who burn wood in their stoves; but this fuel requires much greater attendance than any other, therefore is not very proper for this purpose; but in the building of the stoves, the ovens must be contrived for the sort of fuel which is to be used in them; but these will be afterward described, and the places where they should be situated, are delineated in the plan.

The stoves designed for ripening the fruit of the *Ananas*, should have upright glasses in their front, which should be high enough to admit a person to walk upright under them on the walk in the front of the house; or where this cannot be admitted, the front walk may be sunk one foot lower than that on the back of the tan-bed, so that the surface of the bed will be a foot above the walk, which will be rather an advantage, as the plants will be so much nearer the glass; and a person may with great ease water and attend the plants, when they are thus raised above the walk; therefore, when a stove is so situated, as that the raising of it high above ground, might be attended with inconvenience, the walks quite round the tan-bed may be sunk a foot or eighteen inches below the top of the bed, which will admit of the stove being built so much lower; for if there is height for a person to walk under the glasses, it will be as much as is required; but as the flues, when returned four times against the back wall, will rise near seven feet, so the bottom of the lower flue should be on the same level with the walk, to admit room enough for the whole under the roof. Over the upright glasses there must be a range of sloping glasses, which must run to join the roof, which should come so far from the back wall as to cover the flues, and the walk behind the tan-pit; for if the sloping glasses are of length sufficient to reach nearly over the bed, the plants will require no more light, therefore these glasses should not be longer than is absolutely necessary, which will render them more manageable; but the annexed plan will render this more intelligible than any written description can do.

Two Sorts of Frames with oyled Paper for Covering Melons.

The other sort of stove, which is designed for raising of young plants, until they are of a proper size to produce fruit, need not be built so high as the former; therefore there will not be wanting any upright glasses in the front, but the frames may be made in one slope, as in the annexed plan; indeed of late years, many persons have made tan-beds, with two flues running through the back wall, to warm the air in winter; and these beds have been covered with glasses, made in the same manner as those for common hot-beds, but larger; these were contrived to save expence, and have in many places answered the intention; but to these there are several objections. 1. That of having no passage into them, so that the glasses must be taken off, when the plants want water, &c. 2. The damps very often rise in the winter season, when the glasses are closely shut, which often proves very injurious to the plants. 3. There is danger of the tan taking fire, where there is not great care taken that it doth not lie near the flues; so that although the small stoves here proposed require more expence in their building, yet, being greatly preferable to those pits, and the after expence being the same, they will be found so much more convenient as to render them more general where this fruit is cultivated.

Where there is no danger of the wet settling about the tan in winter, the bark-pit may be sunk two feet deep in the ground, and raised one foot above the surface; the only walk which is necessary in these stoves, is that on the back of the tan-bed, which may be on the level with the surface of the ground; so that the tan-bed will be more than one foot above the walk, and the flues beginning from the level of the walk, there will be room to return them three times, which will warm the air much more with the same fire, than when they are carried but twice the length of the stove.

But in wet land the tan-bed should be wholly raised above the level of the ground, in order to preserve the tan from being chilled by moisture; and in such places the walk on the back should be raised near two feet above the level of the ground, because the tan-bed should not rise much more than one foot above the walk; for if it is higher, it will be more difficult to reach the plants when they require water; the brick wall of the pit, on the side next the walk, need not be more than four inches thick, so far as rises above the walk, but below that it should be nine inches thick. The reason for reducing the wall above, is to gain room for the walk, which would otherwise be too much contracted; and if there is a kirb of Oak laid on the top of the four inch wall, it will secure the bricks from being displaced, and sufficiently strengthen the wall, which being but one foot above the walk, will not be in any danger of falling; and on this kirb there may be two or three upright iron bars fixed with claws, to support the crown-piece of timber, which will secure it from hanging in the middle, which in a great length is very often the case, where there are no supports placed under it; there may be more or less of these bars according to the length of the stove, but if they are about ten feet asunder, it will be near enough. If these iron bars are one inch square, they will be strong enough to answer the design.

But as it is hoped that the annexed plan of this small stove will convey a clear idea of the whole contrivance, this will render it unnecessary to add any farther description here.

An explanation of the plate which represents the two sorts of frames with oiled paper for covering of Melons.

The first of these frames is contrived like the covers of waggons; it has a frame of wood at the base, to which are

fastened broad hoops, which are bent over circularly, as is represented at Fig. 1. The width of this frame should be from five to six feet, for less than five feet will not be sufficient to cover the bed; and if they are more than six feet broad, they will be too heavy and troublesome to move. *a* Shews the section of the width, *b* the frame of wood at the base, *c* the arch of hoops, and *d* a small slip of wood, which is fastened to the under side of the hoops to keep them in their proper position.

The distance between each hoop should not be more than one foot, and there should be two rows of strong pack-thread or rope-yarn on each side of the arch running from hoop to hoop at the places marked, *e. e. e. e.* to keep the oiled paper from sinking down with wet. The length of each frame should not be much more than ten feet, which will be sufficient length for covering three plants, that being about the size of a three light frame, for if they are longer, they will be heavy and troublesome to move; therefore there should be as many of these frames made, as may be necessary for covering the quantity of plants designed. Fig. 2. Represents two lengths of these frames joined, *G.* shews the profile of the frame, and *H.* represents the paper turned back, that it may be seen how it is laid over the frame.

Fig. 3. Represents the other sort of frame which is contrived like the roof of a house, *a* shews a section of the base; *b b* the two slopes, *c* one of the sides which is contrived to be raised at any time to admit air to the plants, *d* shews the place where this shuts down, and *e* the prop which supports it. If in the making of these frames every other light is made with hinges so as to be raised, and on the opposite side they are contrived to rise alternately, it will be a very good method, for then air may be given at the side contrary to the wind; and in very warm weather, when the plants require a large share of air, they may all be raised on both sides, which will make a thorough air to the whole bed. Fig. 4. Shews the plain of these frames; and Fig. 5. the same erected; *g* represents the profile of it, and *f* the covering of paper. This sort of frame may be made of pantile laths, or of slips of deal of like dimensions, because they should not be too heavy; but the base of the frame to which these are fastened, should be more substantial. Some persons who have made trial of both, recommend the latter for the convenience of giving air to the plants, for there is no other contrivance in the first sort for admitting the air, but by raising the whole frame on one side in proportion to the quantity of air intended to be admitted, and when the season is warm, they generally raise those frames on both sides, and permit the plants to run out from under them.

When these frames are made, if they are well painted over with the following composition, it will greatly preserve them, *viz.* To every six pounds of melted pitch, add half a pint of Linseed oil, and a pound of brick-dust; these should be well mixed together, and used warm; when this dries it becomes a hard cement, so that no moisture can penetrate through it, and is the best sort of pigment for all timber exposed to the weather, I have ever seen used; so that where the colour is not offensive to the sight, it should be preferred to every other.

When the frames are thoroughly dry, the paper should be pasted on to the frames. The best sort of paper for this purpose, is what they call *Dutch Wrapper*; this is strong, and when oiled over becomes pellucid, so admits the rays of light through it extremely well. After the paste is well dried, the paper should be oiled over on the outside, which, if well done with Linseed oil, will be sufficient, for the oil will soak quite through the paper, so there will be no necessity for oiling both sides, nor for doing it over more than

once. The oil should be dry before the frames are exposed to the wet, otherwise the paper will tear. In the pasting of the paper on the frames, there should be care taken to stretch it very smooth, and also to paste it to all the ribs of the frames, and also to the packthreads, to prevent the wind from raising the paper, which would soon tear it, when it became loose.

The above description, together with the annexed plan, it is hoped, will be sufficient instructions for any one who is desirous of making these covers; and what has been before mentioned under the article MELON, will be directions enough for the use of them; so that I shall only add one caution which may be necessary to repeat here, which is, not to keep these covers too close down over the plants, lest it draw them too weak, so that air should always be admitted to the plants at all times in proportion to the warmth of the season.

These covers of oiled paper are not only useful for covering of Melons, but are the best things to cover cuttings of exotick plants, when planted, that can be contrived; and are also capable of being used for many other purposes.

The paper will seldom last longer than one season, so it will require a new covering every spring; but if the frames are well made, and when they are out of use, laid up in shelter from the wet, they will last several years, especially if there is a band of Straw laid round the Melon bed, upon which the frames may stand, so they will not rest upon the ground, and the Straw-bands will prevent the damp from rising so as to rot them. These Straw-bands are such as are recommended for the hot-beds of Asparagus in winter.

STRAMONIUM. See Datura.

STRATIOTES. *Lin. Gen. Plant.* 607. Water Soldier.

The Characters are,

It has one flower, inclosed in a compressed obtuse sheath, composed of two leaves, which are keel shaped and permanent. The empalement of the flower is of one leaf, trifid, and erect. It has three almost heart-shaped petals, which are twice the size of the empalement, and about twenty stamina inserted in the receptacle of the flower, terminated by single summits. The germen is situated under the empalement, supporting six styles, divided in two parts, crowned by single stigmas. The germen afterward becomes an oval capsule, narrowed on every side, having six angles, and as many cells, filled with oblong incurved seeds.

We know but one Species of this genus, viz.

STRATIOTES. *Lin. Flor. Lapp.* 222. Water Soldier, Water Aloe, or Fresh Water Soldier.

This plant is in shape like the Aloe, but the leaves are thinner, and serrated on the edges very sharply; they are of a grayish colour, and about a foot long; between the leaves from the center of the plant arise one, two, and sometimes three stalks, almost the length of the leaves, each being terminated by a three-forked sheath, out of which bursts one white flower, composed of three roundish heart shaped petals, with many yellow stamina in the middle. Below the flower is situated a conical germen, which is reversed, the broad end standing upward, and the narrow downward. This becomes a six-angled capsule, having six cells, filled with seeds. It grows plentifully in standing waters in the *Ile of Ely*, and many places in the north of *England*, from whence young plants may be procured in spring, when they first rise on the surface of the water; and these being placed in large ponds or canals, will strike down their roots, and propagate without any farther care. In autumn the plants sink down to the bottom of the water, and rise again in the spring.

STRAWBERRY. See *Fragaria*.

STRAWBERRY-TREE. See *Arbutus*.

STYRAX. *Tourn. Inst. R. H.* 598. *tab.* 369. Storax-tree.

The Characters are,

The flower has a short cylindrical empalement, indented in five parts; it has one funnel-shaped petal, with a short cylindrical tube, whose brim is cut into five large obtuse segments, which spread open; it has ten or twelve awl-shaped stamina, disposed circularly, inserted in the petals, and terminated by oblong summits; and a roundish germen, supporting a single style the length of the stamina, crowned by a ragged stigma. The germen afterward turns to a roundish fruit with one cell, including two nuts, which are plain on one side, and convex on the other.

We know but one Species of this genus, viz.

STYRAX. *Hort. Cliff.* 187. The Storax-tree.

This plant grows plentifully in the neighbourhood of *Rome*, and also in *Palestine*, and several of the islands in the *Archipelago*, from whence the fruit has been brought to *England*, where there have been many plants raised of late years in some curious gardens.

It has a woody stalk, which rises twelve or fourteen feet high, covered with a smooth grayish bark, sending out many slender ligneous branches, garnished with oval leaves, shaped like those of the Quince-tree, of a bright green on their upper side, but hoary on their under, placed alternately on short foot-stalks. The flowers come out from the side of the branches upon foot-stalks, which sustain five or six flowers in a bunch; these have one very white petal, which is funnel-shaped, the lower part being tubulous and cylindrical, and the upper divided into five obtuse segments, which spread open, but not flat, rather inclining to an angle. These are often succeeded by berries in *England*.

It may be propagated by sowing the seeds in pots, filled with fresh light earth, and plunged into a moderate hot-bed. If they are sown the latter end of summer, and the pots kept in a moderate hot-bed of tanners bark all the winter, the plants will come up the succeeding spring; whereas those sown in the spring, often remain in the ground a whole year before the plants come up.

When the plants are come up, they should be hardened gradually to the open air, into which they should be removed in *June*, placing them in a sheltered situation, observing to keep them clean from weeds, as also to supply them with water duly in dry weather. In this place they may remain till autumn, when they should be placed under a common hot-bed frame, where they may be screened from hard frost in winter, but in mild weather enjoy the free air as much as possible; for if they are kept too close, their tops are very subject to grow mouldy. The leaves of these plants fall off in autumn, and in the spring, before they begin to shoot, they should be shaken out of the pots, and their roots carefully parted, and each transplanted into a separate small pot, and plunged into a very moderate hot bed, observing to water and shade them until they have taken root; after which they should be inured to the open air by degrees, into which they must be removed in *June*, placing them in a warm situation; in which place they may remain till the end of *October*, at which time they should be removed into shelter for the winter season. These plants are tolerably hardy, and only require to be sheltered from severe frost while they are young, for in *Italy* they grow extremely well in the open air, and produce fruit in great plenty. When the plants have grown three or four years in pots, and are become strong, some of them may be turned out of the pots, and planted in the full ground, against a wall to the south aspect, to which their branches should be trained, in the same manner as is practised with fruit-trees; in which situation they will bear the cold of our winters very well, but in very severe frost it will be proper to cover the branches either with mats, Straw, or other light covering to protect them. With this care

care the plants will flower annually, and in warm seasons ripen their seeds.

The gum of this tree is used in medicine, which is obtained by making incisions in the tree. It is brought from *Turkey*, but it is so adulterated by mixing saw-dust or other stuff with it, that it is very difficult to meet with any that is pure. It has a most pleasant fragrant odour; it is called *Styrax Calamita*, because it was transported in hollow canes.

Of late years there has been another species of *Storax* imported here from *North America*, which is collected from the liquid Amber tree. This has been titled *Liquid Storax* by some, but is very different from that which is brought from *Turkey*, and is clear, inclining to yellow; it is brought sometimes liquid, and at others it is dried in the sun to a concrete resin before it is transported.

SUBER. See *Quercus*.

SUCCORY. See *Cichorium*.

SUMACH. See *Rhus*.

SURIANA. *Plum. Nov. Gen. 37. tab. 40.*

The Characters are,

The empalement of the flower is permanent, composed of five spear-shaped small leaves. The flower has five oval petals the length of the empalement, which spread open; it has five slender stamina, which are shorter than the petals, terminated by single summits, and five roundish germen, supporting a slender style the length of the stamina, which is inserted in the middle to the side of the germen, crowned with an obtuse stigma. The germen afterward becomes five roundish seeds joined together.

We know but one Species of this genus, viz.

SURIANA. *Hort. Cliff. 492. Suriana.*

This plant grows naturally by the sea side in most of the islands of the *West-Indies*, where it rises with a thick shrubby stalk eight or nine feet high, covered with a dark brown bark, dividing into branches; the upper part of which are closely garnished with leaves on every side, standing without order; they are rounded at their points, and sit close to the branches, having no foot-stalks, and of a dirty green colour. From between the leaves come out the foot-stalks of the flowers, which are about an inch long; these do each sustain two, three, or four yellow flowers, which have some four, and others five petals, rounded at their points, and almost heart-shaped; these are succeeded by roundish seeds, which are joined together, sitting in the empalement. Some flowers have two, others three, four, or five seeds to each.

It is propagated by seeds, which must be sown on a hot-bed early in the spring; and when the plants are come up, they must be carefully cleared from weeds, and frequently refreshed with water. In warm weather the glasses of the hot-bed should be raised every day, to admit fresh air to the plants, to prevent their drawing up too weak. When the plants are fit to remove, they should be taken up carefully, and each planted in a separate small pot, and plunged into a hot-bed of tanners bark, observing to shade them until they have taken new root; after which they must have fresh air admitted to them every day, in proportion to the warmth of the season. In this hot-bed the plants may remain till autumn, when the nights begin to be cold; at which time they should be removed into the stove, and plunged into the bark-bed. During the winter season these plants must be kept very warm, especially while they are young, otherwise they will not live through the winter in this country. They must also be frequently refreshed with water; but it must not be given to them in large quantities in cold weather, for too much moisture in winter will soon destroy them. These plants make but slow progress the first year; afterwards they will grow pretty freely, if they are not stinted. In summer they must have a large share air, by opening the glasses of the stoves; and if their

leaves are covered with filth (which the plants in stoves often contract), they should be carefully washed with a sponge, otherwise the plants will not only appear unsightly, but it will retard their growth.

SYCAMORE. See *Acer majus*.

SYMPHYTUM. *Tourn. Inst. R. H. 138. tab. 56. Comfrey.*

The Characters are,

The flower has a five-cornered, erect, permanent empalement, cut into five acute parts; it has one petal with a short tube, above which the limb has a swelling belly and thicker tube; the brim is indented in five obtuse parts, which are reflexed; the chaps are armed with five awl shaped rays, which are connected in a cone; it has five awl-shaped stamina, which are alternate with the rays of the chaps, terminated by erect acute summits, and four germen, supporting a slender style the length of the petal, crowned by a single stigma. The germen afterward turns to four gibbous acute-pointed seeds, which ripen in the empalement.

The Species are,

1. SYMPHYTUM *foliis ovato-lanceolatis decurrentibus. Hort. Cliff. 47.* Comfrey with oval, spear-shaped, running leaves; Comfrey with a purple flower.

2. SYMPHYTUM *foliis summis oppositis. Lin. Sp. Plant. 136.* Comfrey with the upper leaves placed opposite.

3. SYMPHYTUM *foliis ovatis subpetiolatis. Lin. Sp. Plant. 136.* Comfrey with oval leaves and short foot-stalks.

There are several other species of this genus, but those which are here enumerated, are all the sorts at present to be found in the *English* gardens.

The first sort grows naturally in *England*, but the most common here is that with a whitish yellow flower, which is found growing by the side of ditches and other moist places in great plenty, but that with purple flowers is the most common in *Holland* and *Germany*; these are supposed to be accidental varieties, which differ in the colour of their flowers; however, this difference is permanent in the plants raised from seeds, as I have many times found; nor are the two kinds ever found mixed where they grow wild, for in those places where the blue is found, the white is never seen, and vice versa: but as there are no specific differences between them, I shall not separate them.

The common Comfrey has thick roots, composed of many fleshy fibres or fangs, which run deep in the ground; they are black on the outside, but white within, full of a slimy tenacious juice. The lower leaves are large, long, sharp-pointed, hairy, and rough. The stalks rise two feet high, which are garnished with oval spear-shaped leaves, ending in acute points; they are hairy, rough, and from their base runs a leafy border along the stalk. From the upper part of the stalk are sent out some side branches, which are commonly garnished with two smaller leaves, and are terminated by loose bunches of flowers, which are reflexed; each flower has one tubulous petal, whose upper petal is bellied and thicker than the lower, and the chaps are closed by the stamina and rays, which cross it, and shuts up the tube. These in the common *English* sort are of a yellowish white, and the foreign one is of a purple colour.

The second sort grows naturally in *Germany*. The roots of this are composed of many thick fleshy knobs or tubers, which are joined by fleshy fibres; the stalks incline on one side; they rise a foot and a half high; the leaves on the lower part are six inches long and two and a half broad in the middle, ending in acute points, and are not so rough and hairy as those of the other species; they are placed alternate, and sit close to the stalks. The two upper leaves on every branch stand opposite, and just above them are loose spikes or bunches of pale yellow flowers, whose petals are stretched out farther beyond the empalement than those of the other.

The third sort grows naturally on the side of rivers near *Constantinople*; this has a perennial root like the first; the stalks grow two feet high; the leaves are rounder, and are armed with rough prickly hairs. The flowers are blue, and grow in bunches like those of the first sort.

These plants may be cultivated either by sowing their seeds in the spring, or by parting of their roots; the latter way being the more expeditious, is chiefly practised, where they are planted for use. The best season for parting the roots is in autumn, at which time almost every piece of a root will grow. They should be planted about two feet and a half asunder, that they may have room to spread, and will require no farther care but to keep them clear from weeds, for they are extremely hardy, and will grow upon almost any soil or in any situation.

SYRINGA. *Lin. Gen. Plant.* 22. Lilac.

The Characters are,

The flower has a small, tubulous, permanent empalement of one leaf, indented in four parts; it has one petal, with a long cylindrical tube, cut into four obtuse segments at the brim, which spread open, and two very short stamina, terminated by small summits, standing within the tube; it has an oblong germen, supporting a short slender style, crowned by a thick bifid stigma. The germen afterward turns to an oblong, compressed, acute-pointed capsule, with two cells, opening with two valves contrary to the partition, including in each cell one oblong acute-pointed seed, with a membranaceous border.

The Species are,

1. SYRINGA *foliis ovato-cordatis*. *Hort. Cliff.* 6. Syringa with oval heart-shaped leaves; or blue Lilac.
2. SYRINGA *foliis lanceolatis*. *Lin. Sp. Plant.* 9. Syringa with spear-shaped leaves; commonly called *Persian Jasmine*.
3. SYRINGA *foliis lanceolatis integris dissectisque laciniata*. *Hort. Cliff.* 6. Syringa with entire spear-shaped leaves, and others which are cut and jagged; commonly called cut-leaved *Persian Jasmine*.

The first sort is very common in the *English* gardens, where it has been long cultivated as a flowering shrub. It is supposed to grow naturally in some parts of *Persia*, but is so hardy as to resist the greatest cold of this country. There are three varieties of this shrub, which are commonly cultivated in the *English* gardens, which differ in the colour of their flowers, and also in that of their shoots and leaves; one of these has white flowers, one blue, and the third has purple flowers; the latter is commonly known by the title of *Scotch Lilac*, to distinguish it from the other. This is the most beautiful of the three, and is probably called the *Scotch Lilac*, because it was first mentioned in the Catalogue of the *Edinburgh* garden. Whether this was raised from seeds, or which other way it was obtained, I could never learn; but I take it to be a distinct species from the others, though there is not marks enough upon them to distinguish their specific differences, because I have raised many of the plants from seeds, which have always retained their difference; as have also the white, when they were propagated by seeds, so that they may be rather esteemed as distinct sorts, although by the rules now admitted for determining specific differences, they may not have sufficient marks whereby to distinguish them; and as they have been by most of the modern botanists joined together, I shall not separate them again, but shall mention the particulars in which they differ.

These shrubs grow to the height of eighteen or twenty feet in good ground, and divide into many branches; those of the white sort grow more erect than the other, and the purple or *Scotch Lilac* has its branches more diffused than either. The branches of the white are covered with a smooth bark, of a gray colour; those of the other two are darker. The leaves of the white are of a very bright green,

but those of the other are of a dark green; their shape and size are so near as not to be distinguished thereby. They are heart-shaped, and are placed opposite. The buds of the future shoots, which are very turgid before the leaves fall, are of a very bright green in the white sort, but those of the other two are of a dark green. The flowers are always produced at the ends of the shoots of the former year, and below the flowers come out shoots to succeed them; for that part upon which the flowers stand, decays down to the shoots below every winter. There are generally two bunches or panicles of flowers joined at the end of each shoot; those of the blue are the smallest, and are placed thinner than either of the other. The bunches on the white are larger; the flowers are closer placed, and larger than the blue; but those of the *Scotch* are larger, and the flowers are fairer than those of either of the other, so make a much finer appearance. The panicles of flowers grow erect, and being intermixed with the fine green leaves, have a fine effect; and if we add to this the fragrantcy of their flowers, it may be ranged among the most beautiful shrubs which now decorate the *English* gardens. They flower in *May*, and when the season is cool, these shrubs will continue three weeks in beauty, but in hot seasons the flowers soon fade. Their seeds are ripe in *September*, which, if sown soon after, the plants will come up the following spring; but as their roots send out great plenty of suckers annually, so few persons ever take the trouble to propagate these plants by seeds. I have raised several plants of the three sorts from seeds, and constantly found them prove the same as the shrubs from which the seeds were taken. These plants do generally flower the third year from seed; and I have always found these plants not so apt to send out suckers, as those which were produced by suckers, so are much more valuable, for the others put out such plenty of suckers, as that if they are not annually taken from the plants, they will starve them.

These plants thrive best upon a light rich soil, such as the gardens near *London* are for the most part composed of; and there they grow to a much larger size, where they are permitted to stand unremoved than in any other part of *England*, for in strong loam, or upon chalky land, they make little progress. If the suckers are small, when they are taken from the old plants, they should be planted in a nursery, in rows three feet asunder, and one foot distance in the rows, where they may stand a year or two to get strength, and then they should be removed to the places where they are to remain. The best time to transplant these shrubs is in autumn.

There is a variety or two of these shrubs with blotched leaves, which some persons are fond of; but as these variations are the effect of weakness, so whenever the shrubs become healthy, their verdure returns again.

The second sort grows naturally in *Persia*, but has been long cultivated in the *English* gardens, where it is best known among the gardeners by the title of *Persian Jasmine*. This is a shrub of much lower growth than the former, seldom rising more than six or eight feet high. The stalks of this shrub are woody, covered with a smooth brown bark; the branches are slender, pliable, and extend wide on every side; these frequently bend downward where they are not supported; they are garnished with narrow spear-shaped leaves, placed opposite, of a deep green colour, ending in acute points. The flowers are produced in large panicles at the end of the former year's shoots, in like manner as the former; they are of a pale purple colour, and have a very agreeable odour. These appear the latter end of *May*, soon after those of the common sort, and continue longer in beauty; but these do not perfect their seeds in *England*.

There

There is a variety of this with almost white flowers, which has of late years been obtained; but whether it came from seeds, or was accidentally produced by suckers from the purple kind, I cannot say.

The third sort differs from the second in having two sorts of leaves; those on the lower part of the branches are for the most part entire; these are broader and shorter than those of the second, and do not end in so sharp points. The leaves on the younger branches are cut into three or five segments, like winged leaves almost to the midrib. The branches of this sort are slenderer and weaker than those of the second; their bark is of a darker brown, and the flowers of a brighter purple colour.

This was brought into *Europe* before the other, and came by the *Persian* title *Agem*. Both these sorts are usually propagated by suckers, which their roots send out in great plenty; these should be carefully taken off from the old plants in the autumn, and planted in a nursery in the same manner as is before directed for the first, where they may grow two years to get strength, and may then be transplanted to the places where they are designed to remain. The plants which are so propagated, are always very prolific in suckers; for which reason it will be a better way to raise them by laying down their young branches, which in one year will be sufficiently rooted to transplant, and may then be treated in the same way as the suckers.

T.

T A B

TABERNÆMONTANA. *Plum. Gen. Nov. 18. tab. 30.*

The Characters are,

The flower has a small empalement, cut into five acute parts; it has one funnel-shaped petal, with a long cylindrical tube, which is bellied at both ends, and at the brim is cut into five oblique segments; it has five small stamina in the middle of the tube terminated by summits which join together, and two germen, supporting an awl-shaped style, crowned by decayed stigmas. The germen afterward turns to two bellied capsules, which are horizontally reflexed, opening with one valve, having one cell, filled with oblong oval seeds, lying imbricatum, and surrounded with pulp.

The Species are,

1. TABERNÆMONTANA *foliis lanceolatis oppositis, floribus corymbosis lateralibus*. Tabernæmontana with spear-shaped leaves, which are placed opposite, and flowers growing in a corymbus on the sides of the branches.

2. TABERNÆMONTANA *foliis oblongo-ovatis acuminatis oppositis, floribus corymbosis terminalibus*. Tabernæmontana with oblong, oval, acute pointed leaves, which are placed opposite, and flowers growing in a corymbus, terminating the branches.

The first sort grows naturally in *Jamaica*, and some of the other islands in the *West-Indies*. Sir *Hans Sloane* has figured it in his *History of Jamaica*, under the title of *Nerium arboreum folio latiore obtuso, flore luteo minore. Tab. 186. f. 2.* Tree-like *Nerium* with a broader obtuse leaf, and a smaller yellow flower.

This rises with an upright woody stalk to the height of fifteen or sixteen feet, covered with a smooth gray bark, which abounds with a milky juice, and sends out several branches from the side, which grow erect, garnished with thick leaves, which have a milky juice, of a lucid green, and have many transverse veins from the midrib to the border, standing opposite on foot-stalks an inch long. The flowers come out in roundish bunches from the wings of the stalk; they are small, of a bright yellow colour, and have an agreeable odour. The tube of the flower is half an inch long; the brim is cut into five acute points, which spread open like those of the common *Jasmine*. These flowers,

T A B

in their native soil, are succeeded by two swelling capsules, joined at their base, but spread from each other horizontally, and are filled with oblong seeds, lying over each other like the scales of fish, and are included in a soft pulp.

The second sort was discovered by the late *Dr. William Houfoun* in the year 1730, growing naturally at *La Vera Cruz*. This rises with a woody stalk ten or twelve feet high, covered with a wrinkled gray bark, sending out many branches toward the top, which are garnished with oblong oval leaves, of a lucid green, and of a thick consistence; they are five inches long, and two and a half broad, rounded at both ends, but terminate with an acute point. These are placed opposite, and have short foot-stalks. The flowers come out in pretty large roundish bunches at the end of the branches; they are white, and smaller than those of the first sort, having an agreeable scent. These are succeeded by shorter and rounder pods, which spread from each other horizontally like the former.

Both these plants are very impatient of cold, so will not live in this country, unless they are placed in a warm stove. They may be propagated by seeds or cuttings; if by seeds, they may be procured from the countries where the plants grow naturally; these should be sown early in the spring on a hot-bed, and when the plants are come up, they must be carefully transplanted into small pots, filled with light rich earth, and plunged into a hot-bed of tanners bark, being careful to shade them in the heat of the day, until they have taken new root; after which time they must have free air admitted to them every day when the weather is warm; but if the nights should prove cold, the glasses of the hot-bed should be covered with mats every evening, soon after the sun goes off from the bed. These plants must be often refreshed with water, but it must not be given to them in large quantities, especially while they are young, for as they are full of a milky juice, they are very subject to rot with much moisture.

The plants may remain during the summer season in the hot-bed, provided the tan is stirred up to renew the heat when it wants, and a little new tan added; but at *Michaelmas*, when the nights begin to be cold, the plants should be removed, and plunged into the bark-bed in the stove; where,

where, during the winter season, they must be kept in a moderate degree of warmth, and in cold weather they should have but little water given them. As these plants are too tender to live in the open air in this country, they should constantly remain in the stove, where, in warm weather they may have free air admitted to them, by opening the glasses, but in cold weather they must be kept warm. With this management the plants will thrive and produce their flowers; and as their leaves are always green, they will make a pleasant diversity amongst other tender exotick plants in the stove.

These plants may also be propagated by cuttings during the summer season, which should be cut off from the old plants, and laid to dry in the stove five or six days before they are planted, that the wounded parts may heal, otherwise they will rot. These cuttings should be planted in pots filled with fresh light earth, and plunged into the hot-bed of tanners bark, and closely covered with a hand-glass, observing to shade them from the sun in the middle of the day in hot weather, as also to refresh them now and then with a little water. When the cuttings have taken root, they may be transplanted into separate pots, and treated in the same manner as those which are raised from seeds.

TACAMAHACA. See Populus.

TAGETES. *Tourn. Inst. R. H.* 478. *tab.* 278. *African*, or *French Marigold*.

The Characters are,

The common empalement of the flower is single, oblong, erect, and five-cornered; the flower is compound and radiated; the ray or border is composed of five female half florets, which are tongue-shaped. The disk or middle is made up of hermaphrodite florets, which are tubulous, cut into five obtuse segments; these have five short hair-like stamina, terminated by cylindrical summits, and an oblong germen, supporting a slender style, crowned by a bifid reflexed stigma. The germen afterward becomes a single, linear, compressed seed, almost the length of the empalement, crowned by five acute-pointed unequal scales.

The Species are,

1. TAGETES caule simplici erecto, pedunculis nudis unifloris. *Hort. Cliff.* 418. Tagetes with a single erect stalk, and naked foot-stalks bearing one flower; or upright *African Marigold*.
2. TAGETES caule subdiviso diffuso. *Hort. Cliff.* 418. Tagetes with a diffused subdivided stalk; commonly called *French Marigold*.
3. TAGETES caule simplici erecto, pedunculis squamosis multifloris. *Hort. Cliff.* 419. Tagetes with a single erect stalk, and scaly foot-stalks bearing many flowers.
4. TAGETES caule simplici erecto, foliis cordatis simplicibus, pedunculis nudis unifloris. Tagetes with a single stalk, simple heart-shaped leaves, and naked foot-stalks, having one flower.

The first sort grows naturally in *Mexico*, but has been long cultivated in the *English* gardens, where it is commonly titled *African*, or *African Marigold*; of this there are the following varieties:

1. Pale yellow, or brimstone colour, with single, double, and fistulous flowers.
2. Deep yellow, with single, double, and fistulous flowers.
3. Orange-coloured, with single, double, and fistulous flowers.
4. Middling *African*, with Orange-coloured flowers.
5. Sweet-scented *African*.

These are all very subject to vary, so that unless the seeds are very carefully saved from the finest flowers, they are very apt to degenerate; nor should their seeds be too long sown in the same garden without changing it, for the same reason; therefore, those who are desirous to have these flowers in perfection, should exchange their seeds with some

person of integrity at a distance where the soil is of a different nature, at least every other year. If this is done, the varieties may be continued in perfection.

This plant is so well known as to need no description. It flowers from the beginning of *July*, till the frost puts a stop to it.

The second sort grows naturally in *Mexico*, but has been long in the *English* gardens, where it is distinguished from the first by the title of *French Marigold*.

Of this there are several varieties, some of which have much larger flowers than others, and their colour varies greatly; there are some which are beautifully variegated, and others quite plain; but as these are accidents arising from culture, so they do not merit farther distinction; for I have always found that seeds saved from the most beautiful flowers will degenerate, especially if they are sown in the same garden for two or three years together, without changing the seed.

These plants are annual, so must be propagated from seeds every spring, which may be sown upon a moderate hot-bed the beginning of *April*; and when the plants are come up, they should have plenty of fresh air, for if they are drawn too much, they will not afterward become handsome, notwithstanding they have all possible care taken of them. When they are about three inches high, they should be transplanted on a very moderate hot-bed, which may be arched over with hoops and covered with mats, for these plants are hardy enough to be brought up without glasses; in this bed they should be planted about six inches asunder each way, observing to water and shade them until they have taken root; but as the plants acquire strength, they should be inured to bear the open air by degrees; and about the end of *May* they should be taken up with a ball of earth to the root of each plant, and planted into the borders of the parterre-garden, or into pots, for furnishing the courts, &c. shading them carefully from the sun till they have taken new root, and also supplying them duly with water. When their flowers appear, if any should prove single, the plants should be destroyed, and then those in pots may be removed to the court where the several varieties, being intermixed with other annual plants, afford an agreeable variety.

These plants have a strong disagreeable scent, especially when handled, for which reason they are not so greatly esteemed for planting near habitations; but the flowers of the sweet-scented sort being more agreeable, are generally preferred, especially for planting in small gardens.

The third sort grows naturally in *Chili* in the *Spanish West-Indies*. This is a plant of taller growth than either of the former. The stalk is single, erect, and branches a little toward the top; it rises about ten feet high; the branches grow erect. The leaves are narrower than either of the other. The foot-stalks of the flowers are scaly, and stand erect close to the stalk; these sustain three or four small white flowers, which appear very late in autumn; so that unless it is kept in a glass-case, the seeds will not ripen here. This plant has very little beauty, so is only preserved for the sake of variety.

The fourth sort rises with an upright stalk about two feet high, sending out a few branches toward the top, garnished with heart-shaped leaves, standing upon long slender foot-stalks, ending in very acute points, being in shape like those of the black Poplar, rough to the touch, and are slightly crenated on their edges; the branches and stalks are each terminated by one large yellow flower, standing upon a long naked foot-stalk. The empalement of the flower is short; the leaves of which it is composed are oblong and oval, drawing to a point. The female florets, which compose the rays or border, are much longer than the

the empalcment. The hermaphrodite florets, in the disk or middle, are equal; they are of a deep yellow colour, and make a good appearance, for the flowers are double. This plant was discovered by the late Dr. *Houssoun* growing naturally at *La Vera Cruz*, in *New Spain*, from whence he sent the seeds to *England*.

The two last sorts are not so hardy as the former, so the seeds of these should be sown earlier in the spring upon a good hot-bed; and when the plants are fit to remove, they should be transplanted on a fresh hot-bed, at about three inches distance each way, observing to shade them from the sun till they have taken new root; then they should be treated in the same way as the *Amaranthus*, and other tender annual plants, being careful not to draw them up weak; when they have spread so as to meet each other, they should be taken up with balls of earth to their roots, and planted in pots with light rich earth, and plunged into a hot-bed under a deep frame, where the plants may have room to grow, being careful to shade them from the sun till they have taken new root; after which they must have air and water in proportion to the warmth of the season; and when the plants have grown too tall to remain longer in the frame, they should be removed to an airy glass-case, where they may stand to flower and ripen their seeds.

TAMARINDUS. *Tourn. Inst. R. H. 660. tab. 445.* The Tamarind-tree.

The Characters are,

The empalcment of the flower is composed of five oval plain leaves, which are equal; the flower has five petals, which are almost like those of the butterfly kind, one of them standing erect, two are placed like wings on each side, and two reflect downward; it has three awl-shaped stamina, situated in the sinuses of the empalcment, and are arched toward the upper petal, terminated by single summits, and an oblong oval germen, supporting an awl-shaped ascending style, crowned by a single stigma. The germen afterward becomes a long, swelling, compressed pod, having a double cover, and one cell containing three, four, or five angular compressed seeds, surrounded with pulp.

We know but one Species of this genus, viz.

TAMARINDUS. *Hort. Cliff. 18.* The Tamarind-tree.

This tree grows naturally in both *Indies*, and also in *Egypt*; but it has been supposed by some eminent botanists, that the Tamarind which grew in the *East-Indies*, was different from that of the *West*, because the pods of the first are almost double the length of those of the latter. The pods which have been brought me from the *East-Indies*, have generally been so long as to contain five, six, and sometimes seven seeds, whereas those of the *West-Indies* have very rarely more than four; but the plants which I have raised from the seeds of both sorts, are so like as not to be distinguished, therefore I suppose it may be owing to the soil or culture, that one is so much larger than the other.

This tree grows to a very large size in those countries where it is a native, but in *England* it will not thrive out of a stove, especially in winter. The stem is very large, covered with a brown bark, and divides into many branches at the top, which spread wide every way, and are closely garnished with winged leaves, composed of sixteen or eighteen pair of lobes, without a single one at the end. The lobes are about half an inch long, and a sixth part of an inch broad, of a bright green, a little hairy, and sit close to the midrib. The flowers come out from the side of the branches five, six, or more together upon the same foot-stalk in loose bunches; these are composed of five reddish petals, one of which is reflexed upward like the standard in some of the butterfly flowers, two others stand on each side like the wings, and the other two are turned downwards; these, (in the countries where the plants grow naturally) are succeeded by thick compressed pods, two, three, four, or five

inches long, having a double skin or cover, and swell in every place where the seeds are lodged, full of an acid stringy pulp, which furrounds smooth, compressed, angular seeds.

The Tamarinds which are brought from the *East-Indies*, are darker and drier, but contain more pulp, being preserved without sugar, and are fitter to be put into medicines than those from the *West-Indies*, which are redder, have less pulp, and are preserved with sugar, so are pleasanter to the palate.

The plants are preserved in the gardens of those who have conveniency to maintain rare exotick trees and shrubs.

They are easily propagated by sowing their seeds on a hot-bed in the spring; and when the plants are come up, they should be planted each into a separate small pot, filled with light rich earth, and plunged into a hot-bed of tanners bark to bring them forward, observing to water and shade them until they have taken root; and as the earth in the pots appear dry, they must be watered from time to time, and should have air given to them in proportion to the warmth of the season, and the bed in which they are placed; when the pots in which they are planted, are filled with their roots, the plants should be shifted into pots of a larger size, which must be filled up with rich light earth, and again plunged into the hot-bed, giving them air, as before, according to the warmth of the season; but in very hot weather the glasses should be shaded with mats in the heat of the day, otherwise the sun will be too violent for them through the glasses, nor will the plants thrive, if they are exposed to the open air, even in the warmest season; so that they must be constantly kept in the bark stove both summer and winter, treating them as hath been directed for the *Coffee-tree*, with whose culture they will thrive exceeding well.

These plants, if rightly managed, will grow very fast; for I have had them upwards of three feet high in one summer from seed, and have had two plants which produced flowers the same season they were sown; but this was accidental, for none of the older plants have produced any flowers, although I have several plants of different ages, some of which are sixteen or eighteen years old, and about twelve feet high, with large spreading heads.

TAMARIX. *Lin. Gen. Plant. 337.* The Tamarisk.

The Characters are,

The empalcment of the flower is obtuse, erect, and permanent; it is cut into five parts; the flower has five oval concave petals, which spread open, and five hair-like stamina, terminated by roundish summits; it has an acute pointed germen without a style, crowned by three oblong, feathery, twisted stigmas. The germen afterward turns to an oblong acute-pointed capsule with three corners, having one cell, opening with three valves, containing many small downy seeds.

The Species are,

1. **TAMARIX floribus pentandris.** *Hort. Cliff. 111.* Tamarisk with flowers having five stamina; or *French Tamarisk*.

2. **TAMARIX floribus decandris.** *Hort. Cliff. 111.* Tamarisk whose flowers have ten stamina; or *German Tamarisk*.

The first sort grows naturally in the south of *France*, in *Spain*, and *Italy*, where it rises to a middling size, but in *England* is seldom more than fourteen or sixteen feet high. The bark is rough, and of a dark brown colour; it sends out many slender branches, most of which spread out flat and hang downward at their ends; these are covered with a Chestnut-coloured bark, and garnished with very narrow finely divided leaves, which are smooth, of a bright green colour, and have small leaves or indentures which lie over each other like scales of fish. The flowers are produced in taper spikes at the end of the branches, several of them growing on the same branch. The spikes are about an

inch long, and as thick as a large earth-worm. The flowers are set very close all round the spike; they are very small, and have five concave petals, of a pale flesh colour, with five slender stamina, terminated by roundish red summits, and are succeeded by oblong, acute-pointed, three-cornered capsules, filled with small downy seeds, which seldom ripen in *England*.

The wood, bark, and leaves of this tree, are used in medicine, and are accounted specifick for all disorders of the spleen, as being believed to lessen it much. The bark is sometimes used for rickets in children.

The second sort grows naturally in *Germany*, in moist land; this is rather a shrub than tree, having several ligneous stalks arising from the same root, which grow erect, sending out many side branches, which are also erect, having a pale green bark when young, which afterward changes to a yellowish colour. The leaves are shorter, and set closer together than those of the other sort, and are of a lighter green, approaching to a gray colour; the flowers are produced in long loose spikes at the end of the branches, standing erect; they are larger than those of the former, and have ten stamina standing alternately.

These both cast their leaves in autumn, and it is pretty late in the spring before the young ones push out, which renders them less valuable; they are now frequently planted in gardens for ornament, and, when they are mixed with other shrubs, make a pretty variety.

They may be easily propagated by laying down their tender shoots in autumn, or by planting cuttings in an east border in the spring before they begin to shoot, which, if supplied with water in dry weather, will take root in a short time; but they should not be removed until the following autumn, at which time they may be either placed in a nursery to be trained up two or three years, or else into the quarters where they are designed to remain, observing to mulch their roots, and water them according as the season may require, until they have taken root; after which, the only culture they will require is to prune off the straggling shoots, and keep the ground clean about them.

TAMUS. *Lin. Gen. Plant.* 991. The black Briony.

The Characters are,

It has male and female flowers on different plants. Those of the male plants have empalements, composed of six oval, spear-shaped, spreading leaves; they have no petals, but have six short stamina, terminated by erect summits; the flowers of the female have bell-shaped empalements of one leaf, cut into six spear-shaped segments, which sit upon the germen; these have no petals, but have oblong punctured nectarii sitting on the inside of each segment of the empalement, and a large, oblong, oval, smooth germen under the empalement, with a cylindrical style, crowned by three reflexed indented stigmas. The germen afterward becomes an oval berry with three cells, including two globular seeds.

The Species are,

1. TAMUS foliis cordatis indivisis. *Hort. Cliff.* 458. Black Briony with heart-shaped undivided leaves; common black Briony.

2. TAMUS foliis trilobis. *Lin. Sp. Plant.* 1028. Black Briony with leaves which are divided into three lobes.

The first sort is rarely cultivated in gardens, but grows wild under the sides of hedges in divers parts of *England*, and is there gathered for medicinal use. The root is very large, fleshy, and has a dark brown skin or cover; the stalks are smooth, and twine round any neighbouring support, whereby they rise to the height of ten or twelve feet, garnished with smooth heart-shaped leaves, of a lucid green, which are alternate. The flowers are produced in long bunches from the side of the stalks; those of the male plants fall off soon after their farina is cast abroad, but the female flowers are succeeded by oval smooth berries, which are red when ripe.

It may be easily propagated by sowing the seeds soon after they are ripe, under the shelter of bushes, where, in the spring, the plants will come up, and spread their branches over the bushes, and support themselves, requiring no farther care, and their roots will abide many years in the ground without decaying.

The second sort was discovered in the island of *Crete* by *Dr. Tournefort*, who sent the seeds to the Royal Garden at *Paris*; this has a rounder root than the other. The stalks twine round any neighbouring support in like manner; the leaves of this are divided into three lobes, in which the principal difference consists. This is an abiding plant, which is hardy enough to live in the full ground in *England*, and may be propagated as the other.

TANACETUM. *Tourn. Inst. R. H.* 461. *tab.* 261. Tansey.

The Characters are,

It has a flower composed of hermaphrodite and female florets, contained in one common, hemispherical, imbricated empalement, whose scales are compact and acute-pointed. The hermaphrodite florets, which compose the disk of the flower, are funnel-shaped, cut into five segments, which are reflexed; these have five short hair-like stamina, terminated by cylindrical tubulous summits, and a small oblong germen, supporting a slender style, crowned by a bifid revolved stigma. The germen afterward becomes an oblong naked seed. The female florets are trifid, which compose the rays or border, and are deeply divided within; these have an oblong germen, with a slender style, crowned with two reflexed stigmas, but no stamina.

The Species are,

1. TANACETUM foliis bipinnatis incisiss serratis. *Hort. Cliff.* 398. Tansey with doubly-winged cut leaves, which are sawed; or common yellow Tansey.

2. TANACETUM foliis pinnatis, laciniis lineari-filiformibus, corymbis glabris, caule herbaceo. *Lin. Sp. Plant.* 844. Tansey with winged leaves, which are cut into linear thread-like segments, a smooth corymbus, and an herbaceous stalk.

3. TANACETUM foliis ovatis integris serratis. *Hort. Cliff.* 398. Tansey with oval, entire, sawed leaves; Coltmary, or Alecoast.

4. TANACETUM foliis pinnatifidis, laciniis lanceolatis obtusiusculis integerrimis. *Lin. Sp. Plant.* 844. Tansey with wing-pointed leaves, having spear-shaped, entire, obtuse segments; or African Tree Tansey.

5. TANACETUM foliis pinnato-multifidis, laciniis linearibus subdivisis. *Hort. Cliff.* 398. Tansey with many-pointed winged leaves, having linear segments, which are divided and acute; or shrubby African Tansey with leaves like the cut-leaved Lavender.

6. TANACETUM foliis pinnatis, pinnis linearibus remotis integerrimis. *Lin. Sp. Plant.* 843. Tansey with winged leaves, whose lobes are linear, grow at a distance from each other, and are entire.

The first sort is the common Tansey, which is used in medicine and the kitchen; this grows naturally by the sides of roads, and the borders of fields in many parts of *England*. It has a fibrous creeping root, which will spread to a great distance, where they are not confined, from which arise many channelled stalks from two to almost four feet high, according to the goodness of the soil, garnished with doubly-winged leaves, whose lobes are cut and sharply sawed, of a deep green colour, and have a pleasant grateful odour. The stalks divide near the top into three or four branches, which stand erect, and are terminated by umbels of naked yellow flowers, composed of many florets, which are included in hemispherical scaly empalements.

There are three varieties of this, one with a curled leaf, which is titled Double Tansey by gardeners; another with variegated

variegated leaves; and a third with larger leaves, which have little scent; but, as these have accidentally been produced from seeds of the common Tansey, they are not enumerated as distinct species.

This sort is easily propagated by the creeping roots, which, if permitted to remain undisturbed, will, in a short time, overspread the ground where they are permitted to grow; so that where-ever this is planted in a garden, the slips should be placed two feet asunder, and in particular beds, where the paths round them may be often dug, to keep their roots within bounds. They may be transplanted either in spring or autumn, and will thrive in almost any soil or situation.

The common Tansey is greatly used in the kitchen early in the spring, at which season, that which is in the open ground, or especially in a cold situation, is hardly forward enough to cut, so that where this is much wanted at that season, it is the best way to make a gentle hot-bed in *December*, and plant the old roots thereon without parting them, and arch the bed over with hoops, to cover it with mats in cold weather, by which method the Tansey will come up in *January*, and be fit to cut in a short time after.

The second sort grows naturally in *Siberia*; this has a perennial fibrous root. The stalks rise three feet high; the leaves are narrow and winged; the lobes are very narrow, and end in two or three points, which are entire; the flowers are produced in small thin umbels from the side, and at the top of the stalk; they are yellow and but small, the umbels having few florets in each. It may be propagated in the same way as the first.

The third sort grows naturally in the south of *France* and *Italy*, but is here planted in gardens, and was formerly pretty much used in the kitchen, and also in medicine. The roots of this are hard, fleshy, and creep in the ground; the lower leaves are oval, sawed on their edges, of a grayish colour, and have long foot-stalks. The stalks rise from two to three feet high, and send out branches from the side, garnished with oval sawed leaves like those at the bottom, but smaller, and sit close to the stalk. The flowers are produced at the top of the stalks in a loose corymbus; they are naked, and of a deep yellow colour. The whole plant has a soft pleasant odour.

It is propagated easily by parting of their roots; the best time for this is autumn, that they may be well established in the ground before the spring. Where this plant is cultivated for use, the plants should be planted in beds at two feet distance every way, that they may have room to grow, for in two years the roots will meet, so every other year they should be transplanted and parted to keep them within compass; they will thrive in almost any soil or situation, but will continue longest in dry land.

The fourth sort grows naturally at the *Cape of Good Hope*; this rises with a shrubby stalk eight or ten feet high, sending out branches on every side, garnished with wing-pointed leaves, whose segments are spear-shaped, entire, and blunt-pointed. The flowers are produced in small roundish bunches at the end of the branches; they are of a Sulphur colour. The seeds rarely ripen in *England*.

The fifth sort was brought from the *Cape of Good Hope*, where it grows naturally; this rises with a branching shrubby stalk three or four feet high, garnished with wing-pointed leaves, whose lobes are very narrow, and frequently cut into acute segments. The flowers are produced in small roundish bunches at the end of the branches; they are larger than those of the former sort, and are of a bright yellow colour.

The sixth sort grows naturally at the *Cape of Good Hope*; this has a thick shrubby stalk, covered with a gray bark, which rises seven or eight feet high, sending out many

branches on every side, which are closely garnished with linear-winged leaves, whose lobes or pinnæ are very narrow, and spread from each other. The leaves sit close to the stalks on every side; the branches are terminated by close, large, roundish bunches, of bright yellow flowers. Some of the foot-stalks sustain but one, others two, three, or four flowers upon each; there is a succession of them on the same plants till late in autumn, and those which come early in the season will be succeeded by seeds.

These three last-mentioned sorts are too tender to live through the winter in the open air, so must be kept in pots, and removed into shelter before hard frosts come on; they are all of them easily propagated by cuttings, which may be planted in a bed of loamy earth, during any of the summer months; these should be shaded from the sun until they have taken root, and must be frequently refreshed with water. When they have good roots, they should be taken up with balls of earth, and planted in pots, placing them in a shady situation till they have taken new root; then they may be removed to a sheltered situation, placing them among other hardy exotick plants, where they may remain till late in *October*, when they must be put into shelter. These plants are so hardy, as only to require protection from hard frost, so must not be tenderly treated, and in mild weather should always be as much exposed to the air as possible, to prevent their drawing weak.

TAN, or TANNERS BARK, is the bark of the Oak-tree, chopped or ground into coarse powder, to be used in tanning or dressing of skins; after which it is of great use in gardening: first, by its fermentation (when laid in a proper quantity), the heat of which is always moderate, and of long duration, which renders it of great service for hot-beds; and secondly, after it is well rotted, it becomes excellent manure for all sorts of cold stiff land, upon which one load of tan is better than two of rotten dung, and will continue longer in the ground.

The use of tan for hot-beds has not been many years known in *England*. The first hot-beds of this sort which were made in *England*, were at *Blackbeath* in *Kent*, above threescore years ago; these were designed for the raising of Orange-trees; but the use of these hot-beds being but little known at that time, they were made but by two or three persons, who had learned the use of them in *Holland* and *Flanders*, where the gardeners seldom make any other hot-beds; but in *England* there were very few hot-beds made of tanners bark, before the Ananas plants were introduced into this country, which was in 1719, since which time the use of these hot-beds have been more general, and are now made in all those gardens where the Ananas plants are cultivated, or where there are collections of tender exotick plants preserved; and the gardeners here are now better skilled in the making and managing of these hot-beds, than in most other countries, which might render it less necessary to give a full description of them here; but yet, as there may be some persons in the remote parts of *England*, who have not had an opportunity of informing themselves of the use of tanners bark for this purpose, I shall insert the shortest and plainest method of making and managing them, as they are practised by the most knowing persons, who have long made use of these hot-beds; and first I shall begin with the choice of the tan.

The tanners, in some parts of *England*, do not grind the bark to reduce it into small pieces, as is commonly practised by the tanners near *London*, where there is great difference in the size of the bark, some being ground much smaller than the other, according to the different purposes for which it is intended; but in many places the bark is only chopped into large pieces, which renders it very different for the use of hot-beds; for if the tan is very coarse, it will require a

longer time to ferment than the small tan, but when it begins to heat, it will acquire a much greater degree, and will retain the heat a much longer time than the small; therefore where there is choice, the middling-sized tan should be preferred, for it is very difficult to manage a hot-bed when made of the largest tan; the heat of which is often so great, as to scald the roots of plants, if the pots are fully plunged into the bed; and I have known this violent heat continue upward of two months, so that it has been unsafe to plunge the pots more than half their depth into the tan, till near three months after the beds have been made; therefore where the persons, who have the care of these beds, do not diligently observe their working, they may in a short time destroy the plants which are placed in the beds: on the other hand, if the tan is very small, it will not retain the heat above a month or six weeks, and will be rotten and unfit for a hot-bed in a short time; so that where the middle-sized tan can be procured, it should always be preferred to any other, otherwise it will be proper to mix the small with the large tan.

The tan should be always such as has been newly taken out of the pits, for if it lies long in the tanners yard before it is used, the beds seldom acquire a proper degree of heat, nor do they continue their heat long; so that when it has been more than three weeks or a month out of the pit, it is not so good for use as that which is new. If the tan is very wet, it will be proper to spread it abroad for two or three days, to drain out the moisture, especially if it is in autumn or winter season, because then, as there will be little sun to draw a warmth into the tan, the moisture will prevent the fermentation, and the beds will remain cold, but in the summer season there is no great danger from the moisture of the tan. The heat of the sun through the glasses will be then so great, as soon to cause a fermentation in the tan.

These tan-beds should always be made in pits, having brick-walls round them, and a brick pavement at the bottom, to prevent the earth from mixing with the tan, which will prevent the tan from heating. These pits must not be less than three feet deep, and six feet in width; the length must be in proportion to the number of plants they are to contain, but if they are not ten feet in length, they will not retain their heat long, for where there is not a good body of tan, the outside of the bed will soon lose its heat; so that the plants, which are there plunged, will have no benefit of the warmth, nor will the middle of these beds retain their heat long, so that they will not answer the purpose for which they are intended.

When the tan is put into the bed, it must not be beaten or trodden down too close, for that will cause it to adhere, and form one solid lump, so that it will not acquire a proper heat; nor should it be trodden down at the time when the pots are plunged into the beds; to avoid which, there should be a board laid cross the bed, which should be supported at each end, to prevent its resting upon the tan, upon which the person should stand who plunges the pots, so that the tan will not be pressed down too close. When the tan is quite fresh, and has not been out of the pits long enough to acquire a heat, the beds will require a fortnight or three weeks time, or sometimes a month, before they will be of a proper temperature of warmth to receive the plants; but in order to judge of this, there should be three or four sticks thrust down in the tan about eighteen inches deep, in different parts of the bed, so that by drawing out the sticks, and feeling them at different depths, it will be easy to judge of the temper of the bed; and it will be proper to let a few of these sticks remain in the bed, after the plants are plunged, in order to know the warmth of the tan, which may be better judged of by feeling these sticks, than by drawing out the pots, or plunging the hand into the tan.

When the tan is good, one of these beds will retain a proper degree of heat for near three months; and when the heat declines, if the tan is forked up, and turned over, and some new tan added to it, the heat will renew again, and will continue two months longer; so that by turning over the tan, and adding some new tan every two months, or thereabouts, as the bed is found to decline of its heat, they may be continued one year; but every autumn it will be proper to take out a good quantity of the old tan, and to add as much new to the bed, that the heat of the bed may be kept up in winter, for if the heat is suffered to decline too much during the cold season, the plants will suffer greatly; to prevent this, there should always be some new tan added to the bed in winter, when the heat is found to decline; but the tan should be laid in a dry place a week or ten days to dry, before it is put into the bed, otherwise the moisture will chill the old tan in the bed, and prevent the fermentation; so that unless the tan is turned over again, there will be little or no heat in the beds, which often proves fatal to the plants which are plunged in them; therefore whoever has the management of these beds, should be very careful to observe constantly the warmth of the tan, since, upon keeping the beds in a due temperature of warmth, their whole success depends; and where this caution is not taken, it frequently happens that the Ananas plants run into fruit very small, or the plants are infested by insects; both which are occasioned by the growth of the plants being stopped, either by the decline of the heat of the tan, or the heat being too great; therefore great regard must be had to that, especially in winter.

The great advantages which these tan-beds have of those which are made of horse-dung, are the moderate degree of heat which they acquire, for their heat is never so violent as that of horse-dung, and they continue this heat much longer; and when the heat declines, it may be renewed, by turning the beds over, and mixing some new tan with the old, which cannot be so well done with horse-dung, and likewise the beds will not produce so great steams, which are often injurious to tender plants, so that these tan-beds are much preferable to those of horse-dung for most purposes.

Tan, when it is well rotted, is also an excellent manure for all cold and stiff lands; and if it is laid upon Grass ground in autumn, that the rains in winter may wash it into the ground, it will greatly improve the Grass; but when it is used new, or in the spring of the year, when dry weather comes, it is apt to cause the Grass to burn, which has occasioned the disuse of tan in many places, but if properly used, it will be found an excellent dressing for all stiff lands.

TAPIA. See Crateva.

TARCHONANTHUS. *Lin. Gen. Plant.* 846.

The Characters are;

It has a flower composed of several hermaphrodite florets, included in one common top-shaped empalement, which is short, permanent, and hairy. The florets are uniform, funnel shaped, and of one petal, indented in five parts at the top; they have each five very short hair-like stamina, terminated by cylindrical tubulous summits longer than the petal, and an oblong germen, supporting a style the length of the stamina, crowned by two awl-shaped stigmas, which open lengthways. The germen afterward turns to a single oblong seed, crowned with down, which ripens in the empalement.

We know but one Species of this genus, viz.

TARCHONANTHUS. *Hort. Cliff.* 398. Shrubby African Fleabane with Sage leaves smelling like Camphire.

This plant grows naturally at the Cape of Good Hope; it has a strong woody stalk, which rises to the height of twelve or fourteen feet, sending out many ligneous branches at the top, garnished with leaves, which are in shape like those

those of the broad-leaved Sallow, having a downy surface like those of Sage, and their under sides are white; these resemble in smell the Rosemary leaves when bruised. The flowers are produced in spikes at the extremity of the shoots, which are of a dull purple colour, so do not make any great appearance. The usual time of its flowering is in autumn; they continue great part of winter, but are not succeeded by seeds here. These plants are preserved to make a variety in the green-house, during the winter season, by those who are curious in collecting of foreign plants; they retain their leaves all the year.

It is too tender to live through the winter in the open air in *England*, but requires no artificial heat, therefore may be placed in a common green-house with Myrtles, Oleanders, and other hardy exotick plants in winter, and in summer may be exposed with them in the open air, and treated in the same manner as they are.

It may be propagated by cuttings, which should be planted in *May*, in pots filled with light earth, and if they are plunged into a moderate hot bed, it will promote their putting out roots. These should be shaded with mats, or covered with oiled paper, to screen them from the sun until they are rooted. By the middle of *July* these cuttings will have taken root, when they should be each transplanted into a separate pot, and placed in the shade until they have taken new root; after which time they may be placed with other hardy exotick plants in a sheltered situation, where they may remain till the middle or end of *October*, when they should be removed into the green-house, placing them where they may have a large share of air in mild weather. This plant is very thirsty, so must be often watered, and every year the plants must be shifted, and, as they increase in size, should be put into larger pots.

TARRAGON. See *Abrotanum*.

TAXUS. *Tourn. Inst. R. H.* 589. *tab.* 362. The Yew-tree.

The Characters are,

The male flowers are for the most part produced on separate trees from those with fruit; they have neither empalement or petals, but the germ is like a four-leaved cover; they have a great number of stamina, which are joined at the bottom in a column longer than the germ, terminated by depressed summits, having eight points, opening on each side their base, casting their farina. The female flowers are like the male, having no empalement or petals, but have an oval acute-pointed germen, but no style, crowned by an obtuse stigma. The germen afterward becomes a berry lengthened from the receptacle, globular at the top, covered by a proper coat at bottom, open at the top, full of juice, and of a red colour, but, as it dries, wastes away, including one oblong-oval seed, whose top without the berry is prominent.

We have but one Species of this plant in *England*, viz.

TAXUS foliis approximatis. *Lin. Sp. Plant.* 1040. Yew-tree with leaves growing near each other; or the common Yew.

This tree grows naturally in *England*, and also in most of the northern countries of *Europe*, and in *North America*, where if it is suffered to stand long, will rise to a good height, and have very large stems; it naturally sends out branches on every side, which spread out, and are almost horizontal; these are closely garnished with narrow, stiff, blunt-pointed leaves, of a very dark green. The flowers come out from the side of the branches in clusters; the male flowers having many stamina, are more conspicuous than the female; these for the most part are upon different trees, but sometimes are upon the same tree; they appear the latter end of *May*, and the berries ripen in autumn.

There is hardly any sort of ever-green tree, which has been so generally cultivated in the *English* gardens as the Yew, upon the account of its being so tonfise, as to be with

ease reduced into any shape the owner pleased; and it may be too often seen, especially in old gardens, what a wretched taste of gardening prevailed formerly in *England*, from the monstrous figures of beasts, &c. we find these trees reduced into; but of late this taste has been justly exploded by persons of superior judgment, for what could be more absurd than the former methods of planting gardens? where, those parts next the habitation, were crowded by a large quantity of these and other sorts of ever-green trees, all of which were clipped into some trite figure or other, which, besides the obstructing the prospect from the house, and filling up the ground, so that little room was left for other shrubs and flowers. Beside, it occasioned an annual expence to render the trees disagreeable, for there never was a person, who had considered the beauty of a tree in its natural growth, with all its branches diffused on every side, but must acknowledge such a tree infinitely more beautiful than any of those shorn figures, so much studied by persons of a grovelling imagination.

The only use this tree is fit for in gardens, is to form hedges for the defence of exotick plants; for which purpose, when it is necessary to have hedges, it is the most proper of any tree in being; the leaves being small, the branches are produced very closely together; and if carefully shorn, they may be rendered so close, as to break the winds better than any other sort of fence whatever, because they will not be reverberated, as against walls, pales, and other close fences; therefore consequently, are much to be preferred for such purposes.

These trees may be easily propagated by sowing their berries in autumn as soon as they are ripe (without clearing them from the pulp which surrounds them, as hath been frequently directed), upon a shady bed of fresh undunged soil, covering them over about half an inch thick with the same earth.

In the spring the bed must be carefully cleared from weeds; and if the season prove dry, it will be proper to refresh the bed with water now and then, which will promote the growth of the seeds; many of which will come up the same spring, but others will remain in the ground until autumn or spring following; but where the seeds are preserved above ground till spring before they are sown, the plants never come up till the year after, so that by sowing the seeds as soon as they are ripe, there is often a whole year saved.

These plants, when they come up, should be constantly cleared from weeds, which, if permitted to grow amongst them, would cause their bottoms to be naked, and frequently destroy the plants when they continue long undisturbed.

In this bed the plants may remain two years; after which, in autumn, there should be a spot of fresh undunged soil prepared, into which they should be removed the beginning of *October*, planting them in beds about four or five feet wide, in rows about a foot asunder, and six inches distance from each other in the rows, observing to lay a little mulch upon the surface of the ground about their roots, as also to water them in dry weather until they have taken root; after which they will require no farther care, but to keep them clear from weeds in summer, and to train them according to the purpose for which they are designed.

In these beds they may remain two or three years, according as they have grown, when they should again be removed into a nursery, placing them in rows at three feet distance, and the plants eighteen inches asunder in the rows, observing to do it in autumn, as was before directed, and continue to trim them in the summer, for what they are intended; after they have continued three or four years in this nursery, they may be transplanted where they are to remain, always observing to remove them in autumn where

the ground is very dry; but on cold moist land it is better in the spring.

These trees are very slow in growing, but yet there are many very large trees upon some barren cold soils, in divers parts of *England*. The timber of these trees is greatly esteemed for many uses.

TELEPHIOIDES. See *Andrachne*.

TELEPHIUM. *Tourn. Inst. R. H. 248. tab. 128.* Orpine.

The Characters are,

The empalement of the flower is permanent, composed of five leaves, which are obtuse, and the length of the petals. The flower has five oblong obtuse petals, and five awl-shaped stamina, which are shorter than the petals, terminated by prostrate summits, with a three-cornered acute germen, having no style, crowned by three acute spreading stigmas. The germen afterward turns to a short three-cornered capsule with one cell, opening with three valves, containing many round seeds.

We have but one Species of this genus in the English gardens, viz.

TELEPHIUM. *Hort. Upsal. 70.* Orpine, Live long, or the true Orpine of *Imperatus*.

This plant grows naturally in the south of *France* and *Italy*. The root is composed of ligneous fibres of a yellowish colour. The branches or stalks are slender, and trail upon the ground; they are garnished with small, oval, smooth leaves, of a grayish colour, which are ranged alternately along the stalk, having one longitudinal nerve running through the middle. The flowers are produced at the end of the branches in short thick spikes, which are reflexed like those of the *Heliotropium*. They are composed of five white petals, which spread open, and are the length of the empalement, having five very slender stamina, terminated by yellow summits.

This is propagated by seeds, which should be sown in autumn, on a bed of fresh light earth, in an open situation, for if they are sown in the spring, the plants will not come up till the following spring. When the plants are come up, they should be thinned, so as to leave them six or eight inches asunder, and should be constantly kept clear from weeds; for if these are permitted to grow, they will soon overbear the plants, and destroy them. These plants do not bear removing well, so should stand in the place where they were sown. In the summer they will flower, and the seeds will ripen in autumn, which will scatter soon if it is not gathered when ripe; and, if the ground is not disturbed, the plants will come up in plenty, and require no other care than to keep them clear from weeds.

TEREBINTHUS. See *Pistachia*.

TERNATEA. See *Clitoria*.

TERRACES. A terrace is a bank of earth, raised on a proper elevation, so that any person who walks round a garden, may have a better prospect of all that lies round him; and these elevations are so necessary, that those gardens which are flat, and that have them not, are deficient.

When the terraces are rightly situated, they are great ornaments, especially when they are well made, and their ascent not too steep.

There are several kinds of terrace walks:

1. The great terrace, which generally lies next to the house.

2. The side terrace, which is commonly raised above the level of the parterre, lawn, &c.

3. Those terraces which encompass a garden.

As to the breadth of side terraces, this is usually decided by its correspondence with some pavilion, or some little jetty or building; but most of all by the quantity of stuff that is to spare for those purposes.

The side terrace of a garden ought not to be less than twenty feet, and seldom wider than forty.

As for the height of a terrace, some allow it to be but five feet high, but others more or less, according to their fancies; but more exact persons never allow above five or six feet, but in a small garden, and a narrow terrace walk, three feet; and sometimes three feet and a half high are sufficient for a terrace twelve feet wide, and four feet are sufficient for a terrace of twenty feet wide; but when the garden is proportionably large, and the terrace is thirty or forty feet wide, then it must be at least five or six feet high.

The noblest terrace is very deficient without shade, for which Elm-trees are very proper; for no seat can be said to be complete, where there is not an immediate shade almost as soon as out of the house, and therefore these shady trees should be detached from the body and wings of the edifice.

TETRACERA. *Lin. Gen. Plant. 604.*

The Characters are,

The flower has a permanent empalement of six roundish spreading leaves; the three outer are alternate, and smaller than the other; it has six small petals, which soon fall off, and a great number of stamina, which are permanent, the length of the empalement, terminated by single summits; it has four oval germen, supporting a short awl-shaped style, crowned by an obtuse stigma. The germen afterward becomes four oval reflexed capsules, each having one cell, opening at the suture on the upper side, inclosing one roundish seed.

We have but one Species of this genus, viz.

TETRACERA. *Hort. Cliff. 214.*

This plant grows naturally at *La Vera Cruz*, where it was discovered by the late Dr. *Houssoun*, who sent it to *England*. It has a woody stalk, which rises to the height of twelve or fourteen feet, covered with a gray bark, sending out several slender ligneous branches, which twine about any neighbouring support, garnished with oblong oval leaves, whose surface are very rough, slightly indented on their edges toward their points, having many transverse veins running from the midrib to the edges, placed alternate on the branches, standing upon short foot-stalks, of a grayish colour on their upper surface, and brown on their under. The flowers are produced in panicles at the end of the branches; these panicles are composed of three or four short thick spikes, which branch out from the lower part of the principal spike, which is much longer and thicker than the other. The flowers have six thin purple petals, of the same length as the empalement, which are very fugacious, so that they soon fall off; these sit upon the germen. After the flowers are past, the four germen become so many oval capsules, which are reflexed backward; these open lengthways on the upper side, and have each one oblong seed inclosed.

This shrub is very different from that which Dr. *Plukenet* titles *Fagus Americanus ulmi amplissimis foliis, capsulis bigemellis*. *Amalth. 87.* though Dr. *Linnaeus* has added this synonyme to it.

This is propagated by seeds, which must be procured from the countries where the plant naturally grows, which may probably be found in some of the *British* islands in the *West-Indies*. I have received it from the island of *Barbuda*, where it was found by the late Dr. *Cressy*, who sent me specimens and seeds. These seeds are frequently abortive, for, upon examining them, there was scarce more than a twentieth part which had any kernels; the others appeared fair, but were hollow. The seeds should be sown in pots filled with light earth, and plunged into a moderate hot-bed of tanners bark, where they must be treated in the same way as other exotick seeds from the same countries; and as the plants seldom come up the same year, the pots should be removed into the stove before winter, and plunged into the tan-bed, between the other pots of plants, where they

they should remain till spring, when they should be taken out and plunged into a fresh hot-bed of tanners bark, which will bring up the plants if the seeds were good. When the plants are fit to remove, they should be each planted in a separate small pot, filled with light earth, and plunged into a good bed of tan, shading them from the sun till they have taken new root; after which their treatment must be the same as for the *Annona*, and the like tender exotick plants, which require to be kept always in the tan-bed.

TETRAGONIA. *Lin. Gen. Plant.* 551.

The Characters are,

The flower has a permanent coloured empalement, composed of four oval plain leaves, sitting upon the germen. It has no petals, but about twenty hair-like stamina, which are shorter than the empalement, terminated by oblong prostrate summits, and a roundish four-cornered germen under the flower, supporting four oval shaped styles, which are recurved and as long as the stamina, with hairy stigmas the length of the styles. The germen afterward becomes a thick capsule with four cells, having four angles, which have narrow wings or borders, containing one hard oblong seed in each.

The Species are,

1. **TETRAGONIA foliis linearibus.** *Flor. Leyd. Prod.* 250. *Tetragonia* with linear leaves.

2. **TETRAGONIA foliis ovatis integerrimis, caule fruticoso decumbente,** *Tetragonia* with oval entire leaves, and a shrubby trailing stalk.

3. **TETRAGONIA foliis ovatis.** *Flor. Leyd. Prod.* 250. *Tetragonia* with oval leaves.

These plants grow naturally at the *Cape of Good Hope*. The first sort has slender ligneous stalks, which rise three or four feet high, if they are supported, otherwise they trail upon the ground, covered with a light gray bark, and divide into a great number of trailing branches, which, when young, are succulent, of an herbaceous colour, covered with small pellucid drops, somewhat like the *Diamond Ficoides*, which reflect the light. As the branches are older, they become more ligneous; they are garnished with thick, succulent, narrow, concave, blunt leaves, placed alternate, and at their base come out a cluster of smaller leaves. The flowers are produced from the wings of the stalks at every joint toward the end of the branches, sometimes they come singly, at others there are two, and sometimes three flowers at each joint; these have empalements of five leaves, which spread open, and are a little reflexed; they are green without, and yellow within, each having about forty stamina, which are terminated by oblong prostrate summits, which fill up the middle of the flower. They appear in *July* and *August*, and are succeeded by large four-cornered capsules, having four wings or borders, and four cells, each containing one oblong seed, which ripens in winter.

The second sort has larger stalks than the former, which branch out in like manner; the branches trail upon the ground where they are not supported; the young branches are very succulent, and almost as thick as a man's little finger; the leaves are two inches long, and one broad; their surface are covered with very small pellucid drops, as are the stalks. The flowers are larger, and stand upon pretty long foot-stalks, three or four arising from the same points; the empalement, and also the summits, are of a pale Sulphur colour.

These may be propagated by cuttings, which should be cut from the plants a few days before they are planted, that the part where they are cut may be healed, otherwise they will rot; for the leaves and stalks of this plant are very full of moisture. The best time to plant these cuttings is in *July*, that they may have time to make good roots before winter. They may be planted on a bed of fresh earth; and if they are shaded from the sun in the heat of the day,

it will be of service to them. They should be frequently refreshed with water; but they must not have it in too great plenty, for that will rot them. In about six weeks after planting, the cuttings will be sufficiently rooted to transplant, therefore they should be taken up, and planted in pots filled with light, fresh, undunged earth, and placed in a shady situation, until they have taken new root; after which time they may be placed with other hardy exotick plants, in a sheltered situation, where they may remain till the middle or latter end of *October*; at which time they should be removed into the green-house, and placed where they may enjoy as much free air as possible in mild weather, for they only require to be protected from the frost, being pretty hardy with respect to cold; but they should not have too much moisture in winter. If these plants are planted in the full ground in the summer season, they will grow prodigiously rank and large, as they also will if they are permitted to root into the ground through the holes at the bottom of the pots; therefore the pots should be frequently removed to prevent it, for when they grow too freely, their leaves will be very full of moisture; which, together with the weight of the fruit, which are always produced at the extremity of the branches, will weigh the branches upon the ground, and render the plants very un-fightly. The plants of this kind commonly grow very straggling; therefore the more their roots are confined in the pots, the more close and stunted will be the heads of the plants, which is what they should always be kept to, in order to render them fightly. The flowers of this plant have no great beauty, but as the whole face of the plant is peculiar, it may be allowed a place in every collection of plants for the sake of variety, since it requires no great trouble to cultivate it.

These plants may also be propagated by seeds, which should be sown on a warm border of light fresh earth, where sometimes they will remain a whole year before the plants come up; therefore when they do not come up the first season, the borders should not be disturbed, but kept constantly clear from weeds; and when the plants are come up about four inches high, they should be taken up and planted in pots (and treated in the same manner as hath been directed for the cuttings); for if they are suffered to grow in the border till they are large, they will not transplant so well, nor will they make so handsome plants.

The third sort hath large fleshy roots; the branches are weak, and trail upon the ground; these generally decay about *Midsummer*, and new shoots are produced late in autumn. The leaves of this come out in bunches; they are oval, plain, and not so thick and succulent as those of the other sorts. The flowers are produced from the wings of the leaves in *February*; these are like those of the second sort, and have pretty long slender foot-stalks. The cuttings of this sort will grow, if they are planted early in the spring; so that it may be propagated with the same facility as either of the other kinds.

All these sorts require protection in winter; but if they are placed in an airy glass-case, or under a frame in winter, with *Ficoides*, and other hardy plants, where they may have a large share of free air in mild weather, and protected from the frost, they will thrive much better than when they are more tenderly treated.

TETRAGONOTHECA. *Hort. Elth.* 283. Sun-flower.

The Characters are,

The flower is composed of hermaphrodite and female florets, which are included in one large common empalement, cut into four plain, triangular, heart shaped segments, which spread open. The disk or middle of the flower is made up of hermaphrodite florets, which are funnel-shaped, cut into five parts at the brim, which are reflexed; they have five short hair-like stamina, terminated

minated by cylindrical summits, and a naked germen, supporting a slender style, crowned by two reflexed stigmas. The germen after-ward becomes one naked roundish seed. The female half florets, which compose the ray or border of the flower, have their petals stretched out like a tongue on one side, and are cut at their points into three equal acute parts. These have no stamina, but a naked germen, supporting a slender style with two twisted stigmas, and are succeeded by single naked seeds.

We have but one Species of this genus, viz.

TETRAGONOTHECA. *Lin. Sp. Plant.* 903. Dwarf Sun-flower.

This plant is a native of *Carolina*; the roots of this plant are perennial, but the stalks are annual, and perish in autumn on the approach of cold. The roots will abide through the winter in the full ground, if they are planted in a warm situation, so do not require any shelter, except in very severe winters; when, if they are covered over with rotten tan, or Peas haulm, to keep out the frost, there will be no danger of their being killed.

About the latter end of *April*, or the beginning of *May*, the roots will send forth new shoots, which are garnished with large, oblong, rough leaves, placed by pairs, closely embracing the stalks; these are a little sinuated on their edges, and are covered with small hairs. The stalks usually grow about two feet high in *England*, and branch out toward the top into several smaller stalks, each having one large yellow flower at their top, shaped like a Sun-flower, which, before it expands, is covered with the inflated empalement, which is four-cornered. The seeds of this plant rarely ripen in *England*, but when they are obtained from abroad, they should be sown in the fall ground in the spring of the year, where sometimes they will remain a year before the plants come up; so that if they do not come up the same year, the ground should not be disturbed, but kept clean from weeds, and wait till the second year to see what plants will come up. When the plants appear, they must be kept clean from weeds, and if the season should prove dry, they will require to be frequently watered. In autumn the plants should be transplanted into the places where they are to remain.

These plants will live three years in a proper soil and situation; but as it does not ripen seeds here, the best method is to procure good seeds from abroad annually.

TEUCRIUM. *Lin. Gen. Plant.* 625. Tree Germander.

The Characters are,

The empalement of the flower is of one leaf, cut into five acute equal segments at the top, and is permanent. The flower is of the lip kind with one petal, having a short cylindrical tube a little incurved at the chaps. The upper lip is erect, and deeply cut into two acute segments. The lower lip spreads, and is cut into three; the middle one is large and roundish; the two side ones are acute and erect. It has four awl-shaped stamina, which are longer than the upper lip, and are prominent between the segments, terminated by small summits. It has a germen divided in four parts, supporting a slender style, crowned by two slender stigmas. The germen after-ward turns to four roundish naked seeds, which ripen in the empalement.

The Species are,

1. TEUCRIUM foliis cordatis undulatis obtusè serratis, floralibus integerrimis concavis, caule fruticoso. *Lin. Sp. Plant.* 565. Tree Germander with heart-shaped waved leaves, which are bluntly sawed, those between the flowers concave and entire, and a shrubby stalk; common Tree Germander.

2. TEUCRIUM foliis ovatis crenatis, floralibus lanceolatis integerrimis, caule fruticoso. Tree Germander with oval crenated leaves, those between the flowers spear-shaped and entire, and a shrubby stalk; shrubby *Alpine* Tree Germander with shining leaves.

3. TEUCRIUM foliis integerrimis oblongo-ovatis petiolatis,

suprà glabris, subtus tomentosis. *Lin. Sp. Plant.* 563. Tree Germander with entire, oblong, oval leaves, having foot-stalks, smooth above, and hoary underneath; or *Spanish* Tree Germander.

4. TEUCRIUM foliis integerrimis, rhombeis, acutis, villosis, subtus tomentosis. *Hort. Upsal.* 195. Tree Germander with entire leaves, which are hairy, shaped like an acute rhombus, and woolly on their under side.

5. TEUCRIUM foliis multifidis, floribus solitariis. *Lin. Sp. Plant.* 562. Germander with many-pointed leaves, and flowers growing singly.

6. TEUCRIUM foliis multifidis, floribus verticillatis utrinque ternis. *Lin. Sp. Plant.* 562. Germander with many-pointed leaves, and flowers growing in whorls by threes.

7. TEUCRIUM foliis ovatis inciso-crenatis petiolatis, floribus subverticillatis. *Hort. Cliff.* 302. Germander with oval leaves on foot-stalks, with crenated cuts, and flowers growing almost in whorls; or smaller creeping Germander.

8. TEUCRIUM foliis ovatis utrinque acutis, supernè serratodentatis, floribus racemosis. *Flor. Leyd. Prod.* 307. Germander with oval leaves, which are pointed at both ends, saw-indented toward their points, and flowers growing in bunches.

9. TEUCRIUM foliis oblongo ovatis inciso-crenatis acuminatis, floribus subverticillatis. Germander with oblong oval leaves, which are acute-pointed, jagged, and crenated, and have flowers growing almost in whorls; or greater creeping Germander.

10. TEUCRIUM foliis ovatis tomentosis, obtusè crenatis, floralibus integerrimis, calycibus aculeatis. Teucrium with oval woolly leaves, which are obtusely crenated, those among the flowers entire, and the empalements of the flowers ending in acute points.

11. TEUCRIUM foliis oblongo ovatis supernè serratis villosis, subtus incanis sessilibus, floribus subverticillatis. Teucrium with oblong oval leaves, which are sawed toward their points, hairy, and hoary on their under side, sitting close to the branches, and flowers growing almost in whorls; or hoary *Alpine* Germander.

12. TEUCRIUM foliis cordatis serratis petiolatis, racemis lateralibus secundis, caule erecto. *Lin. Sp. Plant.* 564. Germander with heart-shaped sawed leaves, having foot-stalks, many long bunches of flowers growing from the wings, and an upright stalk; or wild Sage.

13. TEUCRIUM foliis oblongis sessilibus dentato serratis, floribus geminis axillaribus, caule diffuso. *Lin. Sp. Plant.* 565. Germander with oblong saw-indented leaves sitting close to the branches, and flowers growing by pairs at the wings of the stalk, which is diffused; or Water Germander.

14. TEUCRIUM foliis integerrimis ovatis utrinque acutis, racemis secundis villosis. *Lin. Sp. Plant.* 564. Germander with oval entire leaves, which are pointed at both ends, and hairy bunches of flowers; *Syrian* Mastick, or common Marum.

15. TEUCRIUM foliis trifidis linearibus integerrimis, floralibus sessilibus axillaribus. *Hort. Upsal.* 160. Germander with linear, trifid, entire leaves, and flowers sitting close, growing out of the wings of the branches; or common Ground Pine.

16. TEUCRIUM foliis linearibus villosissimis supernè dentatis, floralibus sessilibus. Germander with the most hairy linear leaves, which are indented toward their points, and flowers sitting close to the wings of the stalk; or Musk Ground Pine.

17. TEUCRIUM foliis linearibus tomentosis integerrimis, floralibus sessilibus. Germander with linear, woolly, entire leaves, and flowers sitting close to the branches; or Musk Ground Pine with entire leaves.

18. TEUCRIUM foliis oblongo-ovatis obtusè dentatis, floralibus solitariis alaribus pedunculatis, calycibus acutis. Germander with

with oblong oval leaves which are bluntly indented, and flowers placed singly at the wings of the stalks, having acute empalements.

19. *TEUCRIUM foliis ovato-lanceolatis, inæqualiter serratis, racemis alaribus terminalibusque calycibus inflatis.* Germander with oval spear-shaped leaves which are unequally sawed, and long bunches of flowers springing from the wings, and terminating the stalks, and inflated empalements.

The first sort grows naturally in the south of *France*, in *Spain*, and in *Italy*; it rises with a shrubby stalk two or three feet high, sending out many ligneous branches, garnished with heart-shaped leaves, a little waved, bluntly sawed on their edges, of a lucid green on their upper side, but a little hoary on their under, standing upon short foot-stalks. The upper part of the branches, for six or eight inches in length, are adorned with flowers, which come out from the wings of the stalk, two or three standing on each side at every joint; they are of a dirty white colour, and stand upon slender foot-stalks; under each of these whorls stand two smaller leaves, which are entire and concave.

This sort was formerly preserved in green-houses with great care, but of late years it hath been planted in the full ground, and is found hardy enough to endure the cold of our severest winters without shelter, provided it is planted on a dry soil.

This may be propagated by planting cuttings in the spring, on a bed of fresh light earth, observing to shade and water them until they have taken root; after which they will require no farther care, but to keep them clear from weeds, until the following autumn, when they may be transplanted where they are to remain, being very careful in removing them not to shake off all the earth from their roots, as also to water them, if the season should prove dry, until they have taken fresh root; after which, the only care they require is to keep the ground clean about them, and to prune off such shoots as are ill situated, and the flowering branches when they decay, whereby their heads will appear more regular.

It may also be propagated by seeds, which generally are produced in plenty. If these are sown upon a bed of light earth in *April*, the plants will come up in six weeks after, and may be transplanted in autumn, where they are designed to remain.

The second sort grows naturally on the *Alps*, but in the lower parts, where the cold is not very severe, and generally on moist ground; this hath a shrubby stalk like the former, and rises about the same height, but branches out more than that. The stalks are covered with a short hairy down; the lower leaves are oval, crenated, and of a lucid green on their upper side, but a little hoary on their under; the leaves between the flowers are spear-shaped and entire; the spikes of flowers are much longer; the flowers are larger, and their colour more inclining to a yellow than those of the former, and may be propagated in the same way.

The third sort grows naturally in *Spain* and *Sicily*, near the borders of the sea; this has a shrubby branching stalk, which rises six or eight feet high, covered with a hoary bark. The branches are garnished with small oval leaves, placed opposite, sitting close to them; they are smooth on their upper side, of a lucid green, but their under sides are hoary. The flowers come out singly from the wings of the stalk at the upper part of the branches, one on each side standing upon short foot-stalks; their empalements are short and hoary. The middle segment of the lower lip is large, and indented at the point; the stamina are long-hooked, and supply the place of the upper lip; the flowers are blue, and come in succession great part of summer, but the plants seldom produce good seeds in *England*.

There is a variety of this with variegated leaves, which is preserved in some gardens.

The third sort is tenderer than the former, though this will endure the cold of our ordinary winters, if planted on a dry soil and in a warm situation, but in severe frost it is sometimes destroyed; for which reason the plants are often preserved in pots, and removed into the greenhouse in winter. This is propagated by cuttings in the same manner as the former.

The fourth sort grows naturally in *Spain*; this has a great resemblance of the third, but the branches spread more horizontally. The leaves are sometimes heart-shaped, and at others in form of a rhombus; the lower leaves, which are the largest, are an inch and a half long, and three quarters of an inch broad; the upper are smaller, and of a different shape; these are downy on both sides, but the lower leaves are only so on the under. The flowers come out at the upper parts of the branches in like manner as the former, but are larger, and of a paler blue colour.

This is propagated in the same way as the other, and the plants require the same treatment.

The fifth sort grows naturally in *Spain* and *Italy* upon moist ground. The stalks of this are herbaceous, and trail upon the ground; they grow about a foot in length, and are garnished with deep green leaves cut in many points almost to the midrib; they are smooth, and stand opposite. The flowers are white, and come out on each side the stalks singly; these are succeeded by four seeds, which ripen in autumn.

This plant is preserved in botanick gardens for variety; it is propagated by seeds, which may be sown in the spring in the place where the plants are to remain, and, when they come up, will require no other culture but to thin them where they are too close, and keep them clean from weeds. These plants ripen their seeds the first year, but, if they are in a warm situation, they will live through the winter.

The sixth sort grows naturally in the south of *France*, in *Italy* and *Germany* in the Corn fields; this is an annual plant, which perishes soon after seeds are ripe. The stalks are four-cornered and hairy, about a foot long, garnished at every joint by leaves placed opposite, which are hairy and almost cut to the midrib; the segments are cut into three points. The flowers come out at the wings of the stalks in whorls, three standing together on each side upon short foot-stalks; they are white, and shaped like those of the other species; the seeds ripen in *August* and *September*.

This is propagated by seeds in the same way as the last; but if the seeds of this are sown in autumn, or permitted to scatter when ripe, they will succeed better than if sown in the spring, and the plants will come earlier to flower.

The seventh sort grows naturally in the south of *France*, and in *Germany*; this has a creeping fibrous root, which spreads in the ground, and multiplies greatly, sending out many four-cornered hairy stalks, which are eight or nine inches long, having a few short branches, garnished with oval leaves, which are deeply crenated on their borders, upon foot-stalks; they are of a light green above, but hoary on their under side. The flowers grow from the wings of the stalks, towards the upper part almost in whorls, standing chiefly to one side of the stalk; they are of a reddish colour, the lower lip turning inward. The seeds ripen in autumn.

It is a perennial plan, and propagates very fast by its creeping roots, and will thrive in almost any soil or situation: the best time to transplant it is in autumn. This was a few years since in great request as a specifick for the gout, but is at present in little esteem.

The eighth sort grows naturally in *Spain*; this is a perennial plant, having some resemblance of the former, but the roots do not creep. The stalks are taller and more erect; the leaves are narrower, pointed at both ends, and not so

deeply indented; the indentures are sharper; the stalks are garnished with flowers great part of their length, which come out in bunches at the wings; they are longer than those of the former, and of a brighter red colour.

It may be propagated by parting of the roots in autumn, or by sowing of the seeds at the same season, which will more certainly succeed than those which are sown in the spring. It loves an open situation exposed to the sun, but will thrive in almost any soil which is not too moist.

The ninth sort grows naturally in *Italy*; this is like the seventh sort, but the stalks grow almost twice the length of those, and send out a greater number of branches. The leaves of this are more acutely indented on their edges; they are hairy, of a light green on their upper side, and hoary on their under. The flowers grow almost in whorls from the wings of the stalks, to which they sit very close; they are sometimes red, and at others white, and both colours are often on the same plant. This sort may be propagated in the same way as the former.

The tenth sort grows naturally in the island of *Crete*, and also about *Nice* in *Italy*; this is a perennial plant with a low shrubby stalk, sending out many four-cornered branches, garnished with oval leaves, woolly on both sides, and are bluntly crenated on their borders. The upper parts of the branches are adorned with purple flowers in whorls, having two small oval entire leaves under each whorl; the flowers are as large as those of the first sort, but their cups are very woolly, and their indentures end in sharp points. When the season proves warm and dry, the plants will produce good seeds in *England*.

This may be propagated either by seeds or cuttings, in the same way as the two first sorts; but the plants should have a dry soil and a warm situation, otherwise they will not live through the winter in the open air in *England*.

The eleventh sort grows naturally on the *Alps*; this is like the seventh sort, but the stalks and leaves are very hairy, sawed toward their points, hoary on their under side, and sit close to the branches. The flowers are larger than those of the seventh sort, and are of a paler red colour. The seeds ripen in *August*.

This may be propagated by seeds or parting of the roots, in the same manner as the seventh.

The twelfth sort is the common wild or Wood Sage, which grows naturally in woods and thickets in many parts of *England*, so is rarely admitted into gardens; this has a creeping perennial root, from which arise stiff, ligneous, four-cornered stalks, a foot and a half high, garnished at each joint by two heart-shaped leaves placed opposite; slightly sawed on their edges, and stand upon foot-stalks. The upper part of the stalks have three or four long spikes of flowers, which incline to one side of the stalk; they are of an herbaceous white colour, and the stamina are terminated by purple summits. It flowers in *July*, and the seeds ripen in autumn. This plant will grow in any soil or situation, and was formerly used in medicine.

The thirteenth sort is the common Water Germander, which grows naturally in the isle of *Ely*, and some other fenny parts of *England*; it has a small, stringy, fibrous, creeping root, which is perennial, from which arise many four-cornered, trailing, diffused stalks, garnished with oblong, hairy, indented leaves, sitting close to the stalks. The flowers are produced at the wings of the stalks, two arising on each side, at every joint; they are of a purple colour, and sit very close to the bottom of the leaves; these appear in *July*, but are seldom succeeded by seeds. The whole plant has an odour like that of Garlick. The herb is used in medicine.

This plant may be propagated by its creeping roots, or planting the young shoots in the spring, in the same man-

ner as Mint, Penny Royal, &c. and should have a moist soil, otherwise it will not thrive in gardens.

The fourteenth sort is the common or *Syrian* Marum, which grows naturally in *Syria*, and also in the kingdom of *Valencia*; this has a low shrubby stalk, sending out many ligneous branches, which in warm countries will rise three or four feet high, but in *England* it is rarely seen half that height. The stalks are very hoary, garnished with small oval leaves opposite at each joint, about the size of those of Thyme, and are pointed at both ends; they are hoary, and have a piercing grateful scent, so quick as to cause sneezing. The flowers grow in loose whorled spikes at the end of the branches, of a bright red colour; they appear in *July* and *August*, but are not succeeded by seeds in *England*.

This plant is easily propagated by slips or cuttings, which, if planted during the summer months on a bed of light loamy earth, covering them down close either with bell or hand-glasses, and shading them from the sun, will put out roots very freely. When these have made good roots, they may be transplanted either into separate small pots, or on a warm border at about six inches distance every way, observing to shade them from the sun, and supply them with water till they have taken new root; after which they will require no other care, but to keep them clean from weeds. These plants will live through the winter in the open air, if they are planted in a dry soil and a warm situation, when the frosts are not very severe; but in very hard winters they are frequently killed, if they are not protected by mats or some other covering. There was, about forty years ago, a great number of these plants growing in the warm borders of the royal gardens at *Kenfington*, which were clipped into conical forms, and were near three feet high; but now there are few plants of a large size to be found in the *English* gardens, because their branches are annually cut to keep them short.

The cats are very fond of this plant, and where there are but few of these plants will destroy them, unless they are protected from them; but where there is a great number of the plants together, the cats seldom touch them.

The fifteenth sort is the common Ground Pine, which is used in medicine; it grows naturally on chalky arable land, in several parts of *England*; it is an annual plant, with a single ligneous root, sending out a few slender fibres from the side, from which arise many weak, trailing, hairy stalks, garnished with narrow leaves ending with three points, set by pairs and cross each other at every joint; they are hairy, and, when bruised, emit a strong resinous odour. The flowers sit close to the stalks at the wings of the leaves; there are two or three of them at each joint, of a bright yellow colour, and shaped like the other species. If the seeds are permitted to scatter, the plants will come up better than if sown, and require no other care but to thin them, and keep them clean from weeds.

This plant is greatly recommended for its virtues; there is scarce a better herb than this for opening obstructions; it is a strong diuretick, and an excellent remedy for the rheumatism.

The sixteenth sort grows naturally in the south of *France*, in *Italy*, and *Spain*; it is an annual plant, with a single ligneous root sending out a few fibres. The stalks are about six inches high, closely garnished with very hairy narrow leaves, which are indented towards their points. The flowers come out from the wings of the stalks, to which they sit very close; they are large, of a bright purple colour, and appear in *July*, but unless the season proves favourable, they are not succeeded by seeds in *England*.

The seventeenth sort grows naturally about *Nice* in *Italy*; this is also an annual plant, much like the former, but the leaves are narrower and entire. The whole plant is covered

vered with white woolly hairs, and the flowers are smaller than those of the former.

Both these plants succeed best, if, when they perfect their seeds, they are permitted to scatter in the same manner as the fifteenth sort; or, if the seeds are sown, it should be in autumn, for they rarely succeed when they are sown in the spring.

The eighteenth sort was discovered by the late Dr. *Houfston*, growing naturally at *La Vera Cruz*; this is an annual plant, with an erect four-cornered stalk a foot and a half high, garnished with smooth, oblong, oval leaves, which are bluntly indented. The flowers come out from the wings of the stalks, two of them arising at each joint, upon short slender foot stalks; they are small and white, having short empalements, which are cut at the brim into five very acute points. The flowers appear in *July*, and are succeeded by seeds which ripen in autumn.

The nineteenth sort was discovered by the late Dr. *Houfston*, at the same place with the former; this is also an annual plant, with a slender, upright, four-cornered stalk, which rises three feet high, and divides into several smooth branches, garnished with oval spear-shaped leaves, three inches long and one broad, of a bright green on their upper side, but pale on their under; they are unequally sawed on their edges, and stand upon long foot-stalks. The flowers come out in long bunches from the wings of the stalk and also at the top; they are pretty large, white, and have bladdered empalements; these appear late in *July*, and, unless the season proves favourable, they will have no good seeds succeed them.

The two last sorts are tender, so will not thrive in the open air in *England*; and, unless the season proves warm, they will not perfect their seeds here. The seeds of these should be sown in small pots in autumn, which should be plunged into the tan-bed in the stove between the other pots, where they should remain till spring, and then they may be taken out, and plunged into a hot bed, which will bring up the plants. When these are fit to remove, they should be each planted in a separate pot, and plunged into a hot bed, and afterward treated in the same way as other tender plants which require constant shelter.

THALICTRUM. *Tourn. Inst. R. H. 270. tab. 143.* Meadow Rue.

The Characters are,

The flower has no empalement, but has four or five roundish concave petals, which fall off soon, and a great number of broad stamina, which are compressed toward their tops, terminated by twin summits, with several very short styles sitting singly upon roundish germen, crowned by thick stigmas. The germen afterward turn to so many keel shaped capsules collected in a head, each containing one oblong seed.

The Species are,

1. THALICTRUM caule folioso sulcato, paniculâ erectâ. *Hort. Cliff. 226.* Meadow Rue with a furrowed leafy stalk, and many erect panicles of flowers.

2. THALICTRUM caule anguloso, foliis linearibus bifidis trifidisque, paniculâ multiplici erectâ. Meadow Rue with an angular stalk, narrow leaves ending in two or three points, and many erect panicles of flowers.

3. THALICTRUM fructibus pendulis triangularibus reëtis, caule tereti. *Lin. Sp. Plant. 547.* Meadow Rue with a pendulous triangular fruit, and a taper stalk; commonly called Feathered Columbine.

4. THALICTRUM caule folioso sulcato, foliis linearibus carnosis. *Dalib. Prif. 162.* Meadow Rue with a furrowed leafy stalk, and linear fleshy leaves.

5. THALICTRUM floribus pentapetalis, radice fibrosâ. *Flor. Leyd. Prod. 486.* Meadow Rue with flowers having five petals, and a fibrous root; *Canada Meadow Rue.*

6. THALICTRUM floribus pentapetalis, radice tuberosâ.

Hort. Cliff. 227. Meadow Rue with flowers having five petals, and a tuberous root.

7. THALICTRUM foliis sexpartitis, floribus cernuis. *Lin. Sp. Plant. 546.* Meadow Rue with leaves cut into six segments, and pendulous flowers.

8. THALICTRUM caule paniculato ramosissimo folioso. *Lin. Sp. Plant. 545.* Meadow Rue with a very branching paniculated leafy stalk; the least stinking Meadow Rue.

9. THALICTRUM floribus dioicis. *Lin. Sp. Plant. 545.* Meadow Rue with male and female flowers upon different plants.

10. THALICTRUM foliolis lanceolato-linearibus integerrimis. *Hort. Cliff. 226.* Meadow Rue with spear-shaped linear leaves, which are entire.

11. THALICTRUM caule simplicissimo subnudo, racemo simplici terminali. *Hort. Cliff. 227.* Meadow Rue with a single stalk, which is almost naked, and terminated by a single bunch of flowers.

The first sort grows naturally by the side of rivers and in moist meadows in many parts of *England*. This has a yellow creeping root, from which arise several furrowed stalks four or five feet high, garnished at each joint with leaves composed of many lobes, which differ in their form and size; some are spear-shaped and entire, others are obtuse, and cut into three points; they are of a deep green colour on their upper side, but pale on their under. The flowers are of an herbaceous white colour, and formed into many panicles, standing erect on the top of the stalks. These appear in *July*, and are succeeded by short triangular capsules containing one oblong seed.

The second sort grows naturally in the meadows about *Montpelier*. The root of this is like the former; the stalks are angular, and rise five feet high; they are better furnished with leaves, whose lobes are very narrow, some of them ending with two, and others with three points, of a bright green colour. The flowers are yellow, and are formed into many panicles which terminate the stalks. This sort flowers about the same time with the former.

The third sort grows naturally upon the *Alps*; of this there are two varieties; one with a green stalk and white stamina, the other has purple stalks and stamina. These two are propagated in gardens, by the title of Feathered Columbine; this has a thick fibrous root, the stalks are taper and rise three feet high; the leaves are like those of the Columbine. The flowers grow in large panicles at the top of the stalk. It flowers in *June*, and the seeds, which are in triangular capsules, ripen in *August*.

The fourth sort grows naturally in the meadows about *Paris*; this hath upright channelled stalks, which rise three feet high, garnished at each joint with winged leaves composed of many linear fleshy lobes, which are for the most part entire, ending in acute points. The flowers are of a yellowish white colour; they appear in *July*, and are succeeded by small angular capsules, with one small oblong seed in each, which ripens in *August*.

The fifth sort grows naturally in *North America*; this has a fibrous root of a dark colour. The stalks are smooth, of a purple colour, and rise three or four feet high, branching toward the top. The leaves are like those of Columbine, of a grayish colour, and smooth. The flowers are produced in large panicles at the top of the stalks; they are larger than those of the former sorts, and have five white petals which soon fall off, and a great number of white stamina with yellow summits. This flowers in *June*, and the seeds ripen in *August*.

The sixth sort grows naturally in *Spain*; this has knobbed roots; the leaves are small, obtuse, and indented in three parts at their points; they are of a grayish colour and smooth. The stalks rise a foot and a half high, naked almost to the top, where they divide into two or three

small ones, under which is situated one leaf. Each division of the stalk is terminated by a small bunch of pretty large flowers, having five white petals. The flowers are almost disposed in form of an umbel. They appear in *June*, and are succeeded by small angular capsules, containing one oblong seed in each, which ripen in *August*.

The seventh sort grows naturally in some parts of *Cambridgehire*; this has a creeping fibrous root. The stalks rise about a foot high, and are garnished with winged leaves composed of many obtuse short lobes, which are cut into six segments. The stalks branch out wide; the flowers grow in loose panicles; they are small and nodding. The stamina are of an herbaceous white, and the summits are yellowish. It flowers in *June*.

The eighth sort grows naturally in the south of *France*; this hath a very branching stalk, which rises about six or seven inches high, garnished with winged leaves which are downy, composed of a great number of small lobes which are bluntly indented, and have a foetid scent. The flowers grow in loose panicles, they are small, of an herbaceous white colour, with yellowish stamina. This flowers in *June*.

The ninth sort grows naturally in *North America*. The root of this is fibrous; the stalks rise near a foot high, and are almost naked to the top, where they have one leaf, composed of many small lobes of a grayish colour, indented at their points. The flowers are produced in small bunches at the top of the stalks; they are male and female in different plants. These appear in *June*.

The tenth sort grows naturally in *Italy* and some parts of *Germany*; this hath a perennial root. The stalks rise from two to three feet high; the leaves are winged like those of the other sorts; their lobes are narrow and entire. The flowers are small, and are collected in panicles at the top of the stalks, and are of an herbaceous white colour.

The eleventh sort grows naturally on the *Alps*; this hath a fibrous creeping root: the leaves are small, blunt, and of a grayish colour. The stalks rise about six inches high, and are almost naked; they are terminated by a loose single spike of flowers, each having four petals. This flowers the latter end of *April* or the beginning of *May*.

These plants are generally propagated by parting their roots. The best time for this work is in *September*, when their leaves and stalks begin to decay, that they may take fresh root before the frost comes on to prevent them; they should also be planted in a fresh light soil, and have a shady situation, in which they will thrive exceedingly, though they may be planted in almost any soil or situation, provided it be not too hot and dry; but most of them creep so much under ground, as to become very troublesome in a garden, for which reason there are but few of the sorts admitted into gardens. The third, fifth, and sixth sorts are frequently cultivated in gardens. The roots of these do not creep like the others, and their flowers have some beauty to recommend them, but the others are only kept in botanick gardens for the sake of variety; therefore when they are admitted, their roots should be confined in pots, otherwise they cannot be kept within bounds.

THAPSIA. *Journ. Inst. R. H.* 321. *tab.* 171. The deadly Carrot, or scorching Fennel.

The Characters are,

It has an umbellated flower; the general umbel is large, composed of about twenty rays which are nearly equal, these have no involucri; the general umbel is uniform. The flowers have five spear-shaped incurved petals, and five hair-like stamina the length of the petals, terminated by single summits. It has an oblong germen situated under the flower, supporting two short styles crowned by obtuse stigmas. The germen afterward becomes an oblong fruit, girt with a longitudinal membrane dividing into two parts, each containing one oblong seed, pointed at both ends, having plain borders on both sides.

The Species are,

1. THAPSIA *foliolis dentatis basi coadunatis*. *Hort. Cliff.* 105. Scorching Carrot, with indented lobes which are joined at their base.

2. THAPSIA *foliis pinnatis, foliolis latissimis pinnatifidis subtus villosis petiolis decurrentibus*. Scorching Carrot with winged leaves, having very broad wing-pointed lobes, which are hairy on their under side, and running foot-stalks.

3. THAPSIA *foliolis multifidis basi angustatis*. *Hort. Cliff.* 105. Scorching Carrot with many-pointed lobes, which are narrowed at their base.

4. THAPSIA *foliolis multifidis setaceis*, *Hort. Cliff.* 106. Scorching Carrot with many-pointed bristly lobes.

5. THAPSIA *foliis ternatis ovatis*. *Lin. Sp. Plant.* 262. Scorching Carrot with oval trifoliate leaves.

6. THAPSIA *foliolis multifidis acutis, subtus villosis, petiolis bispidis*. Scorching Carrot with many pointed acute lobes, which are hairy on their under side, and have hairy foot-stalks.

The first sort grows naturally in *Spain*, *Portugal*, and the south of *France*; this hath a thick fleshy root in shape of a Carrot, which has an outward blackish skin; the inside is white, bitter, and very acrid, with a little aromack taste. The leaves are winged; the lobes are thick, hairy, and indented; they are regularly cut into opposite segments like other winged leaves. The stalk is spongy, and rises about two feet high, dividing upward into two or three small branches, each being terminated by a large umbel of yellow flowers. These appear in *June*, and are succeeded by large, flat, bordered seeds, which ripen in *August*.

The second sort grows naturally in *Spain*, particularly all over *Old Castile*, quite to the *Pyrenean* mountains. The root of this sort is large, thick, and of a dark colour without. The leaves are very thick, and hairy on their under side; they spread circularly on the ground, and are divided into broad lobes, like most of the other umbelliferous plants. The stalks rise three or four feet high; they are large, jointed, and full of pith, having one leaf at each joint, shaped like those at the bottom, but are smaller as they are nearer the top. The stalk is terminated by a large umbel of yellow flowers, which appear the latter end of *June*, and the seeds ripen two months after.

The third sort grows naturally in *Italy* and *Spain*. The leaves of this sort are cut into many narrow segments, almost as small as those of the Garden Carrot, but are rough and hairy; their segments are always opposite, and are narrower at their base than their points. The stalks rise about two feet high, and are terminated by umbels of small yellow flowers which appear in *July*; these are succeeded by flat bordered seeds, which ripen the beginning of *September*.

The fourth sort grows naturally in *Apulia*. The root of this is about the thickness of a man's thumb; the bark is yellow and wrinkled, the inside white, and abounds with an acrid milky juice; the leaves are finely divided like those of Fennel; they are hairy, and sit close to the root. The stalk rises from two to three feet high; it is naked, and branches into two or three stalks, each being terminated by a small umbel of flowers, which are large, yellow, and appear in *July*; these are succeeded by flat seeds, having cartilaginous borders, which ripen in *September*.

The fifth sort grows naturally in *North America*. The seeds were sent me by *Dr. Bensef* from *Philadelphia*. This has a slender tap-root, which is shaped like those of Parsley; the leaves at the bottom are heart-shaped. The stalk is single, and does not branch; it rises near two feet high, is of a purple colour, and slender, garnished at each joint with one trifoliate leaf, whose lobes are oval and crenated. The stalk is terminated by a small umbel of purple flowers, which appear in *July*, and are succeeded by compressed chan-

channelled seeds which ripen in *September*. Dr. Gronovius thinks this plant very like that which is figured by *Kempfer*, by the title of *Nindzi*.

The sixth sort grows naturally in *Austria*; this has a taper root as large as a man's thumb. The leaves spread circularly on the ground, and are divided into several parts; the lobes are very small, cut into many acute segments or points, which are opposite like winged leaves; they are rough and hairy. The foot-stalks of the leaves are broad, and are closely set with prickly hairs; the stalk rises near two feet high, and is terminated by an umbel of yellow flowers, which appear in *July*, and are succeeded by bordered compressed seeds, which ripen in *September*.

These plants are only propagated by seeds, which should be sown in autumn; for if they are kept out of the ground till spring, they often miscarry; or if they grow, they commonly lie a whole year in the ground before the plants come up; whereas those seeds which are sown in autumn, generally grow the following spring. These should be sown in drills, in the place where they are designed to remain. The drills should be at least two feet and a half asunder, because the plants spread their leaves very wide. When the plants come up in the spring, they must be carefully cleared from weeds; and where they are too close together, some of them should be drawn out, to give room for the others to grow; but at this time they need not be left more than two or three inches apart; for the first year the plants arise from seeds, they make but slow progress, so the autumn following the remaining part of the plants may be taken up, leaving those which are designed to remain about eighteen inches asunder; and those plants which are taken up, may be transplanted into another bed, if they are wanted. After the first year these plants will require no farther care, but to keep them clean from weeds; and every spring, just before the plants begin to push out new leaves, the ground should be carefully dug between them, to loosen it, but the roots must not be injured, lest it should cause them to decay. The plants being thus managed, will continue several years, and produce flowers and seeds annually, from which new plants may be raised. They delight in a soft loamy soil, and if they are exposed only to the morning sun, they will thrive better than if they have a warmer situation, for they endure the cold of our winters very well.

The roots of the third sort were formerly used in medicine, but are now never ordered, being supposed to have a poisonous quality. *Boerhaave* says it has much the same qualities as *Euphorbium*; it burns the bowels, and produces a diarrhoea.

THELIGONUM. *Lin. Gen. Plant.* 947. Dogs Cabbage.

The Characters are,

It has male and female flowers on the same plant. The male flowers have a turbiated empalement of one leaf, cut into two segments, which turn backward. It has no petal, but several erect stamina the length of the empalement, terminated by single summits. The female flowers have a small bifid empalement of one leaf, which is permanent. It has no petals, but has a globular germen, supporting a short style, crowned by an obtuse stigma. The germen afterward becomes a thick globular capsule with one cell, inclosing one globular seed.

We have but one Species of this genus, viz.

THELIGONUM. *Sauv. Monsp.* 129. This is the Cynocrambe, or Dogs Cabbage of *Dioscorides*.

This plant grows naturally in the south of *France*, in *Italy*, and *Tartary*. It is annual. The stalks trail on the ground like those of *Chickweed*; they grow about a foot long; their joints are pretty close, garnished with oval acute-pointed leaves, standing on pretty long foot-stalks,

which are bordered. At each joint is placed one of these leaves, and from the same point come out several smaller, of the same shape, on shorter foot-stalks. The flowers are produced from the wings of the stalk in clusters, sitting very close; they are small, of an herbaceous white colour, so make no great appearance. The male and female flowers grow from the same joint. The female flowers are succeeded by a single roundish seed, which ripens in autumn.

It is preserved in botanick gardens for the sake of variety. The seeds of this must be sown in autumn, in the place where the plants are to remain; for when they are sown in the spring, the plants rarely come up the same year. They require no other culture but to keep them clean from weeds, and thin them where they are too close.

THEOBROMA. *Lin. Gen. Plant.* 806. Bastard Cedar.

The Characters are,

The empalement of the flower is composed of three oval concave leaves, which are reflexed. The flower has five oval petals, which spread open, and are hollowed like a spoon; from the top of each petal comes out a bifid bristly ligula, divided like two horns. It has a great number of short stamina joined in five bodies, which are terminated by roundish summits, and a roundish germen, supporting a single style the length of the petals, crowned by a single stigma. The germen afterward turns to a roundish fruit with five angles, opening in five cells, each containing several seeds.

We have but one Species of this genus, viz.

THEOBROMA foliis serratis. *Hort. Cliff.* 379. Theobroma with sawed leaves.

This grows naturally in most of the islands in the *West-Indies*, where it rises to the height of forty or fifty feet, having a trunk as large as a middle-sized man's body, covered with a dark brown furrowed bark, sending out many branches toward the top, which spread wide on every hand, garnished with oblong heart-shaped leaves, placed alternate, of a bright green on their upper side, and pale on their under, sawed on their edges, with a strong midrib, and several transverse veins, standing upon short foot-stalks. The flowers come out in bunches from the wings of the leaves; they are small, of a yellow colour, having five concave petals, which spread open circularly, and a great number of stamina, which at their base are joined in five bodies, terminated by roundish summits. In the center is situated a roundish germen, supporting a slender style the length of the stamina, crowned by a single stigma. The germen afterward turns to a roundish warted fruit, having five obtuse angles, and five cells, which contain several irregular seeds.

The wood of this tree is white and ductile, so is frequently cut into staves for casks. The fruit and leaves are good fodder for cattle, therefore when the planters clear the land from wood, they leave the trees of this sort standing for the feed, which is of great use in dry seasons, when the common fodder is scarce.

There are some plants of this sort in *England* preserved in the gardens of curious persons; it is propagated by seeds, which must be procured as fresh as possible, from the countries where the plants grow naturally. These should be sown upon a good hot-bed in the spring; and when the plants are fit to remove, they should be each planted in a separate small pot, and plunged into a hot-bed of tanners bark, observing to shade them from the sun till they have taken new root; then they should be treated in the same way as the *Coffee-tree*, keeping them always in the tan-bed in the stove.

THERMOMETERS, or THERMOSCOPES, are instruments of very great use to gardeners in the management of stoves. They shew, by inspection, the present condition of the air, whether it be hot or cold; which day in summer is the hottest, and in the winter which is the coldest,

er any part of the day; and from thence many useful experiments have and may be made, *viz.* how much one spring exceeds another in coldness; which baths are the hottest or coldest; and, if being held in the hand of a person in a fever, or otherwise applied, will nicely shew the abatement or increase of a fever.

The common thermometer, which is used for hot-houses, has a tube of about two feet in length, and about the eighth part of an inch diameter; and in this it is remarked, that the air is cold for the plants when the spirit rises to fifteen inches above frost; that it is temperate at sixteen inches and a half; that it is warm when it rises to eighteen inches, which is the standard for Pine-apple heat. It is marked for hot air at twenty inches, and sultry hot at twenty-one and a half; but in the common thermometers, these degrees are differently marked; this temperate air is about our warm, this warm air our hot, and our hot air is about the same as the sultry.

These thermometers are marked with the names of some of the remarkable plants which are preserved in the hot-houses; but as the number of these plants has been greatly increased in *England* of late years, I have directed some thermometers to be made with a scale, divided into degrees, and with three different points of heat marked in classes, which correspond with these thermometers; and under each class, I have drawn up lists of the several plants, ranged according to the degrees of heat in which they are found to succeed, whereby the culture of them is made easy to persons of small skill.

By this means every gardener may know when it is proper to apply his heat in its full force, and what degree of heat ought to be used for the welfare of any plant from any part of the world.

Mr. *Boyle*, by placing a thermometer in a cave, which was cut strait into the bottom of a cliff, fronting the sea, to the depth of 130 feet, found the spirit stood, both in winter and summer, at a small division above temperate; the cave had 80 feet depth of earth above it.

I, says Dr. *Hales*, marked six thermometers numerically, 1, 2, 3, 4, 5, 6. The thermometer, number 1, which was the shortest, I placed with a south aspect in the open air; the ball of number 2, I set two inches under ground; that of number 3, four inches; number 4, eight inches; number 5, sixteen inches; and number 6, twenty-four inches: and that the heat of the earth at those several depths may the more accurately be known, it is proper to place near each thermometer a glass tube, sealed at both ends, of the same length with the stems of the several thermometers, and with tinged spirit of wine in them to the same height as in each corresponding thermometer; the scale of degrees of each thermometer being marked on a sliding ruler, with an index to the back of it, pointing to the corresponding tube.

When at any time an observation is to be made, by moving the index to point to the top of the spirit in that tube, an accurate allowance is hereby made for very different degrees of heat and cold in the stems of the thermometers at all depths; by which means the scale of degrees will shew truly the degrees of heat in the balls of the thermometers, and consequently the respective heats of the earth at the several depths where they are placed.

The stems of these thermometers, which were above the ground, were fenced from weather and injuries, by square wooden tubes. The ground they were placed in, was a brick earth in the middle of my garden.

July the 30th he began to keep a register of their rise and fall: during the following month of *August* he observed, that when the spirit in the thermometer, number 1, (which was exposed to the sun) was about noon risen to 48 de-

grees, then the second thermometer was 45, the fifth 33, and the sixth 31; the third and fourth at intermediate degrees: the fifth and sixth thermometers kept nearly the same degree of heat, both night and day, till towards the latter end of the month, when, as the days grew shorter and cooler, and the nights longer and cooler, they then fell to 25 and 27 degrees.

Now so considerable a heat of the sun, at two feet depth under the earth's surface, must needs have a strong influence in raising the moisture at that and greater depths, whereby a very great and continual reek must always be ascending during the warm summer season, by night as well as by day, for the heat at two feet deep is nearly the same night and day, the impulse of the sun-beams giving the moisture of the earth a brisk undulating motion; which watery particles, when separated and rarefied by heat, ascend in the form of a vapour; and the vigour of the warm and confined vapour (such as is that which is one, two, or three feet deep in the earth) must be very considerable, so as to penetrate the roots with some vigour, as we may reasonably suppose from the vast force of confined vapour in *Eolipiles*, in the *Digester of Bones*, and the engine to raise water by fire.

If plants were not in this manner supplied with moisture, it were impossible for them to subsist under the scorching heats within the tropicks, where they have no rain for many months together; for though the dews are much greater there than in these more northern climates, yet, doubtless, where the heat so much exceeds ours, the whole quantity, evaporated in a day there, does as far exceed the quantity that falls by night in dew, as the quantity evaporated here in a summer's day is found to exceed the quantity of dew which falls in the night.

But the dew which falls in the hot summer season, cannot possibly be of any benefit to the roots of trees, because it is remanded back from the earth by the following day's heat, before so small a quantity of moisture can have soaked to any considerable depth.

The great benefit therefore of dew in hot weather must be, by being plentifully imbibed into vegetables, thereby not only refreshing them for the present, but also furnishing them with a fresh supply of moisture towards the great expences of the succeeding day.

It is therefore probable, that the roots of trees and plants are thus, by means of the sun's warmth, constantly irrigated with fresh supplies of moisture, which, by the same means, insinuates itself with some vigour into the roots; for if the moisture of the earth were not thus actuated, the roots must then receive all their nourishment merely by imbibing the next adjoining moisture from the earth; and consequently the shell of the earth, next the surface of the roots, would always be considerably drier the nearer it is to the root, which I have not observed to be so.

But when, towards the latter end of *October*, the vigour of the sun's influence is so much abated, that the first thermometer was fallen to three degrees above the freezing point, the second to ten degrees, the fifth to fourteen degrees, and the sixth to sixteen degrees; then the brisk undulations of the moisture of the earth, and also of the ascending sap, much abating, the leaves faded and fell off.

The greatest degree of cold, in the following winter, was in the first twelve days of *November*; during which time, the spirit in the first thermometer was fallen four degrees below the freezing point, the deepest thermometer ten degrees; the ice on ponds was an inch thick; the sun's greatest warmth, at the winter solstice, in a very serene, calm, frosty day, was, against a south aspect of a wall, 19 degrees, and, in a free open air, but 11 degrees above the freezing point.

From the 10th of *January* to the 29th of *March* was a very

very dry season, when the green Wheat was generally the finest that was ever remembered: but from the 29th of March 1725, to the 29th of September following, it rained more or less every day, except ten or twelve days about the beginning of July; and that whole season continued so very cool, that the spirit in the first thermometer rose but to 24 degrees, except now and then a short interval of sun-shine; the second only to 20 degrees, the fifth and sixth to 24 and 23 degrees, with very little variation; so that, during this whole summer, those parts of roots which were two feet under ground, had three or four degrees more warmth than those which were but two inches under ground; and, at a medium, the general degree of heat through this whole summer, both above and under ground, was not greater than the middle of the preceding September.

THLASPI. Town. Infl. R. H. 212. tab. 101. Mithridate, or Treacle Mustard.

The Characters are,

The empalement of the flower is composed of four oval concave leaves, which fall off. The flower has four oval petals, double the size of the empalement, placed in form of a cross; it has six stamina half the length of the petals, two of which are shorter than the others, terminated by acute summits, and a roundish compressed germen, supporting a single style the length of the stamina, crowned by an obtuse stigma. The germen afterward becomes an oval, heart-shaped, compressed little pod, with an acute border, divided into two cells by an intermediate partition, containing two or three seeds in each.

The Species are,

1. THLASPI *filiculis subrotundis, foliis sagittatis dentatis incanis*. Hort. Cliff. 330. Mithridate Mustard with roundish pods, and arrow-pointed, hairy, and indented leaves.

2. THLASPI *filiculis orbiculatis, foliis oblongis dentatis glabris*. Flor. Lapp. 251. Treacle Mustard with orbicular pods, and oblong, indented, smooth leaves; Treacle Mustard, or Penny Cress.

3. THLASPI *filiculis subrotundis, foliis oblongo-cordatis amplexicaulibus integerrimis*. Treacle Mustard with roundish pods, and oblong, heart-shaped, entire leaves, which embrace the stalks.

4. THLASPI *filiculis suborbiculatis, foliis lanceolatis integerrimis*. Hort. Cliff. 330. Treacle Mustard with leaves which are almost orbicular, and spear-shaped entire pods.

5. THLASPI *filiculis subovatis ventricosus, foliis oblongis obtusis dentatis glabris*. Prod. Leyd. 334. Treacle Mustard with almost oval swelling pods, and oblong, blunt, smooth, indented leaves.

6. THLASPI *filiculis subrotundis pilosis, foliis caulinis sagittatis hirsutis*. Prod. Leyd. 333. Treacle Mustard with roundish hairy pods, and hairy arrow-pointed leaves on the stalks.

7. THLASPI *filiculis obcordatis, foliis radicalibus cuneiformibus integerrimis*. Lin. Sp. Plant. 647. Treacle Mustard with heart-shaped pods, and the lower leaves wedge-shaped and entire.

8. THLASPI *filiculis ellipticis, foliis lanceolato-linearibus integerrimis*. Saw. Monsp. 53. Treacle Mustard with elliptical pods, and linear, spear-shaped, entire leaves.

The first sort grows naturally amongst the Corn in divers parts of England, as also on the side of dry banks; it is a biennial plant, which perishes soon after it has ripened its seeds. The root is composed of ligneous fibres, which spread in the ground; the bottom leaves are long, narrow at their base, and broader toward their points, where they have several indentures, and are hoary on both sides. The stalk rises about a foot high, branching toward the top, and is pretty closely garnished with leaves, placed alternately, whose ears embrace the stalk. The flowers are produced in short spikes at the end of the stalks; they are

small, white, and composed of four petals, placed in form of a cross; these are succeeded by roundish capsules, having two cells, containing two or three seeds in each. The whole plant has a warm biting taste. The seeds of this are frequently used instead of those of the next, which is the sort directed to enter the composition of Venice Treacle.

The second sort is an annual plant, which grows naturally in several parts of England: I have found it growing in plenty in the meadows on the right hand side of Gedolming. The root of this is composed of slender fibres; the stalk rises a foot high, is angular, channelled, and smooth; the leaves are smooth and indented, of a deep green colour, and sit close to the stalks; the flowers are produced in loose spikes toward the upper part of the stalks, which are small, white, and composed of four petals, placed crosswise like the former; these are succeeded by broad, flat, roundish, compressed pods, having leafy borders, which have two cells, each containing two or three dark brown seeds, tasting like Garlick. The seeds are an ingredient in Theriaca.

The third sort is an annual plant, which grows naturally in the northern counties of England. Of this there are two sorts mentioned in books, which differ only in size, so that I believe it is owing to the different soils in which they grow; for I have frequently sown the seeds of both in the garden, where, when the plants came up, they have proved to be the same. The stalks of this rise about nine inches high, divided at the top into several branches, which are clothed with smooth, oblong, heart-shaped, entire leaves, whose base embrace the stalks. The flowers are small, white, and are produced in loose short spikes at the end of the branches.

The fourth sort grows naturally in Sicily; this is a biennial plant, whose stalks rise eight or nine inches high, branching out toward the top, garnished with blunt thick leaves, of a grayish colour, which are spear-shaped and entire, placed opposite, sitting close to the stalk; they have a bitter warm taste. The flowers are produced in loose spikes at the top of the stalks; they are small, and of a purple colour, having four heart-shaped petals, placed in form of a cross; these are succeeded by heart-shaped pods, of a fine green colour, which are divided into two cells, each containing three or four small, oblong, yellowish seeds, which have an acrid taste.

The fifth sort is an annual plant, which grows naturally in the northern parts of Europe; this rises about six or eight inches high. The stalk branches toward the top, and is garnished with oblong, smooth, blunt leaves, which are a little indented; these sit close to the stalk, which, if bruised, have a strong scent of Garlick. The branches are terminated by loose spikes of small white flowers, composed of four roundish petals, placed in form of a cross, and are succeeded by swelling roundish pods, containing a few dark brown seeds.

The sixth sort grows naturally in Wales, and in a few places in England; this has a perennial creeping root. The lower leaves are oblong and hoary; they are very slightly sinuated on the edges. The stalks are about five or six inches long, and incline toward the ground; the flowers are rather larger than those of the first sort, but are of the same form; the pods are hoary, but not hairy. This grows naturally on the side of a bank beyond Wandsworth in the road to Putney.

The seventh sort grows naturally upon the Alps, and in some parts of Yorkshire in dry stony pastures. The root of this is perennial and creeping; the stalks rise four or five inches high; the lower leaves are wedge-shaped, being broad and rounded at their points, but narrow at their base, of a deep green colour, and entire; those upon the stalks

are rounder, and sit very close. The flowers are produced in loose spikes at the end of the branches; they are small and white, shaped like those of the other sorts, which are succeeded by roundish heart-shaped pods, divided into two cells, each containing two or three brown seeds.

The eighth sort grows naturally in rocky places in the south of *France*, in *Spain*, and *Italy*; it is a biennial plant with us. The root is composed of ligneous tough fibres, which penetrate the crevices of the rocks; the lower leaves are roundish, fleshy, and entire; the stalks rise about five inches high, and divide into small branches, garnished with fleshy, linear, spear-shaped, entire leaves, of a deep green colour, having smooth surfaces. The flowers grow in loose spikes at the end of the branches; they are of a beautiful red colour, with some dark bloody stripes; these are succeeded by oblong elliptical pods, which contain several small red seeds.

These plants are propagated by seeds, which should be sown where the plants are to remain; this may be performed either in the spring or autumn, but the latter is to be preferred, because the seeds at that season never fail, and the plants, which come up before winter, will grow much stronger, and produce a greater quantity of seeds than those which are sown in the spring, especially if the season proves dry; and there is very little danger of the plants being injured by frost in winter, if they are upon dry ground. When the plants come up, they will require no other care but to thin them where they are too close, and keep them clean from weeds.

The two sorts which are first mentioned, may be cultivated for their seeds to be used in medicine, so may be sown thin upon beds of light ground, in the same way as for other garden plants; and when they come up, the ground should be hoed to destroy the weeds; and where the plants are too thick, they should be cut up in the same manner as is practised for Onions, Carrots, &c. leaving them three or four inches apart; and by twice hoeing the ground, if it is well performed, and in dry weather, it will keep the ground clean till the seeds are ripe.

The other sorts are seldom cultivated but in botanick gardens for variety, so a few plants of each will be sufficient; therefore these may be sown in drills, and when the plants come up, they must be thinned, and kept clean from weeds. If the seeds of these plants are permitted to scatter, the plants will come up without care.

THISTLE. See *Carduus*.

THORN APPLE. See *Datura*.

THORN, the *Glastenbury*. See *Mespilus*.

THUYA. *Tourn. Inst. R. H. 586. tab. 358.* The *Arbor Vitæ*.

The Characters are,

It has male and female flowers in the same plant; the male flowers are produced in an oval katkin, placed opposite upon the common foot stalk, each flower embracing it with its base; these come out of an oval concave scale; they have no petals, but have four stamina, which are scarce discernible; their summits adhere to the base of the scale of the empalment. The female flowers are collected in a common almost oval cone, two flowers standing opposite in each scale; they have no petals, but have a small germen, supporting a slender style, crowned by a single stigma; these are succeeded by an oblong oval cone, opening longitudinally, whose scales are almost equal, convex on the outside, and obtuse, each containing an oblong seed.

The Species are,

1. THUYA *strobilis lævibus, squamis obtusis.* Hort. Cliff. 449. Thuya with smooth cones, and obtuse scales. This is the common *Arbor Vitæ*.

2. THUYA *strobilis squarrosis, squamis acuminatis reflexis.* Hort. Upsal. 289. Thuya with rugged cones, and acute-pointed reflexed scales; or *China Arbor Vitæ*.

The first sort grows naturally in *Canada*, *Siberia*, and other northern countries. In some of the *English* gardens which have not been altered, there are some of these trees which are of a large size: it has a strong woody trunk, which rises to the height of forty feet or more. The bark, while young, is smooth, and of a dark brown colour, but, as the trees advance, the bark becomes cracked, and less smooth. The branches are produced irregularly on every side, standing almost horizontal, and the young slender shoots frequently hang downward, thinly garnished with leaves; so that when the trees are grown large, they make but an indifferent appearance. The young branches are flat, and the small leaves lie imbricatum over each other like the scales of fish; the flowers are produced from the side of the young branches pretty near to the foot-stalk; the male flowers grow in oblong katkins, and between these the female flowers are collected in form of cones. When the former have shed their farina, they soon after drop off, but the female flowers are succeeded by oblong cones, having obtuse smooth scales, containing one or two oblong seeds. The leaves of this tree have a rank oily scent when bruised.

The second sort grows naturally in the northern parts of *China*, where it rises to a considerable height; but this has not been long enough in *Europe* to have any trees of large size. The seeds of this sort were first sent to *Paris* by some of the missionaries, and there are some of the trees growing in the gardens of some curious persons there, which are more than twenty feet high. The branches of this sort grow closer together, and are much better adorned with leaves, which are of a brighter green colour, so make a much better appearance than the other, and, being very hardy, is esteemed preferable to most of the ever-green trees with small leaves, for ornament in gardens. The branches of this tree cross each other at right angles; the leaves are flat, but the single divisions of the leaves are slender, and the scales are smaller, and lie closer over each other than those of the first sort. The cones are also much larger, and of a beautiful gray colour; their scales end in acute reflexed points.

These trees may be propagated by seeds, layers, or cuttings. The first sort is commonly propagated by cuttings; these should be planted in *September*, upon a shady border, and in a loamy soil; the cuttings should be chosen from the shoots of the same year, with a small joint of the former year's wood at the bottom of each. These should be planted three or four inches deep, in proportion to their length, treading the ground close to them to prevent the admission of air. If the following spring should prove dry, there should be a little mulch laid over the surface of the ground to prevent its drying; where this is performed in time, it will save the trouble of watering the cuttings; and it will be much better for them, because when these are putting out their young fibres, if they are much watered, it will rot them while they are tender. These cuttings will be rooted enough to transplant by the next autumn, when they may be either planted in beds, or in nursery-rows to be trained up.

When they are propagated by layers, the young branches only should be laid down in autumn, which will also put out roots by the next autumn, when they may be taken up, and transplanted in the same manner as those raised from cuttings; but although these are very expeditious methods of propagating this tree, yet those who are desirous to have large trees, should always propagate them by seeds, for the plants so raised will be much preferable to the other.

There is a variety of the first sort with variegated leaves, which some people keep in their gardens; but as this proceeds from a weakness in the plants, so whenever the plants

plants become strong and vigorous, they always return to their plain colour again; to prevent which, they generally plant them in very poor ground. This variety can only be preserved by propagating the plants, either by cuttings or layers.

The *China* sort is generally propagated by layers in the same way as the former, but the cuttings of this, if rightly managed, will take root very freely; but most people have over nursed them. If these are planted in *September* in a border of soft loam, exposed to the east, and if before the hard frost sets in, the surface of the ground is covered with old tanners bark about two inches thick, it will prevent the frost from penetrating the ground; and if this remains in the spring, it will also keep the ground moist, for if the cuttings or layers of this sort are watered too much in the spring, when they are beginning to put out young fibres, it will certainly rot them, as I have frequently experienced; therefore I advise every one not to water these cuttings or layers, nor should the plants be much watered when they are transplanted, for the same reason; but as there are many plants now in *England* which ripen their seeds, so those who can be supplied with them, should prefer them to the other; for, after the first two years, the seedling plants will greatly outstrip the other in growth, and the plants will be much handsomer.

These seeds should be sown soon after they are ripe, which is in the spring. They should be sown in pots, filled with soft loamy earth, and plunged into the ground in an east border, where they may have only the morning sun, observing always to keep the pots clean from weeds. Sometimes these seeds will come up the same year, but they often lie in the ground till the next spring; therefore the pots should be put in a common hot-bed frame in winter, and in the spring the plants will come up; these must not be too much exposed to the sun the first year, and if in the next winter they are sheltered under a frame, it will be a good way to preserve them; and the spring following they may be transplanted into beds, and treated in the same way as those propagated by cuttings.

THYMBRA. *Lin. Gen. Plant.* 627.

The Characters are,

It has an empalement of one leaf, whose brim is cut into two lips. The flower is of one petal, of the lip kind. The upper lip is concave, cut into two obtuse segments. The lower lip ends with three almost equal points; it has four slender stamina, the two under being shorter than the other, terminated by twin summits, and a four-pointed germen, supporting a slender half bifid style, crowned by acute stigmas. The germen afterward becomes four seeds, which ripen in the empalement.

The Species are,

1. THYMBRA *floribus spicatis*. *Lin. Sp. Plant.* 569. Thymbra with spiked flowers; or Mountain Macedonian Hyssop.

2. THYMBRA *floribus verticillatis*. *Lin. Sp. Plant.* 569. Thymbra with whorled flowers; or rough, narrow-leaved, Mountain Hyssop.

The first sort grows naturally on *Mount Libanus*, in *Macedonia*, and also in *Spain*; it is a low shrubby plant like Heath, branching out into slender ligneous stalks, which are six or eight inches long, covered with a brown bark, garnished with narrow acute-pointed leaves, sitting close to the stalks opposite; they have an aromatick odour when bruised. The stalks are terminated by thick close spikes of purple flowers, near two inches long. The empalements are stiff and hairy, cut half their length into acute segments; out of these the flowers peep with their two lips, the upper is concave and arched, the under is cut into three equal portions, a little reflexed.

The second sort grows naturally in *Spain* and *Italy*; this

has a shrubby stalk, which seldom rises much more than a foot high, putting out many small ligneous branches, garnished with narrow spear-shaped leaves, which have many punctures; they stand opposite, and are of an aromatick flavour. The flowers grow in whorled spikes at the end of the branches. The leaves which stand under each whorl, are broader than those below, and are covered with fine hairs. The flowers are purple, and sit close to the stalks; the upper lip is concave, ending with two obtuse points; the lower ends with three equal points.

These plants are propagated by seeds, which should be sown in the spring on a bed of light earth, where, if the seeds are good, the plants will appear in about six or eight weeks. When they come up, they must be kept clean from weeds, and in *July* they will be fit to remove; at which time part of them should be planted in small pots, and the other may be planted in a warm border of dry ground, being careful to shade them from the sun, and supply them with water until they have taken new root; after which those in the full ground will require no other care but to keep them clean from weeds, and, if the winter should prove very severe, they should be covered with mats, or some other light covering, to protect them; for the young plants are in greater danger of being destroyed than those which are older. Those plants in the pots should be sheltered under a common frame in winter, where they may enjoy the free air in mild weather, and be protected from hard frost.

These plants will live in the open air in *England* unless the winters prove very severe, especially if they are planted in a poor, dry, stony soil.

THYMELÆA. See *Daphne* and *Passerina*.

THYMUS. *Tourn. Inst. R. H.* 196. tab. 93. Thyme.

The Characters are,

The flower has a permanent empalement, divided into two lips, whose chaps are hairy and stout. The upper lip is broad, plain, erect, and indented in three parts; the under lip ends in two equal bristles. The flower is of the lip kind; it has one petal, with a tube the length of the empalement. The chaps are small, the upper lip is short, erect, obtuse, and indented at the point; the lower lip is long, broad, and divided into three parts. It has four incurved stamina, two being longer than the other, terminated by small summits, and a four-pointed germen, supporting a slender style, crowned by a bifid acute stigma. The germen afterward turns to four small roundish seeds, ripening in the empalement.

The Species are,

1. THYMUS *erectus, foliis revolutis ovatis, floribus verticillato-spicatis*. *Hort. Cliff.* 305. Upright Thyme with oval leaves, which turn backward, and flowers growing in whorled spikes; or common broad-leaved Thyme.

2. THYMUS *foliis lineari-lanceolatis incanis, floribus verticillato-spicatis*. Thyme with linear, spear-shaped, hoary leaves, and flowers growing in whorled spikes; or common Thyme with narrow leaves.

3. THYMUS *capitulis imbricatis magnis, bracteis ovatis, foliis lanceolatis*. *Lin. Sp. Plant.* 592. Thyme with large imbricated heads, oval bractæ, and spear-shaped leaves.

4. THYMUS *capitulis imbricatis magnis, bracteis dentatis, foliis setaceis pilosis*. *Lin. Sp. Plant.* 592. Thyme with large imbricated heads, indented bractæ, and bristly hairy leaves.

5. THYMUS *floribus capitatis, caulibus repentibus, foliis ovatis pilosis*. Thyme with flowers growing in heads, creeping stalks, and oval hairy leaves; or broad-leaved, hairy, Mother of Thyme.

6. THYMUS *floribus capitatis, caulibus repentibus, foliis lanceolatis glabris*. Thyme with flowers growing in heads, creeping stalks, and smooth spear-shaped leaves; or common greater Mother of Thyme, with a purple flower.

7. *THYMUS caulibus repentibus, foliis ovatis glabris, floribus verticillato-spicatis.* Thyme with strong creeping stalks, oval smooth leaves, and flowers growing in whorled spikes; or common greater Mother of Thyme, with a smaller flower.

8. *THYMUS caulibus repentibus, foliis ovato lanceolatis rigidis lanuginosis, floribus capitatis.* Thyme with creeping stalks, oval, spear-shaped, stiff leaves, which are downy, and flowers growing in heads; or hairy Rock Mother of Thyme.

9. *THYMUS caulibus decumbentibus, foliis lineari-lanceolatis glabris, floribus alaribus terminalibusque.* Thyme with trailing stalks, linear, spear-shaped, smooth leaves, and flowers growing at the wings and tops of the stalks.

The first sort is the common Thyme, which is cultivated in the gardens for the kitchen, and also for medicine. This grows naturally on stony rocky places in the south of France, in Spain and Italy, and is so well known here as to need no description.

It is propagated either by seeds, or parting the roots; the season for the latter is in March or October. If it is propagated by seeds, they should be sown upon a bed of light earth in the spring, observing not to bury the seeds too deep, nor to sow them too thick, for the seeds are very small. When the plants are come up, they should be carefully cleared from weeds; and if the spring should prove dry, if they are watered twice a week, it will greatly promote their growth. In June the plants should be thinned, leaving them about six inches asunder each way, that they may have room to spread; and those plants which are drawn out, may be transplanted into fresh beds at the same distance, observing to water them until they have taken root; after which they will require no farther care, but to keep them clear from weeds; and when the plants are big enough, they may be drawn up for use.

But if the plants are propagated by parting their roots, the old plants should be taken up at the times before-mentioned, and split into as many parts as can be taken off the roots; these should be transplanted into beds of fresh light earth at six or eight inches distance, observing, if the season is dry, to water them until they have taken root; after which they must be duly weeded, which will cause them to thrive, and soon be fit for use.

In order to save the seeds of these plants, some of the old roots should remain unremoved in the place where they were sown the preceding year; these will flower in June, and in August the seed will ripen, which must be taken as soon as it is ripe, and beat out, otherwise the first rain will wash it all out of the husks.

These plants root greatly in the ground, and thereby draw out the goodness of the soil sooner than most other plants; so that whatever is sown or planted upon a spot of ground, whereon Thyme grew the preceding year, will seldom thrive, unless the ground be trenched deeper than the Thyme rooted, and well dunged.

If this plant grows upon walls, or on dry, poor, stony land, it will endure the greatest cold of this country; but in rich ground, where the plants grow vigorously, they are sometimes destroyed by very severe frost.

There is a variety of this with variegated leaves, which is by some preserved in their gardens.

The second sort has shorter stalks; the leaves are longer, narrower, and end in sharper points than the first, and the whole plant is hoary. The flowers grow in long whorled spikes, and are larger than those of the common Thyme. This may be propagated and treated in the same way as the first sort.

The third sort grows naturally in Spain and Portugal; this has a low woody stalk, from which come out many

stiff branches about five or six inches long, garnished with small, narrow, spear-shaped leaves, placed opposite, terminated by pretty large heads of flowers, which come out from oval scaly leaves lying over each other like the scales of fish; they are white and small, so make no great appearance. The whole plant is of a hoary colour, and has an aromattick weak scent.

The fourth sort grows naturally in Portugal; this has slender, ligneous, hairy stalks, which grow erect about six inches high, garnished with very narrow, bristly, hairy leaves, which, at the lower part of the stalk, come out in clusters, but upward they are placed by pairs. The stalks are terminated by large scaly heads. The leafy scales are indented in acute points; these lie over each other in the same order as the other, and between them the flowers peep out, which are of a purple colour, shaped like those of the common Thyme.

These two sorts may be propagated by slips, if they are planted in April on an east border, and closely covered with a bell or hand-glass, they will soon put out roots, when some of them may be transplanted into pots, to be sheltered under a frame in winter; but the others should be planted on a warm border of dry ground, observing to shade and water them till they have taken new root. These plants will live through the winter in the open air in a warm dry situation, but in severe frost they are generally destroyed; therefore to preserve the kinds, a few plants of each should be sheltered under a frame in winter; they may be propagated by seeds, when they can be procured. If these are sown on a bed of light earth, in the same way as common Marjoram, the plants will come up, and may be treated as those raised from slips.

The fifth sort is the common Mother of Thyme, which is frequently titled wild Thyme; it grows naturally upon dry commons and pastures in most parts of England, so is very rarely admitted into gardens. This is so well known as to need no description. There is a very common mistake which has prevailed in regard to this plant, which is, that the sheep and deer which feed upon it, have much finer flavoured flesh than others, whereas no cattle will meddle with it; for in the places where it grows, when the Grass is as closely eaten down as possible, the wild Thyme will be found in flower with all its stalks entire.

Of this there are the following varieties. The small creeping Mother of Thyme without scent. Narrow-leaved Mother of Thyme, smelling like the leaves of the Walnut-tree. Shrubby Mother of Thyme with pale red flowers, and the Lemon Thyme. The last is frequently kept in gardens for the agreeable odour of its leaves. But when this is propagated by seeds, the plants have not the same scent; so it is an accidental variety, which is maintained by propagating it by slips and cuttings.

The sixth sort has broader and smoother leaves than the common sort; the stalks grow much longer; the joints are farther distant; the heads of flowers are larger, and the flowers are of a brighter purple colour. There is a variety of this with variegated leaves, which is propagated in gardens, and was formerly planted for edgings to borders; but it is now frequently brought in pots to the markets to supply the London gardens.

The seventh sort has creeping stalks like the common kind, but they grow longer, and their joints are farther asunder; the leaves are oval, smooth, and of a lucid green. The flowers grow in close thick whorls, which are distant from each other, forming a loose spike five or six inches long. The flowers of this sort are much smaller than those of the common sort, appearing but little beyond their empalements. This is pretty common in the neighbourhood of Paris, but is rarely found growing naturally in England.

The eighth sort grows naturally in the forest of *Fontainebleau* in *France*; this has creeping slender stalks like the first, which are garnished with small, oval, spear-shaped, hoary leaves; the young shoots of the same year are also very white and hoary. The leaves are stiffer than those of the other sorts. The flowers are produced in round heads at the end of the branches; they are of a bright purple colour, and appear at the same time as those of the other sorts.

The ninth sort grows naturally in *Tartary*; this is a biennial plant. The stalks are long, slender, and trail upon the ground, but do not emit roots from their joints as most of the others do. The stalks are smooth, of a light brown colour, garnished with narrow spear-shaped leaves, which are smooth. The small whorls of flowers come out at the wings of the leaves, and the stalks are terminated by oblong heads of flowers, whose empalements are hoary. The flowers are of a bright purple colour. The whole plant has an agreeable aromack scent.

All these sorts may be easily propagated by those who are desirous to have them in their gardens, either by slips, or parting of their roots in the same manner as *Thyme*, or their seeds may be sown in the spring. They delight in dry undunged ground, where they will propagate themselves by their trailing stalks, and require no other care but to keep them clean from weeds.

THYME THE MARUM. See *Teucrium*.

THYME THE MASTICH. See *Satureja*.

TIARELLA. *Lin. Gen. Plant.* 495 Sanicle.

The Characters are,

The flower has a permanent empalement, divided into five oval acute parts; it has five oval petals the length of the empalement; and ten awl-shaped stamina, which are much longer than the petals, terminated by roundish summits, and a bifid germen ending with two styles, crowned by single stigmas. The germen afterward becomes an oblong capsule with one cell, opening with two valves, containing several small oval seeds.

The Species are,

1. TIARELLA foliis cordatis. *Lin. Gen. Nov.* 188. *Sp. Plant.* 405. Tiarella with heart-shaped leaves.

2. TIARELLA foliis ternatis. *Lin. Gen. Nov.* 188. *Sp. Plant.* 405. Tiarella with trifoliate leaves.

The first sort grows naturally in *North America*; this has a perennial fibrous root, which creeps and multiplies, from which come out many heart-shaped leaves upon slender foot-stalks. The leaves are unequally indented on their edges, and are of a light green colour. The flowers stand upon slender naked foot-stalks, which arise immediately from the root between the leaves, which is about four inches long, and is terminated by a loose spike of small herbaceous white flowers, but are seldom succeeded by seeds in *England*.

This plant is propagated by its creeping roots which spread in the ground, and shoot up heads, these may be taken off and transplanted in the autumn. It loves a moist soil and shady situation, and requires no other care but to keep it clean from weeds.

The second sort grows naturally in the northern parts of *Afia*; this has a perennial fibrous root, from which spring up a few trifoliate leaves upon foot-stalks, like those of the *Bilberry*, but much smaller. The stalk is slender, and rises five or six inches high; it is rough and hairy, garnished with two leaves at the bottom, and another toward the top, a little below the spike of flowers; they are angular and sawed on their edges. The stalk is terminated by a loose spike of flowers, which are composed of five white small petals, inserted in the empalement, and ten awl-shaped stamina which are longer than the petals, terminated by roundish summits.

This sort is propagated by parting of the root, in the

same manner as the former, and delights in a moist soil and a shady situation.

TILIA. *Tourn. Inst. R. H.* 611. *tab.* 381. The Lime, or Linden-tree.

The Characters are,

The flower has a concave coloured empalement, which is cut into five parts; it has five oblong blunt petals, which are crenated at their points, and many awl-shaped stamina, terminated by single summits, with a roundish germen, supporting a slender style the length of the stamina, crowned by an obtuse five-cornered stigma. The germen afterward becomes a thick globular capsule with five cells, opening at the base with five valves, each containing one roundish seed.

The Species are,

1. TILIA foliis cordatis acuminatis, inæqualiter serratis, fructibus quinque locularibus tomentosis. Lime-tree with heart-shaped acute-pointed leaves, which are unequally sawed, and a woolly fruit having five cells; Lime-tree with a smaller leaf.

2. TILIA foliis acuminatis, serratis, subhirsutis, fructibus quadri-locularibus subpilosis. Lime-tree with acute-pointed leaves, which are sawed, somewhat hairy, and a hairy fruit having four cells; the red-twined Lime-tree.

3. TILIA foliis cordatis acuminatis serratis, subtus pilosis floribus nectario instructis. Lime-tree with heart-shaped, acute-pointed, sawed leaves, which are hairy on their under side; and flowers furnished with nectarii. This is called the *American black Lime*.

4. TILIA foliis cordatis obliquis glabris subserratis cum acumine, floribus nectario instructis. Lime-tree with heart-shaped smooth leaves, which are oblique to the foot-stalk, somewhat sawed on their edges, ending in acute points, and flowers having nectarii; or *Carolina Lime-tree*.

The first sort grows naturally in the woods in many parts of *England*; of this there are two or three varieties, which differ in size and smoothness of their leaves, some of them having much larger and rougher leaves than the others: I raised plants of three of these varieties from seeds, but have constantly found them vary from one to the other; and I much doubt if the second is more than a seminal variety, but as I have not had an opportunity of raising any of the plants from seeds, I cannot positively determine this.

The large-leaved *Dutch Lime* was generally preferred to our common sort for the size of its leaves; but of late years all these trees are little esteemed, because it is late in spring before their leaves come out, and they begin to decay the first in autumn; and when the trees are planted in a dry soil, their leaves frequently decay in *July*, so are continually falling off, making a litter all the remaining part of summer.

The third sort was brought from *New England*, by the title of *Black Lime*. The branches of this sort are covered with a dark brown bark. The leaves are large, heart-shaped, and end in acute points; they are deeply sawed on their edges, of a deep green on their upper side, but of a pale green and a little hairy on their under side, standing upon long slender foot-stalks. The flowers are produced in bunches, in the same manner as those of the common Lime-tree; but the petals of the flowers are narrower, and have nectarii growing to their base. The flowers of this sort do not appear till late in *July*, so are a full month after the common sort. The capsules are smaller, rounder, and less hairy than those of the common sort.

The seeds of the fourth sort were brought from *Carolina* by the late Mr. *Catesby*. This tree seems to be of much smaller growth than either of the other sorts; the branches spread more horizontally. The leaves are smaller, and have a smoother surface than either of the other; they are heart-shaped, but the midrib runs oblique to the foot-stalk,

so that one side is much larger than the other. Their edges are slightly sawed, and their tops run out into long acute points. The bunches of flowers stand upon long slender foot-stalks; the petals of the flowers are narrow, and end in acute points; these have a narrow nectarium fastened to their base on the inside, which stands erect, close to the petals. The flowers emit a very fragrant odour, and are continually haunted by bees during their continuance.

All these trees are easily propagated by layers, which in one year will take good root, and may then be taken off, and planted in a nursery, at four feet distance row from row, and two feet asunder in the rows. The best time to lay them down, and to remove them, is when their leaves begin to fall, that they may take root before the frost comes on, though they may be transplanted any time from September to March, in open weather; but if the soil is dry, it is much the better way to remove them in autumn, because it will save a great expence in watering, especially if the spring should prove dry. In this nursery they may remain four or five years, during which time the ground should be dug every spring, and constantly kept clear from weeds, and the large side shoots pruned off, to cause them to advance in height; but the small twigs must not be pruned off from the stems, because these are absolutely necessary to detain the sap, for the augmentation of their trunks, which are apt to shoot up too slender, when they are entirely divested of all their lateral twigs. If the soil, in which they are planted, be a fat loam, they will make a prodigious progress in their growth, so that in three years time they will be fit to transplant out where they are to remain.

They may also be propagated by cuttings; but, as this method is not so certain as by layers, the other is generally practised. In order to obtain proper shoots for laying down, a Lime-tree is cut down close to the ground, from the roots of which a great number of strong shoots are produced the following year; these will be large enough to lay down the following autumn, especially if the smallest of them are cut off close early in the summer; for when too many shoots are suffered to grow all the summer, they will be much weaker, than if only a sufficient quantity is left. The manner of laying down these shoots having been already directed under the article of LAYERS, I need not repeat it here.

There are some persons who raise these trees from seeds, which, although it is a slower way, yet when the trees are designed to grow large, is the best method; and if they are only once transplanted, and this performed while they are young, it will be still the better way; for all trees that are transplanted, are shorter lived than those which remain in the places where they arose from the seeds, and their timber will be sounder, and grow to a much larger size.

When this method is practised, the seeds should be sown in autumn, soon after they are ripe, upon a shady border of moist light soil, where the plants will come up the following spring; but, when the seeds are kept out of the ground till spring, the plants will not come up till the year after. When the plants appear, they should be constantly kept clean from weeds till the following autumn; then they should be carefully taken up, and transplanted into a nursery, where they may grow two or three years to get strength, and then may be planted where they are designed to remain; for the younger they are planted out, the more they will thrive.

The timber of the Lime-tree is used by the carvers, it being a soft light wood, as also by architects for framing the models of their buildings; the turners likewise use it for making light bowls, dishes, &c. but it is too soft for any strong purposes.

These trees will continue growing, and remain sound a

great number of years, and, if planted in a good loamy soil, will grow to a considerable bulk. I have measured one of these trees, which was near ten yards in girth two feet above the ground, and was then in a thriving condition; and Sir Thomas Brown mentions one of these trees which grew in Norfolk, that was sixteen yards in circuit, a foot and a half above ground, in height thirty yards, and in the least part of the trunk it was eight yards and a half.

TINUS. See Viburnum.

TITHYMALUS. Tithymaloides. Tourn. Inst. App. 654. Spurge.

The Characters are,

The flower has an empalement of one leaf, indented in three parts; it has one petal which is shaped like a slipper, of a thick fleshy consistence. Under the upper part of the flower are situated the ten stamina, which are inserted in the receptacle of the flower; they are slender, and terminated by globular summits; in the center is situated a roundish three-cornered germen, supporting three bifid styles, crowned by oblong stigmas. The germen afterward becomes a roundish capsule having three cells, each containing one oval seed.

The Species are,

1. TITHYMALUS foliis ovatis acuminatis. Spurge with oval acute-pointed leaves.
2. TITHYMALUS foliis oblongo ovatis obtusis succulentibus. Spurge with oblong, oval, obtuse leaves, which are very succulent.

The first sort grows naturally near Carthage in America, from whence Mr. Robert Millar, surgeon, sent the branches, which were planted here, and succeeded; this rises with shrubby succulent stalks, to the height of twelve or fourteen feet, which are too weak to stand without support, though they are frequently as large as a man's little finger; but their leaves being succulent, are so heavy as to weigh down the branches, if they are not supported. The leaves are oval, and terminate in acute points; and are ranged alternately on two sides of the branches, to which they fit close. The flowers are produced at the end of the branches three or four together; they are of a scarlet colour, of one petal, in shape of a slipper; these are succeeded by roundish capsules with three furrows, dividing them into three cells, each containing one oblong seed. The whole plant abounds with an acrid milky juice.

The second sort grows naturally in Barbadoes, and most of the other islands in the West Indies, where the English inhabitants know it by the title of Poison Bush; this hath thick, shrubby, succulent stalks, which will grow to the height of ten or twelve feet, larger than those of the first sort, and are garnished with oblong oval leaves ending in blunt points, of a very thick consistence, and of a dark green colour, ranged alternately on two sides of the stalk. The flowers grow at the end of the branches; they are shaped like those of the first sort, and are of a deep red colour; these are succeeded by roundish capsules divided into three cells, each containing one oblong seed.

This whole plant abounds with an acrid milky juice, which will draw blisters on the flesh wherever it is applied, and if it mixes with the blood, I have been credibly informed it becomes a deadly poison; for that if the points of arrows or the edges of swords are rubbed over with this juice, it becomes deadly to any animal wounded with those weapons.

These plants are both propagated by cuttings, which may be taken from the plants during any of the summer months; and after having laid in a dry place for a fortnight or three weeks, until the wounded part be healed over, they should be planted into small pots, filled with light sandy earth mixed with lime-rubbish, and then plunged into a hot-bed of tanners bark, observing now and then to refresh

fresh them gently with moisture, but they should never receive much wet, which will rot them.

After they have taken root, they may have a greater share of air by raising the glasses, but they must never be wholly exposed to the open air. In this bed they may remain until the beginning of *October*, when they must be removed, and placed with the Melon and Torch Thistle in a warm dry stove, and during the winter season they should have very little water, which, if given in plenty, seldom fails to rot them.

These plants are too tender to thrive in the open air in *England*, therefore should constantly remain in the stove, observing in the summer season, when the air is warm, to admit a large share of fresh air to them, and in the winter to place them in a warm part of the stove, otherwise they cannot be preserved.

They must be shifted every summer, and fresh earth given to them. If the earth is light or sandy it will require no mixture, for rich or strong ground is very improper for them; therefore where the soil is inclinable to either of these, there should be a good mixture of sand and lime-rubbish to prevent its binding, or detaining moisture.

These plants are preserved for their odd appearance amongst other succulent plants, their leaves being very large, thick, and full of a milky acrid juice.

TITHYMALUS. See Euphorbia.

TOAD FLAX. See Linaria.

TOBACCO. See Nicotiana.

TOLUIFERA. *Lin. Gen. Plant.* 470. Balsam of Tolu Tree.

The Characters are,

The flower has a bell-shaped empalement of one leaf, which is slightly indented in five parts at the brim; it has five petals inserted in the receptacle of the flower, four of which are narrow and equal, being a little longer than the empalement, and the fifth is much larger, and almost heart-shaped, having a tail the length of the empalement; it has ten short stamina terminated by oblong erect summits, and a roundish germen, supporting a very short style, crowned by an acute stigma. The germen afterward turns to a roundish fruit with four cells, each containing one oval seed.

We know but one Species of this genus, viz.

TOLUIFERA. *Lin. Mat. Med.* The Balsam-tree of Tolu.

This tree grows naturally near *Carthage* in *America*, from whence the late *Dr. Housloun* sent the seeds to *England*: in its native place this grows to a tree of a large size. The bark is very thick, rough, and of a brown colour; the branches spread out wide on every side, and are garnished with winged leaves, composed of several oblong oval lobes, placed alternately along the foot-stalk, terminated by an odd one, rounded at both ends, but run out to an acute point at the top; they are smooth, of a light green colour, and sit close to the foot-stalk. The flowers are produced in small bunches at the wings of the branches, each standing upon a slender foot-stalk almost an inch long; their empalements are of the round bell-shape, being of one leaf, which is slightly scolloped at the brim into five obtuse parts. The flower has four narrow petals of a yellow colour, which are a little longer than the empalement, and one more whose tail is of the same length of the other petals; the top is of an oval heart-shape, stretched out beyond the other parts; it has ten short stamina within the tube of the flower, which are terminated by oblong erect summits of a Sulphur colour, and at the bottom of the tube is situated a roundish germen, having a very short style crowned by an acute-pointed stigma. After the flower is past, the germen turns to a roundish fruit the size of a large Pea, divided into four cells, each containing one oblong oval seed.

This tree may be propagated by seeds, which must be procured from the country where it grows naturally, and should be fresh, otherwise they will not grow. When they are gathered from the tree, they should be put up in sand to preserve them; for when they are sent over in papers, the insects generally devour them. These seeds must be sown in pots filled with light earth as soon as they arrive, and plunged into the tan. If it should happen in autumn or winter they must be plunged into the stove, but in spring or summer they may be plunged in the tan-bed under a frame; they should be taken out of their covers, otherwise they will be long in the ground before they vegetate. When the plants come up, and are fit to remove, they should be carefully transplanted, each into a separate pot, and plunged into a good hot-bed of tanners bark, shading them from the sun till they have taken new root; after which they should be treated in the same way as the Coffee-tree, with which management the plants will succeed.

TORDYLIUM. *Tourn. Inst. R. H.* 320. *tab.* 170. *Lin. Gen. Plant.* 293. Hartwort.

The Characters are,

It hath an umbellated flower; the principal umbel is composed of many small ones, compounded of many rays; the involucre of the greater umbel is composed of narrow leaves, as long as the rays of the umbel; those of the rays are half the length; the umbels are difformed; the flowers have five heart-shaped inflexed petals, which are equal; they have each five hair-like stamina terminated by single summits, and a roundish germen, situated under the flower, supporting two small styles crowned by obtuse stigmas. The germen afterward turn to a roundish compressed fruit longitudinally indented, dividing in two parts, each containing one roundish compressed seed with an indented border.

The Species are,

1. TORDYLIUM *umbellâ confertâ radiatâ, foliolis lanceolatis inciso-serratis.* *Hort. Cliff.* 90. Hartwort with the rays of the umbel closed together, the lobes of the leaves spear-shaped, and cut like saws.

2. TORDYLIUM *involucris partialibus longitudine petalorum, foliolis ovatis laciniatis.* *Hort. Cliff.* 90. Hartwort with the involucrii of the rays as long as the petals of the flower, and oval-jagged leaves.

3. TORDYLIUM *involucris umbellâ longicribus.* *Hort. Cliff.* 90. Hartwort with longer involucrii to the umbels.

4. TORDYLIUM *umbellâ confertâ radiatâ, foliolis linearilanceolatis pinnato-dentatis.* Hartwort with the rays of the umbel closed together, and linear spear-shaped leaves, which are wing-indented on their edges.

5. TORDYLIUM *umbellulis remotis, foliis pinnatis, pinnis subrotundis laciniatis.* *Hort. Cliff.* 90. Hartwort with the umbels growing at a distance, winged leaves having roundish lobes, which are cut on their edges.

6. TORDYLIUM *umbellulis remotis, foliis duplicato-pinnatis, pinnis incisiss tomentosiss.* Hartwort whose umbels are distant from each other, and doubly-winged leaves whose lobes are cut and downy; by the *Arabians* called *Secacul*.

7. TORDYLIUM *umbellis simplicibus sessilibus seminibus exterioribus hispidis.* *Lin. Gen. Plant.* 240. Hartwort with single umbels sitting close to the stalks, and the outer side of the seeds prickly; or *Knotted Parsley*.

8. TORDYLIUM *umbellâ confertâ, foliolis ovato-lanceolatis pinnatifidis.* *Hort. Cliff.* 90. Hartwort with closed umbels, and oval, spear-shaped, wing-pointed lobes; called *Hedge Parsley*.

The first sort grows in *Italy* and *Spain*; this is a biennial plant, which dies soon after it has perfected its seeds. The lower leaves of this sort are large and winged, each having three or four pair of lobes terminated by an odd one. They are rough and hairy, having many deep indentures on their edges like the teeth of a saw; the stalk

rises three feet high, sending out two or three branches from the side, garnished at each joint by one winged leaf; those on the lower part of the stalk have two pair of small lobes terminated by an odd one, but those toward the top have one pair, and the middle lobe is long and narrow. The stalk and branches are terminated by umbels of white flowers, whose rays are closed together; these are succeeded by oval compressed seeds, having a thick white border.

The second sort grows plentifully about *Rome*, and also in the south of *France*; this is mentioned in the last edition of *Ray's Synopsis* as an *English* plant, growing naturally in *Oxfordshire*, where I have found it growing on the side of banks, but the seeds were sown there by Mr. *Jacob Bobart*, gardener at *Oxford*. The leaves of this sort are composed of three or four pair of oval lobes, terminated by an odd one; they are soft and hairy, bluntly indented on their edges. The stalks rise a foot and a half high, and divide into three or four branches, having one small leaf at each joint, and are terminated by umbels of white flowers, composed of several small umbels or rays, which stand upon long foot-stalks, spreading out wide from each other. The flowers are succeeded by smaller compressed seeds, which are bordered.

The third sort grows naturally in *Syria*; this is a low plant, whose stalks seldom rise a foot high. The lower leaves are composed of two pair of oval lobes, terminated by one large one; these are hairy, and slightly crenated on their edges; they branch out into two or three divisions, and are terminated by umbels of white flowers, which have large involucrems, for the most part trifid. The points are spear-shaped, and at their base is situated a small umbel, composed of a few flowers sitting very close to the tails of the involucrii. The flowers are succeeded by large, oval, compressed, bordered seeds.

The fourth sort grows naturally in *Sicily*. The stalks of this sort are deeply channelled, hairy, and rough; they rise near three feet high; the leaves are composed of two or three pair of narrow lobes terminated by one long one, which are hairy, and regularly indented on their borders in form of winged leaves; those on the upper part of the stalk have but one pair of small lobes, with a very long narrow middle lobe, which is deeply and regularly indented. The umbels, which terminate the stalks, are small; the rays are closely connected together; the flowers are large and white, and are succeeded by oval, compressed, bordered seeds, which have white edges deeply crenated.

The fifth sort grows naturally in *Italy*. The stalks of this sort branch out from the bottom, and seldom rise a foot high; they are hairy and rough. The lower leaves are composed of three pair of roundish lobes, terminated by an odd one, which are hairy and jagged. The general umbel is composed of eight small ones, which stand upon very long foot-stalks, and spread out wide from each other. The flowers are white, and the exterior petal of each is much larger than those of the two first sorts; these are succeeded by roundish, compressed, bordered seeds.

The sixth sort grows naturally about *Aleppo*, and in other parts of *Syria*. The bottom leaves are doubly-winged, each leaf being composed of four pair of wings terminated by an odd one. The wings are composed of seven oval lobes, standing alternately, which are deeply jagged; they are of a yellowish green colour, and a little hairy. The stalks are taper, and not channelled; they rise two feet and a half high, have a few small hairs scattered over them, and at each joint are garnished with one smaller winged leaf; they send out one or two short branches toward the top, terminated by large umbels of yellow flowers, composed of ten small umbels, whose foot-stalks are alternately longer, spreading open wide from each other. The flowers are succeeded by

compressed oval seeds, shaped like those of Parsneps, of a yellowish colour.

The seventh sort grows naturally in arable land, in several of the maritime counties in *England*, so is rarely admitted into gardens; this has trailing stalks which spread flat on the ground. The leaves are like those of Parsley, but are cut into finer segments; the umbels of flowers are small, and sit close to the joints of the stalks; the flowers are small, white, and are succeeded by short seeds a little compressed, set with sharp burry prickles on their outside.

The eighth sort grows naturally on the side of banks and foot-paths in many parts of *England*; this rises with a slender stalk three feet high. The leaves are like those of Parsley; their lobes are spear shaped and have winged points; they are hairy, and stand thinly on the stalks. The flowers are produced in small umbels at the top of the stalks, which are composed of several smaller umbels or rays, which close together, of a pale red colour; these are succeeded by small prickly seeds.

All these plants may be termed annual, because they do not live more than one year; but some of them are called biennial, from the young plants which come up in autumn, living through the winter, and producing their flowers and fruits the following summer; but, as the seeds which are sown, or permitted to scatter, perfect their seeds in the compass of one year, they should be termed annual, for this is the property of many of the plants with umbellated flowers, whose seeds should be sown in autumn, otherwise, if they come up (which frequently does not happen the same year when they are sown in the spring), the plants generally decay before their seeds ripen; but, as their whole growth is performed within the year, they should be esteemed as annual plants.

They are propagated by seeds, which should be sown in autumn soon after they are ripe, when the plants will soon appear, and are very hardy, so that they require no farther care, but to keep them clear from weeds, and where they come up too close together, they should be thinned so as to leave them six inches asunder. In *June* following the plants will flower, and their seeds will ripen in autumn, which, if permitted to scatter on the ground, will produce a supply of plants without any trouble. These plants will grow on any soil or situation, so may be put into any obscure part of the garden.

TORMENTILLA. *Tourn. Inst. R. H. 298. tab. 153.*
Tormentil.

The Characters are,

The flower has a plain empalement of one leaf, divided into eight segments at the top; it has four oval heart-shaped petals, whose tails are inserted in the empalement, and many awl-shaped stamina, which are inserted in the empalement, terminated by single summits; it has eight small germen collected in a head, which have slender styles the length of the germen, inserted to their sides, crowned by obtuse stigmas. The germen afterward turns to a fruit, containing many small seeds included in the empalement.

The Species are,

1. TORMENTILLA caule erecto. *Lin. Sp. Plant. 500.* Tormentil with an erect stalk; common Tormentil.

2. TORMENTILLA caule repente. *Lin. Sp. Plant. 500.* Tormentil with a creeping stalk; or creeping winged Cinquefoil.

The first sort grows wild on dry pastures and commons, in most parts of *England*, so is never cultivated in gardens; this is so commonly known as to need no description. The roots of this plant have been frequently used for tanning of leather, in places where Oak bark is scarce. This root is also much used in medicine, and is accounted the best astringent in the whole vegetable kingdom.

The second fort is found in some particular places of England growing wild, but particularly in Oxfordshire. The stalk of this fort spreads on the ground, and emit-roots from their joints, whereby they propagate very fast: this is rarely preserved, unless in some botanick gardens for the sake of variety. It requires no care to propagate these plants, since, if their roots are once planted in almost any soil or situation, the plants will flourish without any other care, but to prevent their being over-run with great weeds.

TOURNEFORTIA. *Lin. Gen. Plant.* 176.

The Characters are,

The empalement of the flower is permanent, of one leaf, cut into five small segments at the top. The flower is of one petal, of the globular bell-shape, cut at the brim into five acute points, which spread open horizontally; it has five awl-shaped stamina the length of the tube, terminated by single summits, and a globular germen, supporting a single style the length of the stamina, crowned by a single stigma. The germen afterward becomes a spherical succulent berry, inclosing four oblong oval seeds, resting upon the empalement.

The Species are,

1. TOURNEFORTIA *foliis ovato lanceolatis, spicis longissimis racemosis erectis, caule fruticoso.* Tournefortia with oval spear-shaped leaves, long branching erect spikes of flowers, and a shrubby stalk.

2. TOURNEFORTIA *foliis ovatis petiolatis, caule hirsuto, spicis ramosissimis-terminalibus.* *Lin. Sp. Plant.* 140. Tournefortia with oval leaves growing upon foot-stalks, and a hairy stalk, terminated by very branching spikes of flowers.

3. TOURNEFORTIA *foliis ovatis acuminatis, petiolis reflexis, caule volubili.* *Lin. Sp. Plant.* 143. Tournefortia with oval acute-pointed leaves, having reflexed foot-stalks, and a twining stalk.

4. TOURNEFORTIA *foliis cordatis hirsutis, spicis racemosis reflexis, caule volubili.* Tournefortia with hairy heart-shaped leaves, branching reflexed spikes of flowers, and a twining stalk.

5. TOURNEFORTIA *foliis cordatis subtus tomentosis, spicis racemosis brevibus, caule volubili.* Tournefortia with heart-shaped leaves, which are woolly on their under side, very short branching spikes of flowers, and a twining stalk.

6. TOURNEFORTIA *foliis ovatis rugosis petiolatis, spicis racemosis axillaribus, caule fruticoso.* Tournefortia with oval rough leaves growing upon foot-stalks, branching spikes of flowers proceeding from the wings of the stalks, and a shrubby stalk.

7. TOURNEFORTIA *foliis ovato-lanceolatis acutis, subtus tomentosis, spicis ramosis incurvis caule ramoso.* Tournefortia with oval spear-shaped leaves, having acute points, woolly on their under side, branching incurved spikes of flowers, and a branching stalk.

8. TOURNEFORTIA *foliis lanceolatis sessilibus, spicis simplicibus recurvis lateralibus.* *Lin. Sp. Plant.* 141. Tournefortia with spear-shaped leaves sitting close to the stalk, and single recurved spikes of flowers growing at the wings.

The first fort grows naturally in Jamaica, and in some of the other islands in the West-Indies, where it rises with shrubby stalks ten or twelve feet high, sending out many branches, garnished with oval spear-shaped leaves, placed alternately round the stalks, hairy on their under side, and stand upon short foot-stalks. The branches are terminated by long branching spikes of flowers, which are ranged on one side the foot stalks in the same manner as those of the Heliotrope or Turnsol. Some of the foot stalks sustain two, others three, and some four spikes of flowers, reflexed like a scorpion's tail at the top. The flowers are of a dirty white colour, small, and closely ranged on one side the spike; these are succeeded by small succulent fruit, inclosing four oblong seeds in each.

The second fort is also a native of the islands in the West-Indies. The stalks of this are shrubby, taper, and rough; they rise to the height of eight or ten feet, dividing into many branches, covered with a light, brown, hairy, rough bark, garnished with oval leaves, placed alternately, having many transverse veins running from the midrib to the sides; they are of a deep green on their upper side. The branches are terminated by branching spikes of flowers, succeeded by small, roundish, succulent fruit, each inclosing four oblong seeds.

The third fort grows naturally in Jamaica, and some of the islands in America; this hath a twining ligneous stalk, which twists about the neighbouring trees for support, and rises to the height of ten or twelve feet, sending out several slender ligneous branches, garnished with oval acute-pointed leaves, whose foot-stalks are reflexed. The flowers are produced in branching spikes from the side and the top of the branches; they are small, white, and are succeeded by small, white, succulent berries, having one or two black spots on each.

The fourth fort was discovered by the late Dr. Houstoun, growing naturally in Jamaica; this hath shrubby branching stalks, which twine about the neighbouring trees, and rise to the height of ten or twelve feet. The branches are garnished with heart-shaped hairy leaves, ending in acute points, of a thinner contexture than those of the former species, and stand upon short foot-stalks. The flowers come out at the end of the branches in very slender spikes; they are small, and of a dirty brown colour, ranged along the upper side of the foot-stalk; these are succeeded by small pulpy berries, each containing four seeds.

The fifth fort grows naturally near Carthagena, in New Spain; this has climbing stalks, which twine about any neighbouring support, and rise to the height of ten or twelve feet. The branches are garnished with heart-shaped leaves, downy on their under side, and stand upon very short foot-stalks. The flowers are produced in short branching spikes, which come out from the wings of the branches; they are of a dirty white colour, small, and are succeeded by small succulent berries, inclosing two, three, and sometimes four seeds.

The sixth fort grows naturally near Carthagena, in New Spain; this has strong ligneous stalks, which rise near twenty feet high, sending out several, strong, ligneous branches, covered with a light, brown, rough bark, garnished with thick oval leaves, rough on their upper surface, and of a dark green colour, but pale and smoother on their under side, standing upon pretty long foot-stalks. The flowers are produced in spikes from the wings of the branches; they are small, white, and shaped like those of the other species, and are succeeded by small succulent berries, each including two or three oblong seeds.

The seventh fort grows in the same country; this has woody stalks, which rise five or six feet high, from which spring out many slender ligneous branches, garnished with oval spear-shaped leaves, which are rounded at each end, but have acute points, of a dark green on their upper surface, but have a white down on their under side, sitting close to the branches. The flowers are produced from the wings of the stalks, and also at the top, formed in slender branching spikes, which are recurved; they are white, and are succeeded by small succulent berries, which contain two or three seeds.

The eighth fort grows naturally at Campeachy; this plant has low shrubby stalks, which seldom rise more than three feet high, sending out a few, slender, ligneous branches, garnished with rough spear-shaped leaves, sitting close to the branches, of a dark green on their upper side, but pale on their under. The flowers come out in single spikes from

from the wings of the stalk; they are white, and are succeeded by small succulent berries like the former sort.

These plants are propagated by seeds or cuttings; if by seeds, they must be procured from the countries where they grow naturally; these should be sown in small pots filled with light earth, and plunged into a hot-bed of tanners bark. These seeds sometimes grow the first year, but they often remain in the ground a whole year; therefore, if the plants should not come up the same season, the pots should be plunged in autumn into the tan-bed in the stove, where they should remain all the winter; and in the spring they should be removed out, and plunged into a fresh tan-bed, which will soon bring up the plants, if the seeds were good. When these are fit to remove, they should be each planted in a small pot, and plunged into a tan-bed, where they must be shaded from the sun till they have taken new root; and then they must be treated in the same way as other tender plants from the same countries, which require to be kept constantly in the bark-stove. The plants raised from cuttings, must be treated in the same way.

TOXICODENDRON. *Tourn. Inst. R. H. 610. tab. 381.*
Poison-tree.

The Characters are,

The male flowers are upon different plants from the female; they have a small empalement, cut into five points at the brim, but have no petals; they have five short stamina, terminated by roundish summits. The female flowers have empalements like the male; they have no stamina, but in the center is situated a roundish germen, supporting three small styles, crowned with globular stigmas. The germen afterwards turns to a berry with one or two cells, inclosing one seed in each.

The Species are,

1. TOXICODENDRON *foliis ternatis, foliolis obcordatis, glabris, integerrimis, caule radicante.* Poison-tree with trifoliate leaves, having roundish, heart-shaped, smooth, entire leaves, and a stalk putting out roots; called Poison Oak.

2. TOXICODENDRON *foliis ternatis, foliolis ovatis inciso-angulatis pubescentibus.* Poison-tree with trifoliate leaves, whose lobes are oval, angularly cut, and covered with soft short hairs.

3. TOXICODENDRON *foliis ternatis, foliolis ovato-lanceolatis glabris, caule erecto fruticoso.* Poison-tree with trifoliate leaves, whose lobes are oval, spear-shaped, smooth, and an erect shrubby stalk.

4. TOXICODENDRON *foliis pinnatis, foliolis ovato-lanceolatis integerrimis.* Poison-tree with winged leaves, whose lobes are oval, spear-shaped, and entire; called Poison Ash.

5. TOXICODENDRON *foliis ternatis, foliolis ovatis crenatodentatis glabris.* Poison-tree with trifoliate leaves, whose lobes are oval, smooth, and bluntly indented.

6. TOXICODENDRON *foliis ternatis, foliolis ovatis inciso-sinuatis glabris, caule volubili radicante.* Poison-tree with trifoliate leaves, whose lobes are oval, smooth, and cut into sinuses, and a twining rooting stalk.

7. TOXICODENDRON *foliis sæpius ternatis, foliolis oblongo-ovatis rugosis serratis, caule radicante.* Poison-tree with leaves, which are generally trifoliate, oblong, oval, rough, sawed lobes, and a rooting stalk.

8. TOXICODENDRON *foliis ternatis, foliolis lanceolatis superne inæqualiter serratis, subtus tomentosis, caule arborescente.* Poison-tree with trifoliate leaves, spear-shaped lobes, unequally sawed toward their points, downy on their under side, and a tree-like stalk.

9. TOXICODENDRON *foliis ternatis, foliolis ovato-lanceolatis acuminatis glabris, caule fruticoso ramoso.* Poison-tree with trifoliate leaves, having oval, spear-shaped, acute-pointed, smooth lobes, and a shrubby branching stalk.

The first sort grows naturally in most parts of North America; it has a low shrubby stalk, which seldom rises

more than three or four feet high, sending out shoots near the bottom, which trail upon the ground, putting out roots from their joints, whereby it multiplies and spreads greatly; so that when it is not confined, or trained up to a support, the stalks seldom rise upward. If the stalks happen to be close to a wall, they emit roots which fasten to the joints in the wall, and support themselves when they are severed from the root; and the stalks of such plants will become more ligneous, and rise much higher, than those which grow in the ground. The foot-stalks of the leaves are near a foot long; the leaves are composed of three smooth, oval, heart-shaped lobes, which are entire. The flowers come out from the side of the stalk in loose panicles, of an herbaceous colour, and small, so make no great appearance. Some plants have only male flowers with five stamina in each; these decay without producing fruit; but upon other plants there are only female flowers, which have a germen and three very short styles; these are succeeded by roundish, channelled, smooth berries, of a yellowish gray colour, which inclose one or two seeds.

This plant, when once planted in a garden, will propagate fast enough by its trailing branches, which put out roots at every part. It will thrive in almost any soil or situation.

The second sort grows naturally in most parts of North America. The stalks of this rise higher than those of the former; the branches are slender, but ligneous; they have a brown bark, and are garnished with downy leaves, standing upon pretty long foot-stalks, composed of three oval lobes, indented angularly, and hoary on their under side. The male flowers, which are produced on separate plants from the fruit, come out from the side of the stalks in close short spikes; these are of an herbaceous colour, and have five short stamina in each. The female flowers are produced in loose panicles; these are in shape and colour like the male, but larger, and have a roundish germen, supporting three very short styles, and are succeeded by roundish berries, which ripen in autumn.

The third sort grows naturally in North America; this has a shrubby, erect, branching stalk, which rises six or seven feet high, covered with a brown bark, garnished with smooth trifoliate leaves, whose lobes are oval, spear-shaped, and have a few sinuated indentures on their borders. The male and female flowers grow upon separate plants; their shape and colour like those of the former, and the fruit is also like that.

The fourth sort grows naturally in Virginia, Pennsylvania, New England, and Carolina; from all these countries I have received seeds: it also grows in Japan. This, in the countries where it grows naturally, rises with a strong woody stalk to the height of twenty feet or upward; but in England we seldom see any of them more than five or six; the reason of this is from the plants being tender, so are destroyed in severe winters; but I have seen some plants, which were kept in pots and sheltered in winter, upward of ten feet high, in the garden of Samuel Reynardson, Esq; at Hillendon, which, after his death, were purchased with all his other exotick plants, by Sir Robert Walpole. This has a strong woody stalk, covered with a light brown bark, inclining to gray. The branches are garnished with winged leaves, composed of three or four pair of lobes, terminated by an odd one. The lobes vary greatly in their shape, but for the most part they are oval and spear-shaped; they are sometimes rounded at their base, but generally end in acute points; their upper surface is smooth, of a lucid green, but their under side is pale, and a little hairy. The foot-stalks of the leaves change to a bright purple colour toward the latter part of summer, and in autumn all the leaves are of a beautiful purple colour before they fall off. The male flowers

flowers are produced upon loose panicles from the wings of the branches; they are small, of an herbaceous white colour, composed of five small roundish petals, and have five short stamina within, terminated by roundish summits. The female flowers are upon separate plants from the male, and are disposed on loose panicles; these are shaped like the male, but are somewhat larger, and have in their center a roundish germen, supporting three very short styles, crowned with globular stigmas. The germen afterward turns to a berry, variable in shape, sometimes almost oval, at others shaped like a small spear; but the most general form is roundish, with a protuberance almost like the Cicer; these include one seed. It flowers in July, and in warm seasons the female plants produce fruit, but they seldom ripen here.

This is undoubtedly the same plant which is mentioned by Dr. *Kempfer* in his *Amœnitates Exoticarum*, by the title of *Sitz*, *vel Sitz Adju*, or *Arbor vernicifera legitima, folio pinnato juglandis, fructu racemosa Ciceris facie*. Fasc. v. p. 791, 792. The true Varnish-tree, with a Walnut-tree leaf, and a branching fruit-like Cicers. But the figure he has exhibited of it, is the most inaccurate of any perhaps to be found in any of the modern books of botany; it is drawn from a side shoot of a branch which has been cut off, so has neither flower or fruit to it, and being a vigorous shoot, the leaves are very different in size and shape from those on plants which have not been headed; and his description of the leaves seems to have been taken from this branch, otherwise he could not have compared them to those of the Walnut-tree. He seems to have been conscious of this fault, by his adding another figure of the plant in small under his own; taken from a *Japan* herbal, in which there is a much better representation of it than his own conveys. How a person who was employing himself in making drawings of plants in a country, where the natural history of it was so little known, should make choice of such an imperfect sample for his figure, is amazing, for there can be no doubt of his meeting with perfect plants in flower or fruit, in a place where the shrubs are cultivated so plentifully as he mentions; and in his description of it, he sets out by comparing the height of the shrubs to those of Willow, than which he could not have chosen any plant by way of comparison, which would have conveyed a more indetermined idea; for it is well known there are different species of Willow, whose growth is from four to forty feet high; therefore there can be no other way of reconciling his description with what he afterward mentions, unless when he is giving an account of the method used by the natives in collecting the varnish; where he says the shrubs are cut down every third year, but by comparing their growth with that of the Willows, which are cut down for fuel, &c. every four or five years.

However, as the dried samples of the plant which he brought over, agrees with the *American* Toxicodendron, and the milky juice of both have the same qualities of staining, so there can be no doubt of the plants being the same; therefore if it is thought that varnish may be of publick utility, it may be collected in plenty in most of the *English* settlements in *North America*.

Kempfer has also given a figure and description of a spurious Varnish-tree, which is called *Fasi-no-Ki* by the natives, and is by him titled *Arbor vernicifera spuria, sylvestris angustifolia*. Spurious wild Varnish-tree with a narrow leaf, which he says agrees with the other in every part, excepting the lobes of the leaves, which are narrower. This led me into a mistake in the former editions of the *Gardeners Dictionary*, by supposing their difference might arise from culture only; but having since raised from seeds a shrub which has all the appearance of his spurious Varnish-tree, and is evidently a distinct species, if not of a different genus

from the true sort, I am certain *Kempfer* has been guilty of a great mistake in this particular. The seeds of this were sent from *China*, for those of the Varnish-tree; but when I sowed them, I remarked they were pretty much shaped like those of the Beech-tree, but smaller; being thick on one side and slender on the other, in shape of a wedge, from whence I supposed there were three of the seeds included in one capsule. There is a shrub of this kind now growing in the *Chelsea* garden, which is more than fifteen feet high; but, as it has not yet produced flowers, I am at a loss where to range it.

The fifth sort grows naturally in *North America*, from whence the seeds were a few years since brought to *England*. This has a shrubby stalk, which sends out many ligneous branches, covered with a smooth purple bark, garnished with smooth trifoliate leaves, standing upon foot-stalks an inch long; the lobes are oval, of a deep lucid green on their upper side, but of a pale green on their under, deeply crenated or indented on their edges, their base joining close to the foot-stalks. The leaves, when bruised, emit an odour like that of Orange peel, from whence the gardeners have titled it the sweet-scented Toxicodendron. The male flowers are produced in short close panicles; they are small, of an herbaceous white colour; they are upon separate plants from the fruit, which grow in sparfed panicles, and are of an oval shape.

The sixth sort grows naturally in *North America*. The stalks of this sort emit roots their whole length, whereby they fasten to trees or any neighbouring support, and climb to the height of six or eight feet, garnished with trifoliate oval leaves, which are smooth, and cut into sinuses on their edges. The flowers are produced in short panicles from the side of the branches; they are male and female on different plants like the other species.

The seventh sort was sent me by Mr. *John Bartram* from *Philadelphia*, by the title of Great Toxicodendron; this hath trailing roots, which run near the surface of the ground, sending up stalks in different places; the leaves stand upon long foot-stalks, composed of three or four obtuse rough lobes, sawed on their edges.

The first, sixth, and seventh sorts propagate in plenty by their creeping stalks and roots; the others are propagated by laying down their branches, which will put out roots in one year, and may then be taken off and transplanted, either in the places where they are to remain, or in a nursery to grow two or three years, to get strength before they are planted out for good; they may also be propagated by seeds, which should be sown on a bed of light earth, and when the plants come up, they must be kept clean from weeds the following summer; and before the frost comes on in autumn, the bed should be hooped over, that the plants may be covered with mats, for otherwise the early frosts will kill their tops, which frequently causes their stalks to decay to the ground; for as the young plants are tender, and generally shoot late the first year, they are in much greater danger than when they get more strength. In spring the plants may be transplanted into nursery-beds to grow a year or two, and may then be transplanted for good.

These plants are preserved by the curious in botany, for the sake of variety; but as there is little beauty in them, there are not many of the sorts cultivated in *England*. The wood of these trees, when burnt, emits a noxious fume, which will suffocate animals when they are shut up in a room where it is burnt: an instance of this is mentioned in the *Philosophical Transactions* by Dr. *William Sherard*, which was communicated to him in a letter from *New England* by Mr. *Moore*, in which he mentions some people who had cut some of this wood for fuel, which they were burning, and in a short time they lost the use of their limbs, and became

stupid; so that if a neighbour had not accidentally opened the door, and seen them in that condition, it is generally believed they would soon have perished. This should caution people from making use of this wood for such purpose.

When a person is poisoned by handling this wood, in a few hours he feels an itching pain, which provokes a scratching, which is followed by an inflammation and swelling. Sometimes a person has had his legs poisoned, which have run with water. Some of the inhabitants of *America* affirm, they can distinguish this wood by the touch in the dark, from its extreme coldness, which is like ice; but what is mentioned of this poisonous quality, is most applicable to the fourth sort here mentioned, which, by the description, agrees with this species.

The juice of the tree is milky, when it first issues out of the wounded part; but soon after it is exposed to the air, it turns black, and has a very strong foetid scent, and is corroding; for I have observed, on cutting off a small branch from one of these shrubs, that the blade of the knife has been changed black in a moment's time, so far as the juice had spread over it, which I could not get off without grinding the knife.

The eighth sort grows naturally in *Jamaica* on the red hills, and at *Campeachy* in great plenty. It has a thick woody stem, which rises near thirty feet high, with a smooth Ash-coloured bark, sending out ligneous branches on every side, which have a hairy rusty-coloured bark, garnished with trifoliate leaves, which have hairy foot-stalks. The lobes are spear-shaped, unequally sawed toward the top, and have many transverse veins running from the midrib to the borders, and have a brown woolly down on their under side. The flowers are ranged in a single racemus, which springs from the wings of the branches; they are small, of a yellowish colour, and the female flowers are succeeded by small oval berries, of an Orange colour when ripe.

The ninth sort grows naturally about *Carthagera* in *New Spain*; this rises with a shrubby stalk twelve or fourteen feet high, covered with a gray bark, sending out a great number of branches on every side, which are garnished with trifoliate smooth leaves, whose lobes are oval, spear-shaped, and oblique to their foot-stalks. The male and female flowers are upon different plants; they are formed in loose panicles, are small, and of a dirty white colour. The female flowers are succeeded by small, oval, smooth berries, each including one seed.

The two last sorts are tender plants, so will not thrive in this country, without the assistance of artificial heat; they are propagated by seeds, when these can be procured from the countries where the plants grow naturally. These should be sown as soon as they arrive here, in pots filled with light earth, and plunged into a tan-bed. Sometimes the plants will come up the same year, but the seeds often lie long in the ground when they are sown in the spring; and when they do not grow the first year, the pots should be plunged in the bark-bed in the stove in autumn, where they may remain all the winter; and in the spring they should be plunged into a fresh hot-bed under a frame, which will soon bring up the plants. When these are fit to remove, they should be each planted in a small pot, filled with light earth, and plunged into a new tan-bed, observing to shade them from the sun till they have taken new root; then they should be treated in the same way as other tender exotick plants, which are constantly kept in the bark-stove.

TRACHELIUM. *Tourn. Inst. R. H.* 130. tab. 50. *Lin. Gen. Plant.* 204. Throatwort.

The Characters are,

The flower has a small empalement, cut at the top in five parts, sitting upon the germen. The flower has one petal, which is funnel shaped, having a long, slender, cylindrical tube, cut at

the top into five small oval segments, which spread open; it has five hair-like stamina the length of the petal; terminated by single summits; and a roundish three-cornered germen, situated under the flower, supporting a long slender style, crowned by a globular stigma. The germen afterward turns to a roundish obtuse capsule with three lobes, having three cells, which are filled with small seeds.

We have but one Species of this genus in the *English* gardens, viz.

TRACHELIUM. *Hort. Upsal.* 41. Blue Mountain Throatwort.

This plant grows naturally in shady woods in many parts of *Italy*. It has a perennial root, which is fleshy and tuberos. The leaves are oval, spear-shaped, sawed on their edges, ending in acute points. The stalks rise a foot and a half high, garnished with leaves, shaped like those at the bottom, but come out irregularly. Sometimes there are two pretty large leaves, and one or two smaller rising from the same joint; at others, one large and three smaller; these come out alternate, and the upper part of the stalk, immediately under the umbel, is naked of leaves, except two or three narrow ones, which are close to the foot-stalks of the flowers; these are disposed in form of an umbel, composed of many small umbels. The flowers are small, funnel-shaped, and of an azure blue colour; these are succeeded by roundish capsules, with three cells, filled with small seeds, which ripen in autumn.

This plant is propagated by seeds, which should be sown in autumn soon after they are ripe; for when they are kept out of the ground till spring, they frequently fail, or if they do grow, it is not before the following spring. When the plants come up, they should be kept clean from weeds, and as soon as they are big enough to remove, should be transplanted on an east aspected border of light undunged earth, placing them in rows six inches apart, and four inches distant in the rows, shading them from the sun till they have taken new root; after which they require no other care but to keep them clean from weeds till autumn, when they may be transplanted into the borders of the flower-garden, where they will flower the following summer.

But as these plants thrive better on old walls, when by accident they have arisen there from seeds, so their seeds, when ripe, may be scattered on such walls as are old, or where there is earth lodged sufficient to receive the seeds, where the plants will come up and resist the cold much better, and continue longer than when sown in the full ground; and when a few of the plants are established on the walls, they will shed their seeds, so that they will maintain themselves without any farther care. I have observed some plants of this kind, which have grown from the joints of a wall, where there has not been the least earth to support them, which have resisted the cold, though they have been greatly exposed to the winds, when most of those in the full ground were killed; so that these plants are very proper to cover the walls of ruins, where they will have a very good effect.

TRADESCANTIA. *Lin. Gen. Plant.* 360. Spiderwort.

The Characters are,

The flower has a disformed sheath. The proper empalement is permanent, composed of three oval concave leaves. The flower has three roundish equal petals, which spread open, and six hairy slender styles, terminated by kidney-shaped summits, and an oval, obtuse, three-cornered germen, supporting a slender style, crowned by a triangular blunt stigma. The germen afterward turns to an oval capsule, shut up in the empalement, having three cells, containing a few angular seeds.

We have but one distinct Species of this genus, viz.

TRADESCANTIA. *Hort. Cliff.* 127. Spiderwort.

The root of this plant is composed of several fleshy fibres, which spread wide, from which arise many long, narrow, keeled leaves, which embrace each other at their base; they are veined, rough on their edges, of a grayish colour, and succulent; between the leaves arise a thick jointed stalk about a foot long, garnished at each joint with one leaf, whose base embraces it. At the top of the stalk are two leaves, which spread asunder; above these come out many flowers almost in a sort of umbel; these have a three-leaved empalement, and three large roundish petals, of a deep blue colour, which in the morning spread open flat, but in the middle of the day they shrink up, and do not open again; but there is a succession of flowers from the same bunch daily, for a considerable time. The germen afterward swells to a roundish capsule with three angles, having three cells, including a few angular seeds.

We have two other varieties of this plant, one with a white, the other has a purple flower; but these are supposed changeable from seeds.

It is easily propagated by seeds, which, if they are permitted to scatter, will produce plenty of young plants the following spring; or if the seeds are sown soon after they are ripe, the plants will come up the spring after; and when they are fit to remove, they should be planted in a nursery-bed at about nine inches distance, and the ground kept clean from weeds. In autumn they should be removed into the borders of the flower-garden, where they will flower and produce seeds, and the roots will continue several years.

TRAGACANTHA. *Tourn. Inst. R. H. 417. tab. 234.*
Goats-thorn.

The Characters are,

The empalement of the flower is indented in five parts, the lower segments being the shortest. The flower is of the butterfly kind; the standard is long, erect, indented at the point; the borders are reflexed. The wings are shorter than the standard. The keel is of the same length with the wings, and is indented; it has ten stamina, nine are joined and one is separated, terminated by roundish summits, and a sharp taper germen, supporting an awl-shaped style, crowned by an obtuse stigma. The germen afterward becomes a short swelling pod, having two longitudinal cells, including kidney-shaped seeds.

The Species are,

1. TRAGACANTHA *petiolis longioribus spinescentibus, foliis ovatis obtusis.* Goats-thorn with longer foot-stalks, ending in spines, having oval obtuse lobes to the leaves.

2. TRAGACANTHA *foliolis lanceolatis, floribus solitariis axillaribus, siliculis ovatis inflatis.* Goats-thorn with spear-shaped lobes, flowers proceeding singly from the sides of the branches, and oval, inflated, bladder pods.

3. TRAGACANTHA *foliolis lanceolatis acuminatis tomentosis, floribus alaribus terminalibusque.* Goats-thorn with spear-shaped, acute-pointed, woolly leaves, flowers growing on the sides, and at the ends of the branches.

4. TRAGACANTHA *foliolis linearibus glabris, floribus congestis axillaribus.* Goats-thorn with very narrow smooth leaves, and flowers growing in clusters on the sides of the branches.

The first sort grows naturally on the sea-shore about *Marseilles*, and in *Italy*; this has a thick, short, ligneous stalk, which branches out greatly on every side. The young branches are woolly, closely garnished with winged leaves, whose foot-stalks end in acute thorns. The lobes are small, oval, obtuse, and of a silvery colour. The flowers are large, white, and shaped like a butterfly; they are produced in clusters at the end of the branches, and are succeeded by short pods, having two longitudinal cells, containing two or three kidney-shaped seeds, which seldom ripen in *England*.

The second sort grows naturally in the islands of *Majorca* and *Minorca*; this hath a thick woody stalk, rising about two feet high, sending out many ligneous branches, closely garnished with small, spear-shaped, hoary leaves, ranged by pairs along a very strong foot-stalk, ending with a sharp thorn. The flowers are produced singly from the sides of the branches; they are large, white, and are succeeded by oval bladder pods, containing four kidney-shaped seeds, which do not ripen in *England*.

The third sort grows naturally in the islands of the *Archipelago*; this has a very low shrubby stalk, divided into many downy branches, garnished with winged leaves, composed of nine or ten pair of spear-shaped woolly lobes, ending in acute thorns. The flowers are produced from the side and at the top of the branches; they are white, and shaped like those of the other species, but smaller.

The fourth sort grows naturally in *Spain*; this is a very low plant. The stalks are pretty thick and woody, but seldom rise more than five or six inches high; dividing into several branches, closely garnished with small winged leaves, composed of several pair of small, linear, smooth lobes, of a bright green colour. The foot-stalks of these end in very sharp thorns, which stand out beyond the lobes; the flowers grow in clusters from the side of the stalks; they are smaller than those of the other species, and of a dirty white colour.

These sorts may be propagated by seeds, when they can be procured from the countries where the plants grow naturally, which should be sown on a bed of fresh earth in *April*; and when the plants come up, they should be carefully kept clean from weeds. If the season should prove very dry, it will be of great service to water the plants now and then; when they are large enough to transplant, they should be carefully taken up, and some of them planted in small pots, filled with fresh earth, placing them in the shade until they have taken new root; then they may be removed into an open situation, where they may remain till the latter end of *October*, when they should be placed under a common frame, where they may be sheltered from severe frost, but may have free air in mild weather.

The remainder of the plants may be planted on a warm dry bank, where they must be shaded until they take root; and if the season should continue dry, they must be refreshed with water, otherwise they will be in danger, because, while they are so young, their roots will not have established themselves in the ground sufficiently to nourish them in great droughts.

Those plants which were planted in pots, may be preserved under frames in winter, until they have obtained strength, when they may be shaken out of the pots, and planted in a lean dry soil and a warm situation, where they will endure the cold of our ordinary winters very well; but, as they are sometimes destroyed by hard frost, it will be proper to keep a plant of each kind in pots, which may be sheltered in winter to preserve the species.

These plants may also be propagated by slips, for as they rarely produce seeds in this country, the latter method is generally used here. The best time for this work is in *April*, just as the plants begin to shoot, at which time the tender branches of the plants should be slipped off, and their lower parts divested of the decayed leaves; then they should be planted on a very moderate hot bed, which should be covered with mats, to screen them from the great heat of the sun by day and the cold by night. These cuttings should be gently watered until they have taken root; then they may be exposed to the open air, observing always to keep them clear from weeds.

On this bed they may remain until the following spring, where, if the winter should be very severe, they may be

covered with mats as before; and in *April* they may be transplanted out either into pots, filled with sandy light earth, or into warm borders, where, if the soil be dry, gravelly, and poor, they will endure the severest cold of our climate; but if they are planted in a very rich soil, they often decay in winter.

From one species of this genus, Monsieur *Tournefort* says, the Gum Adragant, or Dragon, is produced in *Crete*.

TRAGIA. *Plum. Gen. Nov. 14. tab. 12.*

The Characters are,

It hath male and female flowers in the same plant. The empalement of the male flower is cut into three oval acute-pointed segments; it has no petals, but there are three stamina in each the length of the empalement, terminated by roundish summits. The empalement of the female flowers are permanent, cut into five oval concave segments. The flowers have no petals or stamina, but a roundish germen, having three furrows, supporting an erect style, crowned by a bifid spreading stigma. The germen afterward turns to a roundish three-lobed capsule, having three cells, each containing one globular seed.

The Species are,

1. TRAGIA *foliis cordato-oblongis, caule volubili. Lin. Sp. Plant. 980.* Tragia with oblong heart-shaped leaves, and a twining stalk.

2. TRAGIA *involutris fæmineis pentaphyllis pinnatifidis. Lin. Sp. Plant. 980.* Tragia with five-leaved involucri to the female flowers, which are wing-pointed.

The first sort grows plentifully in the *Savannas* in *Jamaica*, and other warm parts of *America*, where it twines round whatever plants or trees it grows near, and rises seven or eight feet high, having tough stems. The leaves are oblong, heart-shaped, ending in acute points, deeply sawed on their edges, standing alternately upon pretty long foot-stalks. The male flowers come out from the wings of the stalk in bunches of about two inches in length; the female flowers are produced on separate foot-stalks, arising from the same point as the male; these are succeeded by roundish capsules with three cells, each inclosing one roundish seed. The whole plant is covered with burning spines, like those of the *Nettle*, which renders it very unpleasant to handle.

The second sort grows naturally in *India*; this rises with an erect ligneous stalk about three feet high, which rarely sends out any side branches, garnished with oblong spear-shaped leaves, which end in very long acute points, sharply sawed on their edges, ranged alternately on the stalk, and are closely covered with yellowish stinging hairs. The flowers are produced in small clusters from the wings of the stalk, standing several together upon the same foot-stalk; the upper are all male, and the under female; the latter are succeeded by roundish capsules with three cells, each inclosing one seed.

As these are plants of no great beauty, they are seldom preserved in this country, except in some botanick gardens for variety; they are propagated by seeds, which must be sown on a hot-bed early in the spring, and afterward transplanted into pots, and plunged into a hot-bed of tanners bark, and treated in the same manner as other tender plants, which require to be kept in the bark-stove.

TRAGOPOGON. *Tourn. Inst. R. H. 477. tab. 270.* Goats-beard.

The Characters are,

The common empalement of the flower is single, composed of eight acute-pointed leaves, which are alternately large, joined at their base. The flower is composed of many hermaphrodite florets, which are uniform, of one petal, stretched out like a tongue, indented at their points in five parts, and lie over each other like the scales of fish; these have each five short hair-like stamina, terminated by cylindrical summits, and an oblong germen, situated

under the floret, supporting a slender style the length of the stamina, crowned by two revolving stigmas. The empalement of the flower afterward swells to a belly, inclosing many oblong, angular, rough seeds, slender at both ends, crowned by a feathery down.

The Species are,

1. TRAGOPOGON *calycibus corollæ radium æquantibus, foliis integris striatis. Lin. Sp. Plant. 789.* Goats-beard with an empalement equal to the rays of the flower, and entire leaves; or common Goats-beard.

2. TRAGOPOGON *calycibus corollæ radiis longioribus, foliis linearibus striatis.* Goats-beard with the empalement longer than the rays of the flower, and linear closed leaves; or small, yellow, Meadow Goats-beard.

3. TRAGOPOGON *calycibus corollæ radiis longioribus, foliis integris striatis, pedunculis supernè incrassatis. Hort. Upsal. 243.* Goats-beard with an empalement longer than the rays of the flower, entire closed leaves, and the foot-stalk thicker at the upper part; commonly called Salsafy.

4. TRAGOPOGON *calycibus corollæ radio longioribus, foliis integris, seminibus lævibus, disci plumosis, radii setaceis. Hort. Upsal. 243.* Goats-beard with an empalement longer than the rays of the flower, entire leaves, and smooth seeds, those of the disk being covered with a feathery down, and those on the borders bristly; another Goats-beard with a soft red flower.

5. TRAGOPOGON *calycibus corollæ radio brevioribus, foliis linearibus striatis, caule hirsuto.* Goats-beard with the empalement shorter than the rays of the flower, narrow closed leaves, and a hairy stalk; hairy Goats-beard.

6. TRAGOPOGON *calycibus corollæ brevioribus aculeatis, foliis pinnato-bastatis. Hort. Cliff. 382.* Goats-beard with prickly empalements, which are shorter than the petals, and arrow wing-pointed leaves; or rough Sowthistle of *Crete*.

The first sort grows naturally in the meadows of *Austria* and *Germany*; this is very different from the second, which grows naturally in *England*, for I have sown the seeds of both sorts several years in the same bed of earth, and have always found the plants have retained their difference. The lower leaves of this are three quarters of an inch broad at their base, where they embrace the stalk, and more than a foot long, closed together, ending in acute points. The stalk rises near three feet high, garnished at each joint with one leaf, of the same shape with those below, but smaller; it is terminated by one large yellow flower, composed of hermaphrodite florets, which lie over each other like the scales of fish; these are included in one common simple empalement, which is equal in length to the rays of the flower. Each floret is succeeded by an oblong seed, which is larger at the base than at the point, where it is crowned with a large feathery down. The seeds of the border or ray are crooked and rough, but those of the disk are straight and smooth.

The second sort grows naturally in moist pastures in many parts of *England*; it is by the common people titled Sleep-at-noon, or Go-to-bed-at-noon, because the flowers are generally closed up before that time every day. The lower leaves of this sort are almost as long as those of the first sort, but are not more than a third part so broad; they are of a deep green colour, and end in acute points. The stalks rise about a foot high, and sustain one yellow flower at the top, not more than half so large as those of the first; the empalements of these flowers are longer than the rays; and the seeds are much smaller than those of the other.

When this sort shoots up in stalks four inches high, the common people gather it out of the fields, and boil it in the same way as *Asparagus*, and some give it the preference.

The third sort is cultivated in gardens by the title of Salsafy. The roots of this are dressed in different ways, and served

served up to the table; but of late years some persons cultivate it for the stalks, which are cut in the spring when they are four or five inches high, which are dressed like Asparagus, in the like manner as the second sort. The stalks of this are much longer, and are tenderer than the other, so are better for the purpose than those of the second sort; the leaves are broad; the flowers are large and blue; the foot-stalk immediately under the flower is much thicker than below, and the empalement is longer than the rays of the flower.

The fourth sort grows naturally in *Italy*; this is of low stature. The stalks seldom rise a foot high; the leaves are long and narrow; the flowers are small, and of a pale red or Peach-blossom colour; the empalement is much longer than the rays of the flower, and the seeds are smooth.

The fifth sort grows naturally in *Istria*; this has narrow hairy leaves. The stalks rise about a foot and a half high, are naked most part of their length, very hairy, and sustain one pretty large yellow flower, whose empalement is much shorter than the rays of the flower, which is also very hairy.

The sixth sort grows naturally in *Crete*, and also in *Italy*; this is an annual plant, very like the Sowthistle in stalk and leaf, but the empalement of the flower is prickly. It is seldom admitted into gardens, because the seeds are wafted by the winds to a great distance, and thereby fill the garden with the plants.

These plants are propagated from seeds, which should be sown in *April* upon an open spot of ground, in rows about nine or ten inches distance; and when the plants are come up, they should be hoed out, leaving them about six inches asunder in the rows. The weeds should also be carefully hoed down as they are produced, otherwise they will soon overbear the plants, and spoil them. This is all the culture required, and if the soil be light and not too dry, the plants will have large roots before winter; at which time the Salsafy, whose roots are eaten at that season, will be fit for use, and may be taken up any time after their leaves begin to decay; but, when they begin to shoot again, they will be sticky, and not fit for use; but many persons cultivate this sort for the shoots, as was before mentioned.

The common yellow sort, whose shoots are sold in the market, will be fit for use in *April* or *May*, according to the forwardness of the season. The best time to cut them is, when their stems are about four inches long, for if they stand too long, they are never so tender as those which are cut while young.

Some people in cultivating these plants, sow their seeds in beds pretty close; and when they come up, they transplant them out in rows at the before mentioned distance; but, as they form tap-roots, which abound with a milky juice, when the extreme part of their roots is broken by transplanting, they seldom thrive well afterward; therefore, it is by far the better way to make shallow drills in the ground, and scatter the seeds therein, as before directed, whereby the rows will be at a due distance, and there will be nothing more to do than to hoe out the plants when they are too thick in the rows, which will be much less trouble than the other method of transplanting, and the plants will be much larger and fairer.

TRAGOSELINUM. See Pimpinella.

TRIBULUS. *Tourn. Inst. R. H. 265. tab. 141.* Caltrops.

The Characters are,

The empalement of the flower is cut into five acute parts; there are five oblong blunt petals to the flower, which spread open, and ten small awl-shaped stamina, terminated by single summits, and an oblong germen the length of the stamina, having no style, but crowned by a headed stigma. The germen afterward turns to a roundish prickly fruit, divided into five capsules, armed

with three or four angular thorns on one side, joining together. The cells are transverse, and contain two or three Pear-shaped seeds.

The Species are,

1. TRIBULUS *foliolis sexjugatis subæqualibus.* Hort. Cliff. 160. Caltrops with six pair of lobes to each leaf, which are almost equal.

2. TRIBULUS *foliolis quadrijugis exterioribus majoribus.* Lin. Sp. Plant. 386. Caltrops with four pair of lobes to each leaf, of which the outer are the largest.

3. TRIBULUS *foliolis octojugatis subæqualibus.* Lin. Sp. Plant. 387. Caltrops with eight pair of lobes to each leaf, which are almost equal.

The first sort is a very common weed in the south of *France*, in *Spain*, and *Italy*, where it grows among Corn, and on most of the arable land, and is very troublesome to the feet of cattle; for the fruit being armed with strong prickles, run into the feet of the cattle, which walk over the land. This is certainly the plant which is mentioned in *Virgil's Georgicks*, under the name of Tribulus, though most of his commentators have applied it to other plants.

It is called in *English* Caltrops, from the form of the fruit, which resembles those instruments of war that were cast in the enemies way to annoy their horses.

This hath a slender fibrous root, from which spring out four or five slender hairy stalks, which spread flat on the ground, garnished at each joint with winged leaves, composed of six pair of narrow hairy lobes, almost of equal size; those on the lower part of the stalk stand alternately, but toward the top they are placed opposite. The flowers come out from the wings of the stalk, standing upon short foot-stalks; they are composed of five broad, obtuse, yellow petals, which spread open. In the center is situated an oblong germen, crowned by a headed stigma, attended by ten short stamina, terminated by single summits, and are succeeded by roundish, five-cornered, prickly fruit, which, when ripe, divides into five parts, each having a transverse cell, containing one or two seeds.

This plant is preserved in botanick gardens for variety. It is propagated by seeds, which should be sown in autumn, for those which are kept out of the ground till spring, commonly remain in the ground a whole year before the plants come up. These seeds should be sown on an open bed of light earth, where they are designed to remain; for, as it is an annual plant, it doth not bear transplanting very well, unless it be done when the plants are very young. In the spring, when the plants come up, they should be carefully cleared from weeds; and where they come up too close, some of the plants should be pulled out to give room for the remaining plants to grow; after this they will require no other culture but to keep them clear from weeds. If the seeds are permitted to scatter, the plants will come up the following spring, and maintain their place, if they are not overborne with weeds.

The second sort grows naturally in *Jamaica*, and some of the other islands in the *West-Indies*; this is an annual plant, with pretty thick, compressed, channelled stalks, which trail upon the ground, garnished with smooth winged leaves, placed by pairs opposite; they are sometimes composed of three, but most commonly of four pair of lobes, the outer being the largest. The flowers come out from the wings of the stalk; they are composed of five large yellow petals, which spread open, and have an agreeable odour; these are succeeded by roundish prickly fruit, ending in a long point, but seldom ripen in *England*.

The third sort grows naturally in the *West-Indies*; it was found by the late Dr. *Houssoun* at the *Havanna*; this has a ligneous root, from which spring out many stalks, which are hairy, jointed, and trail upon the ground, garnished

at each joint by winged leaves, which differ greatly in size, some being composed of eight pair of oblong lobes which are nearly equal, but opposite to these come out small leaves composed of but four pair of lobes. The large leaves stand alternately upon the stalks, and the small ones on the opposite side; at the wings of the stalks come out the foot-stalks of the flowers, which are hairy, and near two inches long, each sustaining one pale yellow flower, composed of five large petals, which have narrow tails, but are very broad and rounded at their points. The flowers are succeeded by roundish fruit armed with very acute spines, but these rarely ripen in *England*.

The two last sorts, being natives of hot countries, are very tender, so must be sown in pots in autumn, and plunged into the tan-bed in the stove; when the plants are come up, they must each be transplanted into a separate pot, and then plunged into a hot-bed of tanners bark, where they must be treated in the same manner as other tender exotic plants, being careful to bring them forward as early as possible in the summer, otherwise they will not perfect their seeds in this country.

The third sort will live through the winter, if it is plunged in the bark-stove, and treated in the same manner as other tender plants, and the following summer they will flower earlier, so there will be more time for the seeds to ripen.

TRICHOMANES, Maiden-hair.

There are three or four varieties of this plant, which grow naturally in *Europe*; but in *America* there is a great number of species, which are remarkably different from each other, as also from the *European* kinds.

These, being of the tribe of Ferns, or capillary plants, are seldom preserved in gardens. Their roots should be planted in moist shady places, especially the *European* sorts, which commonly grow from between the joints of old walls, and in other very moist shady situations; but those sorts which are brought from hot countries, must be planted in pots filled with rubbish, and strong earth mixed, and in winter they must be screened from hard frosts, to which, if they are exposed, it will destroy them.

The common sort in *England* is generally sold in the markets for the true Maiden hair, which is a very different plant, and not to be found in *England*, it being a native of the south of *France*, and other warm countries, so is rarely brought to *England*.

TRICOSANTHES. *Lin. Gen. Plant.* 966.

The Characters are,

It has male and female flowers, at separate distances, on the same plant. The male flowers have a long smooth empalement of one leaf, cut into five small segments which are reflexed; the petal is plain, spreading, and cut into five parts, ending in long branching hairs; they have three short stamina arising from the point of the empalement, terminated by cylindrical erect summits joined in a body, and three small styles fastened to the empalement. The female flowers sit upon the germen, and have empalements and petals like the male flowers, but have no stamina; they have a long slender germen situated under the flower, supporting a style the length of the empalement, crowned by three oblong stigmas. The germen afterward turns to a long succulent fruit, having three cells, inclosing many compressed seeds.

We have but one Species of this genus in the *English* gardens, viz.

TRICOSANTHES pomis teretibus oblongis. *Hort. Cliff.* 450. Tricosanthes with a taper, oblong, incurved fruit.

This plant grows naturally in *China*, it is an annual, and of the *Cucumber* tribe. The stalks run to a great length, and, if they are not supported, trail upon the ground, in the same manner as *Cucumbers* and *Melons*. The leaves are angular and rough; the flowers come out from the side of the stalks; they are white, and cut into many small filaments or threads. The fruit is taper, near a foot long,

incurved, and divided into three cells, which include many compressed seeds like those of *Cucumber*.

It is propagated by seeds, which must be sown on a hot-bed early in the spring, and afterwards treated in the same way as *Cucumbers* and *Melons*, keeping them covered with glasses, otherwise they will not ripen their fruit here.

TRICHOSTEMMA. *Gron. Flor. Virg.* 64. *Lin. Gen. Plant.* 652.

The Characters are,

The flower has a lipped empalement; the upper lip is twice as large as the under, cut into three equal acute segments, the under lip in two. The flower is of the lip-kind, and has a very short tube; the upper lip is compressed and hooked, the under is cut into three parts, the middle one being the least; it has four hair-like stamina which are long and incurved, two of them being a little shorter than the other, terminated by single summits, and a four-pointed germen, supporting a slender style, crowned by a bifid stigma. The germen afterward turn to four roundish seeds, inclosed in the swollen empalement of the flower.

The Species are,

1. TRICHOSTEMMA staminibus longissimis exsertis. *Lin. Sp. Plant.* 598. Trichostemma with the longest stretched-out stamina.

2. TRICHOSTEMMA staminibus brevibus inclusis. *Lin. Sp. Plant.* 598. Trichostemma with shorter stamina included in the petal.

The first sort grows naturally in many parts of *North America*; it is an annual plant, which rises about six or eight inches high, dividing into small branches, garnished with small roundish leaves, not unlike those of sweet *Marjoram*, placed opposite, covered with fine, small, downy hairs. The flowers are produced at the wings of the branches; they are small, of a purple colour, gaping with two lips; the upper lip is arched, and is much larger than the lower; it is cut into three acute points; the lower lip is small, and cut into two points. These appear late in *August*, so that unless the season proves warm, the seeds will not ripen in *England*.

The second sort grows naturally in *Virginia*; this hath an herbaceous, angular, branching stalk, which rises from nine inches to a foot high; the leaves stand by pairs on the branches, shaped like those of the wild *Marjoram*; are a little hairy, and sit close to the branches; the flowers are produced at the top of the branches; they are small, of a purple colour. The four stamina stand within the tube of the flower; these flowers do not appear till the end of summer, so the seeds seldom ripen here.

They are propagated by seeds, which should be sown in pots in autumn; and in winter the pots should be placed under a frame to shelter them from severe frost, but should be exposed to the open air at all times when the weather is mild. In the spring the plants will appear; and when they are fit to remove, they should be planted on a bed of light earth, shading them from the sun till they have taken fresh root, then they will require no other culture but to keep them clean from weeds.

TRIDAX. *Lin. Gen. Plant.* 872. *American Starwort*.

The Characters are,

The flower has a common, cylindrical, imbricated empalement. The scales are acute-pointed, and erect. The flowers are composed of hermaphrodite florets in the disk, and the rays of female half florets. The hermaphrodite florets are funnel-shaped, cut at the brim into five points; these have five short hair-like stamina, terminated by cylindrical summits joined together, and an oblong crowned germen, supporting a bristly style, crowned by an obtuse stigma. The germen afterward becomes an oblong single seed, crowned with a simple down. The female half florets are plain, of one petal, cut into three segments at the top; these have an oval germen like the hermaphrodite florets, but no stamina, and are succeeded by single seeds of the same shape.

We know but one *Species* of this genus, *viz.*

TRIDAX. Hort. Cliff. 418. Trailing Starwort with a whitish copper coloured flower, and hairy jagged leaves.

This plant was discovered by the late Dr. *Houftoun*, growing naturally by the road side leading to old *La Vera Cruz*, in *America*. The stalks are herbaceous, hairy, and trail upon the ground, emitting roots at their joints, whereby it spreads and propagates, garnished with rough hairy leaves placed by pairs, ending in acute points, and are acutely jagged on their edges. The flowers are produced upon long naked foot-stalks, which terminate their branches. They have one common empalement, composed of oval scales, ending in acute points, which lie over each other like the scales of fish; within which are ranged many female half florets, which compose the border or rays, and a good number of hermaphrodite florets, which form the disk or middle; these are of a pale copper colour, inclining to white, and are each succeeded by a single oblong seed, crowned with down.

This plant is propagated by seeds, which should be sown in pots and plunged into a hot-bed; when the plants come up and are fit to remove, they should be each planted in a small pot and plunged into a hot-bed of tanners bark, observing to shade them from the sun till they have taken new root; then they must be treated in the same way as other tender plants from the *West Indies*, placing them in the bark-stove in autumn, where they should constantly remain.

It may also be propagated by its trailing stalks, which frequently put out roots at their joints; if these are cut off and planted, they will make new plants. This plant does not produce flowers in plenty here, and but rarely perfects its seeds in *England*.

TRIFOLIUM. Tourn. Inst. R. H. 404. tab. 228. Trefoil, or Clover.

The Characters are,

This flower has a tubulous permanent empalement of one leaf. It is of the butterfly kind, drying in the empalement. The standard is reflexed, the wings are shorter than the standard, and the keel is shorter than the wings; it has ten stamina, nine are joined, and one is separate, terminated by single summits; and an almost oval germen supporting an awl-shaped style, crowned by a single stigma. The germen afterward becomes a short pod with one valve, containing a few roundish seeds.

There are a great number of species of this genus, several of which grow naturally in *England*, and others in many parts of *Europe*; but as great part of them are plants of small estimation, they are rarely cultivated either in the field or garden; therefore it would be swelling this work too much to enumerate them all here, so I shall select only such of them as are cultivated either for use or beauty.

The Species are,

1. TRIFOLIUM caule erecto, foliis oblongo-ovatis integerrimis, spicis ovatis, calycibus setaceis. Trefoil with an erect stalk, oblong, oval, entire leaves, and oval spikes of flowers; or the Red Dutch Clover.

2. TRIFOLIUM capitulis umbellaribus leguminibus tetraspermis, caule repente. Lin. Sp. Plant. 767. Trefoil with umbellated heads, pods having four seeds, and a creeping stalk; White Meadow Trefoil, Honeysuckle-grass, or White Dutch Clover.

3. TRIFOLIUM spicis ovalibus imbricatis, vexillis deflexis persistentibus, calycibus nudis, caule erecto. Flor. Suec. 617. Trefoil with oval imbricated spikes of flowers, having deflexed permanent standards, naked empalements, and an erect stalk; Yellow Meadow Trefoil, or Hop Clover.

4. TRIFOLIUM spicis imbricatis, vexillis deflexis persistentibus, calycibus pedicellatis, caulibus procumbentibus. Lin. Sp. Plant. 773. Trefoil with imbricated spikes of flowers, having deflexed permanent standards, empalements standing

upon foot-stalks, and trailing stalks; the least Yellow Hop Trefoil, called None-such, or Black Seed.

5. TRIFOLIUM spicis ovatis, calycibus foliatis, caule erecto villoso, foliis lanceolatis. Trefoil with oval spikes of flowers, having leafy empalements, an erect hairy stalk, and spear-shaped leaves; greater hairy Meadow Trefoil, with a whitish Sulphur or copper-coloured flower.

6. TRIFOLIUM spicis villosis oblongis obtusis aphyllis, foliis subrotundis. Flor. Leyd. 380. Trefoil with oblong, blunt, hairy spikes of flowers without leaves, and roundish lobes.

7. TRIFOLIUM spicis villosis longis, corollis monopetalis, caule erecto, foliis ferrulatis. Lin. Sp. Plant. 768. Trefoil with long hairy spikes of flowers having one petal, an erect stalk, and leaves very slightly sawed.

8. TRIFOLIUM spicis villosis conico-oblongis, dentibus calycinis setaceis, subequalibus, foliis linearibus. Hort. Cliff. 375. Trefoil with oblong, conical, hairy spikes, having bristly indentures to the empalements, which are almost equal, and linear lobes to the leaves.

9. TRIFOLIUM spicis villosis ovalibus, dentatis calycinis setaceis aequalibus. Hort. Cliff. 375. Trefoil with oval hoary spikes, and bristly indentures to the empalements which are equal; or Hares-foot Trefoil.

10. TRIFOLIUM capitulis subrotundis, calycibus inflatis bidentatis reflexis, caulibus repentibus. Hort. Cliff. 373. Trefoil with roundish heads, reflexed bladder empalements with two teeth, and a creeping stalk; Strawberry Trefoil.

11. TRIFOLIUM leguminibus racemosis nudis dispermis, caule erecto. Hort. Cliff. 376. Trefoil with long naked bunches of pods containing two seeds, and an erect stalk; or Common Melilot.

12. TRIFOLIUM spicis oblongis, leguminibus seminudis mucronatis, caule erecto. Hort. Cliff. 375. Trefoil with oblong spikes, half naked acute-pointed pods, and an upright stalk; Sweet Melilot Trefoil.

The first sort, which is well known in *England* by the title of Red Clover, needs no description; this has been frequently confounded with the red Meadow Trefoil by the botanists, who have supposed they were the same species; but I have often sown the seeds of both in the same bed, which have constantly produced the two species without varying. The stalks of the Meadow Trefoil are weak and hairy, the stipulæ which embrace the foot stalks of the leaves are narrow and very hairy; the heads of flowers are rounder and not so hairy as those of the Clover, whose stalks are strong, almost smooth, furrowed, and rise twice the height of the other; the heads of flowers are large, oval, and hairy; the petal of the flowers open much wider, and their tubes are shorter than those of the other; but the Clover has been so much cultivated in *England* for near a hundred years past, that the seeds have been scattered over many of the *English* pastures, so that there are few of them which have not Clover mixed with the other Grasses; and this has often deceived the botanists, who have supposed that the Meadow Trefoil has been improved to this by dressing of the land.

Since the red Clover has been cultivated in *England*, there has been great improvement made of the clay lands, which before produced little but Rye-grass, and other coarse bents, which, by being sown with red Clover, have produced more than six times the quantity of fodder they formerly had on the same land; whereby the farmers have been enabled to feed a much greater stock of cattle, than they could do before, with the same extent of ground, which has enriched the ground, and prepared it for corn; so where the land is kept in tillage, it is the usual method now amongst the farmers to lay down their ground with Clover, after having had two crops of Corn, whereby there is a constant rotation of Wheat, Barley, Clover, or Turneps, on the same land. The Clover seed is generally sown

with the Barley in the spring, and when the Barley is taken off, the Clover spreads and covers the ground, and this remains two years, after which the land is ploughed again for Corn.

The Clover is a biennial plant, whose roots decay after they have produced seeds; but by eating it down, or mowing it when it begins to flower, it causes the roots to send out new shoots, whereby the plant is continued longer than it would naturally do. The common allowance of seed for an acre of ground is ten pounds. In the choice of the seeds, that which is of a bright yellow colour inclining to brown should be preferred; and the pale-coloured thin seed should be rejected. The Clover-seed should be sown after the Barley is harrowed in, otherwise it will be buried too deep; and after the seeds are sown, the ground should be rolled, which will press the seeds into the ground; but this should be done in dry weather, for moisture will often cause the seeds to burst, and when the ground is wet the seeds will stick to the roll. This is the method which is generally practised by most people in sowing of this seed with Corn, but it will be much better if sown alone; for the Corn prevents the growth of the plants until it is reaped, and taken off the ground, so that one whole season is lost; and many times, if there be a great crop of Corn upon the ground, it spoils the Clover, so that it is hardly worth standing; whereas, when it is sown without any other seed, the plants will come up more equal, and come on much faster than that which was sown the spring before under Corn.

Therefore, from many years trial, I would advise the seeds to be sown in *August*, when there is a prospect of rain soon after; for as the ground is at that season warm, so the first shower of rain will bring up the plants, and these will have time enough to get strength before the winter: and if some time in *October*, when the ground is not too wet, the Clover is well rolled, it will press the ground close to the roots, and cause the plants to send out more shoots; the same should be repeated in *March*, which will be found very serviceable to the Clover. The reason of my preferring this season for the sowing of the seeds rather than the spring is, because the ground is cold and wet in spring, and if much rain fall after the seeds are sown, they will rot in the ground; and many times when the seed is sown late in the spring, if the season should prove dry, the seeds will not grow; so that I have always found the other season has been the surest.

About the middle of *May* this Grass will be fit to cut, when there should be great care taken in making it; for it will require a great deal more labour and time to dry than common Grass, and will shrink into less compass; but if it be not too rank, it will make extraordinary rich food for cattle. The time for cutting it is when it begins to flower; for if it stands much longer, the lower part of the stems, and the under leaves will begin to dry, whereby it will make a less quantity of hay, and that not so well flavoured.

Some people cut three crops in one year of this Grass; but the best way is to cut but one in the spring, and feed it the remaining part of the year, whereby the land will be enriched, and the plants will grow much stronger.

One acre of this plant will feed as many cattle as four or five acres of common Grass; but great care should be taken of the cattle, when they are first put into it, lest it burst them: to prevent which, some turn them in for a few hours only at first, and so stint them as to quantity; and this by degrees, letting them at first be only one hour in the middle of the day, when there is no moisture upon the Grass, and so every day suffer them to remain a longer time, until they are fully seasoned to it; but great care should be had never to turn them into this food in wet weather; or if they have been for some time accustomed to this food, it will be pro-

per to turn them out at night in wet weather, and let them have hay, which will prevent the ill consequences of this food; but there are some who give straw to their cattle while they are feeding upon this Grass, to prevent the ill effects of it; which must not be given them in the field, because they will not eat it where there is plenty of better food. There are others who sow Rye Grass amongst their Clover, which they let grow together, in order to prevent the ill consequences of the cattle feeding wholly on Clover; but this is not a commendable way, because the Rye Grass will greatly injure the Clover in its growth, and the seeds will scatter and fill the ground with bents.

Where the seeds are designed to be saved, the first crop in the spring should be permitted to stand until the seeds are ripe, which may be known by the stalks and heads changing to a brown colour; then it should be cut in a dry time; and when it is well dried, it may be housed until winter, when the seeds should be threshed out; but if the seeds are wanted for immediate sowing, it may be threshed before it be housed or stacked; but then it must be well dried, otherwise the seeds will not quit their husks.

It has been a great complaint amongst the farmers, that they could not thresh out these seeds without great labour and difficulty; which I take to be chiefly owing to their cutting the spring crop when it begins to flower, and so leave the second crop for seed, which ripens so late in autumn, that there is not heat enough to dry the husks sufficiently; whereby they are tough, and the seeds rendered difficult to get out; which may be entirely remedied by leaving the first crop for seed, as hath been directed; and then the ground will be ready to plough, and prepare for Wheat the same year, which is another advantage.

When cattle are fed with this hay, the best way is to put it in racks, otherwise they will tread a great quantity of it down with their feet. This feed is much better for most other cattle than milch cows, so that these should rarely have any of it, lest it prove hurtful to them; though when it is dry, it is not near so injurious to any sort of cattle as when green.

The second sort grows naturally in most of the pastures in *England*, and is generally known among the country people, by the title of white Honeysuckle.

This is an abiding plant, whose branches trail upon the ground, and send out roots from every joint, so that it thickens and makes the closest sward of any of the sown Grasses; and it is the sweetest feed for all sorts of cattle yet known; therefore when land is designed to be laid down for pasture, with intent to continue so, it should be sown with the seeds of this plant. The usual allowance of this seed is eight pounds to one acre of land; but this should never be sown with Corn, for if there is a crop of Corn, the Grass will be so weak under it, as to be scarce worth standing; but such is the covetousness of most farmers, that they will not be prevailed on to alter their old custom of laying down their grounds with a crop of Corn, though they lose twice the value of their Corn by the poorness of the Grass, which will never come to a good sward, and one whole season is also lost; for if this seed is sown in the spring without Corn, there will be a crop of hay to mow by the middle, or latter end of *July*, and a much better after-feed for cattle the following autumn and winter, than the Grass which is sown with Corn will produce the second year. The seed of this sort may also be sown in autumn, in the manner before directed for the common red Clover; and this autumnal sowing, if the seeds grow kindly, will afford a good early crop of hay the following spring; and if, after the hay is taken off the land, the ground is well rolled, it will cause the Clover to mat close upon the ground, and become a thick sward.

The seeds of this white *Dutch Clover* is annually imported from *Flanders*, by the way of *Holland*, from whence it received the name of *Dutch Clover*; not that it is more a native of that country than of this, for it is very common in moist pastures in every county in *England*; but the seeds were never collected for sowing in *England* till of late years; nor are there many persons at present here who save this seed, although it may be done, if the same care as is practised for the red Clover, is taken of this sort; therefore it should be recommended to every farmer, who is desirous to improve his land, carefully to sow an acre or two of this white Clover by itself for seeds, which will save him the expence of buying for some years when the price is great, and there will be no want of sale for any quantity they may have to spare.

The farther account of this Grass, may be seen under the article of PASTURE.

The third sort grows naturally among the Grass in most of the upland pastures in this country; but the seeds are frequently sold in the shops by the title of Hop Clover, and are by many people mixed with the other sorts of Clover and Grass-seeds, for laying down ground to pasture; this grows with upright branching stalks about a foot high, garnished with trifoliate leaves, whose lobes are oblong and heart-shaped, but reversed; the narrow point joining the foot-stalks. The flowers, which are yellow, grow from the wings of the stalk upon long foot-stalks, collected into oval imbricated heads having naked empalements, lying over each other like scales, somewhat like the flowers of Hops, from whence this plant had the title of Hop Clover. But there are two sorts of this which grow naturally in *England*. The other, which is the fourth sort, is a much smaller plant than this, and has trailing stalks. The heads of flowers are smaller, and the flowers are of a deeper yellow colour; these are not abiding plants, so are by no means proper to be sown, where the ground is designed to continue in pasture; but in such places where one or two crops only are taken, and the land is ploughed again for Corn, it may do well enough when it is mixed with other seeds, though the cattle are not very fond of it green, unless when it is very young. The large sort is the most profitable, but this is rarely to be had without a mixture of the small kind, and also of the smaller Melilot, which is commonly called None-such, or sometimes Black-seeds; for those who save the seeds for sale, are seldom curious enough to distinguish the sorts; but where the beauty of the verdure is considered, there must not be any of the seeds sown, because their yellow heads of flowers are very unsightly among the Grass; and if it is in gardens, where the Grass is constantly mowed, the flowers of these plants will come out near the root in such clusters; as to occasion large, unsightly, yellow patches; and as the heads decay, they turn brown, and have a very disagreeable appearance.

The fifth sort grows naturally on chalky lands in many parts of *England*; and in some countries the seed is sown after the same manner as the common red Clover, especially on chalky ground, where it will thrive, and produce a better crop than Clover. The stalks of this are hairy, and grow erect to the height of two feet or more, garnished with trifoliate leaves, standing upon long foot-stalks, whose lobes are longer than those of the red Clover, and have no marks of white; they are of a yellowish green colour, and are covered with soft hairs. The flowers grow in oval spikes at the end of the branches; they are of a pale copper colour; their petals are long and tubulous, but the brim is divided into two lips as the other sorts.

This is known by the title of Trefoil, in the places where it is cultivated; but the seedsmen sell the Hop Clover by that name, so they make no distinction between this, the Hop Clover, and None-such; therefore, by which of these three titles the seeds are bought, they prove the same.

This sort of Trefoil is much cultivated in that part of *Essex* which borders on *Cambridgeshire*.

The sixth sort grows naturally in *Spain* and *Italy*; this has upright stalks near two feet high, which are hairy, garnished with trifoliate leaves, having roundish lobes, which are sawed at their points. The flowers are produced at the top of the stalk in long, obtuse, hairy spikes, of a bright red colour, so make a pretty appearance during their continuance. It is an annual plant, so is not proper for sowing as fodder.

The seventh sort is an annual plant, which grows naturally in the south of *France* and *Italy*; it rises with a strong smooth stalk near three feet high, garnished with trifoliate leaves, whose lobes are two inches and a half long, and near a quarter broad, standing upon long foot stalks, which are embraced by stipulæ or sheaths their whole length. The flowers are produced at the top of the stalks in very long spikes; they are of a beautiful red colour, so make a fine appearance. It flowers in *July*, and the seeds ripen in autumn.

The eighth sort grows naturally in *Spain* and *Italy*; this rises with a slender stiff stalk near two feet high, garnished with trifoliate leaves, whose lobes are very narrow and hairy. The flowers are produced at the top of the stalks in oblong conical spikes; the indentures of their empalements end in long bristly hairs, which are almost equal in length; the spikes are hairy, and the flowers of a pale red colour.

The ninth sort is the common Haresfoot Trefoil, which grows naturally upon dry gravelly land in most parts of *England*, and is a sure indication of the sterility of the soil, for it is rarely seen upon good ground. This plant is seldom eaten by cattle, so is unfit for pasture, and is only mentioned here because it is sometimes used in medicine; it is an annual plant, whose root decays soon after it has perfected seeds.

The tenth sort grows naturally on arable land in many parts of *England*; this has trailing stalks, which put out roots at their joints. The leaves stand upon long slender foot-stalks; the lobes are roundish, and sawed on their edges; the flowers are collected in roundish heads, standing upon slender foot-stalks, which rise from the wings of the stalks; these have bladdery empalements, which terminate in two teeth. When these lie on the ground, their globular heads, having a little blush of red on their upper side toward the sun, and the other part being white, have a great resemblance of Strawberries, and from thence it was titled Strawberry Trefoil.

These sorts are preserved in botanick gardens for variety; they are easily propagated by seeds, which may be sown on an open bed of ground, either in autumn or spring. The plants which come up in autumn, will grow much larger, and flower earlier in the summer than those which are sown in the spring, so from those good seeds may be always obtained, whereas the other sometimes miscarry. When the plants come up, they require no other care than to keep them clean from weeds, and thin them where they are too close.

The eleventh sort is the common Melilot, which is used in medicine; it grows naturally among the Corn in many parts of *England*, particularly in *Cambridgeshire* in great plenty, where it is a most troublesome weed; for in reaping it is scarce possible to separate it from the Melilot, so that it is carried in with the Corn; and the seeds of the Melilot being ripe about the same time with the Corn, they are threshed out with it, and being heavy are difficult to separate from it; and when a few of the seeds are ground with the Corn, it spoils the flour, for the bread, or whatever else is made with it, will have a strong taste like Melilot plaster.

The roots of this plant are strong and ligneous, from which spring out several stalks, which rise from two to four feet high, according to the goodness of the land. The stalks branch out, and are garnished with trifoliate leaves, having oval sawed lobes, of a deep green colour. The flowers are produced in long slender spikes, which spring from the wings of the stalks; they are of a bright yellow, and shaped like the other butterfly flowers; these are succeeded by naked seeds.

The twelfth sort grows naturally in *Bohemia* and *Austria*, but has been long cultivated in *England* as a medicinal plant, though at present it is rarely used; it is annual. The stalks are large, hollow, and channelled; they rise about a foot high, garnished with trifoliate leaves, whose lobes are oval, and slightly sawed on their edges, standing upon pretty long foot-stalks. The flowers are collected in oblong spikes, which stand upon very long foot-stalks, springing from the wings of the stalk at every joint; they are of a pale blue colour, shaped like those of the common Melilot; these appear in *June* and *July*, and are succeeded by small yellow seeds, of a kidney shape, two or three being included in each short pod. The whole plant has a very strong scent like that of Fenugreek, and perishes soon after the seeds are ripe.

If the seeds of these two sorts are permitted to scatter, the plants will rise without care, and require no other culture, but to keep them clean from weeds, and thin them where they grow too close.

TRIGONELLA. *Lin. Gen. Plant.* 804. Fenugreek.

The Characters are,

The empalement of the flower is bell shaped, of one leaf, cut at the top into five almost equal segments. The flower is of the butterfly kind; the standard is oval, obtuse, and reflexed; the two wings are oblong, reflexed, and spreading flat like the standard, so as outwards to appear like a regular flower of three petals; the keel is very short, obtuse, and occupies the navel of the flower. It has ten short rising stamina, nine of which are joined, and one stands separate, terminated by single summits, and an oval oblong germen, supporting a single style, crowned by a rising stigma. The germen afterward turns to an oblong oval pod compressed, filled with kidney-shaped seeds.

The Species are,

1. TRIGONELLA *leguminibus sessilibus strictis erectiusculis subfalcatis acuminatis.* *Hort. Cliff.* 229. Trigonella with sickle-shaped acute-pointed pods, which are close, erect, and sit close to the stalks; or common Fenugreek.

2. TRIGONELLA *leguminibus pedunculatis congestis erectis parallelis linearibus.* *Lin. Sp. Plant.* 777. Trigonella with linear, erect, parallel pods growing in clusters, having foot-stalks; or wild Fenugreek.

3. TRIGONELLA *leguminibus sessilibus arcuatis confertis, caulibus procumbentibus.* Trigonella with arched pods growing in clusters, sitting close to the stalks, which trail on the ground.

4. TRIGONELLA *leguminibus pedunculatis congestis pendulis ovalibus compressis, caule diffuso, foliis subrotundis.* *Hort. Cliff.* 229. Trigonella with clustered, oval, compressed, hanging pods, having foot-stalks, diffused stalks, and roundish lobes.

5. TRIGONELLA *leguminibus pedunculatis congestis pendulis linearibus rectis, foliis sublanceolatis.* *Lin. Sp. Plant.* 776. Trigonella with linear straight pods, which hang down in clusters upon foot-stalks, and spear-shaped lobes to the leaves.

6. TRIGONELLA *leguminibus pedunculatis congestis declinatis subfalcatis compressis, pedunculo communi spinoso foliis longiore.* *Lin. Sp. Plant.* 777. Trigonella with sickle-shaped, compressed, and clustered pods growing upon foot-stalks, and a common spiny foot-stalk longer than the leaves; or greater wild Fenugreek of *Crete*.

The first sort is the common Fenugreek, whose seeds are used in medicine. Where this plant grows naturally is uncertain, but it is cultivated in the fields, in the south of *France*, and in *Germany*, from whence great quantities of the seeds are annually imported here for use. It is also much cultivated in *India*.

It is an annual plant, which rises with a hollow, branching, herbaceous stalk a foot and a half high, garnished with trifoliate leaves, placed alternately, whose lobes are oblong, oval, indented on their edges, and have broad furrowed foot-stalks. The flowers come out singly at each joint from the wings of the stalk; they are white, of the butterfly kind, and sit very close to the stalk; these are succeeded by long compressed pods, shaped somewhat like a broad sword, ending in long points, having a broad membrane on one edge, filled with square yellow seeds, indented on one side like a kidney. The whole plant has a very strong odour.

This plant has not as yet been cultivated in any quantity for use in *England*, as it has generally proved a very uncertain crop, occasioned by the inconstancy of the weather here, for in cold wet seasons the plants are frequently killed before the seeds ripen; and if any of them live long enough to perfect their seeds, the pods change of a dirty colour, and the seeds turn black and unsightly, especially when much rain falls about the time of their ripening; therefore the seeds, which are imported from the continent, are always preferred to those of our own growth.

But as the consumption of these seeds is very great in *England*, there are some persons who are inclinable to make fresh trials to cultivate the plants here. As I have many years cultivated this in small quantities, and have made trials by sowing the seeds at different seasons, and after various manners, by which I have acquired a knowledge of its culture, so I shall here give such directions for the management of this plant, as from experience has been found to succeed best.

The ground in which this plant thrives best, is a light hazel loam, not enriched with dung; this should be cleaned from the roots of weeds, and well ploughed twice, and harrowed fine before the seeds are sown. The best time to sow the seeds is in the beginning of *September*, in shallow drills like Peas. The rows should be two feet asunder, and the seeds must be scattered one inch distant from each other in the drills; for if the plants are too close together in the spring, they may be easily thinned with the hoe, when the ground is cleaned. When the seeds are sown at the before mentioned time, the plants will appear in three weeks or a month after; and if the weeds appear at the same time, the ground should be hoed over as soon as possible in dry weather, to destroy the weeds; and when the plants are grown an inch high, the earth should be drawn up to their stems, in the same manner as is practised for Peas. This will secure their stems from being injured by sharp cutting winds; and if a ridge of earth is drawn up on the north or east side of each row, it will protect the plants from the pinching winds which blow from both those quarters; for although this plant will not be in any danger from the frost in the ordinary winters, yet in very severe frosts they are sometimes killed; but, as this plant will live in any situation, where Peas will stand through the winter, there will be no greater hazard of the one crop than the other.

In the spring of the year the ground must be hoed again in dry weather to kill the weeds, and the plants should be again earthed up in the like manner as Peas, with whose culture this plant will thrive; but there must be great care taken to keep the ground as clean from weeds as possible, for if they are permitted to grow, they will soon advance above the plants, and greatly weaken them; and when their

Pods begin to form, they cannot be too much exposed to the sun and air, whereby they will be less liable to suffer from moisture.

When the seeds are sown in autumn, the plants will grow much stronger, and have many more side branches than those which come up in the spring, so will produce a much greater crop of seeds; and these will produce their flowers five or six weeks earlier, so will have a better season to ripen; but in order to have them better ripened, the top of the plants should be cut off with garden-shears about the middle of *June*, by which time the pods will be formed on the lower part of the stalks, which will be greatly forwarded by topping of the stalks in the same way as is commonly practised for Garden-beans; for where the plants are suffered to extend in length, the lower pods often miscarry, or are less nourished, and those on the top of the stalks are late before they ripen; so where the topping of the plants is omitted, the pods at bottom will open and cast out their seeds, before those above will be ripe; therefore to preserve the first and cut off the other, will be found the best method, for by so doing the pods will ripen equally, and much earlier in the season.

If the summer proves warm, the seeds will ripen in *August*, and the plants should then be cut off, and laid to dry for five or six days, in which time they should be turned two or three times, that the pods may dry equally; then the seeds may be either threshed out in the field, or the haulm may be housed in a barn, to be threshed in a more convenient time.

The second sort grows naturally in *Spain* and *Sicily*. The stalks of this are slender, and rise near a foot high, sending out two or three slender branches, garnished with trifoliate leaves, whose lobes are wedge-shaped, sawed at their ends where they are indented; these stand upon long slender foot-stalks. The flowers are produced in clusters at the end of the branches, upon short foot-stalks, which stand erect; they are small, of a pale colour, and are succeeded by narrow pods, standing parallel and erect. This is an annual plant, which flowers in *July*. The seeds ripen the end of *August*, and the plants decay soon after.

The third sort grows naturally in *Spain* and *Italy*; this is also an annual plant, whose root decays soon after the seeds are ripe. The stalks trail upon the ground, and extend a foot and a half in length, sending out several side branches, garnished with small trifoliate leaves, whose lobes are wedge-shaped, and sawed at their points. The flowers are produced in clusters at the wings of the stalk; they are small, of a pale yellow colour, and sit very close to the stalks; these are succeeded by short hooked pods, which sit close to the stalks in clusters. It flowers in *July*, and the seeds ripen in autumn.

The fourth sort grows naturally in *Siberia*. The root of this is biennial; the stalks trail upon the ground, extend a foot in length, and send out many side branches, garnished with trifoliate leaves, having roundish lobes, which are sawed on their edges. The flowers come out from the wings of the stalks upon foot-stalks, growing in clusters; they are small, of a yellowish white colour, and are succeeded by oval compressed pods, containing two seeds in each.

The fifth sort grows naturally in *Siberia*; this is also a biennial plant, whose roots decay soon after the seeds are ripe. The stalks of this are very slender, and trail upon the ground; they extend a foot and a half in length, and divide into several branches. The leaves are trifoliate; the lobes are wedge shaped, indented at the point, sawed, and are narrower than either of the former. The flowers are small, yellow, and are produced in clusters, upon slender foot-stalks, which spring from the wings of the stalk, and are succeeded by narrow erect pods, which contain three or four small seeds.

The sixth sort grows naturally in *Crete*; this is an annual plant, whose stalks are slender, herbaceous, declining, extending a foot in length, and divide into many branches, garnished with trifoliate leaves, whose lobes are small, heart-shaped, and sawed at their tops, standing upon short foot-stalks. The flowers are small, of a pale yellow colour, and stand upon short foot-stalks, which spring from the wings of the stalk; these are succeeded by fickle-shaped compressed pods, which decline, and contain several oblong small seeds.

These plants are frequently cultivated in botanick gardens for variety, but I do not know any use is made of either of the sorts except the first. The seeds of these should be sown in the places where the plants are designed to stand, for they will not bear transplanting. If they are sown in autumn, in the same way as is before directed for the first sort, the plants will come earlier to flower, and good seeds may be obtained with more certainty than from the spring plants. All the culture these require is to thin them where they stand too close, and keep them clean from weeds. A few plants of each sort in a garden will be sufficient, as they have no great beauty.

TRILLIUM. *Lin. Gen. Plant.* 412. *American Herb Paris.*

The Characters are,

The flower has a three-leaved permanent empalement; it has three oval petals, which are a little larger than the empalement, and six awl-shaped stamina, which are erect, shorter than the petals, and terminated by oblong summits, with a roundish germen, having three slender recurved styles, crowned by single stigmas. The germen afterward becomes a roundish berry with three cells, filled with roundish seeds.

The Species are,

1. TRILLIUM *flore pedunculato cernuo.* *Lin. Sp. Plant.* 339. Trillium with a nodding flower growing upon a foot-stalk.
2. TRILLIUM *flore pedunculato erecto.* *Lin. Sp. Plant.* 340. Trillium with a flower growing erect upon a foot-stalk.
3. TRILLIUM *flore sessili erecto.* *Lin. Sp. Plant.* 340. Trillium with an erect flower having no foot-stalk.

These plants grow naturally in the woods in many parts of *North America*; the first was sent me from *Philadelphia* by Dr. *Bensel*, who found it growing in plenty there. The root of this plant is tuberous, sending out many fibres; the stalk is single, naked, and rises five or six inches high, with three oval smooth leaves, placed at the top upon short foot-stalks, which spread out in a triangle, of a deep green colour. From the center of the foot-stalks of the three leaves comes out one flower upon a short foot-stalk, which nods downward; this has a three-leaved green empalement spreading open, and within are three petals about the size of the empalement, of a whitish green on their outside, and purple within, having six stamina in the center, surrounding the style, which have oblong summits. The flowers of this appear in *April*, and are succeeded by roundish succulent berries, having three cells, filled with roundish seeds, which ripen in *June*.

The second sort has a taller stalk than the first. The three leaves are placed at a distance from the flower, which stands upon a long foot-stalk, and is erect; the petals of the flower are larger, and end with sharper points than those of the first.

The third sort grows in shady thickets in *Carolina*. The stalk of this is purple; the three leaves grow at the top like the first, but they are much longer, and end in acute points; the petals of the flowers are long, narrow, and stand erect.

These plants are propagated by seeds, which should be sown upon a shady border soon after they are ripe; and when the young plants come up the following spring, they

must be kept clean from weeds; and in autumn, after their leaves decay, the roots may be transplanted to a moist shady place, where they are to remain; if the seeds are sown in the spring, they will not vegetate till the next year.

TRIOSTEUM. *Lin. Gen. Plant.* 211. *Dr. Tinkar's Weed, or false Ipecacuana.*

The Characters are,

The flower has a permanent empalement of one leaf, cut into five segments; it has a tubulous flower of one petal, with a short brim, cut into five parts which stand erect, and five slender stamina the length of the tube, terminated by oblong summits, with a roundish germen, supporting a cylindrical style, crowned by a thick stigma. The germen afterward becomes an oval berry with three cells, each including one hard, three-cornered, obtuse seed.

The Species are,

1. **TRIOSTEUM floribus verticillatis sessilibus.** *Lin. Sp. Plant.* 176. Triostrum with flowers growing in whorls, sitting close to the stalks; commonly called *Dr. Tinkar's Weed, or false Ipecacuana.*

2. **TRIOSTEUM floribus oppositis pedunculatis.** *Lin. Sp. Plant.* 175. Triostrum with flowers growing opposite upon foot-stalks.

The first sort grows naturally in the woods in several parts of *North America*; the root is composed of thick fleshy fibres, which are contorted and rough, from which spring several strong herbaceous stalks a foot and a half high, garnished at each joint by two oblong broad leaves, sitting close to the stalk. From the bosoms of these come out the flowers in whorls, sitting very close to the stalks; the empalements are cut into five segments. The flowers are small, tubulous, of a dark red colour, and cut slightly at the brim into five obtuse segments, and are succeeded by roundish berries, which turn yellow when ripe, having three cells, in each of which is contained one hard seed. The root is perennial, but the stalks decay every autumn.

The second sort differs from the first in its leaves, being longer and narrower. The flowers stand single upon short foot stalks, but two at each joint, whereas the other has many growing in whorls round the stalks, but the roots of both are indifferently used in *America* by the title of *Dr. Tinkar's Weed.*

Both these plants are natives of *Virginia*, and some other northern parts of *America*, where their roots have been frequently used as an emetick, and are commonly called *Ipecacuana.* One of the first persons who brought the roots into use was *Dr. Tinkar*, from whence many of the inhabitants have called them by the name of *Dr. Tinkar's Weed.* The leaves of the first sort greatly resemble those of the true *Ipecacuana*, but the roots are of a different form; but so far as I can judge by the imperfect fruit of a specimen in my collection of the true *Ipecacuana*, as also by the figure and description given by *Piso* in his history of *Brasil*, it seems to belong to this genus.

The first grows on low marshy grounds, near *Boston* in *New England*, very plentifully, where the roots are taken up every year, and are continued in use amongst the inhabitants of *Boston.*

This plant is preserved in several curious gardens in *England*, and is hardy enough to thrive in the open air; but it should be planted on a moist light soil, for if it is on a dry ground, there must be care taken to water the plants constantly in dry weather, otherwise they will not thrive. It may be propagated by seeds, which should be sown in autumn on a border of light earth, exposed to the morning sun, for if the seeds are sown in the spring, they will remain in the ground a whole year before the plants will come up, so that during this time the border must be constantly kept clear from weeds; the following spring, when

the plants appear, they should be duly watered in dry weather, which will greatly promote their growth; but if the seeds are sown in autumn, the plants will come up the following spring, and must be constantly kept clear from weeds, which, if permitted to grow amongst them, will soon overbear the plants while they are young, and either quite destroy them, or so much weaken them, that they will not recover in a long time.

The plants may remain in this seed border until the *Michaelmas* following, when they should be carefully taken up, and transplanted where they are designed to remain. Some of them should be planted in pots, that they may be sheltered in winter, lest those which are in the full ground should be destroyed by severe frost.

They may be also propagated by parting of the roots. The best season for this work is in the spring, just before the plants begin to shoot, which is commonly about the middle or latter end of *March*; but in doing of this, the roots must not be parted too small, for that will prevent their flowering strong.

These plants perfect their seeds in this country every year, if sown in autumn as soon as they are ripe, which is the best way to propagate them. The seedling plants will not flower until the third year, and then they are seldom so strong as the older plants.

TRIPOLIUM. See *Aster.*

TRITICUM. *Tourn. Inst. R. H.* 512. *tab.* 292, 293. *Wheat.*

The Characters are,

It has an oval chaffy empalement with two valves, which inclose two or three flowers. The petals have a double valve as large as the empalement; the outer valve is bellied and acute-pointed; the inner is plain. The flowers have three hair-like stamina, terminated by oblong forked summits, and a top-shaped germen, supporting two hairy reflexed styles, crowned by feathered stigmas. The germen afterward becomes an oblong oval seed, obtuse at both ends, convex on one side, and channelled on the other, wrapped up in the petal of the flower.

The Species are,

1. **TRITICUM glumis ventricosis lewibus imbricatis submuticis.** *Hort. Upsal.* 21. *Wheat* without beards, and smooth, bellied, imbricated husks; or common *Wheat.*

2. **TRITICUM glumis ventricosis glabris imbricatis aristatis.** *Hort. Upsal.* 21. *Bearded Wheat* with smooth, imbricated, bellied husks; or *Spring Wheat.*

3. **TRITICUM glumis ventricosis villosis imbricatis obtusis.** *Hort. Upsal.* 21. *Wheat* with hairy, bellied, imbricated; obtuse husks; or *four-cornered Wheat*, with short, hairy, turgid spikes, commonly called *gray Pollard* or *Duckbill Wheat.*

4. **TRITICUM glumis ventricosis villosis imbricatis, spicis oblongis pyramidatis.** *Wheat* with hairy, bellied, imbricated husks, and oblong pyramidal spikes; commonly called *Cone Wheat.*

There are some other varieties of *Wheat*, which the farmers in different parts of *England* distinguish by different titles; but they are only seminal variations, which have risen from culture. Some of these differ in the colour of their chaff, and others in the form of their spikes; but as they are subject to vary, we shall not enumerate them as different species. The varieties are, the red *Wheat* without awns, the red-eared bearded *Wheat*, *Poland Wheat*, many-eared *Wheat*, and naked *Barley.* But the four sorts above enumerated, I have sown several years, and have always found them constant without variation.

Where *Wheat* grows naturally, is very hard to determine at present; but it is generally supposed that *Africa* is the country, because in the earliest accounts we have of it, there is mention of its being transported from thence to other

other countries, and *Sicily* was the first country in *Europe* where this grain was cultivated; but although the country of its natural growth is in a very warm climate, yet it is found to bear the inclemency of rough climates very well; and in countries more north than *England*, where the summers are long enough to ripen the grain, it is found to succeed.

The first sort is the common Wheat, which is sown in most parts of *England*, and is so well known as to need no description. The spikes or ears of this are long; the grains are ranged in four rows, and lie over each other like the scales of fish; the chaff is smooth, bellied, and is not terminated by awns or beards.

The second sort is called Summer or Spring Wheat; this will ripen much earlier than the other, so has often been sown in the spring of the year, at the same time with Oats; but if the season proves wet, it is very subject to grow tall, and have very thin grains, which has discouraged people from sowing it at that season; so that unless from the severity of the winter, or some other accident, the winter Corn is injured, the sowing Wheat in the spring is rarely practised.

The third sort is called in some places gray Wheat, in others Duckbill Wheat and gray Pollard; but in *Suffex* it is generally known by the title of Fullers Wheat. This sort grows very tall, and if it is sown too thick, is very apt to lodge with rain and wind, for the ears are large and heavy; they nod on one side as the grain increases in weight. The awns are long; the chaff hairy, which detains the moisture, all which help to lodge it; for which reason many people do not choose to cultivate this sort; but where the roots are at a proper distance from each other, they will put out many stalks from each; the stalks will be stronger, support themselves better, and the grain produces more flour in proportion than any of the other sorts. The awns of this sort frequently drop off when the grain is full grown.

The fourth sort is more cultivated in *Oxfordshire* and *Berkshire* than in any other part of *England*. The ears of this sort are formed like a cone, ending with a slender point, from whence it had the title of Cone Wheat. Of this there are the white and red, which I believe are only varieties, for I have generally seen them mixed in the field. The awns of this are long and rough, so the farmers say it guards the grain from birds, which has been a recommendation to sow it, especially near inclosures, where there is shelter for birds. Mr. *Tull* prefers this sort for sowing in drills, but I have seen the third sort answer much better in the horse-hoeing husbandry.

The season for sowing of Wheat is autumn, and always when the ground is moist. In the downs of *Hampshire*, *Wiltshire*, and *Dorsetshire*, the farmers begin sowing of their Wheat in *August*, if there happens rain; so that when they are in their harvest, if the weather stops them, they employ their people in sowing; for if the Corn is not forward in autumn, so as to cover the ground before winter, it seldom succeeds well on those dry lands, especially if the spring should prove dry; but in the low strong lands, if they get their Wheat into the ground by the middle of *November*, the farmers think they are in good season; but sometimes it so happens, from the badness of the season, that in many places the Wheat is not sown till *Christmas* or after; but this late-sown Wheat is subject to run too much to straw, especially if the spring should prove moist.

The usual allowance of Seed-wheat to one acre of land, is three bushels; but from repeated experiments it has been found, that half that quantity is sufficient; therefore, if the farmers have regard to their own interest, they should save this expence of seed, which amounts to a considerable article in large farms, especially when it is to be purchased,

which most of the skilful farmers do, at least every other year, by way of change; for they find that the seeds continued long upon the same land, will not succeed so well as when they procure a change of seeds from a distant country. And the same is practised by the husbandmen of the *Low-Countries*, who commonly procure fresh seeds from *Sicily* every second or third year, which they find succeed better with them than the seeds of their own country. In the choice of the seeds, particular regard should be had to the land upon which it grew, for if it is light land, the Wheat which grew upon strong land is the best, and so *vice versa*.

There have been some persons in *England* curious enough to procure their Seed-wheat from *Sicily*, which has succeeded very well; but the grain of this has proved too hard for our *English* mills to grind, which has occasioned their neglecting to procure their seeds from thence; nor do I think there can be much advantage in procuring the seeds from abroad, since the lands of *England* are so various as to afford as much change of seeds as will be necessary. And the less we purchase from abroad, the greater will be the saving to the publick; so that it should be the business of skilful farmers to want as few seeds as possible, since, by exchange with each other, they may so contrive as not to part with ready money for any seeds.

The land which is usually allotted for Wheat, is laid fallow the summer before the Corn is sown; during which time it is ploughed two or three times, to bring it into a tilth; and the oftener and better the ground is ploughed, and the more it is laboured with harrows between each ploughing to break and divide the clods, the better will be the crop, and the fewer weeds will be produced. But in this article most of the farmers are deficient; for after they have given their lands one ploughing, they frequently leave it to produce weeds, which sometimes are permitted to stand until they shed their seeds, whereby the ground will be plentifully stocked with weeds; and as an excuse for this, they say that these weeds will supply their sheep with some feed, and the dung of the sheep will mend their land; but this is a very bad piece of husbandry, for the weeds will draw from the land more than the dung of the sheep will supply; so that it is undoubtedly the best method to keep the ground as clean from weeds as possible, and to stir it often to separate and break the clods, and render the land fine; and where the land can enjoy a winter's fallow, it will be of much greater service to it than the summer; by thus labouring of the land, it will be of equal service to it as a moderate dressing of dung. Therefore if the farmers could be prevailed on to alter their method of husbandry, they would find their advantage in it; for the expence of dressing in some countries is so great, as to take away the whole profit of the crop.

There is also a very absurd method in common practice with the farmers, which is the carrying of their dressing, and spreading it on the land in the summer, where it lies exposed till the sun has dried out all the goodness of it, before it is ploughed into the ground; so that the dressing is of little value; therefore the dung should never be laid on the land faster than it can be ploughed in, for one load of dung so managed, is better than three in their usual method.

As Wheat remains a longer time upon the ground than most other sorts of Corn, it requires a greater stock of nourishment to lengthen and fill the ears: therefore, if the dressing is exhausted in winter, the Corn will have but short ears, and those but lean, nor will the grain afford much flour; so that it frequently happens, that a light dressing of foot in the spring, at the time the Wheat is beginning to stalk, proves of greater service to the crop than

a dressing of dung laid on the land before it is ploughed, especially if the dung is not very good. Deep ploughing (where the staple of the ground will admit of it) is also of great service to the Corn; for the small fibres of the roots, which are the mouths that supply the nourishment, extend themselves very deep into the ground. I have traced many of them upward of three feet, and believe they spread much farther where the ground is light; therefore it is of great advantage to the crop to have the ground stirred and loosened to a proper depth; for by so doing the roots will find a supply of pasture for the nourishment and augmentation of the ears, at the time they are forming, when it is most required; for if the ground is ploughed shallow, the roots will have extended themselves to that depth by the spring; so that when the nourishment is wanted to supply the stalks, the roots are stunted by the hardness of the soil, which they cannot penetrate; when this is the case, the colour of the blade is frequently seen to change in *April*, and seldom recovers its verdure again; and when this happens, the stalks are always weakened in proportion to the decay of the blade; for it is well known from long experience, that the leaves or blade of Corn are necessary to draw in nourishment from the air and dews, for the increase of the stalk and ear; but in order to ascertain this, I have made trial of it, by cutting off the leaves of some roots of Wheat alternately, early in the spring, and have constantly found the stalks upon those roots much smaller, the ears shorter, and the grain thinner than those of the intermediate roots, whose blades were not cut. This shews the absurdity of that practice of feeding sheep upon Corn in the winter and spring. I have frequently seen in some gardens, plants divested of their lower leaves, which ignorant persons have supposed to draw away the nourishment from the head; but wherever this has been practised, I have always observed, that in proportion to the number of leaves cut off, the plants have been weakened by it; so that until those leaves decay naturally, they should never be taken off.

Of late years, many composts have been advertised for the steeping of the seeds of Corn, in order to improve their growth; some of these have been sold at a dear rate; but as so great success was assured by the inventors, to those who should make use of them, there were numbers of persons who made the trial; but so far as I have been able to get information of their experiments, they did not succeed so well as to encourage the use of these compositions; and from several trials which I made myself with great care, I always found, that the Wheat which had been steeped in these compositions came up sooner, and grew much ranker in the winter than that which had not been steeped; but in the spring the unsteeped Wheat had a greater number of stalks to each plant, and the ears were better fed than those which had been steeped; therefore these sorts of composts have been found of no real use to the crop.

My experiments were made in the following manner. The Wheat was sown in drills, on the same spot of ground; the seeds which had been steeped were sown in alternate rows, and the intermediate rows were sown with unsteeped Corn. The rows were a foot and a half asunder, and the grains were all taken out of one measure, and sown as equally as possible: the steeped Corn appeared above ground three days before the other, and continued to grow faster than the unsteeped Corn, during the winter; but in the spring, the blade of the steeped Corn changed its colour, and their points became brown; then I gave a light dressing one of the rows, which soon recovered its verdure, and caused it to be the strongest row of the whole; but the others which had not this dressing, produced weaker stalks and ears than that which was not steeped.

I have before observed, that in general the farmers sow

more than double the quantity of Corn on their lands than is necessary; therefore there is a great waste of grain, which in scarce years amounts to a considerable sum in large farms, and to a whole country it is an object worthy the attention of the publick; but I fear whatever may be said to prevent this, will have but little weight with the practitioners of agriculture, who are so fond of old customs, as rarely to be prevailed upon to alter them, though they are extremely absurd. But if these people could be prevailed on to make the trial with care, they must be soon convinced of their error; for if they will but examine a field of Corn sown in the common way, they will find but few roots which have more than two or three stalks, unless by chance, where there may be some few roots which have room to spread, upon which there may be six, eight, or ten stalks, and frequently many more; but I have seen a field of Wheat which had not a greater allowance than one bushel of Corn to an acre, so that the roots had room to spread, produce from six to twelve or fourteen stalks, which were strong, and had long well-nourished ears; and the produce of flour was much greater than in any of those fields in the neighbourhood, which were sown with the common allowance. Where the land is good, and the roots stand at a proper distance from each other, there will be few roots which will not produce as many stalks as I have here mentioned, and the ears will be better nourished.

But if the land is not covered with the blades of Corn by the spring, the farmers think they shall have no crop; whereas, if they would have patience to wait till the roots put out their stems, they would soon be convinced of the contrary, especially if they could be prevailed on to draw a weighty roller over the Wheat in *March*, which will cause it to spread; and by settling of the loose ground to the roots, the drying winds in the spring would be prevented from penetrating to their fibres, so will produce the more stalk; but before this operation, it will be proper to have the Corn cleaned from weeds, for if these are permitted to grow, they will draw away much nourishment from it; and if, at this season, the land is made clean from weeds, the Corn will soon after spread, and cover the ground, whereby the growth of weeds will be greatly lessened.

There is not any part of husbandry which requires the farmer's attention more than that of keeping his land clean from weeds; and yet there are few who trouble themselves about it, or who understand the proper method of doing it; few of them know those weeds which are annual, so as to distinguish them from those which are perennial; and without this knowledge, it will be much more difficult for a person to clean his land, let his industry be ever so great, for annual weeds may be soon destroyed, if taken in time; whereas, if they are neglected, their seeds will soon ripen and scatter; after which it will require three times the labour and expence to get rid of them, as would have been sufficient at the beginning; and then the crop would have had no bad neighbours to rob it of its nourishment. The common method now practised is a very absurd one, for the weeds are left to grow till the Wheat is beginning to ear, by which time many of the weeds are in flower, and some will have ripened seeds. Beside the ground being covered by the Corn, all the low weeds are hid, and these are left to ripen and scatter their seeds; the tall weeds only are taken out, and if the people employed are not careful, many of these will escape them, as they will be so intermixed with the stalks of Wheat, as not to appear, unless diligently sought after. By this method the weeds are permitted to stand, and rob the Corn of its nourishment, during the principal time of its growth, and the humble weeds are never destroyed; and by going amongst the stalks when they are tall, great numbers of them are broken and trod under

under the work-peoples feet; yet however obvious this is to every farmer, none of them have thought of altering this practice. I would therefore recommend a method which is now in common practice among the kitchen-gardeners, which has been found of great benefit to their crops, and has also been a great saving to them in the expence of weeding, which is making use of the small kind of hoes for cleaning the Wheat early in the spring, before the ground is covered with the blades of Corn. With this instrument, all the low as well as the tall weeds will be cut up, and if it is performed in dry weather, the weeds being then small will soon die. Where the ground happens to be very full of weeds, it may be necessary to go over it a second time, at about three weeks after the first, to cut up any weeds which may have before escaped. By laying the ground clean at this time, the Corn will not be robbed of its nourishment; and there will not be time for the weeds to grow so as to prejudice it much after, for the ground will be so much shaded by the Corn, as to keep down the weeds, so that they cannot have time to ripen their seeds before harvest.

If, at the time of this operation, the roots of Corn are cut up where they are too close, it will be found of great service to the other; but this, I fear, few of the old farmers will ever agree with me in, though what I mention is not from theory but experiments, which have been repeated with great care; and where it was practised, the produce of twenty rods of ground was much greater both in weight and measure than the same quantity of ground in the best part of the field, where this was not practised, and the stalks stood upright, when a great part of the Corn in the same field was lodged.

I have often observed in those fields where foot-paths are made through the Corn, that by the side of those paths where the Corn is thin, and has been trodden down in the winter and spring, the stalks have stood erect, when most of the Corn in the same field has been laid flat on the ground, which was owing to the stalks being so much stronger from their having more room; the other having been drawn up tall and slender by being so close. There is also another great advantage in keeping Corn clean from weeds, and giving it room to spread, which is, that the Corn is not so liable to take the smut as when it is full of weeds, and the roots too much crowded, this I have frequently observed; so that cleanness and free air is as essential to the growth of vegetables as animals, and the changing of the seed annually is also as necessary as the change of air is to all sorts of animals; for where this has been carefully practised, there has rarely happened any smutty Corn in the field.

Brining of the Seed-wheat is what the farmers generally practise to prevent the smut, which in most years answers very well; but there is nothing which contributes more to this than keeping the plants in good health, which is better effected by the method before proposed, for by stirring of the ground with the hoe between the roots of Corn in the spring, they will be better supplied with nourishment; for in strong lands, where the water may have lain in the winter, the surface of the ground will bind so hard on the first dry weather, as to stint the Corn, and frequently cause it to change colour. When this happens, the roots seldom put out many stalks, and those which are put out are weak; but where the surface of the ground can be stirred to loosen the parts, the Corn will soon recover its colour and strength, and cover the land with shoots.

What has been here directed, must be understood to relate to Wheat sown in broad-cast, which is the usual method practised by farmers in every part of *England*; for the horse-hoeing husbandry, which was practised by Mr. *Tull*, has been almost universally rejected by the farmers in every country, it being so opposite to their accustomed practice,

that few of them can be prevailed upon to make trial of it; and indeed, by the absurdity of the author in a few particulars, he has discouraged many from engaging in it, who would otherwise have practised it; but upon finding Mr. *Tull* positively asserting, that the same land would nourish the same species of plants without changing the crops for ever, and this without manure, which being contrary to all experience, led them to believe his other principles had no better foundation. And he practised this method of sowing the same species upon the same ground till his crops failed, and were much worse than those of his neighbours, who continued their old method of husbandry; and hereby his horse-hoeing husbandry was ridiculed by them, and laid aside by gentlemen who were engaging in it. But notwithstanding those and some other particulars which have been advanced by Mr. *Tull*, yet it is much to be wished that this new husbandry might be universally practised; for some few persons who have made sufficient trial of it, have found their crops answer much better than in the common or old method of husbandry; and the *French*, who have learned it from Mr. *Tull*'s book, are engaging in the practice of it with greater ardour than those of our own country; and although they had not the proper instruments of agriculture for the performance, and met with as strong opposition from the persons employed to execute the business, as in *England*, yet the gentlemen seem determined to persist in the practice of it; though, as yet, few of their experiments have had the success they hoped for, partly from the awkwardness of their labourers, and partly from their averseness to practise this husbandry, and also from their being made in lands not well conditioned; but yet their produce has been equal to that of the old husbandry, and they say, that if the produce of the land in the new method of husbandry, does not exceed that in the old way, yet by saving seven parts from eight of the Seed-corn, it is a great affair to a whole country, especially in times of scarcity.

As Mr. *Tull* has given full directions for the practice of this husbandry, I shall refer the reader to his book for instruction, and shall only mention two or three late experiments which have been made in his method, whereby the utility of it will more fully appear.

The first was in a field of Wheat, which was sown partly in broad-cast in the common method, and partly according to *Tull*'s method; the spots thus sown were not regular in lands, but interspersed indifferently in many directions. Those parts of the field in *Tull*'s method, were in rows at two feet distance, and stood thin in the rows. The roots of the Wheat in these spots had from ten to thirty stalks upon a root, and continued upright till it was reaped; whereas few of the roots in the common method had more than two or three stalks, and these were most of them lodged before harvest; so that upon trial of the grain when threshed, there was near a third part more in weight and measure, than from the same extent of ground, taken in the best part of the field sown in the common way.

Another trial was made in sowing of the Corn in rows at different distances, with some sown in two parts of the ground broad-cast. The event was, that all which was sown broad-cast in the usual way was lodged, as was also most of that where the rows were six or nine inches asunder; those which stood a foot distance escaped better, but the rows two feet asunder were the best, and the produce much greater than any of the other; which plainly shews the absurdity of that practice, in sowing a great quantity of seeds, to have a better produce, which is the opinion of most of the old farmers; and it was formerly the prevailing opinion among gardeners, who allowed near eight times the quantity of seeds for the same space of ground, as is now usually sown, and these crops are greatly superior to any of the se.

The produce of an acre of Wheat is various, according to the goodness of the soil. In some of the shallow, chalky, down lands, where there have been near four bushels of Corn sown, I have known the produce not more than double of the seed; but when this is the case, the farmer had much better let his land lie waste, since the produce will not defray the expence, so that more than the rent of the land is lost: and although these sort of crops are frequently seen on such land, yet such is the passion for ploughing among the husbandmen at present, that if they were not restrained by their landlords, they would introduce the plough into every field, notwithstanding they are sure to lose by it.

But although the produce of these poor downs is so small, as before related, yet upon good land, where the Corn has stood thin upon the ground, I have known eight and ten quarters reaped from an acre over the whole field, and sometimes much more. And I have been informed by persons of great credit, that on good land, which was drilled and managed with the horse-hoe, they have had twelve quarters from an acre of land, which is a great produce; and this is with greater certainty, if the season proves bad, than can be expected by the common husbandry.

The price of Corn varies continually, and this variation is often very great in the space of one or two years; so that from being so cheap, as that the farmers could not pay their rents in the compass of a year or two, the price has been more than doubled; for one or two plentiful harvests have lowered the price of Wheat so much, as to make it difficult for the needy farmer to go on with his business, who wants ready money for his crops as soon as he can prepare them for the market. This has established a set of people called dealers in Corn, who have taken the advantage of the farmer's necessity, and engrossed their Corn to keep it for better markets; and these dealers have of late years increased greatly in their numbers, to the great prejudice of the raisers and also the consumers of Corn, which may in time prove fatal to the country, by monopolizing the greatest part of the produce, and then set their own price upon it; so that between these Corn-factors, as they are called, and the distillers, the price of bread may be too great for the labouring poor, which is an affair that requires more publick attention than has yet been given to it.

The French have been, and are building publick granaries for the conservation of their Corn, in most of their provinces; for as in some years they have great plenty of Corn, and at other times as great scarcity, they are contriving to prevent any great want of it.

When the Wheat is sold much under four shillings the bushel, the farmer cannot pay his rent, and live; nor can the poorer sort of people afford to purchase good bread, when the Wheat is sold at a price much higher than six shillings the bushel; therefore when it is at a medium between these, there can be no great cause of complaint on either side.

TRIUMFETTA. Plum. Gen. Nov. 40. tab. 8.

The Characters are,

The flower has no empalement, but it has five linear, erect, obtuse petals, which turn inward; it has ten awl-shaped rising stamina the length of the petals, terminated by single summits, and a roundish germen, supporting a style the length of the stamina, crowned by an acute bifid stigma. The germen afterward becomes a globular capsule, set with long prickles on every side, having four cells, each containing one seed, which is convex on one side, and angular on the other.

The Species are,

1. TRIUMFETTA caule fruticoso, foliis tricuspis ferratis, floribus axillaribus terminalibusque. Triumfetta with a shrubby

stalk, three-pointed sawed leaves, and flowers springing from the wings, and terminating the stalk.

2. TRIUMFETTA foliis oblongo-ovatis, obtuse serratis, petiolis longissimis. Icon. tab. 298. Triumfetta with oblong oval leaves bluntly sawed, having very long foot-stalks.

The first sort grows naturally in *Jamaica* and most of the other islands in the *West-Indies*; it rises with an upright stem to the height of six or seven feet, which becomes ligneous toward the bottom, dividing upward into four or five branches, garnished with leaves, placed alternately, divided almost into three lobes toward the top, ending in acute points; they are covered with a soft brown down on their under side, but their upper is of a yellowish green; their borders are acutely but unequally sawed, standing upon foot-stalks an inch long. The branches are terminated by long spikes of flowers, and from the side of the stalk come out several small clusters. The flowers are small, the petals narrow, of a yellow colour; these are succeeded by burry capsules, something like those of the Agrimony, but rounder; the prickles are longer than those, and are placed on every side. This plant generally flowers here in *July* and *August*, and in warm seasons the seeds do sometimes ripen.

The second sort grows naturally in *India*; it is an annual plant, rising near three feet high; the stalks are ligneous, branching out toward the top into three or four slender branches, garnished with entire leaves, sawed on their edges, ending in acute points, and are terminated by small clusters of pale yellow flowers, standing upon pretty long foot-stalks. The empalements of the flowers are cut into five narrow segments, but soon fall off; the flower has five erect petals, and generally ten slender stamina, terminated by roundish summits, with a roundish germen, supporting one hairy style, crowned by a single stigma. The germen afterward becomes a round prickly capsule with four or five cells, each including one seed.

These sorts are both propagated by seeds, which must be sown on a hot-bed early in the spring; and when the plants come up, and have four or five leaves, they should be each transplanted into a separate pot, and plunged into a moderate hot-bed of tanners bark, shading them from the sun until they have taken new root; then they must be treated in the same manner as hath been directed for other tender exotic plants. During the summer season the plants may remain in this hot-bed, but in autumn the first must be removed into the stove, and plunged into the bark-bed. If the plants live through the winter, they will flower the following summer, so will ripen their seeds in autumn; but they may be continued two years, provided they are carefully managed.

The second sort is annual; so, if the plants are brought forward early in summer, they will flower in autumn, but must be removed into a stove to perfect the seeds, which seldom ripen in *England* before *Christmas*.

TROLLIUS. Lin. Gen. Plant. 620. Globe Ranunculus, or Locker Gowls.

The Characters are,

The flower has no empalement; it has about fourteen oval petals, whose points meet together with nine nectariums, which are narrow, plain, incurved, and umbilicated, perforated at their base, and a great number of bristly stamina, terminated by erect summits, with numerous germina sitting close like a column, having no styles, but are crowned by pointed stigmas. The germen afterward become so many capsules, collected into an oval head, each containing one seed.

The Species are,

1. TROLLIUS corollis conniventibus, nectariis longitudine staminum. Lin. Sp. Plant. 556. Trollius with the petals of the flower meeting, and nectarii the length of the stamina;

stamina; commonly called Globe Flower, or Locker Gowls.

2. *TROLLIUS corollis patentibus nectariis longitudine petalorum. Lin. Sp. Plant. 557.* Trollius with an open spreading flower, and nectariums the length of the petals.

The first sort grows naturally in the northern counties in England, and in many parts of Wales. I found it in great plenty growing in the park of Burrow-Hall, in Lancashire; it has a perennial, fibrous, black root, from which spring up many leaves, which resemble those of Wolfsbane, cut into five segments almost to the bottom; the stalk rises near two feet high; it is smooth, hollow, and branches toward the top; each branch is terminated by one large yellow flower, shaped like those of Crow-foot, which has no empalement, composed of several concave petals, whose points turn inward toward each other, covering the parts of generation, so are of a globular form; whence it had the title of Globe Ranunculus. It flowers the latter end of May and the beginning of June, and the seeds ripen in August. This plant is frequently kept in gardens about London, and is easily propagated by parting of the roots; the best time for doing this is the latter end of September, when the leaves are beginning to decay. The roots should not be divided into small parts, if they are expected to flower strong the following year, and should be planted at a foot distance from each other; it requires a shady situation and a moist soil. The roots need not be removed or parted oftener than once in three years, unless there is a desire of increasing them.

The second sort grows naturally in Siberia, from whence it was brought to the imperial garden at Petersburg, and has been communicated since to several parts of Europe; this differs from the first in having larger leaves, which are of a lighter green colour; their segments are fewer and larger, resembling those of the yellow Monks Hood. The petals of the flower spread open, and do not converge at their points like those of the first sort. The flowers, stamina, and nectariums are of an elegant Saffron colour. It flowers in May.

This sort may be propagated and treated in the same way as the first, but it requires a moister soil, and should have a shady situation, but not under the drip of trees; it thrives best on a north border where the soil is loamy, but not too stiff. In such situations the plants will produce seeds in England, but if they are in a dry soil, or much exposed to the sun, they frequently die in summer. I have seen this sort in the most flourishing state, where the surface of the ground was covered with moss to keep it moist.

As the flowers of both these plants make a pretty appearance during their continuance, they deserve a place in every good garden for the sake of variety, especially as they will thrive in moist shady places where few better plants will live; and by thus suiting the plants to the different soils and situations of a garden, every part may be furnished with beauties, and a great variety may be preserved.

TROPÆOLUM. Lin. Gen. Plant. 421. Indian Cress.

The Characters are,

The empalement of the flower is of one leaf, ending in five points; it is erect, spreading, and falls off. The two under segments are narrow; their tail ends in a nectarious horn, which is longer than the empalement. The flower has five roundish petals inserted in the segments of the empalement; the two upper sit close to the foot stalk, but the lower have oblong hairy tails. It has eight short awl-shaped stamina, which decline, and are unequal, terminated by oblong rising summits, having four cells, and a roundish germen with three lobes, which are streaked, supporting a single erect style, crowned by an acute trifid stigma. The germen afterward becomes a solid fruit in three parts, convex on the outside, angular within, having many furrows, each part or

cell including one furrowed seed, convex on one side, and angular on the other.

The Species are,

1. *TROPÆOLUM foliis subquincelobis, petalis obtusis. Hort. Upsal. 93.* Tropæolum with leaves which are almost divided into five lobes, and obtuse petals to the flower; the common, or small Indian Cress.

2. *TROPÆOLUM foliis integris, petalis acuminato setaceis. Hort. Upsal. 93.* Tropæolum with entire leaves, and acute-pointed bristly petals to the flower; commonly called greater Indian Cress.

The first sort grows naturally in Peru; this was first brought to Europe in 1684, and was raised in the gardens of count Bevening in Holland.

It has a trailing herbaceous stalk, garnished with leaves almost circular. The foot-stalk is inserted in the center of the leaf, like a buckler, as in the Navelwort; they are smooth, of a grayish colour; the flowers come out from the wings of the stalks, standing upon very long slender foot-stalks, of an admirable structure, composed of five acute-pointed petals; the two upper are large and rounded; the three under are narrow; their tails join together, and are lengthened into a tail two inches long. After the flower is past, the germen turns to a roundish fruit, which is furrowed, and divided into three lobes, each including one streaked seed. It flowers from Midsummer till the frost stops it in autumn.

There are two varieties of this, one with a deep Orange-coloured flower, inclining to red, and the other with a pale yellow flower.

The second sort grows naturally about Lima; this has larger stalks than the former. The leaves are also larger, and their borders are indented almost into lobes; the flowers are larger, and their petals are rounded at their points. There are two colours of this sort as in the former, and one with double flowers, which is propagated by cuttings, for it does not produce seeds.

The first sort is less common at present in the English gardens than the second, though it was formerly more so; the flowers of the latter being larger make a finer appearance, for which it is preferred; they are both esteemed annual plants, though they may be continued through the winter if they are kept in pots, and sheltered in a good green-house, in like manner as that with double flowers is preserved, so may be propagated by cuttings as that is; but, as these ripen their seeds constantly every year, the plants are generally raised from them; these may be sown in April in the places where they are to remain, which should be where their stalks may have support, for they will climb six or eight feet high, when they are trained up, and then their flowers will make a good appearance; but when they trail upon the ground, they will spread over the neighbouring plants, and become unsightly.

The flowers of these plants are frequently eaten in salads; they have a warm taste like the Garden Cress, and are esteemed very wholesome; they are likewise used for garnishing dishes. The seeds are pickled, and by some are preferred to most kinds of pickles for sauce.

TUBEROSE. See Polyanthes.

TULIPA. Tourn. Inst. R. H. 373. tab. 199 & 200. Lin. Gen. Plant. 576. Tulip.

The Characters are,

The flower has no empalement; it is of the bell-shape, composed of six oblong, oval, concave, erect petals; it has six awl-shaped stamina, which are shorter than the petals, terminated by oblong four-cornered summits, and a large, oblong, taper, three-cornered germen, having no style, crowned by a triangular, three-lobed, permanent stigma. The germen afterward turns to a three-cornered capsule, having three cells, which are

filled with compressed seeds, lying over each other in a double order.

The Species are,

1. TULIPA flore subnutante, foliis lanceolatis. Lin. Sp. Plant. 305. Tulip with a nodding flower, and spear-shaped leaves; or the smaller, yellow, Italian Tulip.

2. TULIPA flore erecto, foliis ovato-lanceolatis. Lin. Sp. Plant. 306. Tulip with an erect flower, and oval spear-shaped leaves. This is the common Tulip with all its varieties.

The first sort was formerly preserved in the *English* gardens, but since there has been so many varieties of the second sort propagated in *England*, the first has been rejected, and is now only to be found in old neglected gardens. The petals of this flower end in acute points; the flower is yellow, and nods on one side, and the leaves are narrower than those of the common sort.

The common Tulip is so well known as to need no description; and it would be to little purpose to enumerate the several varieties of these flowers, which may be seen in one good garden, since there is no end of their numbers; and what some people may value at a considerable rate, others reject; beside there are annually a great variety of new flowers obtained from breeders, so those which are old, if they have not very good properties to recommend them, are thrown out and despised, I shall therefore point out the properties of a good Tulip, according to the characteristics of the best florists of the present age. 1. It should have a tall strong stem. 2. The flower should consist of six leaves, three within, and three without; the former ought to be larger than the latter. 3. Their bottom should be proportioned to their top, and their upper part should be rounded off, and not terminate in a point. 4. These leaves, when opened, should neither turn inward, nor bend outward, but rather stand erect, and the flower should be of a middling size, neither over large, nor too small. 5. The stripes should be small and regular, arising from the bottom of the flower, for if there are any remains of the former self-coloured bottom, the flower is in danger of losing its stripes again. The chives should not be yellow, but of a brown colour. When a flower has all these properties, it is esteemed a good one.

Tulips are generally divided into three classes, according to their seasons of flowering; as *Præcocas*, or early blowers, *Medias*, or middling blowers, and *Serotinas*, or late blowers; but there is no occasion for making any more distinctions than two, *viz.* early and late blowers.

The early-blowing Tulips are not near so fair, nor rise half so high, as the late ones, but are chiefly valued for appearing so early in the spring; some of which will flower the end of *February* in mild seasons, if planted in a warm border near a wall, pale, hedge, or other shelter, and a month after the others will succeed them; so that they keep flowering until the general season for the late flowers to blow, which is toward the end of *April*.

The roots of the early-blowing Tulips should be planted the beginning of *September* in a warm border, near a wall, pale, or hedge, because if they are put into an open spot of ground, their buds are in danger of suffering by morning frosts in the spring. The soil for these should be renewed every year, where people intend to have them fair. The best soil for this purpose is that which is taken from a light loamy pasture, with the turf rotted amongst it; and to this should be added a fourth part of sea sand. This mixture may be laid about eighteen inches deep, which will be sufficient, for these need not be planted more than four or five inches deep at most. The offsets should not be planted amongst the blowing roots, but in a border by themselves, where they may be planted pretty close together, especially

if they are small; but these should be taken up when their leaves decay, in the same manner as the blowing roots, otherwise they would rot; for these are not so hardy as the late blowers, nor do they increase half so fast as those, so that a greater care is required to preserve the offsets of them.

When these Tulips come up in the spring, the earth upon the surface of the borders should be gently stirred and cleared from weeds; and as the buds appear, if the season should prove severe, it will be of great service to cover them with mats, for want of which many times they are blighted, and their flower-buds decay before they blow, which is often injurious to the roots, as is also the cropping of the flowers, so soon as they are blown, because their roots, which are formed new every year, are not at that time arrived to their full magnitude, and are hereby deprived of proper nourishment.

If, when these flowers are blown, the season should prove very warm, it will be proper to shade them with mats, &c. in the heat of the day; as also if the nights are frosty, they should be in like manner covered, whereby they may be preserved a long time in beauty; but, when their flowers are decayed, and their seed-vessels begin to swell, they should be broken off just at the top of the stalks, because if they are permitted to seed, it will injure the roots.

When the leaves of these flowers are decayed (which will be before the late blowers are out of flower), their roots should be taken up, and spread upon mats in a shady place to dry; after which they should be cleared from their filth, and put up in a dry place, where vermin cannot come to them, until the season for planting them again, being very careful to preserve every sort separate, that you may know how to dispose of them at the time for planting them again, because it is the better way to plant all the roots of each sort together (and not to intermix them, as is commonly practised in most other kinds of flowers); for as there are few of them which blow at the same time, so, when the several roots of one sort are scattered through a whole border, they make but an indifferent appearance; whereas, when twenty or thirty roots of the same sort are placed together, they will all flower at the same time, and have a better effect.

There are many curious persons, who, in order to preserve their several kinds of Tulips, and other bulbous-rooted flowers separate, have large flat boxes made, which are divided into several small partitions, each of which is numbered in the same manner as the divisions of their beds; so that when a catalogue of their roots is made, and the numbers fixed to each sort in the beds, there is nothing more to do when the roots are taken up, but to put every kind into the division marked with the same number, which was placed to each sort in the bed, which saves a great deal of trouble, and effectually answers the purpose of preserving the kinds separate.

The late-blowing Tulips are so numerous, that, as I before observed, it would be to no purpose to attempt to give a catalogue of them. These are generally obtained from breeders, which is a term applied to all such flowers as are produced from seeds, which are of one self-colour, and have good bottoms and chives; these in time break into various beautiful stripes, according to the ground of their former self-colour; but this must be entirely thrown off, otherwise they do not esteem a flower well broken.

Of these breeders there hath been a great variety brought into *England* from *Flanders* of late years, which is the grand nursery for most sorts of bulbous-rooted flowers; but there are some curious persons, who have lately obtained many valuable breeders from seed in *England*; and doubtless, were we as industrious to sow the seeds of these flowers as the people of *Holland* and *Flanders*, we might in a few years have

as great variety as is to be found in any part of *Europe*; for, although it is six or seven years from the sowing before these flowers blow, yet, if after the first sowing there is every year a fresh parcel sown, when the seven years are expired, there will be constantly a succession of roots to flower every year, which will reward the expectation, and keep up the spirit of raising; but it is the length of time at first, which deters most people from this work.

The manner of propagating these flowers from seeds is as follows: You should be careful in the choice of the seed, without which there can be little success expected. The best seed is that which is saved from breeders which have all the good properties before related, for the seeds of striped flowers seldom produce any thing that is valuable.

The best method to obtain good seeds is to make choice of a parcel of such breeding Tulip roots as you would save seeds from, and plant them in a separate bed from the other breeders, in a part of the garden where they may be fully exposed to the sun, observing to plant them at least eight or nine inches deep; for if they are planted too shallow, their stems are apt to decay before their seed is perfected.

These flowers should always be exposed to the weather, for if they are shaded with mats, or any other covering, it will prevent their perfecting the seed. About the middle of *July* (a little sooner or later, as the summer is hotter or colder) the seeds will be fit to gather, which may be known by the driness of their stalks, and the opening of the seed-vessels; at which time it may be cut off, and preserved in the pods till the season for sowing it, being careful to put it up in a dry place, otherwise it will be subject to mould, which will render it good for little.

Having saved a parcel of good seed, about the beginning of *September* is the best season for sowing it, when there should be provided a parcel of shallow seed pans or boxes, six or eight inches deep, which should have holes in their bottoms to let the moisture pass off; these must be filled with fresh light earth, laying the surface very even, upon which the seeds should be sown as regularly as possible, that they may not lie upon each other; then there should be some of the same light earth sifted over them, about half an inch thick. These boxes or pans should be placed where they may have the morning sun till eleven of the clock, in which situation they may remain until the middle of *October*, at which time they should be removed into a more open situation, where they may enjoy the benefit of the sun all the day, and be sheltered from the north winds, where they should remain until winter, when they must be placed on a south border, to screen them from frost; but in the spring, when the plants are up, they should be again removed to their first situation; and if the season should be dry, they must be refreshed with water, while the plants remain green, but as soon as their tops begin to decay, there must be no more given them, lest it rot their tender bulbs; therefore the boxes should be placed in a shady situation during the summer season, but not under the drip of trees.

These plants, at their first appearance, have very narrow grassy leaves very like those of Onions, and come up with bending heads, in the same manner as they do; so that persons, who are unacquainted with them, may pull them up instead of Grass, whilst they are very young, before their leaves are a little more expanded; which is not performed the first year, for they seldom appear before the middle of *March*, and they commonly decay about the latter end of *May*, or the beginning of *June*, according as the season is hotter or colder.

The weeds and moss should also be cleared off from the surface of the earth in the boxes, and a little fresh earth sifted over them soon after their leaves decay, which will

be of great service to the roots. These boxes should be constantly kept clear from weeds, which, if permitted to grow therein, when they are pulled up, their roots will be apt to draw the bulbs out of the ground. At *Michaelmas* they should be fresh earthed again, and as the winter comes on, they must be again removed into the sun as before, and treated in the same manner, until the leaves decay, when the bulbs should be carefully taken up, and put in a cool shady room till the end of *August*, when they should be planted in beds of fresh sandy earth, which should have tiles laid under them, to prevent the roots from shooting downward, which they often do when there is nothing to stop them, and thereby they are destroyed. The earth of these beds should be about five inches thick upon the tiles, which will be sufficient for nourishing these roots while they are young.

The distance which these young bulbs should be allowed, need not be more than two inches, nor should they be planted above two inches deep; but toward the end of *October*, it will be proper to cover the bed over with a little tanners bark about two inches deep, which will preserve the roots from the frost, and prevent moss or weeds from growing over them; but, if the winter should be very severe, it will be proper to cover the bed either with mats or Peas haulm, to prevent the frost from entering the ground, because these roots are much tenderer while young, than they are after they have acquired strength.

In the spring the surface of the ground should be gently stirred to make it clean, before the plants come up; and if the spring should prove dry, they must be frequently refreshed with water, during the time of their growth; but this must not be given to them in great quantities, lest it rot their tender bulbs; and when the leaves are decayed, the roots should be taken up and treated in the same way as before.

When the bulbs are large enough to blow, they should be planted in fresh beds at the distance, and in the same manner as old roots, where, when they flower, such of them as are worthy to be preserved should be marked with sticks; and at the season for taking up the bulbs, they must be separated from the others, in order to be planted as breeders in different beds; but you should by no means throw out the rest until they have flowered two or three years, because it is impossible to judge exactly of their value in less time; for many, which at first flowering appear beautiful, will afterwards degenerate so as to be of little value, and others, which did not please at first, will many times improve, so that they should be preserved until their worth can be well judged of.

Having thus given an account of the method of raising these flowers from seeds, I shall now proceed to the management of the roots which are termed breeders, so as to have some of them every year break out into fine stripes.

There are some who pretend to have a secret how to make any sort of breeders break into stripes whenever they please; but this, I dare say, is without foundation; for from many experiments which I and others have made of this kind, I never could find any certainty in this. All that can be done by art is, to shift the roots every year into fresh earth of different mixtures and to different situations, by which method I have had very good success.

The earth of these beds should be every year different, for although it is generally agreed that lean, hungry, fresh earth doth hasten their breaking, and cause their stripes to be the finer and more beautiful, yet, if they are every year planted in the like soil, it will not have so much effect upon them, as if they were one year planted in one sort of earth, and the next year in a very different one, as I have several times experienced; and if some fine striped Tulips are planted

in the same beds with the breeders intermixing them together, it will also cause the breeders to break the sooner.

The best compost for these roots is a third part of fresh earth from a good pasture, which should have the sward rotted with it, a third part of sea sand, and the other part sifted lime rubbish; these should be all mixed together six or eight months at least before it is used, and should be frequently turned to mix the parts well together. With this mixture the beds should be made about two feet deep, after the following manner: After the old earth is taken from out of the bed to the depth intended, then some of the fresh earth should be put in about eighteen inches thick; this should be levelled exactly, and then lines drawn each way of the bed chequerwise, at six inches distance; upon the center of each cross, should be placed the Tulip roots, in an upright position; and after having finished the bed in this manner, the earth must be filled in, so as to raise the bed six or eight inches higher, observing, in doing this, not to displace any of the roots, and also to lay the top of the beds a little rounding, to throw off the wet.

There are many persons who are so careless in planting their Tulip roots, as only to dig and level the beds well, and then with a blunt dibble to make holes, into which they put the roots, and then fill up the holes with a rake; but this is by no means a good method; for the dibble, in making the holes, presses the earth closely on each side, and at the bottom, whereby the moisture is often detained so long about the roots as to rot them, especially if the soil is inclinable to bind; besides, the earth being hard at the bottom of the bulbs, they cannot so easily emit their fibres, which must certainly prejudice the roots.

These beds should be sunk, more or less, below the surface, according to the moisture or driness of the ground; for the roots should be so elevated as never to have the water stand near the reach of their fibres in winter, for moisture is very apt to rot them; so that where the soil is very wet, it will be proper to lay some lime rubbish under the earth, in order to drain off the wet, and the beds should be entirely raised above the level of the ground; but to prevent their falling down into the walks, after frost, or hard rains, it will be proper to raise the paths between them, either with sea-coal ashes or rubbish, eight or ten inches, which will support the earth of the beds; and these paths may slope at each end from the middle, which will make passage for the water to run off as it falls. But where the soil is dry, the beds may be sunk eighteen or twenty inches below the surface, for in such places the beds need not be more than four or six inches above the surface, which will be allowance enough for their settling.

During the winter season there will be no farther care required. The roots being planted thus deep, will be in no danger of suffering by ordinary frosts; but if the winter should prove very severe, some rotten tan or Peas haulm may be laid over the beds to keep out the frost during its continuance, but this must be removed when the frost is over; and in the spring, when their leaves begin to appear above ground, the earth upon the surface of the beds should be stirred to clear it from weeds, moss, &c. and when the flower-buds begin to come up, they should be guarded from frost, otherwise they are very subject to blight and decay soon after they appear, if the frost pinches their tops; but they need only be covered in such nights when there is a prospect of frost, for at all other times they should have as much open air as possible, without which they will draw up weak, and produce very small flowers.

When these breeders are in flower, you should carefully examine them to see if any of them have broken into beautiful stripes, which, if you observe, there should be a stick put into the ground by every such root, to mark them,

that they may be separated from the breeders, to plant amongst the striped flowers the following year; but you should carefully observe, whether they have thrown off their former colour entirely, as also when they decay, to see if they continue beautiful to the last, and not appear smeared over with the original colour; in both which cases they are very subject to go back to their old colour the next year: but if their stripes are distinct and clear to the bottom, and continue so to the last (which is what the florists call dyeing well), there is no great danger of their returning back again, as hath been by some confidently reported; for if one of these flowers is quite broken (as it is termed), it will never lose its stripes, though sometimes they will blow much fairer than at others, and the flowers of the offsets will be often more beautiful than those of the old roots.

This alteration in the colour of these flowers may be seen long before they are blown, for the green leaves will appear of a fainter colour, and seem to be striped with white, or of a brownish colour, which is a plain proof, that the juices of the whole plant are altered, or, at least, the vessels through which the juice is strained; so that hereby particles of a different figure are capable of passing through them, which, when entered into the petals of the flower, reflect the rays of light in a different manner, which occasions the variety we see in the colours of flowers. This breaking of the colours in flowers proceeds from weakness, or at least is the cause of weakness in plants; for it is observable, that after Tulips are broken into fine stripes, they never grow so tall as before, nor are the stems, leaves, or flowers so large; and it is the same in all other variegated plants and flowers whatever, which are also much tenderer than they were before they were striped; so that many sorts of exotic plants, which by accident have become variegated in their leaves, are often rendered so tender, as not to be preserved without much more care, though indeed the striping of Tulips doth never occasion so great weakness in them as to render them very tender. The greatest effect it hath on them, is in lessening their growth; the more beautifully their stripes appear, the shorter will be their stems, and the weaker their flowers.

There is nothing more to be observed in the culture of striped flowers than what has been directed for breeders, excepting that these should be arched over with tall hoops and rails, that they may be shaded from the sun in the day time, and protected from strong winds, hard rains, and frosty mornings, otherwise the flowers will continue but a short time in beauty; but where these instructions are duly followed, they may be preserved in flower a full month, which is as long as most other flowers continue.

There are some persons who are so extremely fond of these flowers, as to be at a great expence in erecting large frames of iron work to cover their beds of Tulips, in such a manner, that they may walk between two beds under the frames, over which are spread tarpaulins, so as to keep off sun, rain, and frost, whereby they can view the flowers without being at the trouble of taking off or turning up the tarpaulins, or being incommoded by the sun or rain, which cannot be avoided where the covering is low; besides, by thus raising the covers, the flowers have a greater share of air, so that they are not drawn so weak as they are when the covering is low and close to them; but these frames being expensive, can only be made by persons of fortune; however, there may be some of wood contrived at a smaller expence, which, being arched over with hoops, may answer the purpose as well as the iron frames, though they are not so sightly or lasting.

When the flowers are faded, the heads of all the fine sorts should be broken off, to prevent their seeding; for if this is not observed, they will not flower near so well the following

following year, nor will their stripes continue so perfect: this will also cause their stems to decay sooner than otherwise they would do, so that their roots may be taken up in *June*; for they should not remain in the ground after their leaves are decayed. In taking the roots out of the ground, you must be very careful not to bruise or cut them, which will endanger their rotting, and, if possible, it should be done a day or two after rain. When these roots are taken out of the ground, they must be cleared from their old covers, and all sorts of filth, and spread upon mats in a shady place to dry; after which they should be put up in a dry place, where vermin cannot get to them, observing to keep every sort separated; but they should not be kept too close from the air, nor suffered to lie in heaps together, lest they should grow mouldy, for if any of the roots once take the mould, they commonly rot when they are planted again.

The offsets of these roots, which are not large enough to produce flowers the succeeding year, should be also put by themselves, keeping each sort distinct; these should be planted about a month earlier in autumn than the blowing roots, in particular beds by themselves in the flower-nursery, where they may not be exposed to publick view; but the earth of the beds should be prepared for them in the same manner as for larger roots; these should not be planted above five inches deep, because they are not strong enough to push through so great covering of the earth as the old roots; they may also be placed much nearer together than those which are to flower, and in one year most of them will become strong enough to flower, when they may be removed into the flower-garden, and placed in the beds amongst those of the same kinds.

TULIPIFERA. *Herm. Hort. Leyd.* The Tulip tree.

The Characters are,

The proper involucre of the flower is composed of two angular leaves, which fall off; the empalement is composed of three oblong plain leaves like petals, which fall away. The flower is nearly of the bell-shape, and has six petals, which are obtuse and channelled at their base; the three outer fall off; it has a great number of narrow stamina, which are inserted to the receptacle of the flower, having long narrow summits fastened to their side, and many germen disposed in a cone, having no style, crowned by a single globular stigma. The germen afterward becomes scaly seeds, lying over each other like the scales of fish, and form the resemblance of a cone.

We have but one Species of this genus, viz.

TULIPIFERA. The Virginia Tulip-tree.

This is a native of *North America*, where it grows to be a tree of the first magnitude, and is generally known through all the *English* settlements by the title of Poplar. Of late years there has been great numbers of these trees raised from seeds in the *English* gardens, so that now they are become common in the nurseries about *London*, and there are many of the trees in several parts of *England* which do annually produce flowers. The first tree of this kind which flowered here, was in the gardens of the late earl of *Peterborough* at *Parsons Green* near *Fulham*, which was planted in a wilderness among other trees; before this was planted in the open air, the few plants which were then in the *English* gardens, were kept in pots or tubs, and housed in winter, supposing they were too tender to live in the open air; but this tree, soon after it was planted in the full ground, convinced the gardeners of their mistake, by the great progress it made, while those which were kept in pots and tubs, increased slowly in their growth; so that afterward there were many others planted in the full ground, which are now arrived to a large size, especially those which were planted in a moist soil. One of the handsomest trees of this kind near *London*, is in the garden of *Waltham-Abbey*; and at *Wilton* the seat of the earl of *Pembroke*, there are some

trees of great bulk; but the old tree at *Parsons-Green* is quite destroyed by the other trees which were suffered to overhang it, and rob it of its nourishment, from a fear of taking down the neighbouring trees, and admitting the cold air to the Tulip-tree it should injure it.

The young shoots of this tree are covered with a smooth purplish bark, garnished with large leaves, whose foot-stalks are long; they are ranged alternate; the leaves are of a singular form, being divided into three lobes; the middle lobe is blunt and hollowed at the point, appearing as if it had been cut with scissars. The two side lobes are rounded, and end in blunt points. The upper surface is smooth, and of a lucid-green; the under is of a pale green. The flowers are produced at the end of the branches; they are composed of six petals, three without and three within, which form a sort of bell-shaped flower, from whence the inhabitants of *North America* gave it the title of Tulip. These petals are marked with green, yellow, and red spots, so make a fine appearance when the trees are well charged with flowers. The time of this tree's flowering is in *July*, and when the flowers drop, the germen swells and forms a kind of cone; but these do not ripen in *England*.

This tree is propagated by seeds, which are now annually imported in great plenty from *America*. These should be sown as soon as they arrive, in pots or tubs, filled with light earth, from the kitchen-garden, or in a bed in the fall ground. Those which are sown in the first way, may be placed on a very gentle hot-bed, which will forward their growth; so that if they come up the same season, the plants will acquire more strength before winter. When the plants appear, they must be shaded in the heat of the day from the sun, but fresh air must be admitted daily to prevent their drawing up weak; and as the season advances, they must be gradually hardened to bear the open air. While the plants are young, they do not care for much sun, so they should be either shaded, or placed where the morning sun only shines upon them; they must also be constantly supplied with water, but not have it in too great plenty. As the young plants commonly continue growing late in the summer, so when there happens early frosts in autumn, it often kills their tender tops, which occasions their dying down a considerable length in winter; therefore they should be carefully guarded against these first frosts, which are always more hurtful to them than harder frosts afterward, when their shoots are better hardened; however, the first winter after the plants come up, it will be the better way to shelter them in a common hot-bed frame; or to arch them over with hoops, and cover them with mats, exposing them always to the open air in mild weather.

The following spring, just before the plants begin to shoot, they should be transplanted into nursery-beds, in a sheltered situation, where they are not too much exposed to the sun. The soil of these beds should be a soft gentle loam, not too stiff, nor over light; this should be well wrought, and the clods well broken and made fine. There must be great care taken not to break the roots of the plants in taking them up, for they are very tender; then they should be planted again as soon as possible, for if their roots are long out of the ground, they will be much injured thereby. These may be planted in rows at about a foot distance, and at six inches distance in the rows; for as they should not remain long in these nursery beds, so this will be room enough for them to grow; and by having them so close, they may be shaded in the summer, or sheltered in the winter, with more ease than when they are farther apart.

When the plants are thus planted, if the surface of the beds is covered with rotten tanners bark, or with moss, it will prevent the earth from drying too fast; so that the plants will not require to be so often watered, as they must

be where they are exposed to the sun and air; after this, the farther care will be to keep them clean from weeds, and if the latter part of summer should prove moist, it will occasion the plants growing late in autumn, so their tops will be tender and liable to be killed by the first frosts. In this case they should be covered with mats to protect them.

If the plants make great progress the first summer, they may be transplanted again the following spring; part of them may be planted in the places where they are to remain, and the other should be planted in a nursery where they may grow two years, to acquire strength before they are planted out for good; though the younger they are planted in the places where they are to stand, the larger they will grow, for the roots run out into length; and when they are cut, it greatly retards their growth, so that these trees should never be removed large, for they rarely succeed, if transplanted, when they are grown to a large size. Some trees I have seen removed pretty large, which have survived their removal; but young plants of two years old, which were planted near them, were much larger in fifteen years than the old ones.

When the seeds are sown upon a bed in the full ground, the bed should be arched over with hoops, and shaded in the heat of the day from the sun, and frequently refreshed with water; as should also the plants when they appear, for when they are exposed much to the sun while young, they make but small progress. The care of these in summer must be to keep them clean from weeds, supplying them duly with water, and shading them from the sun in hot weather; but as these seeds will not come up so soon as those which were placed on a hot-bed, they generally continue growing later in autumn, therefore will require shelter from the early frosts in autumn; for as the shoots of these will be much softer than those of the plants which had longer time to grow, so if the autumnal frosts should prove severe, they will be in danger of being killed down to the surface of the ground, by which the whole summer's growth will be lost, and sometimes the plants are entirely killed the first winter, if they are not protected.

As these plants will not have advanced so much in their growth as the other, they should remain in the seed-bed to have another year's growth before they are removed; therefore all that will be necessary to observe the second year, is to keep them clean from weeds, and now they will not be in so much danger of suffering from the warmth of the sun as before, therefore will not require such constant care to shade them, nor should the watering of them be continued longer than the spring; for if the autumn should prove dry, it will prevent the plants from shooting late, and harden those shoots which were made early in the year, whereby the plants will be in less danger from the early frosts.

After the plants have grown two years in the seed-bed, they will be strong enough to remove; therefore, in the spring, just at the time when their buds begin to swell, they should be carefully taken up, and transplanted into nursery-beds, and treated in the same way as has been before directed for the plants which were raised in pots.

There are some people who propagate this tree by layers, but the layers are commonly two or three years before they take root; and the plants so raised, seldom make such straight trees as those raised from seeds, though indeed they will produce flowers sooner, as is always the case with stunted plants.

This tree should be planted on a light loamy soil, not too dry, on which it will thrive much better than upon a strong clay, or a dry gravelly ground; for in *America* they are chiefly found upon a moist light soil, where they will grow to a prodigious size, though it will not be proper to plant these trees in a soil which is too moist, in *England*,

because it might endanger the rotting of the fibres of the roots, by the moisture continuing too long about them, especially if the bottom be a clay, or a strong loam, which will detain the wet.

TURKS CAP. See *Lilium and Castos*.

TURKEY WHEAT. See *Zea*.

TURNEP. See *Rapa*.

TURNERA. *Plum. Gen. Nov. 15. tab. 12.*

The Characters are,

The empalement of the flower is funnel shaped, of one leaf, having an oblong, cylindrical, angular tube, cut into five segments. The flower has five heart-shaped plain petals, with narrow tails, which are inserted in the tube of the empalement; it has five awl-shaped stamina, which are shorter than the petals, inserted in the empalement, terminated by acute-pointed erect summits, and a conical germen, supporting three slender styles, crowned by hairy many-pointed stigmas. The germen afterward turns to an oval capsule with one cell, which opens at the top with three valves, and contains several oblong obtuse seeds.

The Species are,

1. *TURNERA foliis lineari-lanceolatis hirsutis obtusè serratis, acuminatis.* Turnera with linear, spear-shaped, hairy leaves, which are obtusely indented and acute-pointed.

2. *TURNERA foliis ovato-lanceolatis serratis rugosis.* Turnera with oval spear-shaped leaves, which are sawed and rough.

These plants are both of them natives of the warm parts of *America*. The second species was found by father *Plumier* in *Martinico*, who gave it the name of *Turnera*, from *Dr. Turner*, a famous *English* physician, who lived in queen *Elizabeth's* reign.

The first sort was discovered by *Sir Hans Sloane*, who has figured it in his *Natural History of Jamaica*, under the following title; *Cistus urticæ folio, flore luteo, vasculis trigonis.* Vol. 1. p. 202. but both these sorts were observed by my late friend *Dr. William Houstoun*, in several parts of *America*.

The first sort rises with a shrubby stalk to the height of eight or ten feet, sending out branches on every side the whole length, garnished with narrow, spear-shaped, hairy leaves, terminating in acute points, sawed on their edges; these, when rubbed, emit a disagreeable odour. The flowers grow from the foot-stalks of the leaves, to which they sit very close, having two pretty large leafy appendages to their empalements. The flowers are of a pale yellow colour, composed of five large oval petals, whose tails are twisted and join; these are succeeded by short tubular capsules, having one cell, which opens at the top with three valves, which turn back, and let out the seeds.

The second sort has a shrubby stalk like the first, and rises to near the same height. The branches of this are slender, and stiffer than those of the former. The leaves are oval, spear-shaped, rough on their upper side, and of a lucid green; their under side has many strong veins, and is of a lighter colour; they are sawed on their edges, and have longer foot-stalks than those of the first species. The flowers sit close upon the foot-stalks of the leaves, in like manner as the former, but the flowers are larger, and of a brighter yellow than those. These differences remain constant, and never alter when raised from seeds; so that from near thirty years experience in sowing the seeds, I may pronounce them different species.

The plants are easily propagated by sowing their seeds on a hot-bed early in the spring; and when the plants are come up two inches high, they should be transplanted into small pots, and plunged into a hot-bed of tanners bark, observing to water and shade them until they have taken root; after which they must be treated, as hath been directed for the *Guavas*, and other tender plants from the same countries, to which the reader is desired to turn, to avoid

avoid repetition. The seeds of these plants will often fall into the pots which are placed near them in the stove, which will grow, and soon furnish plants enough, after a person is once possessed of them. As they are too tender to live in the open air in *England*, they must be placed in the bark-bed in the stove, where, during the winter season, they must be kept warm, and frequently watered; but in the summer season they must have a great share of air, otherwise they will draw up tender, and not produce many flowers.

When the plants are grown pretty large, they may be treated more hardily, by placing them in the dry stove, where, if they are kept in a moderate degree of heat, they will thrive and flower very well. Those who would save the seeds of these plants, must watch them carefully, because, when they are ripe, they soon scatter if they are not gathered.

These plants produce their flowers great part of the year, if they are kept in a proper degree of warmth, so that there are some of the flowers in beauty for at least nine or ten months, which renders the plants more valuable.

TURNSOLE See *Heliotropium* and *Croton*.

TURRITIS. *Tourn. Inst. R. H.* 223. Tower Mustard.

The Characters are,

The empalement of the flower is composed of four oblong oval leaves, which close together. The flower has four oblong, oval, entire petals, placed in form of a cross, and six erect awl shaped stamina the length of the tube, two of which are shorter than the other, terminated by single summits, and a taper germen a little compressed, having no style, but is crowned by an obtuse stigma. The germen afterward becomes a long four-cornered pod with two cells, which are divided by an intermediate partition, opening with two valves, and filled with small, roundish, indented seed.

The Species are,

1. TURRITIS *foliis radicalibus dentatis hispida, caulinis integerrimis amplexicaulis glabris. Hort. Cliff.* 339. Tower Mustard with prickly lower leaves, which are indented, and the upper ones smooth, entire, and embracing the stalk.

2. TURRITIS *foliis omnibus hispida, caulinis amplexicaulis. Hort. Cliff.* 339. Tower Mustard with all the leaves prickly, and the upper ones embracing the stalk.

3. TURRITIS *foliis omnibus integerrimis glabris. Tower Mustard*, whose leaves are all entire and smooth.

The first sort grows naturally in several parts of *England*, upon walls and dry banks; this hath its lower leaves much jagged on their edges, and rough. The stalks rise two feet high, garnished with smooth grayish leaves, ending in points, which embrace the stalks with their base. The upper part of the stalk has slender branches, proceeding from the wings of the leaves, which sustain spikes of small white flowers, having four petals, placed in form of a cross: These are succeeded by long, slender, compressed, four-cornered pods, which grow erect close to the stalk, filled with small seeds.

The third sort grows naturally in rough stony ground about *Montpelier*. This is much smaller than either of the former; the leaves are smooth, and all of them entire; the stalks are erect, and seldom branch; the leaves embrace them with their base. The flowers and pods are like the former, but are smaller.

The second sort grows naturally upon old walls and buildings in the northern counties of *England*; the lower leaves are shaped like those of the Daisy, but rough. The stalks rise eight or ten inches high, garnished with oval leaves, whose bases embrace the stalks; they are as rough as the lower leaves. The upper part of the stalks branch into slender stalks, which sustain short spikes of white flowers

like those of the former sort, which are succeeded by slender pods, having four corners shorter than those of the first sort.

These plants are kept in botanick gardens for variety; but if their seeds are scattered upon an old wall or building in autumn, soon after they are ripe, the plants will come up, and thrive without farther care, and their seeds will scatter on the walls and spread, so there will be no danger of the plants maintaining their situation, if they are not purposely destroyed.

The other species inserted in the former editions of this work, are referred to *ARABIS*, *BRASSICA*, and *HESPERIS*, under which articles they will be found.

TUSSILAGO. *Tourn. Inst. R. H.* 487. *tab.* 276. *Lin. Gen. Plant.* 856. Colt's-foot.

The Characters are,

The flower has one common cylindrical empalement, whose scales are linear, spear-shaped, and equal. The flower is made up of hermaphrodite florets which compose the disk, and female half florets which form the rays or border. The hermaphrodite florets are funnel shaped, cut at the brim into five segments; these have five short hair-like stamina, terminated by cylindrical summits, and a short crowned germen, supporting a slender style, crowned by a thick stigma. The germen afterward becomes an oblong compressed seed, crowned with a hairy down. The female half florets are stretched out on one side with a narrow tongue-shaped segment; these have no stamina, but have a short crowned germen, which turns to a seed like those of the hermaphrodite florets, which ripen in the empalement.

The Species are,

1. TUSSILAGO *scapo imbricato uniflora, foliis subcordatis, angulatis denticulatis. Lin. Hort. Cliff.* 411. Colt's-foot with an imbricated stalk bearing one flower, and angular indented leaves, which are nearly heart-shaped; or common Colt's-foot.

2. TUSSILAGO *scapo uniflora, foliis lyrato ovatis. Lin. Sp. Plant.* 865. Colt's-foot with one flower on each stalk, and oval lyre-shaped leaves.

3. TUSSILAGO *scapo subnudo uniflora, foliis cordato-orbiculatis crenatis. Hort. Cliff.* 411. Colt's-foot with an almost naked stalk bearing one flower, and orbicular, heart-shaped, crenated leaves.

The first of these sorts is very common in watery places in almost every part of *England*, and is rarely kept in gardens; for the roots creep under ground, and increase so fast, that in a short time they will spread over a large spot of ground. This plant is so well known, as to need no description.

The second sort grows naturally in *Siberia*; this is a very low plant, whose leaves grow close to the ground, of an oval form, indented on the sides like a lute. The flowers stand upon short foot stalks, which rise between the leaves, each sustaining one flower at the top, of a dirty purplish colour. These are succeeded by downy seeds.

The third sort grows naturally on the *Alps*; this is a low perennial plant, whose leaves are round, indented at the foot-stalk in form of a heart; their edges are crenated; their upper surface is smooth, of a bright green colour; their under sides are a little downy and whitish. The foot-stalks of the flowers, which arise from the root, sustain one purplish flower at the top, which is made up of hermaphrodite and female florets, like those of the other sorts.

The two last are frequently kept in gardens for the sake of variety; they are easily propagated by parting their roots in autumn, and must be planted in a moist shady border, where they will thrive, and require no farther care but to keep them clean from weeds.

V.

V A C

VACCARIA. See Saponaria.

VACCINIUM. *Lin. Gen. Plant.* 434. The Bill-berry, Whortle-berry, or Cran-berry.

The Characters are,

The flower has a small permanent empalement sitting upon the germen; it is bell-shaped, of one petal, slightly cut into four segments at the brim, which turn backward; it has eight stamina, terminated by horned summits, having two awns on their backside which spread asunder. The germen is situated below the flower, supporting a single style longer than the stamina, crowned by an obtuse stigma; it afterwards turns to an umbilicated globular berry with four cells, containing a few small seeds.

The Species are,

1. **VACCINIUM pedunculis unifloris, foliis ovatis serratis deciduis, caule angulato.** *Flor. Lapp.* 143. Whortle-berry with one flower upon each foot-stalk, oval sawed leaves which fall off in winter, and an angular stalk.

2. **VACCINIUM racemis terminalibus nutantibus, foliis ob-ovatis revolutis integerrimis subtus punctatis.** *Lin. Sp. Plant.* 351. Whortle-berry with nodding bunches of flowers terminating the branches, and oval leaves which are entire, turned back, and punctured on their under side; Red-whorts, or Whortle-berries.

3. **VACCINIUM foliis ovatis mucronatis, floribus alaribus nutantibus.** Whortle-berries with oval-pointed leaves, and nodding flowers proceeding from the wings of the stalks.

4. **VACCINIUM foliis integerrimis revolutis ovatis, caulibus repentibus, filiformibus, hispidis.** *Lin. Sp. Plant.* 352. Whortle-berries with oval entire leaves turning back, and a slender, creeping, bristly stalk.

5. **VACCINIUM foliis integerrimis revolutis ovatis, caulibus repentibus filiformibus nudis.** *Lin. Sp. Plant.* 351. Whortle-berries with oval, entire, reflexed leaves, and naked, slender, creeping stalks. Moss-berries, or Moor-berries; by some called Cran-berries.

The first sort grows very common upon large wild heaths, in many parts of *England*, but is never cultivated in gardens, it being with great difficulty transplanted; nor will it thrive long when moved thither; for from many trials which I have made, by taking up the plants at different seasons with balls of earth to their roots, and planting them in gardens, I could never succeed so as to preserve the plants above two years, and those never produced any fruit, so that it is not worth the trouble of cultivating.

The fruit of this sort is gathered by the poor inhabitants of those villages which are situated in the neighbourhood of their growth, and carried to the market towns. These are by some eaten with cream or milk; they are also put into tarts, and much esteemed by the people in the north, but they are seldom brought to *London*. The shrub on which these grow, rises about two feet high, having many stems which are garnished with oblong leaves, shaped like those of the Box-tree, but somewhat longer, and are a little sawed on their edges. The flowers are shaped like those of the Arbutus, or Strawberry-tree, of a greenish white colour, changing to a dark red toward the top. The fruit are about the size of large Juniper-berries, and of a deep purple

V A C

colour, having a sue upon them when they are untouched, like the blue Plumbs, which rub off with handling.

The second sort is of a much humbler growth, seldom rising above six or eight inches high. The leaves of this are so like that of the dwarf Box, as that, at a distance, the plants are often taken for it even by persons of skill. This is an ever-green, which grows upon moory ground in several parts of the north, but it is full as difficult to transplant into gardens, as the other sort, though I have been assured by persons of credit, that they have seen this sort planted to make edgings to the borders of the gardens in *Norway* and *Sweden*, where the plants may grow much better from the cold of those climates, than they will do in *England*, for this is a native of very cold countries. I have several times received plants of this sort from *Greenland*, by the whale-ships. The berries of this sort are red, and have a more agreeable acid flavour than those of the first sort. The fruit is frequently used for tarts in several of the northern counties, where the plants grow wild upon the moors.

The third sort grows naturally in *Virginia* and other parts of *North America*; this has a low shrubby stalk like the second. The leaves are small, oval, pointed, and not unlike some sorts of Myrtle; they continue green all the year. The flowers come out from the wings of the leaves at every joint; their foot-stalks are pretty long, and nod downward; they sustain but one flower; they are small, white, and are succeeded by small red berries which seldom ripen here.

The fourth sort grows naturally in marshy grounds in most parts of *North America*. The stalks of this are slender, imbricated, and trail upon the ground; the scales are bristly; the leaves are oval, entire, and their edges turn backward; the flowers come out from the wings of the stalk, of an herbaceous white colour, and in their native soil are succeeded by large red berries, but in *England* the fruit never comes to perfection.

The plants of this sort are difficult to preserve in *England*, for they require a moorish, boggy soil, which should be covered with moss, and constantly kept wet, otherwise they will not thrive.

The fifth sort produces long slender branches, not bigger than thread, which trail upon the mossy bogs, so are often hid by the moss. These branches are thinly garnished with small leaves, about the size and shape of those of Thyme, having their upper surface of a shining green colour, but are white underneath. The flowers are generally produced toward the extremity of the shoots, which are in shape like those of the former sorts, but are smaller, and of a red colour; these grow upon long slender foot-stalks, and are succeeded by round, red, spotted berries, of a sharp acid flavour, which are much esteemed by the inhabitants of the places near the bogs where they grow. Some use them for tarts, and others eat them with milk or cream.

This sort is a native of bogs, therefore cannot by any art be propagated upon dry land; but where there are natural bogs, the plants may be taken up carefully, preserving some of the soil to their roots, and transplanted into the bogs in the autumn; and if they are once fixed in the place

place, they will spread and propagate themselves in great plenty, and require no farther care.

The two sorts first mentioned also propagate very fast by their creeping roots, so that when they are fixed in a proper soil, they will soon overspread the ground, for the heaths, upon which they naturally grow, are generally covered with the plants. The first sort grows with the heath, their roots intermixing together, and frequently is found upon sandy heaths in divers parts of *England*; but the second sort grows only upon moorish land, where, by its creeping roots, the ground is soon covered with the plants.

There are several other species of this genus, some of which are natives of *Spain* and *Portugal*, others of *Germany* and *Hungary*, and several of the northern parts of *America*, from whence those large fruit are brought to *England*, which are used by the pastrycooks of *London*, during the winter season for tarts; but as all these sorts naturally grow upon swamps and bogs, they are not easy to transplant into gardens in their native country, so as to thrive, or produce fruit, therefore there can be little hopes of cultivating them to advantage in *England*.

VALERIANA. *Tourn. Inst. R. H.* 131. tab. 52. Valerian.

The Characters are,

The flower has a small empalement; it has one tubulous petal cut into five obtuse segments at the brim, with a gibbous honey gland on the inside; it has three small, erect; awl-shaped stamina, the length of the petals, terminated by roundish summits. The germen is situated under the flower, supporting a slender style crowned by a thick stigma; it afterward turns to a crowned capsule which falls off, in which is lodged a single seed.

The Species are,

1. VALERIANA floribus triandris, foliis caulinis pinnatis, radicalibus indivisis. *Hort. Upsal.* 13. Valerian with flowers having three stamina, winged leaves to the stalks, but those at the root undivided; Garden Valerian.

2. VALERIANA floribus triandris, foliis omnibus pinnatis. *Hort. Cliff.* 15. Valerian with three stamina to the flowers, and all the leaves winged; Greater wild Valerian.

3. VALERIANA floribus monandris caudatis, foliis lanceolatis integerrimis. *Hort. Cliff.* 15. Valerian with flowers having tails, but one stamina, and spear-shaped entire leaves; Red Valerian.

4. VALERIANA floribus monandris caudatis, foliis linearibus integerrimis. Valerian with tailed flowers having one stamina, and linear entire leaves; Narrow-leaved red Valerian.

5. VALERIANA floribus monandris, foliis pinnatifidis. *Hort. Upsal.* 14. Valerian with flowers having one stamina, and wing-pointed leaves.

6. VALERIANA floribus triandris, foliis cordatis serratis petiolatis, summis ternatis. *Hort. Cliff.* 15. Valerian with three stamina to the flowers, and heart-shaped sawed leaves growing on foot-stalks, placed by threes at the top.

7. VALERIANA floribus triandris, foliis ovato-oblongis obtusis integerrimis. *Lin. Mat. Med.* 23. Valerian with three stamina to the flowers, and oblong, oval, blunt, entire leaves; Celtick Nard.

8. VALERIANA floribus tetrandis æqualibus, foliis pinnatifidis, seminibus paleâ ovali adnatis. *Hort. Upsal.* 13. Valerian with four equal stamina to the flowers, wing-pointed leaves, and seeds fastened to an oval husk.

9. VALERIANA caule dichotomo, foliis lanceolatis integris. *Vir. Cliff.* 5. Valerian with a stalk branching two ways, and spear-shaped entire leaves; Corn-sallad, or Lambs-lettuce.

10. VALERIANA caule dichotomo, foliis lanceolatis serratis, calycibus inflatis. *Hort. Cliff.* 16. Valerian with a stalk branching two ways, spear-shaped sawed leaves, and swollen empalements.

11. VALERIANA caule dichotomo, foliis lanceolatis dentatis,

fructu sexdentato. *Hort. Cliff.* 16. Valerian with a stalk divided two ways, spear-shaped indented leaves, and a fruit having six indentures.

12. VALERIANA floribus diandris ringentibus, foliis ovatis sessilibus. *Hort. Cliff.* 15. Valerian with a ringent flower having two stamina, and oval leaves set close to the stalk.

There are some other species of this genus which grow naturally in *England*, and others in different parts of *Europe*: but, as they are seldom cultivated in gardens, they are omitted, lest the work should swell beyond its intended bulk.

The first of these sorts is propagated in *England* for medicinal use, and is called in the shops by the name of Phu, to distinguish it from the Mountain Valerian, which is also used in medicine, and is preferred to all the other sorts by the modern physicians, though the roots of the first are still continued in some of the capital medicines, and are by some esteemed equal in virtue, if not superior, to the wild sort.

This hath thick, fleshy, jointed roots, which spread near the surface of the ground in a very irregular manner, crossing each other, and matting together by their small fibres; they have a very strong scent, especially when dry. The lower leaves, which rise immediately from the root, are many of them entire; others are divided into three, five, or seven obtuse smooth lobes, of a pale green colour. The stalks rise three or four feet high; they are hollow, and send out branches from their side by pairs, garnished with winged leaves, placed opposite at each joint, which are composed of four or five pair of long narrow lobes terminated by an odd one. The branches are terminated by flowers disposed in form of an umbel, which are small, tubulous, white, and cut slightly at the brim into five parts; these are succeeded by oblong flat seeds having a downy crown. It grows naturally in *Alsatia*, but has been long cultivated in our gardens.

It is propagated by parting of its roots, either in the spring or autumn, but the latter is much preferable; these should be planted in beds of fresh earth about two feet asunder, for they commonly spread and multiply very fast. If the season is dry, you must water the plants until they have taken root; after which they will require no further care, but to keep them clean from weeds, and in autumn, when their leaves are decayed, the roots should be taken up and dried for use.

The second sort is generally found upon dry chalky soils, in shady places, in divers parts of *England*. The roots of this, which grow wild upon such soils, are much preferable to those of the same kind which are cultivated in gardens, when gathered from their native places of growth, where they are smaller, but have a stronger flavour.

The roots of this plant are composed of long fleshy fibres, which unite in heads. All the leaves of this sort are winged; those at the bottom are composed of broader lobes than those on the stalks, they are notched on their edges and are hairy. The stalks, in their natural situation, seldom grow more than a foot high, but, when the roots are cultivated in a garden, they grow twice that height; these are channelled, hollow, hairy, and garnished at each joint with two winged leaves placed opposite, whose lobes are very narrow and almost entire. At the upper part of the stalk comes out two small side branches opposite; these, and also the principal stalk, are terminated by clusters of flowers, formed into a kind of umbel, which are shaped like those of the first sort, but smaller, and have a tinge of purple on their outside.

This plant may also be propagated by parting the roots either in spring or autumn, as was directed for the first sort, but should always be planted upon a dry, fresh, undunged

foil, in which, though the roots will not make near so great progress as in a rich moist soil, yet they will be much preferable for use. These roots should also be taken up, when the leaves decay in autumn, and preserved dry until used.

The third sort grows naturally in rough stony places in the south of *France*, and in *Italy*, but has been long cultivated in the *English* gardens for ornament.

The roots of this sort are ligneous, and as thick as a man's finger, spreading very wide. The stalks rise three feet high; they are smooth, of a grayish colour, and hollow, garnished at each joint with smooth spear-shaped leaves. The upper part of the stalk sends out branches by pairs, which, with the principal stalk, are terminated with red flowers growing in clusters, which have long tubes, cut into five parts at the top, and from the tube is sent out a spur or heel, like the flowers of Larkspur. It flowers most part of summer, and the seeds ripen accordingly in succession.

There is a variety of this with white flowers, and one with pale flesh-coloured flowers, but they do not differ in any other respect.

It is easily propagated by parting of the roots in autumn, or by sowing of the seeds soon after they are ripe, in a shady border, where the plants will sometimes come up the same autumn, especially if the season proves moist, otherwise they will not appear till the following spring. When these are fit to remove, they should be transplanted into beds at about nine inches or a foot asunder, observing to water them till they have taken new root; after which they will require no farther care, but to keep them clear from weeds, and in autumn they must be transplanted where they are to remain.

These plants grow large, therefore should have room, so are not proper furniture for small gardens. When the seeds of these plants light on joints of old walls or buildings, the plants will come up, and thrive as well as in the ground, and will continue much longer, so the seeds may be scattered between the stones of grottos and such like buildings, where the plants will flower from *May* till the frost stops them, and will make a good appearance.

The fourth sort grows about *Montpelier*, and upon mount *Baldus* in *Italy*. The root of this is ligneous, but not so large as that of the former sort; the stalks rise about two feet high or better, and branch out on each side from the root to within six inches of the top, garnished with leaves which are as narrow as those of Flax. The upper part of the stalk is naked, and terminated by a compact cluster of bright red flowers, shaped like those of the former sort, but smaller.

The fifth sort grows naturally in *Spain* and *Portugal*; it is an annual plant, which perishes soon after the seeds are ripe. The lower leaves, which spread on the ground, are cut into many obtuse segments; the stalks, when the plants are in good ground, will rise near a foot and a half high, but on dry stony soils not half so high, and when they grow out of the joints of old walls, not more than three inches; they are hollow, smooth, and send out branches by pairs from the upper joints, garnished with wing-pointed leaves, whose lobes or segments are very narrow. The stalk and branches are terminated by tufts of flowers shaped like those of the Garden Valerian, but smaller, and have a flesh-coloured tinge at the top. The seeds have a down, which helps to spread them, so it propagates without care.

The sixth sort grows naturally on the *Pyrenean* mountains; this has a fibrous perennial root, from which come out many heart-shaped leaves standing upon foot-stalks more than a foot in length. The leaves are bluntly sawed on their edges, smooth, and of a bright green on their upper side,

but their under side is pale and a little hairy. The stalks rise three feet high; they are hollow, channelled, and send out branches opposite toward the top, garnished with leaves placed opposite, which are shaped like those below, but pointed, and frequently at the top there are three leaves placed round the stalk, standing upon short foot-stalks. The stalk and branches are terminated by pale flesh-coloured flowers, disposed in form of umbels, which have very short spurs or heels. The seeds ripen in *August*, which are crowned with down, whereby they are transported to a distance.

This plant delights in shade and a moist soil; it may be propagated by sowing of the seeds on a shady border soon after they are ripe, and when the plants come up, they should be treated in the same way as is before directed for the third sort.

The seventh sort grows naturally upon the *Alps* and *Styrian* mountains; this was sent me by *Dr. Allione* from *Turin*, who gathered it on the *Alps* near that place; it is a very humble plant. The stalks trail upon the ground among the moss, and put out roots at their joints, which swell into knobs or tubers. The leaves are oblong, oval, and entire; the flower-stalks rise three or four inches high, garnished with two or three pair of small oval leaves; the flowers are small, of a pale incarnate colour, and are formed in a loose spike sitting very close to the stalk.

This plant is difficult to preserve in gardens, for it naturally grows upon rocky mountains which are covered with moss, where the snow continues six or seven months, so it requires a very cold situation and a stony soil.

The eighth sort grows naturally in *Siberia*; this is a biennial plant, which flowers and produces seeds the second year, and then decays. The leaves of this are winged; the lobes of the lower leaves are oblong, oval, ending in roundish points; the stalks rise a foot high, garnished with leaves, composed of four or five pair of lobes, terminated by a broad one which is cut into three or five points. The lobes are acute-pointed; the leaves are smooth, placed by pairs, and sit close to the stalks. The upper part of the stalk has two pair of branches; the lower pair are near three inches long, but the upper are not half that length; these, and also the principal stalk, are terminated by bright yellow flowers, collected in a sort of umbel, shaped like those of the first sort. It is propagated by seeds, which should be sown where the plants are to remain; this may be performed either in autumn, soon after they are ripe, or in the spring; they have succeeded with me equally at both seasons. When the plants come up, they must be thinned where they are too close, and kept clean from weeds, which is all the culture they require.

The ninth sort is the common Corn-sallad which is cultivated in gardens, but is found growing naturally upon arable land amongst the Corn, in many parts of *England*; this is an annual plant, which dies when it has perfected its seeds. The lower leaves of this are oblong, and broad at their points, which are rounded, and narrowed at their base, where they embrace each other. From between the leaves arises an angular stalk, from three to eight or nine inches high, which divides into two branches which spread from each other, and these both divide again into two other in like manner, garnished with leaves shaped like those at the bottom, but smaller, placed by pairs at each joint. The branches are terminated by clusters of white flowers, shaped like those of the other species, which are succeeded by pretty large roundish seeds a little compressed on one side. The seeds are very apt to drop before they have changed colour.

It is cultivated as a sallad-herb for the spring, but, having a strong taste which is not agreeable to many palates, it is not so much in use as it was formerly; it is propagated by

by seeds, which should be sown the latter end of August, then the first rains will bring up the plants, which should be hoed to thin them where they are too close, and to destroy the weeds. Early in the spring the plants will be fit for use. The younger the plants are when used, the less strong will be their taste, so they may supply the table in a scarcity of other herbs. When the seeds of this sort are sown in the spring, if the season proves dry, the plants will not appear till autumn or the spring following; besides, in summer the herb is not so fit for use. I have known the seeds of this plant lie in the ground many years, when they have happened to be buried deep, and upon being turned up to the air, the plants have come up as thick as if the seeds had been newly sown.

There are two other species of this which grow naturally in England, but, as they are seldom admitted into gardens, I have not enumerated them; these are by some supposed to be only accidental varieties, but I have sown them all several years, and have never found either of them alter.

The tenth sort grows naturally in *Candia*; this is an annual plant, whose stalks rise six or eight inches high, and divide by pairs like the former. The leaves are much narrower than those of the former, end in acute points, and are sawed on their edges: the flowers are like those of the former sort, but have a swollen bladder empalement, which incloses the seeds.

The eleventh sort grows naturally in *Italy*. The leaves at bottom are long, round-pointed, and deeply notched on their edges; the stalk rises near a foot high, sending out branches opposite; the upper part divides by pairs in the same manner as the former. The flowers are collected in globular heads, of an herbaceous white colour, and are succeeded by starry fruit having six indentures. This and the former sort are supposed to be only varieties arising from the same seeds, but I have sown them more than thirty years, and have not observed either of them vary.

The twelfth sort grows naturally in the arable fields in *Sicily* and *Spain*; this is an annual plant. The stalks are channelled, of a purplish colour, eight or nine inches high, garnished by oval smooth leaves placed by pairs at each joint, sitting close to the stalks, of a lucid green. From each side of the stalk springs out slender branches, but the upper part divides into two spreading branches like the other sorts. The joints are swelling, and the branches divide again by pairs, which are terminated by clusters of red flowers, shaped like those of the red Valerian, but larger; they have two leaves close under the bunches, embracing the stalks with their base. When the flowers are past, the fruit stretches out in shape of a *Cornucopia*, or horn of plenty.

These three sorts are propagated by seeds, which should be sown in autumn where the plants are to remain. When these come up, they will require no other culture but to thin them where they are too close, and keep them clean from weeds. The plants, which rise in autumn, will live through the winter, and come early to flower the following summer, so will produce good seeds; whereas those which are sown in the spring, do not ripen their seeds unless the season proves warm.

VALERIANA GRÆCA. See Polemonium.

VALERIANELLA. See VALERIANA.

VANILLA. Plum. Gen. Nov. 25. tab. 28.

The Characters are,

It has a single stalk. The flowers are included in sheaths sitting upon the germen, and have no empalement; they have five oblong petals which spread open very wide, with turbinated nectariums, whose base are tubulous, situated on the back side of the petals; their brims are oblique and bifid; the upper lip is short and trifid; the under one runs out in a long point; they have two very short stamina sitting upon the pointal, and the summits are

fastened to the upper lip of the nectarium; they have long, slender, contorted germen, situated under the flower, supporting a short style fastened to the upper lip of the nectarium, crowned by an obsolete stigma. The germen afterward becomes a long, taper, fleshy pod, including many small seeds.

The Species are,

1. VANILLA foliis oblongo-ovatis mucronatis, nervosis, floribus alternis. Vanilla with oblong, oval, acute-pointed, veined leaves, and flowers growing alternately.

2. VANILLA foliis oblongis obtusis, compressis articulatis, floribus alaribus. Vanilla with oblong, blunt, compressed, jointed leaves, and flowers proceeding from the sides of the stalks.

The first sort is that which the Spaniards cultivate in the *West Indies*, which we shall describe hereafter.

The second sort was sent me from *Carthagena* in *New Spain*, where it grows naturally; this has a climbing stalk, sending out roots from the joints, which fasten to the stems of trees or any neighbouring support, and climb to a great height. The leaves, which come out singly at each joint, are oblong, smooth, and jointed. The flowers come out from the side of the branches, shaped like those of the great Bee Orchis, but longer: the galea or helmet of the flower is of a pale Pink colour, and the labia is purple. This plant flowered in the *Chelsea* garden, but wanting its proper support, it lived but one year.

There are two or three varieties of the first sort, which differ in the colour of their flowers and the length of their pods; and there are many other species which grow naturally in both the *Indies*, which have been brought to this genus, but those abovementioned are all I have seen growing.

The plant, which produces the fruit called Vanilla or Bannilla, by the Spaniards, hath a trailing stem, somewhat like common Ivy but not so woody, which fastens itself to whatever tree grows near it, by small fibres or roots produced at every joint, which fasten to the bark of the tree, and by which the plants are often nourished, when they are cut or broken off from the root a considerable height from the ground, in like manner as the Ivy is often seen in *England*. The leaves are as large as those of the Common Laurel, but are not of so thick a substance; they are produced alternately at every joint, of a lively green colour on the upper side, but paler underneath. The stems of these plants shoot into many branches, which fasten themselves also to the branches of the trees, by which means they rise to the height of eighteen or twenty feet, and spread quite over some of the smaller trees, to which they are joined. The flowers are of a greenish yellow colour, mixed with white, which, when fallen, are succeeded by the fruit, which are six or seven inches long.

The sort which is manufactured, grows not only in the *Bay of Campeachy*, but also at *Carthagena*, at the *Caracas*, *Honduras*, *Darien*, and *Cayan*, at all which places the fruit is gathered and preserved, but is rarely found in any of the *English* settlements in *America*, though it might be easily carried thither and propagated; for the shoots of these plants are full of juice, so may be easily transported, because they will continue fresh out of the ground for several months. I had some branches of this plant, which were gathered by Mr. Robert Millar at *Campeachy*, and sent over between papers by way of sample, and had been at least six months gathered when I received them; but upon opening the papers I found the leaves rotten, with the moisture contained in them, and the paper was also perished with it, but the stems appeared fresh; upon which I planted some of them in small pots, and plunged them into a hot-bed of tanners bark, where they soon put out leaves, and sent forth roots from their joints; but, as these plants naturally fasten themselves to the stems of the trees, in the woods where they

grow naturally, so it is with great difficulty that they are kept alive, when they have not the same support; therefore, whoever would preserve any of these plants in *Europe*, should plant them in tubs of earth, near the stem of some vigorous *American* tree, which requires a stove, and can bear a great deal of water, because the *Vanillas* must be plentifully watered in the summer season, otherwise they will not thrive. They require also to be shaded from the sun by trees, so that if these are planted at the foot of the *Hernandia*, or *Jack-in-a-Box*, whose leaves are very large, and afford a good shade, they will succeed better than when they are exposed in single pots alone; and as these plants require the same degree of heat in winter, they will agree well together.

When these plants are designed for propagation in the warm parts of *America*, there is nothing more required than to make cuttings of about three or four joints in length, which should be planted close to the stems of trees, in low marshy places, and to keep down other troublesome plants, which, if permitted to grow about the cuttings before they are well rooted, would overbear and destroy them; but after they are established, and have fastened their shoots to the stems of the trees, they are not in much danger of being injured by neighbouring plants, though, when the ground is kept clear from weeds, the plants will be much better nourished.

These plants do not produce flowers until they are grown strong; so that the inhabitants affirm, that it is six or seven years from the planting to the time of their bearing fruit; but when they begin to flower and fruit, they continue for several years bearing, and this without any culture; and as it is a commodity which bears a good price, it is well worth cultivating in several of the *English* settlements, especially as they will grow on moist woody places, where the land is not cleared from timber.

The method used to preserve the fruit is, when it turns of a yellow colour, and begins to open, to gather it, and lay it in small heaps to ferment two or three days, in the same manner as is practised for the *Cocoa* or *Chocolate* pods; then they spread them in the sun to dry, and when they are about half dried, they flat them with their hands, and afterwards rub them over with the oil of *Palma Christi*, or of the *Cocoa*; then they expose them to the sun again to dry, and afterward they rub them over with oil a second time; then they put them in small bundles, covering them with the leaves of the *Indian Reed* to screen them from air.

These plants produce but one crop of fruit in a year, which is commonly ripe in *May*, fit for gathering, for they do not let them remain on the plants to be perfectly mature, because then they are not fit for use; but when they are about half changed yellow, they esteem them better for keeping than when they are changed to a dark brown colour; at which time the fruit splits, and shews a great quantity of small seeds, which are inclosed within it. While the fruit is green, it affords no remarkable scent, but as it ripens, it emits a most grateful aromack scent. When the fruit begins to open, the birds attack them and devour all the seeds very greedily, but do not eat any other part of the fruit.

The fruit which are brought to *Europe*, are of a dark brown colour, about six inches long, and scarce an inch broad; they are wrinkled on the outside, and full of a vast number of black seeds, like grains of sand, of a pleasant smell, like *Balsam of Peru*.

The fruit is only used in *England*, as an ingredient in *Chocolate*, to which it gives a pleasant flavour to some palates, but to others it is very disagreeable; but the *Spanish* physicians in *America* use it in medicine, and esteem it grateful to the stomach and brain, for expelling of wind, to pro-

voke urine, to resist poison, and cure the bite of venomous animals.

As this plant is so easily propagated by cuttings, it is very strange that the inhabitants of *America* should neglect to cultivate it, especially as it is an ingredient in their *Chocolate*, which is so much drank all over *America*; but, as the *English* have in a manner quite neglected the culture of the *Cocoa*, it is no wonder they should neglect this, since the former was cultivated in great plenty by the *Spaniards* in *Jamaica*, while that island remained in their possession; so that the *English* had an example before them, if they would have followed it, whereas the *Vanilla* was not found growing there; and therefore it is not to be supposed, that the persons, who were so indolent as to quit the culture of many valuable plants then growing on the spot, should be at the trouble of introducing any new ones.

VEGETABLE, a term applied to all plants, considered as capable of growth, *i. e.* to all natural bodies, which have parts organically formed for generation and accretion, but not for sensation.

VEGETATION is the act whereby plants receive nourishment and grow, and signifies the way of growth, or increase of bulk, parts, and dimensions proper to all trees, shrubs, herbs, plants, &c. *a.*

In some trees it is chiefly the roots which vegetate; so that if they are cut into as many pieces as reasonably may be, if these pieces are but planted in the ground, they quickly grow, as is seen in the *Elm*, and many other trees.

In some it is seated both in the roots, and all over the trunk and branches, as in the *Willow* and other kinds, which, if cut into a thousand pieces, it is scarce possible to destroy or kill them, unless they are stripped of both their barks; for if they are in the earth but the length of three or four inches, they will put out roots and branches, so will certainly grow again.

The use of this principle of life is accounted to be for the concoction of the indigested salts, which ascend through the roots, where they are supposed to assimilate the nature of the tree they are helping to form, though perhaps the root may likewise assist in the work.

These things being presupposed in the spring of the year, as soon as the sun begins to warm the earth, and the rains melt the latent salts, the whole work of vegetation is set on foot; then the emulgent fibres seek for food, which has been prepared as aforesaid.

There are some who suppose that subterraneous fires are concerned in the work of vegetation, or the growth of plants; yet as, upon the best observation that can be made, none can pretend to have discovered any heat or fumigation to issue from the bowels of the earth, adequate to the meanest artificial fire, it is plain that the sun is the principle, and so may be called the Father of Vegetation, and the earth the Mother, the rain and air being necessary co-efficients in this surprising work.

The curious *Malpighius* has very accurately delivered the process of nature in the vegetation of plants to the effect following:

The ovum or seed of the plant being excluded out of the ovary (which is called the pod or husk), and requiring farther fostering and brooding, is committed to the earth. The earth, like a kind mother, having received it into her bosom, does not only perform the office of incubation, by her own warm vapours and exhalations, in conjunction with the heat of the sun, but gradually supplies what the seed requires to its farther growth, as abounding every-where with canals and sinuses, in which the dew and rain water, impregnated with fertile salts, glide like the chyle and blood in the arteries, &c. of animals.

This moisture, meeting with the new-deposited feed, is percolated or strained through the pores or pipes of the outer rind or husk, answering to the secundines of fœtuses, on the inside whereof lie one or more, commonly two, thick seminal leaves, corresponding to the placenta in women, and the cotyledons in brutes.

The seed-leaves consist of a great number of little vesiculæ or bladders, with a tube corresponding to the navel-strings in animals.

The moisture of the earth, strained through the rind of the seed, is received into these vesiculæ, which causes a slight fermentation with the proper juice before contained therein.

This fermented liquor is conveyed by the umbilical vessel to the trunk of the little plant, and to the gem or bud which is contiguous to it, upon which a vegetation and increase of the plant succeed.

As to the vegetable matter, or the food where the plants grow, there is some doubt. It hath been a general opinion amongst almost all the modern naturalists, that the vegetation of plants, and even of minerals too, is principally owing to water, which not only serves as a vehicle to convey to them the fine rich earth, &c. proper for their nourishment, but being transmuted into the body of the plant, affords the greatest part, if not all the matter with which they are nourished, and by which they grow and increase in bigness. This opinion is countenanced by very great names, particularly by the ingenious Dr. Woodward, who, in order to ascertain this point, made many curious experiments; an account of which may be seen in the Transactions of the Royal Society.

The vegetable matter being very fine and light, is surprisingly apt and disposed to attend water in all its motions, and follow it into each of its recesses, as appears from many instances, percolate it with all the care imaginable, filter it with ever so many filtrations, yet some terrestrial matter will remain.

Dr. Woodward filtered water through several sheets of thick paper, and after that through very close fine cloth, twelve times double, and this over and over; and yet a considerable quantity of this matter discovered itself in the water after all.

Now if it thus passes interstices that are so very small and fine along with the water, it is less strange it should attend it in its passage through the ducts and passages of plants. It is true, filtering and distilling of water interrupts, and makes it quit some of the earthy matter it was before impregnated withal; but then that which continues with the water after this, is fine and light, and such consequently as is in a peculiar manner fit for the growth and nourishment of vegetables.

And this is the case of rain water. The quantity of terrestrial matter it bears up into the atmosphere is not great; but what it doth bear up is chiefly of that light kind, or vegetable matter, and that too perfectly dissolved, and reduced to single corpuscles, all fit to enter the tubes and vessels of plants; on which account it is that this water is so very fertile and prolifick.

Hence it is, that in agriculture, be the earth never so rich, good, and fit for the production of Corn, or other vegetables, little will come of it, unless the particles be separated and loose; and it is on this account such pains are bestowed in the digging, tilling, ploughing, fallowing, harrowing, and breaking the clodded lumps of earth; and it is the same way that sea salt, nitre, and other salts promote vegetation.

It is evident to observation, how apt all sorts of salts are to be wrought upon by moisture, how easily they run with it; and when these are drawn off, and have deserted the

lumps with which they are incorporated, they must moulder immediately, and fall asunder in course.

Lime likewise is in the same way serviceable in this affair. The husbandmen say, it does not fatten, but only mellows the ground; by which they mean, it doth not contain any thing in itself, that is of the same nature with the vegetable mould, or afford any matter fit for the formation of plants, but merely softens and relaxes the earth; by that means rendering it more capable of entering the seeds and vegetables set in it, in order to their nourishment, than otherwise it would have been.

If therefore the soil, wherein any vegetable or seed is planted, contains all or most of the ingredients, and those in due quantity, it will grow and thrive, otherwise it will not. If there be not as many sorts of corpuscles as are requisite for the constitution of the main and more essential parts of the plant, it will not prosper at all. If there are these, and not in sufficient plenty, it will never arrive to its natural stature; or if any of the less necessary and essential corpuscles are wanting, there will be some failure in the plant. It will be defective in smell, taste, colour, and some other way.

Indeed it is inconceivable, how one uniform homogeneous matter, having its principles, or original parts, of the same substance, constitution, magnitude, figure, and gravity, should constitute bodies so unlike in all those respects, as vegetables of different kinds are, nay even as the different parts of the same vegetable; that one should carry a resinous, another a milky, a third a yellow, and a fourth a red juice in its veins; that one affords a fragrant, another an offensive smell; one sweet to the taste, another acid, bitter, acerb, austere, &c. that one should be nourishing, another poisonous; one purging, another astringent; and these all receive their nourishment from the same soil.

But a proof of this matter is, that the soil once proper for the protection of some sort of vegetables, does not ever continue so, but in tract of time loses its property; sooner in some lands, and later in others.

As for example: If Wheat be sown upon land proper for that grain, the first crop will succeed very well, and perhaps the second and third, as long as the ground is in heart, as the farmers call it; but in a few years it will produce no more, if sowed with that Corn; some other grain it may, as Barley; and after this has been sown so oft, that the land can bring no more of it, it may afterward yield some good Oats, and perhaps Peas after them.

At length it becomes barren; the vegetative matter that at first it abounded with, being reduced by the successive crops, and most of it borne off, each sort of grain takes out that peculiar matter that is proper for its own nourishment.

It may be brought to bear another series of the same vegetables, but not till it is supplied with another fund of matter of the like sort with what it first contained, either by the ground's lying fallow for some time, till the rain hath poured a fresh stock upon it, or by the manuring it.

That this supply is of the like sort, is evident by the several manures found best to promote the vegetation, which are chiefly either of parts of vegetables, or of animals; of animals, which either derive their own nourishment immediately from vegetable bodies, or from other animals that do so; in particular, the blood, excrements, and urine of animals that do so; shaving of horns and hoofs, hair, feathers, calcined shells, lees of wine and beer, ashes of all sorts of vegetable bodies, leaves, straw, roots, and stubble, turned into the earth by ploughing, or otherwise, to rot and dissolve there.

These are our best manures, and, being vegetable substances, when refunded back again into the earth, serve for the formation of other bodies.

But to apply this to gardens, where the trees, shrubs, and herbs, after their having continued in one station till they have derived thence the greatest part of the matter fit for their increase, will decay and degenerate, unless either fresh earth, or some fit manure, be applied to them.

It is true they may maintain themselves there for some time, by sending forth roots farther and farther, to an extent all around, to fetch in more provision; but at last they must have a fresh supply brought to them, or they will decay.

All these instances argue a particular terrestrial matter, and not water, for the subject to which plants owe their increase; were it water only, there would be no need of manures, or changing the species; the rain falls in all places, in this field and in that, indifferently, on one side of an orchard or garden, as well as the other; nor could there be any reason, why a tract of land should yield Wheat one year and not the next, since the rain showers down all alike upon the earth.

That the concurrence of heat is really necessary in vegetation, appears from all the experiments, and also from nature, from the fields and forests, gardens and orchards. We see in autumn, as the sun's power is gradually less and less, so its effect on plants is emitted, and vegetation slackens by little and little

Its failure is first discernible in trees, which, being raised highest above the earth, require a more intense heat to elevate the water charged with nourishment to their tops; so that, for want of fresh support and nutriment, they shed their leaves, unless supported by a very firm and hard constitution, as our Ever-greens are. Next, the shrubs part with theirs; then the herbs and lower tribes, the heat at length not being sufficient to supply even to these, though so near the earth, the fund of their nourishment.

As the heat returns the succeeding spring, they all recruit again, and are furnished with fresh supplies and verdure; but first, those which are lowest and nearest the earth, and that require a less degree of heat to raise the water with its earthy charge into them, then the shrubs and higher vegetables in their turn, and lastly the trees.

As the heat increases, it grows too powerful, and hurries the matter with too great rapidity through the finer and more tender plants; these therefore go off and decay, and others, that are more hardy and vigorous, and require a greater degree of heat, succeed in their order. By which mechanism, provident nature furnishes us with a very various and different entertainment, and what is best suited to each season all the year round.

As the heat of the several seasons affords us a different face of things, the several distant climates shew the different scenes of nature, and productions of the earth.

The hotter countries ordinarily yield the largest and tallest trees, and those too in a much greater variety than the colder; even those plants common to both, attain to a much greater bulk in the southern than in the northern climates.

Nay, there are some regions so cold, that they raise no vegetables at all to a considerable size; this we learn from *Greenland*, *Iceland*, and other parts of like cold situation and condition: in these there are no trees, and the shrubs are poor, little, and low.

Again, in the warmer climates, and such as furnish trees and the large vegetables, if there happen a remission or diminution of the usual heat, their productions are impeded in proportion. Our own summers give us proof enough of this, for though at such times there is heat sufficient to raise the vegetative matter into the lower plants, as Wheat, Barley, Peas, and the like, and we have plenty of Strawberries, Raspberries, Gooseberries, Currants, and the fruits

of such vegetables as are low, and near the earth, and a moderate store of Cherries, Plumbs, &c. and some others, that grow at something of a greater height, yet our Apples, Pears, Peaches, Nectarines, and Grapes, and the production of warmer countries, have been fewer, and those not so thoroughly ripened and brought to perfection, as they are in more benign seasons.

Nor is it that heat only which promotes vegetation, but any other indifferently, according to its power and degree, as we find from our stoves, hot-beds, &c.

And by the rightly adapting of these artificial heats, the *English* gardeners have of late years so much improved their art, as in a great measure to supply the want of natural heat, and to vie with the people who inhabit countries several degrees south of *England*, in the early products of esculent plants, and the accelerating and ripening the fruits of the warmest climates. And as the knowledge of vegetation is improved, and the practitioners of the art are better acquainted with the theory, it may be hoped the art may be farther extended and improved; therefore it is highly necessary, that the theory of vegetation should be studied by every person who proposes to make any proficiency in gardening and agriculture.

VELLA. *Lin. Gen. Plant.* 714. *Spanish Cress.*

The Characters are,

The empalement of the flower is cylindrical, and composed of four linear obtuse leaves, which drop off. The flower has four petals, placed in form of a cross, whose tails are the length of the empalement, and six stamina of the same length, two of which are a little shorter, terminated by single summits, and an oval germen, supporting a conical style, crowned by a single stigma. The germen afterward turns to a globular capsule with two cells, divided by an intermediate partition twice as large as the pod, oval, erect, stretching beyond the capsule, each cell containing one seed.

The Species are,

1. VELLA *foliis pinnatifidis, siliculis pendulis.* *Lin. Sp. Plant.* 641. Vella with wing-pointed leaves, and hanging pods.

2. VELLA *foliis integris siliculis erectis.* *Lin. Sp. Plant.* 641. Vella with entire leaves, and erect pods.

The first sort grows naturally in *Valencia*; it is an annual plant, which seldom rises more than one foot high. The stalk divides toward the top into several branches, each ending in a loose spike of flowers, which are followed by round swelling pods, having a leafy border or crest on the top, which is hollowed like a helmet. The pod opens with two valves, and has two cells, which contain roundish seeds like those of Mustard. The leaves are jagged, and end in many points.

This plant is preserved in botanick gardens for variety, but as it is not very beautiful, nor of use, it is seldom cultivated in other gardens. If the seeds are permitted to scatter, the plants will come up and thrive very well; or if they are sown in autumn, they will succeed much better than those which are sown in the spring; for when the season proves dry, those seeds which are sown in the spring frequently lie in the ground till the following autumn, before the plants appear; whereas those which are sown in autumn, always come up soon after, or early in the spring, so will more certainly produce ripe seeds. The seeds should be sown where the plants are to remain, and if they are kept clean from weeds, and thinned where they are too close, they will require no other culture.

The second sort grows naturally in *Spain*. The leaves of this are entire, hairy, and sit close to the stalk; they are of a grayish colour. The stalks become ligneous, and rise about two feet high, terminated by roundish bunches of pale yellow flowers, which stretch out in length; the flowers have four cross-shaped petals, and are succeeded by

Pods like the former. This plant will continue two or three years; it is propagated by seeds in the same manner as the former.

VERATRUM. *Tourn. Inst. R. H. 272. tab. 145.* White Hellebore.

The Characters are,

It has hermaphrodite and male flowers intermixed in the same spike. The flowers have no empalement; they have six oblong spear-shaped petals, which are permanent, and six awl-shaped stamina sitting on the point of the germen, spreading asunder, terminated by quadrangular summits; they have three oblong erect germen sitting upon the style, which are scarce visible, crowned by a single spreading stigma. The germen afterward becomes three oblong, erect, compressed capsules with one cell, opening on the inside, including many oblong, compressed, membranaceous seeds. The male flowers have the same characters of the hermaphrodite, but are barren.

The Species are,

1. VERATRUM *racemo supradecomposito, corollis erectis.* *Lin. Sp. Plant. 1044.* White Hellebore with a decomposed spike, and erect petals; or White Hellebore with a greenish flower.

2. VERATRUM *racemo composito, corollis patentissimis.* *Lin. Sp. Plant. 1044.* White Hellebore with a compound spike, and very spreading petals; or White Hellebore with a dark red flower.

3. VERATRUM *racemo simplicissimo, foliis sessilibus.* *Lin. Sp. Plant. 1044.* White Hellebore with a single spike, and leaves sitting close to the stalk.

4. VERATRUM *racemo simplicissimo, corollis patentibus, staminibus longioribus.* White Hellebore with a single spike of flowers, spreading petals, and longer stamina.

The first sort grows naturally on the mountains in *Austria, Helvetia, and Greece.* The root is perennial, composed of many thick fibres gathered into a head; the leaves are ten inches long, and five broad in the middle, rounded at the points, having many longitudinal plaits like those of Gentian; the stalks rise three or four feet high, and branch out on every side almost their whole length; under each of these branches is placed a narrow plaited leaf, which diminishes in its size as it is nearer the top of the stalk. The branches and principal stalk are terminated by spikes of flowers set very close together, which are composed of six green erect petals; in their center is situated three obtuse germen. From the point of these arise six stamina, which spread asunder, terminated by four-cornered summits. These are succeeded by oblong compressed capsules with one cell, filled with membranaceous seeds.

The second sort grows naturally in *Hungary and Siberia;* it has a perennial root like the former. The leaves are longer and thinner than those of the first sort; they are plaited in the like manner, but are of a yellowish green colour, and appear sooner in the spring; the stalks rise higher than those of the former. It has fewer leaves upon it, and does not branch into so many spikes. The flowers of this are of a dark red colour, and the petals spread open flat, in which it differs from the former.

The third sort grows naturally in *Virginia,* and other parts of *North America,* where it is sometimes called Rattle-snake Root. The root of this is tuberous; the leaves are oblong, and shaped like those of Plantain, having several longitudinal furrows or plaits, spreading themselves on the ground. Between these come out a single stalk which rises near a foot high, having a few very small leaves or sheaths, placed alternately; and at the top the flowers are produced in a single, thick, close spike; they are small, and of a yellowish white colour, but are rarely succeeded by seeds here.

The fourth sort was sent me from *Philadelphia* by Mr. *John Bartram,* who found it growing naturally in that coun-

try: The root of this is composed of thick fleshy fibres; the leaves are oblong, oval, of a light green colour, having six longitudinal veins or plaits, spreading on the ground, rounded at their points, and continue all the year. In the center of the leaves springs up a single erect stalk a foot high, having a few vestiges, or small leaves, standing alternately close to the stalk, which end in acute points. The stalk is terminated by a thick obtuse spike of dark red flowers, whose petals spread open flat. In the center of the petals is situated three obtuse germen joined together, from whose point arises six stamina, which spread asunder, and are longer than the petals; these are terminated by four-cornered summits, of a purple colour. This plant flowers the latter end of *June,* and in warm seasons the seeds will ripen here.

The first of these plants is that which is ordered for medicinal use, and is by much the stronger and more acid plant of the two; for when both sorts are placed near each other, the snails will entirely devour the leaves of the second sort, when at the same time they scarcely touch those of the first.

The plants are also very pretty ornaments, when planted in the middle of open borders of the pleasure garden; for if they are placed near hedges or walls, where snails generally harbour, they will greatly deface the leaves, especially of the second sort, by eating them full of holes before they are unfolded; and as a great part of the beauty of these plants is in their broad-folded leaves, so, when they are thus defaced, the plants make but an indifferent appearance.

Both these sorts may be propagated by parting their roots in autumn, when their leaves decay; but they should not be parted too small, for that will prevent their flowering the following summer; these heads should be planted in a light fresh soil, in which they will thrive exceedingly, and produce strong spikes of flowers. The roots should not be removed oftener than once in four or five years, by which time (if they like the soil) they will be very strong, and produce many heads to be taken off; but if they are frequently transplanted, it will prevent their increasing, and cause them to flower very weak.

They may also be propagated by seeds, which should be sown as soon as ripe, either in a bed or box, filled with fresh light earth. In the spring the plants will appear, at which time, if the season proves dry, you should now and then refresh them with water, which will greatly promote their growth; you must carefully clear them from weeds, which, if permitted to grow, will soon overspread and destroy these plants while young. The autumn following, when their leaves decay, you should prepare a bed of fresh light earth; then carefully take up the young plants (observing not to break their roots), and plant them therein about six inches square, where they may remain until they are strong enough to flower, when they should be transplanted into the borders of the pleasure-garden; but, as these plants seldom flower in less than four years from seeds, this method of propagating them is not much practised.

The two *American* sorts are at present scarce in the *English* gardens, but, as they are hardy enough to thrive in the open air, in a few years they may be more plenty; these may be propagated by offsets or seeds, in the same manner as the former.

VERBASCUM. *Tourn. Inst. R. H. 146. tab. 161.* Mullein.

The Characters are,

The flower has a small permanent empalement of one leaf, cut into five parts; it hath one wheel-shaped petal, with a very short cylindrical tube, the brim cut into five oval obtuse segments, and five awl shaped stamina, which are shorter than the petal, terminated by roundish, compressed, erect summits, with a roundish germen, supporting a slender style inclining to the stamina, crowned by

by a thick obtuse stigma. The germen afterward becomes a roundish capsule with two cells, opening at the top, having on half oval receptacle fixed to the partition, filled with angular seeds.

The Species are,

1. VERBASCUM foliis decurrentibus utrinque tomentosis. Vir. Cliff. 13. Mullein with running leaves, which are woolly on both sides; or white Mullein, Hig-taper, or Cows-lungwort.

2. VERBASCUM foliis cuneiformi-oblongis. Hort. Upsal. 45. Mullein with oblong wedge-shaped leaves.

3. VERBASCUM foliis cordato-oblongis, subtus incanis, spicis racemosis. Mullein with oblong heart-shaped leaves which are hoary on their under side, and branching spikes of flowers; or Female Mullein.

4. VERBASCUM foliis radicalibus ovatis petiolatis, caulinis oblongis sessilibus subtus tomentosis serratis. Mullein with oval lower leaves growing on foot-stalks, but those on the stalks oblong, sawed, woolly on their under side, and sitting close.

5. VERBASCUM foliis ovato-acutis utrinque tomentosis, floribus in spicâ densissimâ sessilibus. Haller. Helvet. 507. Mullein with oval acute-pointed leaves which are woolly on both sides, and flowers disposed in thick spikes sitting close to the stalk; or Female Mullein with a large yellow flower.

6. VERBASCUM foliis serratis supernè rugosis, infernè subhirsutis, petiolis ramosis, staminum barbâ purpurascente. Haller. Helvet. 511. Mullein with sawed leaves whose upper sides are rough, those on the under side hairy, branching foot-stalks, and purplish beards to the stamina; commonly called Sage-leaved black Mullein.

7. VERBASCUM foliis radicalibus oblongis sinuatis undatis tomentosis, caulinis cordatis amplexicaulibus nudiusculis. Lin. Sp. Plant. 178. Mullein with the lower leaves oblong, sinuated, woolly, waved, and those on the stalks heart-shaped, embracing the stalks with their base, and almost naked; or black Mullein with a horned Poppy leaf.

8. VERBASCUM foliis amplexicaulibus oblongis glabris, pedunculis solitariis. Hort. Upsal. 46. Mullein with oblong smooth leaves embracing the stalks, and single foot-stalks to the flowers; or white Moth Mullein.

9. VERBASCUM foliis radicalibus pinnato-sinuatis, caulinis dentatis acuminatis semi-amplexicaulibus, pedunculis solitariis. Mullein with the lower leaves jagged like wings, those on the stalks acute-pointed, indented, and half embracing the stalks, and single foot-stalks to the flowers; yellow Moth Mullein.

10. VERBASCUM foliis ovato-oblongis obsolete crenatis, utrinque virentibus petiolatis, caule ramoso. Mullein with oblong oval leaves having obsolete crenatures, and both sides green, with a branching stalk; or Moth Mullein with an iron-coloured flower.

11. VERBASCUM foliis radicalibus oblongis integerrimis, utrinque viridibus, caulinis acutis sessilibus, pedunculis aggregatis. Mullein with oblong, entire, lower leaves which are green on both sides, those on the stalks acute-pointed, sitting close, and clustered foot-stalks.

12. VERBASCUM foliis ovatis nudis crenatis radicalibus, caule subnudo racemoso. Lin. Sp. Plant. 178. Mullein with naked, oval, crenated, lower leaves, and an almost naked branching stalk; or purple Moth Mullein.

13. VERBASCUM foliis lanatis radicalibus, scapo undo. Lin. Sp. Plant. 179. Mullein with woolly lower leaves, and a naked stalk; commonly called Borage-leaved Auricula.

The first is the common Mullein or Hig-taper which is used in medicine, which grows naturally by the side of highways and on banks in many parts of England; it is a biennial plant, which perishes soon after it has perfected seeds. The lower leaves, which spread on the ground, are long and broad, very woolly, and of a yellowish white co-

lour, having scarce any foot-stalks. The stalk rises four or five feet high, the lower part is garnished with leaves, shaped like those below but smaller, whose base half embraces the stalk, and have wings running along the stalk. The upper part is closely garnished with yellow flowers, sitting very close, formed into a long thick spike, composed of five obtuse roundish petals, having five stamina in the center, of an agreeable odour.

The second sort grows naturally in some parts of England; I have observed it in plenty in some parts of Nottinghamshire: this is also a biennial plant. The lower leaves are oblong, indented on their edges, ending in acute points. The stalk rises three or four feet high, sending out from every joint short spikes of small yellow flowers, which are paler than those of the first, and have a pleasanter odour. At the base of each spike is situated a small, oblong, acute-pointed leaf, covered with a white powder which washes off. When the flowers decay, they are succeeded by oval capsules, filled with small seeds, which ripen in autumn.

The third sort grows naturally in Italy and Spain. The lower leaves of this are broad, rough on their upper side, and a little hoary; their under side is pale and woolly. The stalk rises six or seven feet high, sending out some erect side branches; the flowers are disposed in long branching spikes; they are white, having the most agreeable scent of all the species.

The fourth sort has oval leaves, standing upon thick foot-stalks; they are of a soft texture, of a pale green on their upper side, but hoary on their under. The stalk rises three or four feet high; the upper part is garnished with smaller leaves of the same shape with those below; the upper part of the stalk is garnished with pale yellow flowers, disposed in a loose spike, having small leaves intermixed with the flowers.

The fifth sort has oval leaves which terminate in a point; they are of a yellowish green colour, and woolly on both sides. The stalks rise about four feet high; they are of a purplish colour, covered with a hoary down. The flowers sit very close to the stalk, forming a very thick spike, having no leaves between them; they are much larger than those of the first sort, and are of a deeper yellow colour.

The sixth sort grows naturally in several parts of England. The lower leaves of this are spear-shaped, and rounded at the foot-stalk, where they are indented like a heart; they are of a pale green on their upper side, and hoary on their under, indented on their edges; those upon the stalk are oblong, acute-pointed, and sawed. The stalks rise three or four feet high, the upper part ending in a long spike of yellow flowers, which stand in short spikes or clusters; these have purplish stamina which are bearded; they have an agreeable odour at a small distance, but, when smelt too near, become less agreeable.

The seventh sort grows naturally in Italy, Greece, and also upon the rocks at Gibraltar. The lower leaves are oblong, sinuated on their borders, waved and hoary. The stalk rises four or five feet high, sending out many slender branches, garnished with heart-shaped leaves whose base embrace the stalk; the upper part of the stalk and branches have no leaves, but the flowers are disposed in small clusters at distances; they are small, yellow, and have little odour.

The eighth sort grows naturally in the south of France and Italy. The leaves of this are oblong, smooth, and of a dark green colour; the stalk rises three or four feet high, sending out two or three side branches, garnished with oblong, smooth, green leaves, whose base embrace the stalk. The flowers come out singly from the side of the stalk, upon foot-stalks an inch long; they have one petal cut into five obtuse segments almost to the bottom; they are white within, and have a little blush of red on the outside: the seed-

seed-vessels of this sort are round, and filled with small seeds.

The ninth sort grows naturally in some parts of *England*; this differs from the former, in the lower leaves being much longer, and deeply sinuated on their edges in a regular manner, in imitation of the rangement of the lobes of winged leaves; they are of a brighter green colour than those of the former. The stalks rise much taller; the flowers are of a bright yellow colour, and the stamina, which are hairy, are of a purple colour.

The tenth sort is commonly cultivated in gardens, and is known by the title of iron-coloured Moth-Mullein; this has a perennial root, in which it differs from all the former sorts, though there are some who suppose it to be only a variety of the last mentioned, but it differs greatly from that in other respects. The bottom leaves are oblong, oval, crenated on their edges, but entire; they are of a dark green on their upper side, of a pale green on their under, standing upon pretty long foot-stalks. The stalk rises three or four feet high, branching out on each side, and has a few sharp-pointed small leaves on the lower part sitting close to the stalk. The flowers are disposed in a long loose spike on the upper part of the stalk, having short slender foot-stalks; they are of one petal, cut almost to the bottom into five obtuse segments, of a rusty iron colour, and are larger than those of the common sort. This plant does not produce seeds here.

The eleventh sort grows naturally in *Sicily*; this is a biennial plant, which perishes soon after the seeds are ripe. The lower leaves are long, rounded at their points, are entire, and of a deep green on both sides. The stalk is strong, and rises five or six feet high, garnished with small acute-pointed green leaves, whose base fits close to it. The flowers form a very long loose spike at the top, coming out in clusters from the side of the stalk; they are large, of a deep yellow colour, and are succeeded by large round capsules which are brown, opening in two parts, filled with small dark-coloured seeds.

The twelfth sort grows naturally in *Spain* and *Portugal*. The root of this is perennial; the leaves are oval, entire, of a light green colour, and a little hairy; the stalk rises three feet high, and is almost naked of leaves, but the flowers, which come out singly, are ranged along it almost the whole length, standing upon short foot-stalks. They are of a dark blue inclining to purple; these appear in *June* and *July*, but are not succeeded by seeds here.

The thirteenth sort grows naturally upon the *Alps* and *Pyrenean* mountains; it is a very humble plant, whose leaves spread on the ground. The roots are composed of slender fibres; the leaves are oval, thick, fleshy, and hairy, crenated on their edges, and have compressed hairy foot-stalks. Between them arise slender naked foot-stalks about four inches long, which divide into three or four small ones at the top, each sustaining one large blue flower, composed of five oval petals which spread open flat, and five thick erect stamina which stand erect. After the flowers are past, the germen turns to an oblong-pointed capsule which opens in two parts, and is filled with small seeds.

The root of this is perennial, and the plant is usually propagated by off-sets which come out from the side of the old plant; these should be taken off in autumn, and planted in small pots filled with light sandy earth; they must always have a shady situation, for they will not thrive when they are exposed to the sun.

The first nine and the eleventh sorts are biennial plants; these may be all cultivated by sowing their seeds in *August*, on a bed of light earth, in an open situation, where the plants will come up the succeeding spring. In spring the plants should be transplanted where they are to remain, al-

lowing them a great distance, for as they grow large, they must not be planted nearer than two feet from other plants. The following year they will flower, and their seeds will be ripe in *August* or *September*. Notwithstanding some of these plants grow wild in *England*, yet two or three of each kind may be admitted into large gardens, for the variety of their hoary leaves, together with the extreme sweetness of their flowers, which have a scent something like *Violets*; and, as they require little care, they may be allowed a place in the borders of large gardens, where, during their continuance in flower, they will add to the variety; and, if their seeds are permitted to scatter, will come up without care, but the seventh sort seldom produces good seeds in *England*.

The tenth and twelfth sorts have perennial roots, and as they do not produce good seeds here, they are propagated by off-sets, which should be taken off in autumn, time enough to get good root before winter, otherwise they will not flower the following summer. These plants thrive best in a sandy loam, and should be planted on an east border, where they may have only the morning sun, for they do not thrive well when they are too much exposed to the sun.

VERBENA. *Tourn. Inst. R. H.* 200. tab. 94. Vervain.

The Characters are,

The flower has an angular, permanent empalement, indented in five parts at the brim; it has one petal, with a cylindrical tube the length of the empalement, cut into five points at the brim, which spread open, and are nearly equal; it has sometimes two, at others four very short bristly stamina within the tube, two of which are shorter than the other, with as many incurved summits as stamina, with a four-cornered germen, supporting a slender style the length of the tube, crowned with an obtuse stigma. The germen afterward become two or four oblong seeds, closely shut up in the empalement.

The Species are,

1. VERBENA *tetrandra*, spicis filiformibus paniculatis foliis multifido-laciniatis, caule solitario. *Lin. Sp. Plant.* 20. Vervain with four stamina, slender spikes disposed in panicles, leaves having many-pointed jags, and a single stalk. This is the common Vervain.

2. VERBENA *tetrandra*, spicis longis acuminatis, foliis hastatis. *Hort. Upsal.* 8. Vervain with four stamina to the flowers, long acute pointed spikes, and halbert shaped leaves.

3. VERBENA *tetrandra*, spicis filiformibus solitariis, foliis bipinnatifidis. *Lin. Sp. Plant.* 21. Vervain with four stamina to the flowers, single slender spikes, and double wing-pointed leaves; or narrow-leaved Vervain.

4. VERBENA *tetrandra*, spicis filiformibus paniculatis, foliis indivisis serratis petiolatis. *Hort. Upsal.* 9. Vervain with four stamina to the flowers, slender spikes growing in panicles, and undivided sawed leaves having foot-stalks; *Canada* Vervain.

5. VERBENA *tetrandra*, spicis filiformibus, foliis multifido laciniatis, caulibus numerosis. *Hort. Upsal.* 8. Vervain with four stamina to the flowers, slender spikes, leaves with many jagged points, and numerous stalks; *Nettle* leaved Vervain of *Canada*.

6. VERBENA *tetrandra*, spicis fasciculatis, foliis lanceolatis amplexicaulibus. *Hort. Upsal.* 8. Vervain with four stamina to the flower, spikes disposed in bunches, and spear-shaped leaves embracing the stalks; tallest Vervain of *Buenos Ayres*.

7. VERBENA *tetrandra*, spicis filiformibus paniculatis, foliis inferne cordato oblongis caulibus lanceolatis serratis petiolatis. Vervain with four stamina to the flowers, slender spikes growing in panicles, the under leaves oblong and heart-shaped, and those on the stalks spear-shaped, sawed, having foot-stalks.

8. VERBENA *tetrandra*, spicis capitato-conicis, foliis serratis, caule repente. *Flor. Zeyl.* 399. Vervain with four stamina to

the flowers, spikes growing in conical heads, sawed leaves, and a creeping stalk.

9. *VERBENA diandra, spicis longissimis carnosis subnudis.* *Lin. Sp. Plant.* 19. Vervain with two stamina to the flowers, and very long fleshy spikes which are almost naked.

10. *VERBENA diandra, spicis carnosis subnudis, foliis ovatis obtusis, obsolete crenatis petiolatis.* Vervain with two stamina to the flowers, fleshy spikes which are almost naked, and oval obtuse leaves growing upon foot-stalks, having slight indentures.

11. *VERBENA diandra, spicis longissimis foliolis.* *Lin. Sp. Plant.* 18. Vervain with two stamina to the flowers, and the longest leafy spikes.

12. *VERBENA diandra, spicis brevioribus, foliis ovatis serratis, subtus incanis.* Vervain with two stamina to the flowers, shorter spikes, and oval sawed leaves, which are hoary on their under side.

13. *VERBENA diandra spicis ovatis, foliis lanceolatis serratoplicatis, caule fruticoso.* *Prod. Leyd.* 327. Vervain with two stamina to the flowers, oval spikes and spear-shaped leaves, which are plaited, and a shrubby stalk.

14. *VERBENA diandra, spicis rotundis, foliis ovatis serratis, caule fruticoso ramoso.* Vervain with two stamina to the flowers, round spikes, oval sawed leaves, and a shrubby branching stalk.

15. *VERBENA diandra, spicis carnosis subnudis, foliis linearilanceolatis obsolete serratis.* Vervain with two stamina to the flowers, naked fleshy spikes, and narrow spear-shaped leaves, slightly sawed on their edges.

16. *VERBENA diandra, spicis laxis, calycibus fructibus reflexo-pendulis subglobosis hispidis.* *Lin. Sp. Plant.* 19. Vervain with two stamina to the flowers, loose spikes, the empalement of the fruit almost globular, prickly, and reflexed downward.

17. *VERBENA diandra, spicis laxis, calycibus aristatis, foliis ovatis argute serratis.* *Lin. Sp. Plant.* 19. Vervain with two stamina to the flowers, loose spikes, bearded empalements, and oval leaves which are sharply sawed.

18. *VERBENA diandra, spicis ovatis, foliis subrotundis serratis & rugosis, caule fruticoso ramoso.* Vervain with two stamina to the flowers, oval spikes, roundish, sawed, rough leaves, and a shrubby branching stalk.

The first is very common on the side of roads, foot-paths, and farm-yards near habitations; for although there is scarce any part of *England*, in which this is not found in plenty, yet it is never found above a quarter of a mile from a house; which occasioned its being called *Simpler's Joy*, because wherever this plant is found growing, it is a sure token of a house being near; this is a certain fact, but not easy to be accounted for. It is rarely cultivated in gardens, but is the sort directed by the College of Physicians for medicinal use; and is brought to the markets by those who gather it in the fields.

There is another species which approaches near to this, but is taller, the leaves are broader, and the flowers larger. It came from *Portugal*, and is by *Tournefort* titled *Verbena Lusitanica, latifolia procerior.* *Inst. R. H.* 200. Taller, broad-leaved *Portugal* Vervain. But I am in some doubt of its being specifically different from the common sort, though the plants in the garden grow much taller, branch more, and the flowers are larger than the first, yet as there is so near an affinity, I cannot be sure it is a different species.

The second sort grows naturally in most parts of *North America*; this sends up many four-cornered furrowed stalks from the root, which rise five or six feet high, garnished with oblong leaves, ending in acute points, deeply sawed on their edges, and stand upon slender foot-stalks; from the joints come out short branches, set with smaller leaves of the same form. The stalks are terminated by spikes of blue flowers in clusters, which appear in *August*, and if the autumn proves favourable, the seeds will ripen the middle of *October*.

The third sort grows naturally in *Spain* and *Portugal*; this is a biennial plant, which perishes soon after the seeds are ripe. The stalks branch much, rise near two feet high. The leaves are double wing-pointed, and sit close to the stalks. The flowers are disposed in loose spikes, of a light blue colour, and larger than those of the common sort.

The fourth sort grows naturally in most parts of *North America*; this is a biennial plant. The stalks are four-cornered, about three feet high. The leaves are long, ending in acute points, and sawed on their edges. The stalks are terminated by panicles of spikes, which are long, slender, and sustain small white flowers, which are ranged loosely, and are succeeded by seeds which ripen in autumn.

The fifth sort also grows naturally in *North America*; this is a biennial plant, whose lower leaves are long, deeply jagged, and sawed on their edges, of a deep green colour.

The stalks rise two feet high, garnished with small leaves of the same shape. The upper part of the stalk branches out into numerous foot-stalks, which sustain panicles of spiked blue flowers, and if the season proves favourable, the seeds will ripen in autumn.

The sixth sort grows naturally at *Buenos Ayres*; this has four-cornered stalks, which rise six or seven feet high, branching from the side, garnished with long spear-shaped leaves, whose base embrace the stalks, of a pale green colour. The stalks are terminated by spikes of blue flowers, which are clustered together. These appear late in summer, so do not always produce good seeds in *England* in the open air.

The seventh sort grows naturally at *Philadelphia*. The seeds were sent me by *Dr. Bensef*; this is a perennial plant. The lower leaves are heart-shaped, rough, of a dark green colour, are sawed on their edges, ending in acute points. The stalks rise six feet high, branch toward the top, and are terminated by slender spikes of white flowers, formed into panicles; these appear late in autumn, so that unless the season proves favourable, the seeds do not ripen here.

The eighth sort grows naturally in *Virginia*, and also in *Jamaica*. The stalks of this trail upon the ground, and emit roots from their joints, whereby they spread, and propagate greatly, and from these arise other branches about eight or nine inches high, garnished with oval spear-shaped leaves, sawed on their edges, and sit close to the stalks. The flowers are collected in conical heads, standing upon naked foot-stalks, which spring from the wings of the branches; they are of a yellowish white colour, and come late in autumn, so are rarely succeeded by good seeds here.

The ninth sort grows naturally in most of the islands in the *West-Indies*; it is an annual plant. The stalk rises a foot and a half high, garnished with oblong oval leaves placed opposite, of a light green, and sawed on their edges. The stalk is terminated by a long fleshy spike of blue flowers, which are succeeded by two oblong seeds ripening late in autumn. The spikes of flowers are from a foot to a foot and a half in length.

The seeds of the tenth sort were sent me from *Panama*, where it grows naturally in moist places; this is an annual plant, whose stalks rise a foot high, garnished with oval, blunt-pointed, fleshy leaves, standing upon long foot-stalks; they are notched slightly on their edges, and are of a light green. The stalks are terminated by thick spikes of blue flowers, which appear late in autumn, so that unless the season proves warm, the seeds do not ripen in *England*.

The seeds of the eleventh sort were also sent me from *Panama*; this rises with a shrubby stalk three feet high, which divides into three or four branches, garnished with oblong oval leaves placed opposite, of a deep green on their upper side, but hoary on their under, and are deeply sawed; their foot-stalks are short, and have leafy borders running from

from the base of the leaves. The flowers grow on thick spikes a foot long, which terminate the branches. They are large, and of a fine blue colour, so make a good appearance, and have small acute-pointed leaves intermixed with them on the spikes. This plant, when the season is warm, will perfect seeds in autumn.

The seeds of the twelfth sort were sent me from *Paris*, and were said to come from *Senegal* in *Africa*; this is a perennial plant with a branching stalk, two feet high, garnished with oval sawed leaves placed opposite; of a deep green on their upper side, but hoary on their under. The flowers are disposed in fleshy spikes at the end of the branches, which are shorter, and not so thick as those of the former sorts. The flowers are small, white, so make but little appearance; the seeds ripen in autumn, but the plants may be preserved two years in a warm stove.

The thirteenth sort grows naturally in *Jamaica*, and in several other places in the *West Indies*. This rises with a shrubby branching stalk five or six feet high, adorned with spear-shaped leaves, sawed on their edges, standing upon short foot-stalks. The flowers have long naked foot-stalks, which arise from the wings of the stalk; they are blue, and collected in oval heads; these appear late in autumn, so unless the season proves warm, the seeds do rarely ripen in *England*, but the plants may be kept two or three years in a warm stove.

The fourteenth sort grows naturally at *Campeachy*; this has a shrubby branching stalk four feet high, garnished with oval sawed leaves, of a light green colour. The flowers are of a pale blue, collected into oval heads, which stand upon long naked foot-stalks, springing from the wings of the branches; this flowers late in autumn, so is not succeeded by seeds in *England*.

The fifteenth sort grows naturally at *La Vera Cruz*; this is an annual plant with a branching stalk a foot and a half high, garnished with pale green leaves, ending in acute points, slightly sawed on their edges. The branches are terminated by fleshy spikes of blue flowers which are naked, and in warm seasons are succeeded by seeds which ripen in autumn.

The sixteenth sort grows naturally in *Mexico*; this has a shrubby stalk which rises five or six feet high, dividing into several branches, garnished with oblong sawed leaves which end in acute points, sitting close to the branches, of a light green on both sides. The branches are terminated by slender loose spikes of pale flowers which are very small, whose empalements afterward become swelled, and almost globular; they are reflexed downward, and set with stinging hairs. It flowers late in the summer, and in good years the seeds ripen in *England*.

The seventeenth sort grows naturally at *La Vera Cruz*; this has a slender ligneous stalk, which branches and rises near three feet high, adorned with small oval leaves of a light green, which are sharply indented on their edges. The flowers stand sparsely upon slender foot-stalks, arising from the wings of the branches; toward the top, the flowers are ranged at a distance from each other in a loose spike; they are small, and of a bright blue colour, sitting very close; these are succeeded by two seeds inclosed in the empalement, which is terminated by short awns or beards.

The eighteenth sort grows naturally at *Campeachy*; this has a strong woody stalk ten or twelve feet high, covered with a light brown bark, sending out many ligneous branches, garnished with roundish, sawed, rough leaves, of a light green, standing upon short foot-stalks. The flowers are small, of a pale blue colour, collected into oval heads, standing upon naked foot-stalks; these seldom appear in this country, and are not succeeded by seeds here; but the plants are easily propagated by cuttings during the summer months, so may be preserved many years in a moderate stove.

The first sort, as was before observed, being a common weed in *England*, is not kept in gardens.

The third sort may be easily propagated by seeds which should be sown in autumn, and requires no other culture than to keep it clean from weeds, and thin the plants where they are too close.

The fourth and fifth sorts may also be propagated in the same manner, and are equally hardy. If the seeds are permitted to scatter, the plants will come up the following spring.

The second and seventh sorts have perennial roots, and are hardy enough to thrive in the open air; these may be propagated by seeds, which should be sown in autumn, for when they are sown in the spring, they rarely grow the same year; the plants require no other culture but to keep them clean from weeds, and allow them proper room to spread; they may also be propagated by parting their roots in autumn. They love a soft loamy soil not too dry.

The other sorts being natives of warmer climates require more care. The seeds of these should be sown upon a hot-bed early in the spring, and when the plants are fit to remove, they should be each transplanted into a separate small pot, and plunged into a fresh hot-bed to bring them forward; they must be shaded in the day time with mats until they have taken new root, then they must be treated in the same way as other tender plants from the same countries.

Those sorts which are annual must be removed into the stove, or a good glass-case, when they are become too tall to remain longer under the frames; for if they are placed abroad in the open air, they will not ripen their seeds here unless the summer is very warm; therefore where there is a conveniency of having a bark-bed in a glass-case, for plunging some of these tender annual plants, they will thrive much better, and come to greater perfection, than those which are placed on shelves.

The seventeenth sort is by much the tenderest plant of all the species, and is very difficult to preserve when young. The seeds of this should be sown in a small pot, and plunged into a good hot-bed of tanners bark. When the plants appear, they should be shaded from the sun in the heat of the day. They must also be frequently refreshed with water, but it must be given to them sparingly, for much wet will kill them. When they are transplanted into small pots they must be carefully shaded till they have taken new root, and they must be constantly kept in the bark-bed.

VERBESINA. *Lin. Gen. Plant.* 873. Indian Hemp Agrimony.

The Characters are,

The common empalement of the flower is composed of a double order of leaves which are channelled. The flower is made up of hermaphrodite florets in the disk, and female half florets in the border. The hermaphrodite florets are funnel-shaped; they have five very short hair-like stamina, terminated by cylindrical summits, and a germen the same figure as the seed, supporting a slender style, crowned by two reflexed stigmas. The germen afterward becomes a thick angular seed crowned by a few three-pointed chaff.

The Species are,

1. VERBESINA *foliis alternis decurrentibus undulatis obtusis.* *Hort. Cliff.* 411. Verbescina with alternate running leaves, which are obtuse and waved.

2. VERBESINA *foliis oppositis lanceolatis serratis.* *Hort. Cliff.* 500. Verbescina with spear-shaped sawed leaves which are placed opposite.

3. VERBESINA *foliis oppositis ovatis trinerviis glabris petiolatis, seminibus tricornuis.* *Flor. Zeyl.* 310. Verbescina with oval leaves having three veins, placed opposite on foot-stalks, and seeds with three horns.

4. VERBESINA *foliis oppositis lanceolatis integerrimis, caulibus procumbentibus, floribus sessilibus.* Verbescina with spear-shaped

shaped entire leaves, which are placed opposite, trailing stalks, and flowers fitting close to the branches.

5. *VERBESINA foliis oppositis lanceolatis argutè dentatis, caule ramoso piloso.* Verbesina with spear-shaped, acutely indented leaves placed opposite, and an erect, branching, hairy stalk.

6. *VERBESINA foliis oppositis lanceolato-ovatis petiolatis serratis, pedunculis unifloris dichotomice caulis.* Flor. Zeyl. Verbesina with oval, spear-shaped, sawed leaves, placed opposite, and single flowers upon each foot stalk, produced from the divisions of the stalk.

The first sort grows naturally in most of the islands of the *West Indies*; it is an annual plant, with an upright winged stalk about two feet high, from the sides of which spring out toward the top a few short branches. The leaves are oval, blunt, and waved on their edges; they are placed alternate, and from the base of each leaf is extended a leafy border, running along two sides of the stalk. The flowers stand upon long naked foot-stalks, arising from the top and the wings of the stalk; they are of a deep Orange colour, and are composed of hermaphrodite and female florets, included in one common spherical empalement, which are both fruitful; these are succeeded by broad, compressed, bordered seeds, with two teeth, which ripen in the empalement.

The second sort grows naturally in the *West-Indies*; this has an upright branching stalk a foot and a half high. The leaves are spear-shaped, a little sawed on their edges, fitting close to the stalk opposite. The flowers arise from the wings of the stalk upon slender foot-stalks, three, four, or more springing from the same joint; each of these sustain one white radiated flower, composed of many florets, which are succeeded by oblong black seeds.

The third sort grows naturally in both *Indies*; this rises with an upright branching stalk two or three feet high. The leaves are oval, acute-pointed, and smooth, having three longitudinal veins; they stand opposite upon pretty long foot-stalks. The flowers spring from the wings and ends of the branches; they are yellow, and stand upon short foot-stalks.

The fourth sort grows naturally in *India*; this has trailing stalks, which spread on the ground; they extend two feet or more in length, and put out roots from their joints, sending out many side branches. The leaves are long, broad, smooth, and entire. The flowers are very small and white; these fit close to the stalks at the base of the leaves.

The fifth sort grows naturally in the *West-Indies*; this has a purplish, hairy, branching stalk, which rises a foot and a half high. The leaves are long and broad, ending in acute points; they have a few sharp indentures on their edges, and stand opposite. The flowers are white, standing upon slender foot-stalks, which spring from the wings of the stalk, sometimes single, and at others two or three at the same joint.

The sixth sort grows naturally in both *Indies*; the stalks of this branch out their whole length, and decline downward. The leaves are smooth, heart shaped, and have three veins, indented on their edges, and stand opposite. The flowers stand upon long naked foot-stalks, which spring from the wings of the branches; they are of a yellow colour, and have oblong prominent disks, with a few very small rays.

These plants are propagated by seeds, which should be sown upon a moderate hot-bed in the spring; and when the plants are fit to remove, they should be transplanted on a fresh hot-bed to bring them forward, and must be afterward treated in the same way as other tender annual plants, being careful not to draw them up too weak. In *June* they

may be taken up with balls of earth, and planted in a warm border, where they must be shaded and watered till they have taken new root; after which they will require but little care, and will produce good seeds in autumn.

VERONICA. Tourn. Inst. R. H. 143. tab. 60. Male Speedwell, or Fluellin.

The Characters are,

The flower has a permanent empalement, cut into five acute segments; it has one tubulous petal the length of the empalement; the brim is cut into four oval plain segments, which spread open, and two stamina, which are terminated by oblong summits, with a compressed germen, supporting a slender declining style, crowned by a single stigma. The germen afterward becomes a compressed heart-shaped capsule with two cells, filled with roundish seeds.

The Species are,

1. *VERONICA spicis lateralibus pedunculatis, foliis oppositis, caule procumbente.* Lin. Mat. Med. 11. Speedwell with spikes of flowers growing upon foot-stalks, springing from the sides of the stalks, leaves placed opposite, and a trailing stalk; or common Male Speedwell, or Fluellin.

2. *VERONICA spicis terminalibus, foliis oppositis lineari lanceolatis subserratis.* Speedwell with spikes of flowers terminating the stalks, and narrow, spear-shaped, sawed leaves, placed opposite; or narrow-leaved spiked Speedwell.

3. *VERONICA spicis terminalibus, foliis oppositis lanceolatis serratis acuminatis.* Hort. Upsal. 7. Speedwell with spikes of flowers terminating the stalks, and acute-pointed sawed leaves, which are lance-shaped, placed opposite; or greater broad-leaved upright Speedwell.

4. *VERONICA spicâ terminali, foliis oppositis crenatis obtusis, caule ascendente simplicissimo.* Lin. Sp. Plant. 10. Speedwell with a spike of flowers terminating the stalk, obtuse crenated leaves placed opposite, and a single ascending stalk; or smaller spiked Speedwell.

5. *VERONICA spicis lateralibus paniculatis, foliis ovatis inæqualiter crenatis sessilibus.* Speedwell with spikes of flowers in panicles from the wings of the stalk, and oval leaves, which are unequally notched, and fit close; or *Hungarian* Speedwell.

6. *VERONICA spicis terminalibus, foliis oppositis obtusè serratis scabris, caule erecto.* Lin. Sp. Plant. 11. Speedwell with spikes of flowers terminating the stalk, rough, obtuse, sawed leaves, which are placed opposite, and an erect stalk; or *Welsh* spiked Speedwell.

7. *VERONICA spicis terminalibus, foliis quaternis quinifve.* Lin. Sp. Plant. 9. Speedwell with spikes of flowers terminating the stalks, and four or five leaves at each joint; or tall *Virginian* Speedwell with many spikes of white flowers.

8. *VERONICA spicis terminalibus, foliis ternis æqualiter serratis.* Hort. Upsal. 7. Speedwell with spikes of flowers terminating the stalks, and leaves growing by threes, which are equally sawed; or long-leaved spiked Speedwell.

9. *VERONICA spicis terminalibus, foliis ternis inæqualiter serratis.* Lin. Sp. Plant. 10. Speedwell with spikes of flowers terminating the stalks, and leaves growing by threes, which are unequally sawed.

10. *VERONICA spicis terminalibus, foliis oppositis crenatis, caule erecto.* Speedwell with spikes of flowers terminating the stalks, crenated leaves growing opposite, and an erect stalk.

11. *VERONICA spicis lateralibus pedunculatis laxis, foliis oppositis linearibus argutè dentatis.* Speedwell with loose spikes of flowers growing upon foot-stalks, springing from the wings of the stalk, and very narrow sharply-sawed leaves placed opposite; or *Austrian* Speedwell.

12. *VERONICA spicis terminalibus, foliis pinnato-incisis acuminatis.* Speedwell with spikes of flowers terminating the stalks, and acute-pointed leaves cut in the form of wings; or eastern Speedwell.

13. *VERONICA racemis lateralibus, foliis cordatis rugosis dentatis, caule striato. Lin. Sp. Plant. 13.* Speedwell with spikes of flowers proceeding from the wings of the stalk, rough, heart-shaped, indented leaves, and a strait stalk; or greatest Speedwell.

14. *VERONICA spicis terminalibus, foliis oppositis crenatis obtusis, caule erecto tomentoso. Hort. Upsal. 7.* Speedwell with spikes of flowers terminating the stalks, crenated obtuse leaves placed opposite, and an erect woolly stalk; or hoary, woolly, spiked Speedwell.

15. *VERONICA spicis longissimis lateralibus pedunculatis, foliis oppositis inaequaliter serratis.* Speedwell with the longest spikes of flowers springing from the wings of the stalk upon foot-stalks, and leaves placed opposite, which are unequally sawed.

16. *VERONICA racemis lateralibus, foliis ovatis planis, caule repente. Flor. Succ. 11.* Speedwell with lateral spikes of flowers, oval plain leaves, and a creeping stalk; or greater Water Speedwell, commonly called Brooklime.

There are several other species of this genus, some of which grow naturally in *England*; but, as they are rarely admitted into gardens, it is beside the intention of this work to mention them.

The first sort grows wild in woods, and other shady places, in divers parts of *England*, and is a plant of little beauty; but, as it is the sort which is used in medicine, under the title of *Paul's-Betony*, I thought it necessary to insert it here. This is a low plant, whose stalks trail upon the ground, and put out roots from their joints, whereby it spreads and propagates. The leaves are oval, about an inch long, sawed on their edges, and placed opposite. The flowers are disposed in spikes, which arise from the wings of the stalk; they are small, of a pale blue colour, and have one petal, which is cut at the brim into four segments; when they decay, the germen turns to a capsule, not unlike that of *Shepherd's Pouch* in shape, filled with small seeds.

This is generally brought to market by such persons as make it their business to gather herbs in the fields, so that it is not often cultivated in gardens; but those who have a mind to propagate it, may do it with much ease, for as the branches trail upon the ground, they push out roots from their joints, which branches being cut off and planted, will take root, and grow in almost any soil or situation. The whole herb is used in medicine, and is one of the *Wound-herbs* which are brought from *Switzerland*. A tea of this herb is much recommended for the gout and rheumatism.

The second sort grows naturally in *Italy* and *Spain*; this has a perennial root, which sends out many offsets, by which it is easily propagated. The lower leaves are long and hairy; the stalks rise a foot high, and are garnished with very narrow spear-shaped leaves, placed opposite, which have a few slight serratures on their edges. The stalks are terminated by long spikes of blue flowers, which are succeeded by seeds in capsules like the former. It has been doubted if this was specifically different from the common upright Speedwell; but I have many times propagated this by seeds, and have always found the plants so raised, maintain their difference. There is a variety of this with a flesh-coloured flower.

The third sort grows naturally in *Austria* and *Hungary*. The lower leaves of this are long, broad in the middle, drawing to a point at each end; they are sawed on their edges, and are of a lucid green colour. The stalks rise a foot and a half high, and are garnished with leaves of the same shape with the lower, but smaller, placed opposite; they are terminated by long spikes of blue flowers, which appear in *June*, and are succeeded by flat seed-vessels, filled with compressed seeds, which ripen in autumn.

The fourth sort grows naturally in the northern parts of *Europe*, and also in several closes near *Newmarket-Heath*. The lower leaves of this are about an inch and a half long, and three quarters of an inch broad, of a pale green colour, and notched on their edges. The stalks rise a foot and a half high; they do not branch; the leaves on the lower part stand opposite, but on the upper they are alternate; the stalks are terminated by short spikes of blue flowers, which appear about the same time as the former.

The fifth sort grows naturally in *Hungary*. The lower leaves of this are unequally notched; the stalks rise a foot high, garnished with leaves, placed opposite, of a lucid green, which sit close to the stalks. The flowers are disposed in panicled spikes, which stand upon long naked foot-stalks that spring from the upper wings of the stalk; they are larger than those of the other species, and are of a beautiful blue colour, so make a fine appearance, but are of short duration.

The sixth sort grows naturally on the *Alps* and *Pyrenean* mountains, and also upon the mountains in *Wales*. The lower leaves of this are rough and hairy, blunt-pointed, and obtusely sawed on their edges, standing upon pretty long foot-stalks; the stalks grow erect about six or eight inches high, garnished with oval notched leaves, placed opposite. From the side of the stalk spring out two or three branches, which toward the bottom are garnished with small leaves, placed opposite, but terminate in long spikes of pale blue flowers. The spikes on the side branches are four or five inches long, but those of the principal stalk are eight or nine.

The seventh sort grows naturally in *Virginia*. The stalks of this are erect, and rise four or five feet high, garnished at each joint by four or five spear-shaped sawed leaves, which stand round the stalk in whorls, ending in acute points. The stalks are terminated by long slender spikes of white flowers, which appear late in *July*; these are succeeded by compressed capsules, filled with seeds, which ripen in autumn.

The eighth sort grows naturally in *Italy* and the south of *France*. The stalks of this rise three feet high, garnished with leaves, placed by fours toward the bottom, but at the top by threes at each joint; they are deeply sawed on their edges, ending in acute points, of a bright green colour; the stalks are terminated by spikes of blue flowers.

The ninth sort grows near the sea in several parts of *Europe*. The stalks of this do not rise so high as those of the former; the leaves are placed by fours and threes round the stalk, and have longer foot-stalks; they are broader at the base, and run out into long acute points; they are unequally sawed on their edges, and are of a bright green colour. The flowers are disposed in spikes, which terminate the stalks, of a bright blue colour.

The tenth sort grows naturally in many parts of *France* and *Germany*. The stalks of this are single, and do not branch; they are round, hairy, and rise a foot and a half high, garnished with spear-shaped hairy leaves. The stalk is terminated by a long spike of blue flowers.

The eleventh sort grows naturally in *Austria*. The lower leaves of this are narrow, and cut into fine segments; the stalks are slender, and incline downward, garnished with linear leaves, which are acutely notched on their edges; the flowers are disposed in long loose spikes, which spring from the wings of the stalk, of a bright blue colour, and stand upon foot-stalks.

The twelfth sort grows naturally in the *Levant*; this has slender branching stalks which decline, and are garnished with narrow leaves, which are acutely cut on their edges, of a pale green colour, and smooth. The flowers are disposed in loose spikes on the top and from the side of the stalks, of a pale blue colour.

The thirteenth sort grows naturally upon *Mount Baldus* in *Italy*. The stalks of this are slender, stiff, and upright, garnished by rough heart-shaped leaves, which are indented, and placed opposite; those on the lower part of the stalk are small; in the middle they are much larger, and diminish again in their size toward the top. The flowers come out in spikes from the wings of the stalk toward the top, of a bright blue colour.

The fourteenth sort grows naturally in the *Ukrain Tartary*. The stalks of this are very white and woolly; they rise about a foot and a half high, garnished with oblong hoary leaves, placed opposite, notched on their edges, and sit close to the stalks, which are terminated by spikes of deep blue flowers, which stand erect.

The fifteenth sort grows naturally in *Austria* and *Bohemia*. The stalks are slender, about a foot and a half long, inclining downward; the leaves are nearly oval, but are acute-pointed, unequally sawed, and sit close to the stalks. The flowers are disposed in long loose spikes upon foot-stalks, arising from the wings of the stalk; those on the lower part of the stalk are eight or nine inches long. The flowers are of a bright blue colour: the leaves of this sort are frequently variegated with yellow.

The sixteenth sort is the common Brooklime, which grows naturally in brooks and streams of water in most parts of *England*, so is not cultivated in gardens, but as it is much used in medicine, I have given it a place here. The stalks of this are thick, succulent, and smooth, emitting roots from their joints, whereby they spread and propagate. The leaves are oval, flat, succulent, and smooth; they stand opposite; the flowers come out in long bunches from the wings of the stalk; they are of a fine blue colour, and stand upon short foot-stalks; these appear great part of summer, and are succeeded by heart-shaped seed-vessels, filled with roundish seeds. The whole herb is used, and is esteemed an excellent antiscorbutick.

These plants may all be propagated by parting their roots, which may be done every other year, for if they are not often parted or divided, they will many of them grow too large for the borders of small gardens; but yet they should not be parted into very small heads, because when they have not a number of stems, so as to form a good bunch, they are soon past their beauty, and have but a mean appearance. The best time to part these roots is at *Michaelmas*, that they may be well rooted again before winter; for when they are removed in the spring, they seldom flower strong the same year, especially if the season should prove dry. Those sorts which grow pretty tall, are very proper to plant on the sides of open wilderness quarters, but those with trailing branches are fit for the sides of banks or irregular shady slopes, where they will make an agreeable variety; they are all of them very hardy, so are in no danger of suffering by cold, and require no other care but to keep them clean from weeds, and to be transplanted every second or third year.

They may also be propagated by seeds, which should be sown in autumn, for when they are sown in the spring, the plants rarely come up the same year; but, as most of the sorts propagate very fast by their offsets, their seeds are seldom sown.

If these plants are placed in a shady border, they will thrive much better than when they are more exposed to the sun, and their flowers will continue much longer in beauty.

VIBURNUM. *Lin. Gen. Plant.* 332. The Wayfaring, or pliant Meally-tree.

The Characters are,

The flower has a small permanent empalement, which is cut into seven parts; it has one bell-shaped petal, cut at the brim into five obtuse segments, which are reflexed; it has five awl-shaped sta-

mina the length of the petal, terminated by roundish summits, and a roundish germen, situated under the flower, having no style, but the place is occupied by a roundish gland, and crowned by three obtuse stigmas. The germen afterward turns to a compressed fruit with one cell, inclosing one hard seed.

The Species are,

1. VIBURNUM foliis cordatis serratis venosis subtus tomentosis. *Vir. Cliff.* 25. Wayfaring-tree with heart-shaped, sawed, veined leaves, which are woolly on their under side.

2. VIBURNUM foliis subrotundis crenato-serratis glabris. *Flor. Virg.* 33. Wayfaring-tree with roundish, crenated, sawed leaves, which are smooth; commonly called Black Haw.

3. VIBURNUM foliis ovato-orbiculatis profundè serratis venosis. Way-faring-tree with oval round leaves, which are deeply sawed and veined.

4. VIBURNUM foliis ovatis integerrimis, ramificationibus subtus villoso-glandulosis. *Lin. Sp. Plant.* 267. Wayfaring-tree with oval entire leaves, whose branches are hairy, and glandulous on the under side; or hairy-leaved Laurustinus.

5. VIBURNUM foliis ovato-lanceolatis integerrimis, utrinque virentibus lucidis. The shining-leaved Laurustinus.

6. VIBURNUM foliis ovato-lanceolatis integerrimis, subtus venosis. *American* Tinus with oval leaves, which are entire.

7. VIBURNUM foliis lobatis petiolis glandulosis. *Lin. Sp. Plant.* 261. Common Guelder Rose.

8. VIBURNUM foliis cordato-ovatis acuminatis serratis, petiolis longissimis lævibus. *American* Guelder Rose with acute-pointed sawed leaves, and white flowers.

The first sort grows naturally in many parts of *Europe*, and is the common Viburnum or Lantana of the old botanists. The leaves are heart-shaped, much veined, irregularly sawed on their edges, and are very woolly on their under side. The stalks are woody, and rise twelve or fourteen feet high, sending out strong ligneous branches, which are covered with a light coloured bark; these are terminated by umbels of white flowers, whose summits are red, and are succeeded by roundish compressed berries, which turn first to a bright red colour, and are black when ripe, inclosing one seed of the same shape.

There is a variety of this with variegated leaves, which is preserved in some of the gardens near *London*; but when the plants are removed into good ground, and are vigorous, their leaves become plain.

The second sort grows naturally in most parts of *North America*, where it is commonly called Black Haw. This rises with a woody stalk ten or twelve feet high, covered with a brown bark, and sends out branches from the side; these, when young, are covered with a purple smooth bark, and are garnished with oval smooth leaves, which are slightly sawed on their edges, and stand upon short slender foot-stalks, sometimes opposite, and at others without order. The flowers are disposed in small umbels, which come out from the side and at the end of the branches; they are white, and smaller than those of the common Viburnum; these are succeeded by berries, which ripen in autumn.

The third sort grows naturally in *North America*. The stalks of this are soft and pithy, and branch out greatly from the bottom upward. The bark is of a gray colour; the leaves are roundish, oval, strongly veined, and sawed on their edges, of a light green colour, and placed opposite upon pretty long foot-stalks. The flowers are disposed in a corymbus at the end of the branches, which are white, and almost as large as those of the common sort; these appear the latter end of *June*, but are seldom succeeded by seeds in *England*.

The fourth sort is the Laurustinus with small leaves, which are hairy on their under side; this plant is so well known as to need no description, but as it is frequently confounded with

with the next, it may be necessary to point out its difference. The leaves of this are seldom more than two inches and a half long, and one and a quarter broad; they are rounded at their base, but end in acute points; they are veined and hairy on their under side, and are not of so lucid a green colour on their upper side. The umbels of flowers are smaller, and appear in autumn, continuing all the winter, and the plants are much hardier.

The fifth sort is commonly known in the nursery-gardens by the title of shining leaved Laurustinus. The stalks of this rise higher, the branches are much stronger than those of the former sort. The bark is smoother, and turns of a purplish colour; the leaves are larger, of a thicker consistence, and of a lucid green colour; the umbels are much larger, and so are the flowers; these seldom appear till the spring, and when the winters are sharp, the flowers are killed, so never open unless they are sheltered. The plants of this sort were formerly kept in tubs, and housed in winter, and, when they were so treated, made a fine appearance early in the spring, and in very mild seasons the plants in the open air do the same.

There is a variety of this with variegated leaves, which makes as good a figure as any of the striped plants which are preserved in gardens.

The sixth sort is a native of *North America*, where it rises to the height of ten or twelve feet, sending out branches on every side their whole length; these have a smooth purplish bark, garnished with oval entire leaves, of a thick consistence, and of a lucid green; they stand opposite. The flowers are produced in umbels at the end of the branches; they are white, and not unlike the flowers of Laurustinus; these appear in *July*, and are succeeded by berries, which seldom ripen in *England*.

There seems to be two sorts of this in the gardens, one of which comes from the more northern parts of *America*, and sheds its leaves in winter; the other, which grows in *Carolina* and *Virginia*, is an ever-green, but both are so much alike in summer, as scarce to be distinguished.

The seventh sort is the common Marsh Elder, which grows naturally in marshy grounds, and on the sides of rivers in many parts of *England*, so is not often kept in gardens; it is called by some of the nursery-gardeners Guelder Rose with flat flowers, to distinguish it from the other, whose flowers are globular. The Marsh Elder is the original species, and the Guelder Rose is a variety which accidentally arose from it. The former has a border of male flowers, which are large, and the middle of the umbel is composed of hermaphrodite flowers, which are succeeded by oval red berries; the latter has all male flowers, of the same size and shape with those of the border of the first, so that they swell out into a round figure, which has occasioned some country people giving it the title of Snowball-tree. This sort is cultivated in gardens for the beauty of its flowers, which make a fine appearance during their continuance.

It will rise to the height of eighteen or twenty feet, if it is permitted to stand. The stem becomes large, woody, and hard; the branches come out opposite, and are apt to grow irregular; they have a gray bark. The leaves are placed opposite; they are divided into three or four lobes, somewhat like those of the Maple, jagged on their edges, and of a light green colour. The flowers come out at the end of the branches; those of the first in large umbels, and those of the second in a corymbus; they are very white, and appear the beginning of *June*; those of the first have oval berries succeeding the hermaphrodite flowers, which turn of a scarlet colour when ripe, but the other, having only male flowers, are barren.

The eighth sort grows naturally in *Carolina* and some other parts of *North America*; this rises with a shrubby stalk eight

or ten feet high, sending out many branches, which are covered with a smooth purple bark, garnished with heart-shaped oval leaves, ending in acute points; they are deeply sawed on their edges, have many strong veins, and stand upon very long slender foot-stalks opposite. The flowers are collected into large umbels at the end of the branches; those ranged on the border are male and barren, but the middle is composed of hermaphrodite flowers, which are succeeded by oval berries. The flowers are white, and the berries are red when ripe.

The first sort may be propagated either from seeds, or by laying down the tender branches; but the former method being tedious, is seldom practised, because the seeds seldom grow the first year, unless they are sown in autumn, and as the branches easily put out roots, that is the more expeditious method.

The best time for laying these branches is in autumn, just as the leaves begin to fall (the manner of laying them being the same as for other hardy trees, need not be here repeated). By the succeeding autumn the layers will be rooted, when you may take them off from the old plants, and transplant them into a nursery for two or three years, in which they may be trained up to regular stems and heads, and may afterward be planted where they are to remain.

The second sort is generally propagated by layers here, because the seeds do not often ripen in *England*. The young shoots of this take root very freely; the cuttings will also take root, if they are planted in autumn; the seeds, when they are brought to *England*, always remain in the ground a year like those of the other sorts, so that the propagating the plants by seeds is a tedious method.

The Laurustinuses are propagated by laying down their young branches, which put out roots very freely; so that when they are layed in autumn, they will be well rooted by that time twelve months, when they should be taken off from the old plants, and may either be planted where they are to remain, or into a nursery to grow two years to get strength. The best season to transplant these is at *Michaelmas*, that they may get new root before winter; for as these plants begin to flower early in winter, it is a plain indication of their growing at that season, so they will more surely succeed than at any other time of the year, though they may be removed in the spring with balls of earth to their roots, provided it is done before they begin to shoot; they may also be removed the latter end of *July* or the beginning of *August*, if rain happens at that time, for after they have done shooting, which is soon after *Midsummer*, they will be in no danger, provided they are not kept out of the ground any time.

These plants may also be propagated by seeds, which should be mixed with earth in autumn, soon after they are ripe; these should be exposed to the open air, and receive the rain in winter, and in the spring they may be sown upon a gentle hot-bed, which will bring up the plants; these should remain in the bed till autumn, and then may be transplanted and treated in the same way as the layers. I have raised many of these plants from seeds, which I find hardier than those raised by layers.

Some people train up the Laurustinus with naked stems to have round heads, but if these are planted in the open air, they will be in more danger of suffering by severe frost, than those whose branches grow rude from the bottom; for if the frost kills the outer part of the shoots, the stems will be protected, so will soon put out new branches; but where the stems are naked, the frost frequently kills them to the root.

The sixth sort may be propagated in the same way as the Laurustinus, and requires the same treatment; it loves a soft loamy soil, and should have a sheltered situation.

The seventh and eighth sorts are easily propagated by layers or cuttings. The common Guelder Rose sends out plenty of suckers from the roots, by which it is frequently propagated; but as the plants so raised are very subject to put out suckers, they are not so good as those which come from layers or cuttings. Both these sorts love a moist soil, in which they will make much greater progress, and produce their flowers in greater plenty than on a dry soil.

They are both very hardy, so will thrive in the coldest situations, but not within the spray of the sea. The common Guelder Rose is seldom suffered to stand very long in gardens, but I have seen one in an old garden, whose stem was more than two feet and a half round.

VICIA. *Tourn. Inst. R. H.* 396. *tab.* 221. Vetch, or Tare.

The Characters are,

The flower is of the butterfly kind; the standard is oval, broad at the tail, indented at the point, and the borders are reflexed; the two wings are shorter than the standard; the keel is shorter than the wings; the tail is oblong. It has ten stamina, nine joined and one separated, terminated by erect summits, and a linear compressed germen, supporting a slender style, crowned by an obtuse stigma, which is bearded on the under side. The germen afterward turns to a long pod with one cell opening with two valves, ending with an acute point, containing several roundish seeds.

The Species are,

1. VICIA *pedunculis multifloris, floribus imbricatis, foliolis lanceolatis pubescentibus, stipulis integris.* *Lin. Sp. Plant.* 735. Vetch with many imbricated flowers on a foot-stalk, spear-shaped hairy lobes to the leaves, and entire stipula; or many-flowered Vetch.

2. VICIA *pedunculis multifloris, foliolis ovalibus, stipulis denticulatis.* *Lin. Sp. Plant.* 734. Vetch with foot-stalks supporting many flowers, oval lobes to the leaves, and indented stipula; or the largest many-flowered Wood Vetch.

3. VICIA *pedunculis subsexfloris, foliolis denis ovatis acutis, stipulis integris.* *Lin. Sp. Plant.* 735. Vetch with foot-stalks, having about six flowers, leaves with ten oval acute lobes, and entire stipula.

4. VICIA *pedunculis multifloris, petiolis sulcatis, subdodecaphyllis, foliolis lanceolatis glabris.* *Lin. Sp. Plant.* 736. Many-flowered Vetch with furrowed foot-stalks, and for the most part twelve spear-shaped smooth lobes to each leaf.

5. VICIA *leguminibus sessilibus subbinatis erectis, foliis retusis, stipulis notatis.* *Lin. Sp. Plant.* 736. Vetch with erect pods growing by pairs, and sitting close to the stalks, blunt lobes to the leaves, and spotted stipula; or common cultivated Vetch, with a black seed, frequently called Tares.

There are many more species of this genus, some of which grow naturally in England; but as they are rarely cultivated, except in botanick gardens for the sake of variety, they are omitted, as they are plants of little use or beauty.

The first sort here mentioned grows naturally among bushes, and by the sides of woods in most parts of England. The root is perennial, but the stalks are annual; these are weak, requiring support; they rise five or six feet high, fastening their tendrils, which grow at the end of their leaves, to the bushes or hedges, whereby they climb; they are hairy, as are also the leaves, which are composed of about ten pair of spear-shaped lobes, terminated by a tendril. The flowers stand upon long foot-stalks, which spring from the wings of the stalk; the spikes are long; the flowers lie one over the other; they are of a fine blue colour, so make a pretty appearance, when they come out from between the bushes or shrubs which support them; they appear in July, and are succeeded by compressed pods, filled with round seeds, which ripen in autumn.

The second sort grows naturally in the woods near Bath and Bristol; this has a perennial root. The stalks are weak,

and climb by the help of their tendrils over the neighbouring bushes and hedges, rising to the height of seven or eight feet. The leaves are composed of seven or eight pair of oval smooth lobes, terminated by tendrils. The flowers are produced in long spikes from the wings of the stalks; they are of a pale blue colour, and are larger than those of the former sort; they appear in July, and are succeeded by short smooth pods, filled with round seeds, which ripen in autumn.

The third sort grows naturally in *Cassubia*; this has a ligneous creeping root; the stalks trail upon the ground; they grow three feet long, and their lower part become ligneous toward autumn, but they die to the root in winter. The leaves are composed of ten pair of oval acute-pointed lobes. The flowers come out from the wings of the stalk; they are disposed in short spikes, each containing, for the most part, six pale blue flowers, which appear in July, and are succeeded by short smooth pods like those of Lentils, including three or four round seeds, which ripen in autumn.

These sorts have been recommended to be sown in the fields for fodder for cattle; but as their stalks are slender and less succulent than those of the common Vetch, so it is doubtful, if these will answer the purpose of farmers to cultivate them; for as their stalks trail to a great length, so if they have not support, they will be subject to rot by lying upon the ground; and although their roots are perennial, yet as it is late in the spring before they shoot to a height sufficient to cut for use, so there is little want of green feed for cattle at that time.

However, a few of these plants may be allowed a place in large gardens for the sake of variety, where, if they are properly placed, they may be ornamental, particularly on the borders of wood-walks, or in thickets of shrubs. If some of the first sort are allowed to climb up upon their branches, they will have a good effect during their continuance in flower.

These sorts are propagated by seeds, which should be sown in autumn soon after they are ripe, for if they are kept out of the ground till spring, the seeds often fail, or at least remain in the ground a year before they vegetate; they should be sown in the places where the plants are designed to remain, for they do not bear transplanting well. These plants grow naturally in woods and thickets of bushes, where their roots are screened from the sun, and their stalks furnished with supports by the bushes, point out the places where the seeds should be sown, which should be where they are sheltered by shrubs. If three or four seeds are sown in each patch, it will be sufficient, for if one or two plants come up in each place, it will be enough. When the plants come up, they will require no other culture but to keep them clean from weeds, and their stalks must be permitted to climb upon the neighbouring shrubs; for if they trail upon the ground, they will produce few flowers, and in wet seasons the stalks will rot, so the plants will be rather unsightly.

The fourth sort grows naturally in *Siberia*; this is a biennial plant, which promises fairly to become a useful one for fodder; for the stalks of this grow to a great length, and are well furnished with leaves: these do not decay in autumn, but continue green through the winter in defiance of the most severe frost; so that in *February* and *March*, when there is often a scarcity of green feed for ewes and lambs, this may be of great service.

The stalks of this rise five or six feet high. The leaves are composed of five or six pair of smooth spear-shaped lobes, terminated by tendrils. The foot-stalks are deeply furrowed. The flowers are produced in spikes upon long foot-stalks, which spring from the wings of the stalks; they are of a light blue colour, and appear in July; these are succeeded

by short compressed pods, containing three or four round seeds, which ripen in autumn.

This sort is propagated by seeds, which may be sown in the spring or autumn; and when the plants come up, they will require no other culture but to keep them clean from weeds; and if they are supported from trailing upon the ground, they will continue in verdure all the winter, and the following summer they will flower and produce ripe seeds.

If this plant is designed for feed, the seeds should be sown in rows at four feet distance, and should be dropped thin in the rows, for as the stalks send out many branches, and extend to a great length, so when the plants are too close, the branches will intermix, and mat so closely together, as to rot each other by excluding the air. When the plants come up, they must be kept clean from weeds, which, while they are young, should be performed with *Dutch hoes*, but afterward it may be done by the hoeing-plough, which will save expence; and with this instrument the plants may be earthed up in the same manner as Peas and Beans, which will greatly strengthen their stalks, and make them and the leaves larger and more succulent, so increase the quantity of feed. If this is practised as often as may be found necessary to destroy the weeds in summer, it will prepare the ground for any crop which may afterward be put upon the land; and as this will be in no danger of suffering from frost, so it should be preserved till the spring, when there is a want of green feed for ewes; at which time it may be cut as it is wanted, but a part of the plants should be permitted to stand for seeds, for those which are cut, if they do shoot again, will flower so late in summer, that unless the autumn proves very warm, the seeds will not ripen; therefore it will be a better way to sow a sufficient quantity of seeds for this purpose, in a separate spot of ground, because, when the other is cut, the ground may be ploughed for other crops; and if in mild seasons there may be so great plenty of other green feed as not to want this, if the plants are ploughed into the ground, it will be a good dressing for other crops.

This is what I am now beginning to try in the field, where I have not as yet had experience of its culture; but what I have here advised, is founded upon experiments which I have for several years made, on small patches sown in gardens in different situations. In all these patches I have found the plants continue in great verdure, when most of the perennial plants in the same situation have suffered greatly by the frost; and from eight of these plants I could have cut as much seed as would have been equivalent to half a truss of green Clover.

The fifth sort is the common Vetch or Tare, which is much cultivated in the fields for fodder; of this there are two varieties, if not distinct species. The first, which is the most common, has a black seed; the other has seeds as white, if not whiter than the whitest Peas; and this difference is permanent, for I have sown both sorts many years, and have never found either of them vary. These plants are annual, and perish soon after they have perfected their seeds. The stalks are angular, streaked, and hairy; they are weak and want support, so generally decline where they have nothing near to fasten themselves to. The leaves are composed of several pair of blunt lobes, and are terminated by tendrils. The flowers come out from the wings of the stalk, sitting very close to the base of the foot-stalks of the leaves; two of these generally spring from the same joint; they are pretty large, and of the butterfly shape; they are purple, and appear in *June* and *July*, which are succeeded by erect pods, containing three or four round seeds in each.

There is another kind of Vetch which is cultivated in the fields, with a smaller black seed; this is called in some

counties Rath ripe Vetch, and in others Pebble, or Summer Vetch; but this being much tenderer than the common Vetch, is not much cultivated, as it must always be sown in the spring, and will ripen its seeds the same summer; but it will not afford near so much fodder as the other.

Vetches are generally sown at two seasons, one is in autumn, and the other early in the spring; but the best time is in *August*, for the seeds which are sown then will come up soon, and the plants will have time to get strength before winter, so will be in less danger of suffering by frost than those which are sown later, and will be fit to cut for feed much earlier in the spring, for that is the time when green feed is most wanted; and if they are designed for seed, and not to be cut for fodder, those early-sown Vetches will come soon into flower, and the seeds will be ripe early, so they may be cut and stacked in good weather, which is a great advantage, for those which ripen late are often stacked or housed wet, and then the seeds frequently sprout in the mow and are spoiled.

The usual method of sowing Vetches is in broad-cast, ploughing them lightly in; in this way the common allowance of seeds for one acre of land, is two bushels; but there are some who sow two bushels and a half; this practice may do well enough for those Vetches which are designed to be cut for fodder in the spring, but those which are sown with an intent to stand for seeds, will do much better if they are sown in drills, in the same way as is practised for Peas, and then less than half the quantity of seeds will be sufficient, for the drills should not be nearer to each other than three feet, that the hoe-plough may have room to go between them, to destroy the weeds, and earth up the plants, for by this management they will produce a much greater crop, and ripen earlier in the season. These drills should be about the same depth as those usually made for Peas, and the seeds should be scattered about the same distance in the drills. These seeds should be carefully covered as soon as they are sown; for if they are left open, the rooks will discover them, and when they once find the rows, if they are not carefully watched, they will entirely devour them. Indeed these being sown early in autumn, will be in less danger than those which are sown late, or in the spring, because there is more food for rooks and pigeons in the open fields at this season, and the plants will appear much sooner above ground. The best time to sow them is about the beginning of *August*, for the rains which usually fall about that season, will bring them up in a short time. Toward the latter end of *October* the plants will have obtained considerable strength, therefore they should be earthed up with the hoeing-plough. This work should be performed in dry weather, and in doing it care must be had to lay the earth up as high to the stems of the plants as possible, so as not to cover their stalks, because this will secure them against frost. The whole space of ground between the rows should also be stirred, in order to destroy the weeds, which, if carefully performed in dry weather, will lay the land clean till *March*; at which time the crop should be earthed a second time, and the ground cleaned again between the rows, which will cause the plants to grow vigorous, and in a little time they will spread so as to meet, and cover the spaces; whereas those sown in the spring, will not grow to half this size, and will be much later in flowering.

Some people sow these Vetches, and when they are fully grown, plough them into the ground to manure it. Where this is designed, there will be no occasion to sow them in drills at this distance, nor to husband them in the manner before directed; but in this case it will be the best method to sow them in autumn, because they will be fit to plough in much sooner the following year, so that the land may be better prepared to receive the crops for which it is intended.

tended. In some parts of *France*, and in *Italy*, these Vetches are sown for feeding of cattle while green, and are accounted very profitable, and in many parts of *England* they are cultivated to feed cart-horses, &c. though upon such land where Lucern will thrive, it will be much better husbandry to cultivate that for this purpose.

Where these plants are cultivated for their seeds, they should be cut soon after the pods change brown; and when they are dry, they must be immediately stacked, for if they are suffered to lie out in the field to receive wet, and there come one hot day after it, the pods will most of them burst, and cast out the seeds. When the seeds are threshed out, the haulm is esteemed very good for cattle; and some have recommended the seeds for horses, and affirm they are as proper for those animals as Beans, which, if true, will render them more valuable, because these will grow on the lightest sandy land, where Beans will not thrive, so may be a good improvement to some counties in *England*, where they do not attempt to cultivate Beans.

VINCA. *Lin. Gen. Plant.* 261. Periwinkle.

The Characters are,

The empalment of the flower is permanent. The flower has one salver-shaped petal, whose tube is longer than the empalment. The brim is broad, spreading open, and slightly cut into five obtuse segments; it has five very short inflexed stamina, terminated by erect obtuse summits, and two roundish germen, which have two roundish corpuscles on their side, supporting one common style the length of the stamina, crowned by two stigmas. The germen afterwards turns to a fruit, composed of two taper acute-pointed husks, opening lengthways with one valve, and filled with oblong cylindrical seeds.

The Species are,

1. VINCA *caulibus procumbentibus, foliis lanceolato-ovatis.* *Lin. Sp. Plant.* 209. Periwinkle with trailing stalks, and oval spear-shaped leaves; or common narrow-leaved Periwinkle.

2. VINCA *caulibus erectis, foliis ovatis.* *Lin. Sp. Plant.* 209. Periwinkle with erect stalks, and oval leaves; or broad-leaved Periwinkle.

3. VINCA *foliis oblongo ovatis integerrimis, tubo floris longissimo, caule ramofo fruticoso.* *Tab.* 86. Periwinkle with oblong, oval, entire leaves, a very long tube to the flower, and a shrubby branching stalk.

The first sort grows naturally under hedges and bushes in many parts of *England*. The stalks are slender, and trail upon the ground, emitting fibres from their joints, which take root, whereby the plant multiplies and spreads greatly. The leaves are placed opposite on their stalks; they are oval, spear-shaped, of a thick consistence, very smooth, and entire; their upper side is of a lucid green, and their under of a paler colour. The flowers stand singly upon foot-stalks, which spring from the wings of the stalks; they are nearly of a funnel-shape, but spread more at their brim, which is almost flat like a salver; their brim is divided into five broad obtuse segments. The most common colour of the flower is blue; but it is often found with a white flower, and sometimes the flowers are variegated with both colours. These flowers begin to appear in *April*, and there is often a succession of them continued great part of summer. The flowers are very rarely succeeded by seeds. *Tournefort* says, he was at a loss for the fruit of this plant, to engrave the figure of it in his *Elements of Botany*, which he obtained by planting some plants in small pots to confine their roots and prevent their stalks from trailing upon the ground. This experiment I tried several years without success; but I afterward planted three or four plants in the full ground, and constantly cut off their lateral shoots, leaving only the upper stalks; and these plants the second year produced plenty of the pods.

There are two varieties of this plant with variegated leaves; one has white, and the other yellow stripes; these are by some preserved in their gardens for the sake of variety. There is also one with double purple flowers, which I believe to be only an accidental variation, therefore have not enumerated it here.

The second sort is also found growing naturally in several parts of *England*. The stalks of this are larger than those of the former, and do not trail so close to the ground; they rise two feet high, but their tops decline again to the ground, and often put out roots when they are suffered to lie on the ground. The leaves of this sort are oval, heart-shaped, and stand opposite upon thick foot-stalks; their upper surface is of a lucid green, their under is of a lighter green colour; they are of a thick consistence, and entire. The flowers come out from the wings of the stalk in like manner as the former, and are of the same shape, but much larger. The usual colour is blue, but they are sometimes seen with white flowers. This sort flowers earlier in the spring than the former, and there is a succession of them great part of summer.

As these plants delight to grow under the cover of trees and bushes, so they may be made ornamental in large gardens, if they are planted on the verges of wildernesses, where they will spread and cover the ground; and as their leaves continue green all the year, they will have a good effect in winter, and their flowers appearing great part of summer, will add to the variety.

They are easily propagated by their trailing stalks, which put out roots very freely, especially those of the first sort; and if the stalks of the large sort are laid in the ground, they will root very soon, and may be cut off and transplanted where they are to remain; when they are once rooted, they will spread and multiply very fast without farther care. The first sort is used in medicine, and is esteemed a good vulnerary plant.

The third sort grows naturally in the island of *Madagascar*, from whence the seeds were brought to the Royal Garden at *Paris*, where the plants were first raised, and produced their flowers the following summer; from these plants good seeds were obtained, which were sent me by Mr. *Richard*, gardener to the king at *Versailles* and *Trianon*. It rises with an upright branching stalk to the height of three or four feet, which when young are succulent, jointed, and of a purple colour; but as the plants advance, their lower parts become ligneous. The branches which come out from the side, have their joints very close; they have a smooth purple bark, and are garnished with oblong, oval, entire leaves, which are smooth and succulent, sitting pretty close to the branches. The flowers come out from the wings of the branches singly, standing upon very short foot-stalks; their tube is long and slender; their brim spreads open flat, which is divided into five broad obtuse segments, which are reflexed at their points. The upper surface of the petal is of a bright crimson or Peach colour, and their under side is of a pale flesh colour. There is a succession of these flowers upon the same plant, from *February* to the end of *October*. Those flowers which appear early in the summer, are succeeded by taper seed-vessels, filled with roundish black seeds, which ripen in autumn.

This sort is propagated by seeds or cuttings; those plants which arise from seeds grow more upright, and do not branch so much as the plants which are propagated by cuttings. The seeds of this should be sown upon a moderate hot-bed in the spring; and when the plants come up, and are fit to remove, they should be transplanted on a fresh hot-bed at about four inches distance, shading them from the sun till they have taken new root; then they must be treated in the same way as other tender plants which are natives of warm countries;

countries; but there must be great care had to prevent their drawing up weak, nor should they have water in too great plenty. When the plants have obtained strength, they should be carefully taken up with balls of earth to their roots, and planted in pots filled with good earth, and plunged into a moderate hot-bed to facilitate their taking new root, observing to screen them from the sun; and when they are well rooted in the pots, they must be gradually hardened to bear the open air; but unless the summer proves warm, these plants should not be placed abroad, for they will not thrive if they are exposed to cold or wet; therefore during the summer they should be placed in an airy glass-case, and in winter they must be removed into the stove, where the air is kept to a temperate heat, without which they will not live through the winter in *England*.

If these plants are propagated by cuttings, they should be planted in pots during any of the summer months. The pots should be plunged into a moderate hot-bed, and if they are closely covered with bell or hand glasses, it will cause them to put out roots sooner than they otherwise would do; when these have put out roots, they must be gradually hardened, and afterward planted in pots, and treated in the same way as the seedling plants.

This plant deserves a place in the stove, as much as any of the exotic plants we have in *England*, because the flowers are very beautiful, and there is a constant succession of them all the summer.

VINCITOXICUM. See *Asclepias*.

VINE. See *Vitis*.

VIOLA. *Tourn. Inst. R. H.* 419. *tab.* 236. Violet.

The Characters are,

The flower has a short permanent empalement of five leaves, which are differently ranged in the different species. The flower is of the ringent kind, and is composed of five unequal petals; the upper is broad, obtuse, and indented at the point, having a horned nectarium at the base; two side petals are opposite; the two lower are larger, and reflexed; it has five small stamina, which are annexed as appendages to the entrance of the nectarium, terminated by obtuse summits, which are sometimes connected, and a roundish germen, supporting a slender style, which stands out beyond the summits, and is crowned by an oblique stigma. The germen afterward turns to an oval three-cornered capsule with one cell, opening with three valves, including many oval seeds.

The Species are,

1. *VIOLA acaulis, foliis cordatis, stolonibus reptantibus. Lin. Sp. Plant.* 934. Violet having stalks, heart-shaped leaves, and creeping shoots; or Purple March Violet.

2. *VIOLA acaulis, foliis cordatis piloso-hispidis. Flor. Succ.* 718. Violet without stalk, having heart-shaped leaves with stinging hairs; or hairy, scentless, March Violet.

3. *VIOLA acaulis, foliis reniformibus. Haller. Helvet.* 501. Violet without stalk, and kidney-shaped leaves; or Violet with round smooth leaves.

4. *VIOLA acaulis, foliis lanceolatis crenatis. Lin. Sp. Plant.* 934. Violet without stalks, and spear-shaped notched leaves; or *Acadian* Violet.

5. *VIOLA acaulis, foliis pedatis septempartitis. Lin. Sp. Plant.* 933. Violet without stalks, and leaves growing like feet, divided into seven parts; or three-coloured *Virginia* Violet.

6. *VIOLA acaulis, foliis palmatis quinque lobis dentatis indivisissimisque. Lin. Sp. Plant.* 933. Violet without stalks, and hand-shaped leaves, with five indented undivided lobes; or *Virginia* Violet, with leaves like those of the Plane-tree.

7. *VIOLA acaulis, foliis pinnatifidis. Lin. Sp. Plant.* 734. Violet without stalks, and leaves having many points; or *Alpine* Violet.

8. *VIOLA acaulis, grandiflora, foliis ovalibus uniformibus integerrimis. Allion.* Violet without a stalk, having a large flower, and oval entire leaves, which are uniform.

9. *VIOLA caulibus erectis, foliis cordatis oblongis. Lin. Sp. Plant.* 935. Violet with erect stalks, and oblong heart-shaped leaves; or tree-like purple Violet.

10. *VIOLA caule triquetro diffuso, foliis oblongis dentatis, stipulis multifidis.* Violet with a four-cornered diffused stalk, oblong indented leaves, and many-pointed stipulae; commonly called Hearts-ease or Pansies.

11. *VIOLA caule diffuso decumbente, foliis oblongis incisissimis, stolonibus reptatricibus.* Violet with a diffused trailing stalk, oblong cut leaves, and creeping shoots; or yellow Mountain Violet with a large flower.

The first sort, which is the common sweet Violet, grows naturally under hedges in the neighbourhood of *London*; but in several of the distant counties, the Violet without scent is the sort most frequent. Of the common Violet there are the following varieties. The single blue and white; the double blue and white; and the pale purple. These are all of them commonly preserved in gardens for the odour of their flowers, and are so well known as to need no description.

The second sort is found growing naturally in many parts of *England*. The leaves of this are larger, and are covered with rough stinging hairs. The flowers are larger, and have no scent, which are the only differences.

The third sort grows naturally in marshes and on bogs in several parts of *England*. The leaves of this are small, kidney-shaped, and smooth. The flowers are small, and of a pale blue colour; they appear in *June*, and are succeeded by small oblong capsules, filled with roundish seed.

The fourth sort grows naturally in *North America*. The leaves of this are spear-shaped, and deeply notched on their edges, standing upon short foot-stalks. The flowers are larger than those of the common sort, but have no scent.

The fifth sort is also a native of *North America*. The leaves of this are divided into seven parts or lobes, which are united at the foot-stalk. The flowers stand upon naked foot-stalks; they are of the Pansy kind, and have no scent; they appear in *June*, but are not succeeded by seeds here.

The sixth sort grows naturally in *Virginia*. The leaves of this are most of them divided into five lobes like the fingers of a hand, but some of the lower leaves are entire. The flowers are small, white, and have no scent.

The seventh sort grows naturally on the *Alps*; this was sent me by Dr. *Allione* from *Turin*; it is a very low plant, seldom rising two inches high. The leaves are small, and cut into winged points. The flowers are of a pale blue colour, and appear in *June*.

The eighth sort was sent me by the same gentleman, who found it growing on the *Alps*; this is also an humble plant, with oval, entire, uniform leaves, not more than half an inch long, and a quarter broad, standing upon short foot-stalks. The flowers are large, of a light blue colour, and appear in *June*. These have no scent.

The ninth sort grows naturally on the *Alps*, and the mountains in *Austria*. The root of this is perennial, but the stalks and leaves decay in autumn; it has erect stalks, which rise more than a foot high, garnished with oblong heart-shaped leaves. The flowers stand upon long foot-stalks, which spring from the wings of the stalks; they are shaped like those of the Dog Violet, and are of a pale blue colour; these appear the end of *May*, and are succeeded by roundish capsules, filled with small seeds, which ripen in *August*.

The tenth sort is the Hearts-ease or Pansies, which grows naturally in some of the northern counties of *England*, but is generally cultivated in gardens near *London*. Of this there are many varieties, which differ greatly in the size and colour of their flowers. Some of these varieties have very

large beautiful flowers, which have an agreeable odour; others have small flowers without scent; whether these are distinct species or accidental varieties, I have not been able to determine; for I have sowed the seeds of most of the varieties as carefully as possible, and have sown them separate, but have always had a mixture arise, which may have come from seeds lying in the ground; for in gardens, where these plants have been permitted to scatter their seeds, it is impossible to know how long the seeds may lie in the ground, and when they are turned up to the surface, they will grow, which renders it difficult to determine the specific differences of these plants in such places.

This is an annual plant, whose roots decay after they have flowered and perfected their seeds. The lower leaves are roundish or oblong, and are indented on their edges; the stalks rise seven or eight inches high, sending out many diffused branches, garnished with leaves, which are longer and narrower than those below, notched on their edges, and sit close to the branches. The flowers stand upon long naked foot stalks, which spring from the wings of the stalk, shaped like those of the common Violet. Some of the varieties have flowers much larger, and others are of the size of *March* Violets; some of them have the two upper petals of a deep yellow colour, with a purple spot in each, the two middle of a paler yellow with a deep yellow spot, and the lower petal of a velvet colour; in others the petals are white with yellow and purple spots; in some the yellow is the most prevailing colour, and in others the purple.

The eleventh sort grows naturally upon mountains in the north of *England* and in *Wales*; this has a perennial root, sending out shoots from the side, which spread and propagate, in which it differs from all the Pansies. The lower leaves are oblong and jagged; the stalks seldom rise more than four or five inches high; they decline, and are garnished with narrower leaves than those below, which are deeper cut on their sides. The flowers stand upon naked foot stalks two inches long; they are much larger than those of the common sort, and are of a deep yellow colour, with a few purple streaks in the center. This plant continues flowering great part of summer, but the flowers have no scent.

The common Violets are easily propagated by parting of their roots; this may be done at two seasons. The first or most common season for removing and parting of these roots is at *Michaelmas*, that the young plants may be well rooted before winter; this is generally practised where the plants are put on the borders of wood-walks in large plantations; but in the gardens where they are cultivated for their flowers, the gardeners transplant and part their plants, soon after their flowering season is over. These will have all the remaining summer to grow and get strength, so will produce a greater quantity of flowers the following spring than those which are removed in autumn; but this is not to be practised where they cannot be supplied with water till they have taken new root, unless in moist seasons.

Violets may also be propagated by seeds, which should be sown soon after they are ripe, which is about the end of *August*. The plants will come up the following spring, and when they are fit to remove, they should be transplanted in shady borders to grow till autumn, and then they may be planted where they are to remain; but the double-flowering Violets do not produce seeds. Although the white, blue, and purple Violets are generally supposed to be varieties which have accidentally sprung from seeds, yet I have several years sowed the seeds of all the three sorts, and have not found either of them vary.

The other sorts of Spring Violets are sometimes preserved in botanick gardens for the sake of variety; these may be propagated in the same way as the common sort, but require a moist soil and a shady situation.

The upright sort does not send out shoots like the common Violet, so increases but slowly by offsets; this may be propagated by seeds in plenty, and is as hardy as the common sort.

The several varieties of Pansies will scatter their seeds in a short time after the flowers are past; and from these self-sown seeds the plants, which come up in autumn, will flower very early in the spring, and these will be succeeded by the spring plants; so that where they are indulged in a garden, and their seeds are permitted to scatter, there will be a constant succession of their flowers the greatest part of the year, for they will flower all the winter in mild seasons, and most part of the summer in shady situations, which renders them worthy of a place in every good garden; but then they must not be allowed to spread too far, lest they become troublesome weeds, for their seeds, when ripe, are cast out of their covers with great elasticity to a considerable distance, and the plants will soon spread over a large space of ground, if they are permitted to stand.

The common Pansy stands in the *College Dispensatory* as a medicinal plant, but is rarely used in *England*.

The great yellow Violet propagates by offsets in pretty great plenty, if it has a moist soil and a shady situation; this may be transplanted in autumn, and the offsets may then be taken off; but the roots should not be divided into small heads, nor should they be too often transplanted, because they will not produce many flowers unless the plants are strong, and have good root in the ground. This sort will not live in a dry soil, nor in a situation much exposed to the sun.

VIRGA AUREA. See Solidago.

VISCUM. *Tourn. Inst. R. H. 609. tab. 380.* Mistleto.

The Characters are,

It has male and female flowers upon separate plants. The male flowers have no petals, but have four summits, which are oblong and acute pointed, festened to the leaves of the empalement. The female flowers have an empalement of four small oval leaves sitting upon the germen, but have no petals or stamina, with an oblong three-cornered germen, situated under the flower, having no style, but is crowned by an obtuse stigma. The germen afterward turns to a globular smooth berry with one cell, including a fleshy heart shaped seed.

We have but one Species of this genus in *Europe*, viz.

VISCUM foliis lanceolatis obtusis, caule dichotomo, spicis axillaribus. Lin. Sp. Plant. 1033. Mistleto with blunt spear-shaped leaves, stalks dividing by pairs, and spikes of flowers rising from the wings of the stalk.

This plant, instead of rooting and growing in the earth like other plants, fixes itself, and takes root on the branches of trees; it spreads out with many branches, and forms a large bush. The branches are ligneous; they have a yellow green bark; the largest is about the thickness of a man's finger; the other are gradually smaller, full of joints, which easily part asunder, at each of which grow two thick fleshy leaves, which are broad and rounded at their points, and narrow at their base. The flowers come out from the wings of the stalk in short spikes; they have four yellow leaves, which are by some called petals, and by others the empalement. The female flowers are succeeded by round white berries, which are almost pellucid, about the size of large white Currants, full of a rough viscid juice, in the middle of which lies one heart shaped flat seed.

It grows upon the white Thorn, the Apple, the Crab, the Hazel, the Ash, and Maple, but is rarely found upon the Oak, though the Mistleto of the last has been always accounted the best of all; which opinion, as Mr *Ray* well observe, may be owing to the superstitious honour the ancient *Druids* of this island gave to this Mistleto, to whom nothing was more sacred.

This plant is always produced from seed, and is not to be cultivated in the earth as most other plants, but will always grow upon trees, from whence the ancients accounted it a super-plant, most of whom thought it was an excrescence on the tree, without the seed being previously lodged there; which opinion is now generally confuted from a repeated number of experiments.

The manner of its being propagated is this, *viz.* the Mistle thrush, which feeds upon the berries in winter, when they are ripe, often carry the seeds from tree to tree; for the viscous part of the berry, which immediately surrounds the seed, doth sometimes fasten it to the outward part of the bird's beak, which, to get disengaged of, he strikes his beak against the branches of a neighbouring tree, and thereby leaves the seed sticking by this viscous matter to the bark, which, if it lights upon a smooth part of the tree, will fasten itself thereto, and the following winter will put out and grow; and in the same manner it may be propagated by art, for if the berries, when full ripe, are rubbed upon the smooth part of the bark of a tree, they will adhere closely thereto, and, if not destroyed, will produce plants the following winter.

The trees which this plant doth most readily take upon, are the Apple, the Ash, and other smooth-rinded trees before-mentioned; but I have several times tried it upon the Oak without success, for the bark of that tree is of too close a texture to admit the seeds sticking therein, which is also the reason it is so rarely found upon that tree; and notwithstanding the great encomiums which have been given to the Mistle of the Oak for its medicinal virtues, yet I cannot help thinking that it is equally good from whatever tree it be taken; nor is it possible to find this plant growing in any quantity upon the Oak; so that those persons, who pretend to furnish the town with it for physical use, do but impose upon the world, for it is so rarely met with, that whenever a branch of an Oak-tree hath any of these plants growing upon it, it is cut off, and preserved by the curious in their collections of natural curiosities, and of these there are but few to be seen in *England*.

As to what some persons have asserted of the manner how it is propagated from tree to tree, by the Mistle thrushes, which eat the berries and void the seed in their dung upon the branches of trees, whereby the seeds are stuck thereon, and take root into the bark and produce fresh plants, I can by no means agree to, since, if it were only this way propagated, it would always be found on the upper part or the sides of such branches, upon which the dung can only be supposed to lodge, whereas it is generally found upon the under side of branches, where it is almost impossible for these birds to cast their dung; besides, I believe the stomachs of these birds are too powerful digesters, to suffer any seeds to pass so entire through the intestines as to afterwards grow, but I shall leave this to such as have leisure to make observations in those places where this plant abounds.

Of the berries of this plant birdlime was formerly made in *England*. This was done by boiling the berries in water till they burst, when they were well beaten in a mortar, and afterward washed till all the branny husks were cleared away.

VISNAGA. See Daucus.

VITEX *Tourn. Inst. R. H.* 603. *tab.* 373. Agnus Castus, or the Chaste-tree.

The Characters are,

The empalement of the flower is cylindrical, and indented in *five* parts. The flower has one ringent petal; the brim is plain, and divided into two lips, which are trifid; the middle segment is the broadest in both. It has four hair-like stamina, two being shorter than the other, terminated by moveable summits, and a roundish germen, supporting a slender style, crowned by two awl-

shaped spreading stigmas. The germen afterward turns to a globular berry with four cells, each containing one oval seed.

The Species are,

1. VITEX *foliis digitatis, spicis verticillatis.* *Lin. Sp. Plant.* 938. Chaste-tree with fingered leaves, and whorled spikes of flowers; or common Chaste-tree.

2. VITEX *foliis digitatis serratis, spicis paniculatis.* Chaste-tree with fingered sawed leaves, and spikes in panicles; Chaste-tree with a broader sawed leaf.

3. VITEX *foliis ternatis quinatisve, paniculis dichotomis.* *Lin. Sp. Plant.* 938. Chaste-tree with trifoliate and quinate leaves, and panicles of flowers rising from the division of the branches; smaller *Indian* Chaste-tree.

4. VITEX *foliis ternatis quinatisque pinnato-incisis, spicis verticillatis terminalibus.* Chaste tree with ternate and quinate leaves which are cut like wings, and whorled spikes of flowers terminating the branches.

The first sort grows naturally in *Sicily*, near *Naples*, by the sides of rivers, and in the *Archipelago* in moist places; it has a shrubby stalk ten or twelve feet high, sending out branches opposite the whole length, which are angular, pliable, and have a grayish bark, garnished with leaves for the most part placed opposite, composed of five, six, or seven lobes which unite at the foot-stalk, and spread out like the fingers of a hand, ending in blunt points, of a dark green on their upper side, but hoary on their under. The flowers are produced in spikes at the extremity of the branches, from seven to fifteen inches long, disposed in whorls round the stalks, with intervals between each whorl; they are of the lip kind; the two lips are each cut into three segments, the middle being larger than the two sides; in some plants white, and in others blue; these are generally late before they appear, so that in bad seasons they do not open fair. The flowers have an agreeable odour, and make a good appearance in autumn, when the flowers of most other shrubs are gone, for in warm mild seasons I have seen these shrubs in full flower the middle of *October*.

The second sort grows naturally in the south of *France*, and in *Italy*; this is a lower shrub than the first; it seldom rises more than four or five feet high, coming up with several stalks from the root, which do not branch so much as the former; their bark is also whiter. The leaves are fingered, and composed of five or seven lobes which unite at the foot-stalk; these are not so disproportionate in their length, are sawed on their edges, and are not so stiff as those of the former. The flowers come out in panicled spikes toward the end of the branches; the spikes are shorter, and the flowers smaller than those of the first sort, and appear sooner; they are all of them blue which I have seen.

The third sort grows naturally in both *Indies*; this has a shrubby stalk, which rises nine or ten feet high, sending out many side branches which have a brown bark, garnished with leaves which have sometimes three, and at others five, oval acute-pointed lobes which are entire, and a little downy on their under side. The flowers are disposed in panicles which arise at the division of the branches; these are small and white, but are not succeeded by any seeds in *England*.

The fourth sort grows naturally in the northern parts of *China*, where it rises with woody stalks eight or ten feet high, having a gray bark. The branches come out opposite, garnished with leaves placed opposite upon long foot-stalks; these are composed of three or five spear-shaped lobes, which are deeply sawed on their edges, and end in very acute points, of a dark green on their upper side, but grey on their under. The flowers are disposed in whorled spikes, which come out opposite from the wings of the stalk; these are blue, and about the size of those of the first.

The first sort is pretty common in many *English* gardens, where it has been long an inhabitant, but was not much propagated till of late years. The second sort is less common, and only in some curious gardens at present. These plants are very hardy, and may be propagated by planting their cuttings early in the spring before they shoot; they require a fresh light soil, and must be frequently refreshed with water until they have taken root; after which they must be carefully cleared from weeds during the summer season, and if the following winter prove severe, you must lay a little mulch upon the surface of the ground between the plants, to prevent the frost from penetrating to their roots, which would injure them while they are young; and as these cuttings are apt to shoot late in the year, their tops will be very tender, and the early frosts in autumn often kill them down a considerable length, if they are not protected, therefore they should then be covered with mats, which will be of great service to them. Toward the middle of *March*, if the season is favourable, you should transplant them either into the places where they are designed to remain, or into a nursery to grow two or three years to get strength, where they must be pruned up, in order to form them into regular stalks, otherwise they are very subject to shoot out their branches in a straggling manner.

They may also be propagated by laying down their branches in the spring of the year, in doing of which you must be very careful not to break them, for their shoots are very apt to split if they are much forced; these will take root in one year, provided they are watered in very dry weather, and may then be transplanted out, and managed, as was directed for those plants raised from cuttings.

The third sort is too tender to live in the open air in *England*, so must be planted in pots, and constantly kept in the stove; it is propagated both by cuttings and layers, but the cuttings of this must be planted in pots, and plunged into a moderate hot-bed, covering them close with a bell or hand-glass, to exclude the air; they should be refreshed with water now and then, but it must not be given them too freely. The best time to plant the cuttings is about the middle or latter end of *April*, for if they succeed they will put out roots in six or seven weeks, and will then begin to shoot, so they should have the free air gradually admitted to them, to prevent their shooting weak; then they may be carefully taken up, and each planted in a separate small pot filled with light earth, and plunged into the hot-bed again, shading them from the sun till they have taken new root, after which they should have plenty of free air at all times when the weather is good, treating them in the same manner as other tender plants. In winter they must be kept in a moderate temperature of heat, but in the summer they should have the free air in mild weather, but not removed into the open air.

The fourth sort has been lately introduced into the *English* gardens from *Paris*, where the plants were raised from seeds, which were sent from *China* by the missionaries. I was favoured with some young plants by Monsieur *Richard*, gardener to the king at *Versailles*. The two sorts with white and blue flowers have succeeded in the *Chelsea* garden, but that with red flowers was injured in the way and miscarried.

This is propagated by cuttings, which must be planted in the spring in pots, plunging them into a moderate hot-bed, and, when the cuttings are well rooted, they should be carefully taken up, and each planted in a separate small pot filled with light earth, and placed in the shade until they have taken new root; then they may be removed to a sheltered situation, placing them with other green-house plants, where they may remain all the summer; but in autumn they must be put into shelter, for they will not live in

the open air in this country; but as they cast their leaves early in autumn, so they must not have much wet in winter. The plants are late in putting out new leaves in the spring, and, before these appear, they have so much the appearance of dead plants, that they have been turned out of the pots by some, supposing they were so.

VITIS. *Tourn. Inst. R. H.* 613. tab. 384. The Vine.

The Characters are,

The flower has a small empalement indented in five parts; it has five small petals which drop off, and five awl-shaped stamina, which spread and fall away, terminated by single summits, with an oval germen having no style, crowned by a headed obtuse stigma. The germen afterward turns to an oval or roundish berry with one cell, including five hard seeds or stones.

I shall not trouble the reader with an enumeration of all the sorts of Grapes which are at present known in *England*, which would swell this work much beyond its intended bulk, and be of little use, since many of them are not worth the trouble of cultivating; so I shall only select those which ripen well in this country, or that merit a little assistance to bring them to perfection by artificial heat.

The *July Grape*; this is called by the *French*, *Morillon noir batif*, is a small, round, black berry, growing loose on the bunches. The juice is sugary, but has little flavour, and has no merit but that of ripening early. It ripens the beginning of *August*.

The black Sweet Water is a small roundish berry, growing close in the bunches, which are short. The skin is thin, the juice very sweet, and the birds and flies are very apt to devour them if they are not guarded. It ripens soon after the other.

The white Sweet Water is a large round berry when in perfection, but these are very different in size on the same bunch; some of them will be of a large size, and others extremely small, for which reason it is not much esteemed. The juice is sugary, but not vinous. This ripens about the same time with the former.

The *Chasselas Blanc*, or Royal Muscadine, as it is called by some, is an excellent Grape, the bunches are generally large, and at the upper part divide with two smaller side bunches or shoulders. The berries are round, and, when perfectly ripe, turn of an amber colour. The juice is rich and vinous; it ripens in *September*, but, if carefully preserved, they will hang very late and become excellent.

The *Chasselas Musque*, or *Le Cour Grape*, as it is here called, by some called the *Frankindal*, is an excellent Grape, and generally ripens well in *England*, if it has a good aspect wall. The berries are very like those of the former in shape, size, and colour, but are fleshy and have a little musky flavour. It ripens at the same time with the former.

The black Cluster, or *Munier Grape*, as it is called by the *French*, from the hoary down of the leaves in summer, is a good fruit, and ripens well here. The bunches are short, the berries are oval, and are very close to each other, so that many of those which grow on the inside continue green when the outer are perfectly ripe. It ripens in *September*, and is by some called the *Burgundy Grape*.

The *Auverna*, or true *Burgundy Grape*, sometimes called black *Morillon*, is an indifferent fruit for the table, but is esteemed one of the best sorts for making wine. The berries of this are oval, and hang looser on the bunches than those of the Cluster Grape, so ripen equally, which gives it the preference.

The *Corinth*, or as it is vulgarly called the *Currant Grape*, is a small roundish berry, generally without stone, of a deep black colour, and much clustered on the bunches, which are short; it has a sugary juice, and ripens in *September*, but will not last long.

The red *Chaffelas* is very like the white in size and shape, but is of a dark red colour; it is a very good grape, but ripens later than the white, and is pretty rare in *England*.

The white Muscadine is somewhat like the *Chaffelas*, but the berries are smaller, and hang looser on the bunches, which are longer, but not so thick as those of the *Chaffelas*. The juice is sweet, but not so rich as the *Chaffelas*.

The black *Frontinac*, or *Muscat noir*, is a round berry of good size; they grow loose on the bunches, yet do not ripen equally. The bunches are short, the berries when fully ripe are very black, and are covered with a meal or flue, like the black plumbs. The juice of this is very rich and vinous. It ripens the end of *September*, or the beginning of *October*.

The red *Frontinac*, or *Muscat rouge*, is an excellent Grape when fully ripe, but unless the season proves very warm, they rarely ripen without artificial heat in *England*. The bunches of this sort are longer than those of the former; the berries are large and round; when they are fully ripe they are of a brick colour, but before they are grey with a few dark stripes, and this is frequently taken for a different kind, and is commonly called grisley *Frontinac*; but I am convinced it is the same Grape. The juice of this has the most vinous flavour of all the sorts, and is greatly esteemed in *France*.

The white *Frontinac* has larger bunches than either of the former; the berries are round, and are so closely clustered on the bunches, as that unless they are carefully thinned early in the season, when the berries are very small, the sun and air will be excluded from many of them, so that they will not ripen, and the moisture will be detained in the autumn, which will cause them to rot. The juice of this is excellent, and if the fruit is perfectly ripe is inferior to none. This the *French* call *Muscat blanc*.

The *Alexandrian Frontinac*, or *Muscat d'Alexandrie*, is by some called *Muscat* of *Jerusalem*. The berries of this are oval, and hang loose on the bunches; these are long and are not shouldered. There are two sorts, one with white and the other has red berries; their juice is very rich and vinous, but they seldom ripen in *England* without artificial heat.

The red and black *Hamburgh*, by some called the *Warner Grape*, from the person who brought it to *England*. These have middle-sized berries inclining to an oval shape. The bunches are large, and their juice when ripe is sugary, with a vinous flavour. This ripens in *October*.

The *St. Peter's Grape* has a large oval berry of a deep black colour when ripe. The bunches are very large, and make a fine appearance at the table, but the juice is not rich, and it ripens late in the year. The leaves of this sort are much more divided than those of the other sorts, approaching to those of the Parsley-leaved Grape, so it may be distinguished before the fruit is ripe.

The *Claret Grape*, *Bourdelais*, or *Verjuice Grape*, the *Raisin Grape*, the striped Grape, and many other sorts which never come to perfection here, are not worthy of a place in gardens, unless for the sake of variety; for when they have the assistance of heat to bring them to maturity, their juice is harsh, and without flavour, so they should not occupy the room of better fruit.

All the sorts of Grapes are propagated either from layers or cuttings, the former of which is greatly practised in *England*, but the latter is what I would recommend, as being much preferable to the other; for the roots of Vines do not grow strong and woody, as in most sorts of trees, but are long, slender, and pliable; therefore when they are taken out of the ground they seldom strike out any fibres from the weak roots, which generally shrivel and dry; so that they rather retard than help the plants in their

growth, by preventing the new fibres from pushing out; for which reason I had rather plant a good cutting than a rooted plant, provided it be well chosen, for there is little danger of its growing.

But as there are few persons who make choice of proper cuttings, or at least that form their cuttings rightly in *England*, so it will be proper to give directions for this in the first place, before I proceed. You should always make choice of such shoots as are strong and well ripened of the last year's growth; these should be cut from the old Vine, just below the place where they were produced, taking a knot, or piece of the two-years wood to each, which should be pruned smooth; then you should cut off the upper part of the shoots, so as to leave the cutting about sixteen inches long. When the piece or knot of old wood is cut at both ends, near the young shoot, the cuttings will resemble a little mallet; from whence *Columella* gives the title of *Malleolus* to the Vine-cuttings. In making the cuttings after this manner, there can be but one taken from each shoot; whereas most persons cut them into lengths of about a foot, and plant them all, which is very wrong, for the upper part of the shoots are never so well ripened as the lower, which was produced early in the spring, and has had the whole summer to harden; so that if they take root, they never make so good plants; for the wood of those cuttings being spongy and soft, admits the moisture too freely, whereby the plants will be luxuriant in growth, but never so fruitful as such whose wood is closer and more compact.

When the cuttings are thus prepared, if they are not then planted, they should be placed with their lower part in the ground in a dry soil, laying some litter upon their upper parts to prevent them from drying: in this situation they may remain till the beginning of *April*, (which is the best time for planting them) when you should take them out, and wash them from the filth they have contracted; and if you find them very dry, you should let them stand with their lower parts in water six or eight hours, which will distend their vessels, and dispose them for taking root. Then the ground being before prepared where the plants are designed to remain (whether against walls or for standards, for they should not be removed again) the cuttings should be planted; but in preparing the ground you should consider the nature of the soil, which, if strong, and inclinable to wet, is by no means proper for Grapes; therefore where it so happens, you should open a trench where the cuttings are to be planted, which should be filled with lime-rubbish, the better to drain off the moisture; then raise the border with fresh light earth about two feet thick, so that it may be at least a foot above the level of the ground; then you should open the holes at about six feet distance from each other, putting one good strong cutting into each hole, which should be laid a little sloping, that their tops may incline to the wall; but it must be put in so deep, as that the uppermost eye may be level with the surface of the ground; for when any part of the cutting is left above ground, as is the common method used by the *English* gardeners, most of the buds attempt to shoot, so that the strength of the cuttings is divided to nourish so many shoots, which must consequently be weaker than if only one of them grew; whereas, on the contrary, by burying the whole cutting in the ground, the sap is all employed on one single shoot, which consequently will be much stronger; besides, the sun and air are apt to dry that part of the cutting which remains above ground, and so often prevents their buds from shooting.

Then having placed the cutting into the ground, you should fill up the hole gently, pressing down the earth with your foot close about it, and raise a little hill just upon the top

top of the cutting, to cover the upper eye quite over, which will prevent it from drying; this being done, there is nothing more necessary but to keep the ground clear from weeds until the cuttings begin to shoot; at which time you should look over them carefully, to rub off any small shoots, if such are produced, fastening the first main shoot to the wall, which should be constantly trained up, as it is extended in length, to prevent its breaking or hanging down; you must continue to look over these once in about three weeks during the summer season, constantly rubbing off all lateral shoots which are produced; and be sure to keep the ground constantly clear from weeds, which, if suffered to grow, will exhaust the goodness of the soil and starve the cuttings.

The *Michaelmas* following, if your cuttings have produced strong shoots, you should prune them down to two eyes, which, though by some people may be thought too short, yet I am satisfied, from several experiments, to be the best method. The reason for advising the pruning vines at this season, rather than deferring it till spring, is, because the tender parts of those young shoots, if left on, are subject to decay in winter, for they are apt to grow late in the year, so the tops of their shoots are tender, and the early frosts will pinch them, and then they are frequently killed down a considerable length, which weakens their roots; but if they are cut off early in autumn, the wounds will heal over before the bad weather, and thereby the roots will be greatly strengthened.

In the spring, after the cold weather is past, you must gently dig up the borders to loosen the earth; but you must be very careful in doing this, not to injure the roots of your Vines; you should also raise the earth up to the stems of the plants, so as to cover the old wood, but not so deep as to cover either of the eyes of the last year's wood. After this they will require no farther care until they begin to shoot, when you should look over them carefully, to rub off all weak dangling shoots, leaving no more than the two shoots, which are produced from the two eyes of the last year's wood, which should be fastened to the wall; and so from this, until the Vines have done shooting, you should look them over once in three weeks or a month, to rub off all lateral shoots as they are produced, and to fasten the main shoots to the wall as they are extended in length, which must not be shortened before the middle or latter end of *July*, when it will be proper to nip off their tops, which will strengthen the lower eyes, and during the summer season you must constantly keep the ground clear from weeds; nor should you permit any sort of plants to grow near the Vines, which would not only rob them of nourishment, but shade the lower parts of the shoots, and thereby prevent their ripening; which will not only cause their wood to be spongy and luxuriant, but render it less fruitful.

As soon as the leaves begin to drop in autumn, you should prune these young Vines again, leaving three buds to each of the shoots, provided they are strong; otherwise it is better to shorten them down to two eyes if they are good, for it is a very wrong practice to leave much wood upon young Vines, or to leave their shoots too long, which greatly weakens the roots; then you should fasten them to the wall, spreading them out horizontally each way, that there may be room to train the new shoots the following summer, and in the spring the borders as before.

The third season you must go over the Vines again, as soon as they begin to shoot, to rub off all danglers as before, and train the strong shoots in their proper places, which this year may be supposed to be two from each shoot of last year's wood; but if they attempt to produce two shoots from one eye, the weakest of them must be rubbed off, for there should never be more than one al-

lowed to come out of each eye. If any of them produce fruit, as many times they will the third year, you should not stop them so soon as is generally practised upon the bearing shoots of old Vines, but permit them to shoot forward till a month after *Midsummer*, at which time you may pinch off the tops of the shoots; for if this were done too soon, it would spoil the buds for the next year's wood, which in young Vines must be more carefully preserved than on older plants, because there are no other to be laid in for a supply of wood, as is commonly practised on old Vines.

During the summer you must constantly go over your Vines, and displace all weak lateral shoots as they are produced, and carefully keep the ground clear from weeds, as was before directed, that the shoots may ripen well, which is a material thing to be observed in most sorts of fruit-trees, but especially in Vines, which seldom produce any fruit from immature branches. These things being duly observed, are all that is necessary in the management of young Vines; I shall therefore proceed to lay down rules for the government of grown Vines, which I shall do as briefly as possible. And,

First, Vines rarely produce any bearing shoots from wood that is more than one year old, therefore great care should be taken to have such wood in every part of the trees; for the fruit are always produced upon the shoots of the same year, which come out from buds of the last year's wood. The method commonly practised by the gardeners in *England* is, to shorten the branches of the former year's growth down to three or four eyes, at the time of pruning; though there are some persons who leave these shoots much longer, and affirm, that by this practice they obtain a greater quantity of fruit; but however this may be, it is a very wrong practice, since it is impossible that one shoot can nourish forty or fifty bunches of Grapes, so well as it can ten or twelve, so that what is gotten in number is lost in their magnitude; besides, the greater quantity of fruit there is left on Vines, the later they are ripened, and their juice is not so rich; and this is well known in the wine countries, where there are laws enacted to direct the number and length of shoots that are to be left upon each Vine, lest by over-bearing them, they not only exhaust and weaken the roots, but thereby render the juice weak, and so destroy the reputation of their wine.

Wherefore the best method is to shorten the bearing shoots to about four eyes in length, because the lowermost seldom is good, and three buds are sufficient, for each of these will produce a shoot, which generally has two or three bunches of Grapes; so that from each of those shoots there may be expected six or eight bunches, which is a sufficient quantity. These shoots must be laid about eighteen inches asunder; for if they are closer, when the side shoots are produced, there will not be room enough to train them against the wall, which should always be provided for; and as their leaves are very large, the branches should be left at a proportionable distance from each other, that they may not crowd or shade the fruit.

At the winter-pruning of your Vines you should always observe to make the cut just above the eye, sloping it backward from it, that if it should bleed the sap might not flow upon the bud; and where there is an opportunity of cutting down some young shoots to two eyes, in order to produce vigorous shoots for the next year's bearing, it should always be done; because in stopping those shoots which have fruit upon them as soon as the Grapes are formed, which is frequently practised, it often spoils the eyes for producing bearing branches the following year, and this reserving of new wood is what the *Vignerons* abroad always practise in their vineyards. The best season for pruning of Vines is

about the middle or end of *October*, for the reasons before laid down.

The latter end of *April*, or the beginning of *May*, when the Vines begin to shoot, you must carefully look them over, rubbing off all small buds which may come from the old wood, which only produce weak dangling branches; as also when two shoots are produced from the same bud, the weakest of them should be displaced, which will cause the others to be stronger; and the sooner this is done, the better it is for the Vines.

In the middle of *May* you must go over them again, rubbing off all the dangling shoots as before; and at the same time you must fasten up all the strong branches, so that they may not hang from the wall; for if their shoots hang down, their leaves will be turned with their upper surfaces the wrong way, and when the shoots are afterwards trained upright, they will have their under surface upward, and until the leaves are turned again, and have taken their right position, the fruit will not thrive, so that the not observing this management, will cause the Grapes to be a fortnight or three weeks later before they ripen; besides, by suffering the fruit to hang from the wall, and be shaded with the closeness of the branches, it is greatly retarded in its growth; therefore, during the growing season, you should constantly look over the Vines, displacing all dangling branches and wild wood which come from the side of the buds, and fasten up the other shoots regularly to the wall, as they are extended in length, and towards the middle of *June* you should stop the bearing branches, which will strengthen the fruit, provided you always leave three eyes above the bunches; for if you stop them too soon it will injure the fruit, by taking away that part of the branch which is necessary to attract the nourishment to the fruit, as also to perspire off the crudities of the sap, which is not proper for the fruit to receive.

But although I recommend the stopping those shoots which have fruit at this season, yet this is not to be practised upon those shoots which are intended for bearing the next year, for these must not be stopt before the middle of *July*, lest, by stopping them too soon, you cause the eyes to shoot out strong lateral branches, whereby they will be greatly injured.

During the summer season you should be very careful to rub off all dangling branches, and train up the shoots regularly to the wall as before, which will greatly accelerate the growth of the fruit, and also admit the sun and air to them, which is absolutely necessary to ripen, and give the fruit a rich flavour; but you must never divest the branches of their leaves, as is the practice of some persons, for although the admitting of the sun is necessary to ripen them, yet if they are too much exposed thereto, their skins will be tough, and they will rarely ripen; besides, the leaves being absolutely necessary to nourish the fruit, by taking them off the fruit is starved, and seldom comes to any size, as I have several times observed; therefore a great regard should be had to the summer management of the Vines, where persons are desirous to have their fruit excellent, and duly ripened.

When the fruit are all gathered you should prune the Vines, whereby the litter of their leaves will be entirely removed at once, and their fruit will be the forwarder the succeeding year, as has been before observed.

As many of the richest and best sorts of Grapes will not ripen in *England*, unless the season proves very warm, or the soil and situation are very favourable, there have been many hot-walls built to accelerate the ripening of this fruit, and bring it to full perfection by artificial heat, and as these succeed very well, when they are properly contrived, and the Vines rightly managed, I shall here give proper directions, which, if duly attended to, will be sufficient to instruct persons in both.

The method of building hot-walls will be treated under the article WALL, so I shall pass it over in this place, and proceed to the preparing of the ground for planting. The borders against these hot-walls should have the earth taken out two feet deep (provided the ground is dry), otherwise one foot will be sufficient, because in wet land the borders should be raised at least two feet above the level of the ground, that the roots of the Vines may not be injured by the wet. When the earth is taken out, the bottom of the trench should be filled with stones, lime-rubbish, &c. a foot and a half or two feet thick, which should be levelled and beaten down pretty hard, to prevent the roots of the Vines from running downward. The trenches should be made five feet wide at least, otherwise the roots of the Vines will in a few years extend themselves beyond the rubbish, and, finding an easy passage downwards, will run into the moist ground, and thereby imbibe so much wet, as to lessen the vinous flavour of the Grapes; but before the rubbish is filled into the trench, it is a better method to raise a nine inch wall, at five feet distance from the back wall, which will keep the rubbish from intermixing with the neighbouring earth, and also confine the roots of the Vines to the border in which they are planted, so that they cannot reach to the moist ground. This nine inch wall should be raised to the height of this intended border, so will be of great use to lay the plate of timber of the frames upon, which will be necessary to cover the Vines when they are forced, whereby the timbers will be better preserved from rotting; and where the borders are raised to any considerable height above the level of the ground, they should be a brick and a half thick; these walls will preserve the borders from falling down into the walks, but in carrying up these walls it will be proper to leave little openings, about eight or ten feet distance, to let the water pass off, because when the rubbish at the bottom of the trench unites and binds very hard, the water cannot easily find a passage through it; therefore it will be the better method to leave these small passages in the wall, lest the moisture being confined at the bottom, should be pent up as in a ditch, which will be of ill consequence to the Vines.

When the walls are finished and thoroughly dry, the rubbish should be filled in, as before directed; then there should be fresh earth laid upon it two feet thick, which will be a sufficient depth of soil for the Vines to root in. These borders should be thus prepared at least a month or six weeks before the Vines are planted, that they may have time to settle. The best time to plant them is about the end of *September*, or the beginning of *October*, if planted with rooted plants, for when these are removed in the spring, their roots are very subject to bleed, which will greatly weaken them. The distance these Vines should be allowed to remain is the same as for common walls, *i. e.* about six feet; afterward lay a little mulch on the surface of the ground about their roots, to prevent the sun and air from drying the earth, and if the following spring should prove very dry, they should have some water once a week, which will be as often as they require it, for nothing will destroy them sooner than too much water.

The management of these Vines, for the three first years after planting, being the same as is practised for those against common walls, I shall not repeat it in this place, having fully treated of that already, only will observe that, during these three years, the Vines should be encouraged as much as possible, and the shoots not left too long, nor too many in number on each root, that they may be duly ripened and prepared for bearing the fourth year, which is the soonest they should be forced; for when any sort of fruit-trees are forced by fire too young, they seldom continue long in health, so that what fruit they produce is small,

and not well-flavoured; therefore, in being over hasty to save a year or two, very often the whole design miscarries; for unless the trees are in a proper condition to bear much fruit, it is not worth while to make fires for a small quantity of starved ill-tasted fruit, the expence and trouble being the same for ten or twelve bunches of Grapes, as it will be for a hundred or more.

These Vines should not be forced every year, but with good management they may be forced every other year, though it would be better, if it were done only every third year; therefore, in order to have a supply of fruit annually, there should be a sufficient quantity of walling built, to contain as many Vines as will be necessary for two or three years, and by making the frames in front moveable, they may be shifted from one part of the wall to another, as the Vines are alternately forced; therefore I would advise about forty feet length of walling to be each year forced, which is as much as one fire will heat, and when the Vines are in full bearing, will supply a reasonable quantity of Grapes for a middling family, but for great families twice this length will not be too much.

In most places where these hot-walls have been built, they are commonly planted with early kinds of Grapes, in order to have them early in the season; but this, I think, is hardly worth the trouble, for it is but of little consequence to have a few Grapes earlier by a month or six weeks than those against common walls; therefore I should advise, whenever a person is willing to be at the expence of these walls, that they may be planted with some of the best kinds of Grapes, which rarely come to any perfection in this country without the assistance of some artificial heat, of which the following sorts are the most valuable.

The red Muscat of *Alexandria*.

The white Muscat of *Alexandria*.

The red *Frontinac*.

The white *Frontinac*.

The black *Frontinac*.

When the Vines which are planted against the hot-walls are grown to full bearing, they must be pruned and managed after the same manner as hath been directed for those against common walls, with this difference only, *viz.* that those seasons when they are not forced, the Vines should be carefully managed in the summer, for a supply of good wood against the time of their being forced; so that it will be the better method to divest the Vines of their fruit, in order to encourage the wood, for as these sorts will not ripen without heat, it is not worth while to leave them on the Vines during the season of resting, except it be the common *Frontinac*, which in a good season will ripen without artificial heat; but, even these, I would not advise many Grapes to be left on them during the years of their resting, because as the design of this is to encourage and strengthen them, therefore all possible care should be had, that the young wood is not robbed by overbearing; for those years when the Vines are forced, the joints of the young wood are generally drawn farther asunder than they ordinarily grow in the open air, so that when they are forced two or three years successively, the Vines are so much exhausted, as not to be recovered into a good bearing state for some years, especially if they are forced early in the season, or where great care is not taken in the summer to let them have a proper share of free air, to prevent their being drawn too much, and also to ripen their shoots. Those years when the Vines are forced, the only care should be to encourage the fruit, without having much regard to the wood, so that every shoot should be pruned for fruit, and none of them shortened for a supply of young wood, because they may be so managed by pruning in the years of their resting, as to replenish the Vines with new wood. Those Vines which

are designed for forcing in the spring, should be pruned early the autumn before, that the buds which are left on the shoots, may receive all possible nourishment from the root, and at the same time the shoots should be fastened to the trellis in the order they are to lie, but the glasses should not be placed before the Vines till about the middle or end of *January*, at which time also the fires must be lighted; for if they are forced too early in the year, they will begin to shoot before the weather will be warm enough to admit air to the Vines, which will cause the young shoots to draw out weak, and thereby their joints will be too far asunder, so consequently there will be fewer Grapes on them, and those bunches which are produced will be smaller, than when they have a sufficient quantity of air admitted to them every day.

If the fires are made at the time before directed, the Vines will begin to shoot the latter end of *February*, which will be six weeks earlier than they usually come out against the common walls, so that by the time that other Vines are shooting these will be in flower, which will be early enough to ripen any of these sorts of Grapes perfectly well. The fires should not be made very strong in these walls, for if the air is heated to about ten degrees above the temperate point, on the botanical thermometers, it will be sufficiently warm to force out the shoots leisurely, which is much better than to force them violently. These fires should not be continued all the day time, unless the weather should prove very cold, and the sun does not shine to warm the air, at which times it will be proper to have small fires continued all the day, for where the walls are rightly contrived, a moderate fire made every evening, and continued till ten or eleven of the clock at night, will heat the wall, and warm the inclosed air to a proper temperature; and as these fires need not be continued longer than about the end of *April* (unless the spring should prove very cold), so the expence of fuel will not be very great, because they may be contrived to burn either coal, wood, turf, or almost any other sort of fuel, though where coal is to be had reasonable, it makes the event and best fires, and will not require much attendance.

When the Vines begin to shoot they must be frequently looked over to fasten the new shoots to the trellis, and to rub off all dangling shoots; in doing of which great care must be taken, for the shoots of these forced Vines are very tender, and very subject to break when any violence is offered. They should also be trained very regular, so as to lie as near as possible at equal distances, that they may equally enjoy the benefit of the air and sun, which is absolutely necessary for the improvement of the fruit. When the Grapes are formed, the shoots should be stopped at the second joint beyond the fruit, that the nourishment may not be drawn away from the fruit, which must be avoided as much as possible in these forced Vines, upon which no useless wood should be left, which will shade the fruit, and exclude the air from it by their leaves.

As the season advances and the weather becomes warm, there should be a proportionable share of free air admitted to the Vines every day, which is absolutely necessary to promote the growth of the fruit, but the glasses should be shut close every night, unless in very hot weather, otherwise the cold dews in the night will retard the growth of the fruit. The bunches of the white *Frontinac* should also be carefully looked over, and the small Grapes cut out with very narrow-pointed scissars, in order to thin them, for these berries grow so close together on the bunches, that the moisture is detained between them, which often occasions their rotting, and the air being excluded from the middle of the bunches the Grapes never ripen equally, which by this method may be remedied, if done in time; and as these

Grapes are protected by the glasses from the blights which frequently take those which are exposed, there will be no hazard in thinning these Grapes soon after they are set; at which time it will be much easier performed than when the Grapes are grown larger, and consequently will be closer together; but in doing of this the bunches must not be roughly handled, for if the Grapes are the least bruised, or the farina, which there naturally is upon them, be rubbed off, their skins will harden and turn of a brown colour, so the fruit will never thrive after; therefore the scissars which are used for this purpose, should have very narrow points, that they may be more easily put between the Grapes, without injuring the remaining ones. The other sorts of Grapes, which I have recommended for these hot-walls, do not produce their fruit so close together on the bunches, so they will not require this operation, unless by any accident they should receive a blight, which often occasions a great inequality in the size of the Grapes, which, whenever it thus happens, will require to be remedied by cutting off the small Grapes, that the bunches may ripen equally, and appear more sightly.

By the middle of *June* these Grapes will be almost full-grown, therefore the glasses may be kept off continually in the day time, unless the season should prove very cold and wet; in which case they must be kept on, and only opened when the weather is favourable; for as the racy vinous flavour of these fruits is increased by a free air, so, during the time of their ripening, they should have as large a share as the season will admit to be given them.

Before the Grapes begin to ripen, they must be carefully guarded against birds, wasps, and other insects, otherwise they will be destroyed in a short time; to prevent which, the Vines should be carefully covered with nets, so as to exclude the birds, who make great havock with the Grapes, by breaking their skins; and if there are a few twigs covered with birdlime, placed here and there on the outside of the nets, it will be of service, because the birds are often so bold as to attempt to break the nets to get to the Grapes, which, if they attempt, they may be so entangled on these twigs as not to get loose; and whenever that happens, they should not be disengaged, but suffered to remain to keep off their companions; and if they get off themselves, it will have the desired effect, for there will few other birds come to the same place that season, as I have more than once experienced.

As to the wasps, the best method is to hang up some phials about half filled with sugared water, and rub the necks of the phials with a little honey, which will draw all the wasps and flies to them, which, by attempting to get at the liquor, will fall into the phials and be drowned; these phials should be carefully looked over once in three or four days to take out the wasps, and destroy them, and to replenish the phials with liquor. If this be duly observed, and the phials placed in time, before the Grapes are attacked, it will effectually prevent their being injured; but where these precautions are not taken, the Grapes will be in danger of being absolutely destroyed, for as the early Grapes will ripen long before any others against common walls, they will be in much more danger, there being no other fruit for them at that season in the neighbourhood; whereas, when Grapes in general begin to ripen, there is a quantity in almost every garden; so that if they destroy a part in each garden, yet there will be a greater chance to have some escape, than where there is only one wall for them to attack.

These sorts of Grapes, being forced in the manner before directed, will begin to ripen early in *August*, especially the Black and Red *Frontinacs*, which will be fit for the table a fortnight earlier than the other sorts; but, as the design of

forcing them is to have them in as great perfection as possible in this climate, they should not be gathered until they are thorough ripe, for which reason some of the later sorts should be left on the Vines till *September*; but then the glasses should be kept over them in wet and cold weather, to protect the fruit from it; but whenever the weather is fair, the glasses must be opened to let in the free air, otherwise the damps arising from the earth at that season, will cause a mouldiness upon the Grapes, which will rot them; so that if the season should prove very cold and wet, while the fruit are upon the Vines, it will be proper to make a small fire every night to dry off the damps, and prevent this injury. Most people in *England* gather their Grapes too soon, never suffering them to remain on the Vines to ripen perfectly, even in the warmest seasons, when, if they are left on till after *Michaelmas*, they will be good.

Of late years many persons have planted Grapes against espaliers, which in some places have succeeded very well in good seasons; but if they are not planted in a good soil and to a proper aspect, and the sorts rightly chosen, they seldom produce any fruit which are fit to be eaten. The soil proper to plant Vines in espaliers, should be the same as is hereafter directed for vineyards, *viz.* either a chalky, or gravelly bottom, with about a foot and a half, or two feet of light hazel earth on the top, a little sloping to the south, or south-east, that the wet may easily find a passage, so as not to remain on the ground. In such a soil situated to the sun, and screened from cold winds, there are several sorts of Grapes, which in warm seasons will ripen very well in *England*.

But there are some curious persons who line the back-side of their espaliers with low Reed-hedges, and others who do it with thin slit deals; both of which are a good defence to the Vines against blights in the spring, and accelerate the ripening of the Grapes; so that in tolerable seasons they will come to good maturity. Neither of these methods are very expensive, for these close fences need not be more than four feet high; because the Vines being to be managed after the same manner as those in vineyards, the branches which carry the fruit will never rise above that height; for the bearing shoots must always be trained about two feet above the surface of the ground, so that the fruit will be always below the top of the close fences; and as for the upright shoots which are designed for the next year's bearing, it matters not how much they rise above the fence; so these may have a loose trellis to which they may be fastened, to prevent their overhanging the fruit.

In the making of these kinds of close espaliers for Grapes, it will be proper to lay one strong oaken plank, (such as are procured in breaking up old ships or barges) next the surface of the ground, which will last many years sound, and be very useful in supporting the fences. If these planks are fifteen inches broad, as they may always be readily procured, and the upper part of the fence be Reeds, there may be two lengths cut out of them (provided the Reeds are of a due length), without including their tops. In the front of these hedges should be a slight trellis to fasten the Vines to, which may be made of Ash-poles. The upright poles of these trellisses need not be nearer together than eighteen inches; and if there are three cross poles, at about a foot asunder, they will be sufficient to fasten the bearing shoots of the Vines at proper distances, in the manner they are designed to be trained, which should be in such positions, that the fruit may not be overshadowed by the branches; and if the upright poles are cut so long, as to be a foot and a half above the Reeds, they will be tall enough to support the upright shoots for the next year's bearing, which, being trained singly at proper distances, will have the advantage of the sun and air to ripen the wood much better than

than where four or five shoots are fastened to the same pole.

To this trellis the Reeds may be fastened with hoops on the back-side, after the manner usually practised in making common Reed-fences; and if on the top of the Reeds there is fastened a thin slip of deal, to secure their tops from being broken, it will preserve them a long time. In making of these fences, the Reeds should not be laid too thick, for that will not only be more expence, but will be troublesome to fasten, and not last so long as when they are made of a moderate thicknes: therefore as the Reeds will be cut into two lengths, each bundle will spread about six feet in length, observing first to spread the bottom parts of the bundles, which contain the largest ends of the Reeds the whole length; and then the upper parts of the other Reeds should be reversed, and spread in front of them, which will make the upper part of the fence almost as thick as the bottom. But neither these, nor the boarded fences, need be made till the Vines are in full bearing, which will be the fourth or fifth year after planting, according to the progress they make; during which time the shoots may be supported by any common stakes, for if the fences are made before the Vines are planted, as is frequently practised, they will be half decayed by the time the Vines are fit to bear, and before this time the fences are of no use to them.

The sorts of Grapes which are proper to plant against these fences are,

- The Miller Grape.
- The Chasselas White.
- The White Muscadine.
- The Sweet Water, and
- Le Cour Grape.

These, if well managed, will ripen very well, provided the season is tolerably good, and will come soon after those of the walls; so that if they are taken care of, by hanging of mats before them, when the nights prove cold in autumn, and are permitted to hang till *October*, the fruit will prove very good. But where the Sweet Water Grape is planted against these fences, they will require to be covered in the spring, at the time when they are in flower, if there should be cold nights, otherwise the bunches will receive a blast, which will destroy the greatest part of the Grapes; so that many times there will not be more than six or eight good Grapes on each bunch, and the others will be small starved fruit, hardly so large as the smallest Peas.

In planting of these Vines, either for open espaliers or the close fences, it should be performed in the same manner as for walls; the cuttings should be planted six feet asunder; and as these are only designed for the table, a single row of Vines of a moderate length will be sufficient to supply a family, where there are others against walls to come before them. But where a person is inclinable to have more rows than one, they should be placed at least twelve feet asunder, that they may equally enjoy the sun and air.

As to the pruning and other management of these Vines, that being the same as for those against walls, I shall not repeat it in this place, it being fully treated of before; and to which I have nothing here to add.

In the folio edition of the *Gardeners Dictionary*, we inserted the several methods of planting and managing vineyards in the principal parts of *Europe*, where the best wines are produced; but as this volume is an abridgment of that work, we have omitted such articles as we supposed might be of least utility to the public; and have frequently shortened others, so as not to render this imperfect: therefore as there may be some purchasers who may be inclined to make trials of vineyards in *England*, so we have here given the best directions we can, for planting and managing them

in this country to the best advantage; which we have extracted from the practice of those persons who reside in countries where there is good wine made, and where the climate approaches nearest to that of *England*; and also from many repeated trials which have been made with success in different parts of this country, from which any diligent person may readily engage in the practice.

The first and great thing to be considered in planting vineyards is the choice of soils and situations, without which there will be little hopes of success, for upon this the whole affair greatly depends. The best soil for a vineyard in *England* is such, whose surface is a light sandy loam, and not above a foot and a half, or two feet, with a gravelly or chalky bottom, either of which are equally good for Vines; but if the soil is deep, upon either clay or a strong loam, it is by no means proper for this purpose; for although the Vines may shoot vigorously, and produce a great quantity of Grapes, yet these will be later ripe, fuller of moisture, and so consequently their juice not mature, nor well digested, but will abound with crudity, which in fermenting will render the wine sour and ill-tasted, which is the common complaint of those who have made wine in *England*.

Nor is a very rich, light, deep soil, such as is commonly found near *London*, proper for this purpose, because the roots of these Vines will be enticed down too deep to receive the influences of sun and air, and hereby will take in much crude nourishment, whereby the fruit will be later ripe, and replete with moisture, which must necessarily contribute greatly to render the juices less perfect, therefore great attention should be had to the nature of the soil upon which they are planted.

The next thing necessary to be considered is the situation of the place, which, if possible, should be on the north-side of a river, upon an elevation inclining to the south, with a small gradual descent, that the moisture may the better drain off; but if the ground slopes too much, it is by no means proper for this purpose; but if at a distance from this place, there are larger hills which defend it from the north and north-west wind, it will be of great service, because hereby the sun's rays will be reflected with a greater force, and the cold winds being kept off, will render the situation very warm. Add to this a chalky surface, which, if those hills do abound with (as there are many such situations in *England*), it will still add to the heat of the place, by reflecting a greater quantity of the sun's rays.

The country about this should be open and hilly, for if it be much planted, or low and boggy, the air will constantly be filled with moist particles, occasioned by the plentiful perspiration of the trees, or the exhalations from the adjoining marshes, whereby the fruit will be greatly prejudiced (as was before observed). These vineyards should always be open to the east, that the morning sun may come on them to dry off the moisture of the night early, which, by lying too long upon the Vines, greatly retards the ripening of their fruit, and renders it crude and ill-tasted. And since the fruit of Vines are rarely injured by easterly winds, there will be no reason to apprehend any danger from such a situation, the south-west, north-west, and north winds being the most injurious to vineyards in *England* (as indeed they are to most other fruit) so that, if possible, they should be sheltered therefrom.

Having made choice of a soil and situation proper for this purpose, the next thing to be done is to prepare it for planting. In doing of which the following method should be observed: In the spring, if the ground is green sward, it should be ploughed as deep as the surface will admit, turning the sward into the bottom of each furrow; then it should be well harrowed to break the clods, and cleanse it from the roots of noxious weeds; and after this, it must be kept

kept constantly ploughed and harrowed for at least one year, to render the surface light; and hereby it will be rendered fertile, by imbibing the nitrous particles of the air (especially if it be long exposed thereto before it is planted); in the next *March* the ground should be well ploughed again, and after having made the surface pretty even, the rows should be marked out from south-east to north-west, at the distance of ten feet from each other; and these rows should be crossed again at five or six feet distance, which will mark out the exact places where each plant should be placed; so that the Vines will be ten feet row from row, and five or six feet asunder in the rows, nearer than which they ought never to be planted. For herein most people, who have planted vineyards, have greatly erred, some having allowed no more than five feet row from row, and the plants but three feet asunder in the rows, and others, who think they have been full liberal in this article, have only planted their Vines at six feet distance every way; but neither of these have allowed a proper distance to them, as I shall shew; for, in the first place, where the rows are placed too close, there will not be room for the sun and air to pass in between them, when the Vines are fully grown, to dry up the moisture, which, being detained amongst the Vines, must produce very ill effects: and, secondly, where the Vines are placed in exact squares so near together as six feet, the effect will be much the same; for the autumns in *England* are often attended with rains, cold dews, or fogs, so proper care should be taken to remove every thing which may obstruct the drying up the damps which arise from the ground.

The skilful *Vignerons* abroad are also sensible how much it contributes to the goodness of their Vines, to allow a large space between the rows; and therefore where the quality of the wine is more regarded than the quantity, they never plant their Vines at less than ten feet row from row, and some allow twelve. It was an observation of *Bellonius*, almost two hundred years since, that in those islands of the *Archipelago*, where the rows of Vines were placed at a great distance, the wine was much preferable to those which were close planted; and this he positively affirms to be the case in most countries where he had travelled. Indeed we need not have recourse to antiquity for the certainty of such facts, when we are daily convinced of this truth in all close plantations of any kind of fruit, where it is constantly observed, that the fruits in such places are never so well coloured, so early ripe, nor near so well flavoured, as those produced on trees, where the air can freely circulate about them, and the rays of the sun have free access to the branches, whereby the juices are better prepared before they enter the fruit.

Having thus considered the distance which is necessary to be allowed to these plants, we come next to the planting; but in order to this, the proper sorts of Grapes should be judiciously chosen, and in this particular we have egregiously erred in *England*. Most of the vineyards at present planted here, are of the sweetest and best sort of Grapes for eating, which is contrary to the general practice of the *Vignerons* abroad, who always observe, that such Grapes never make good wine; and therefore from experience, make choice of those sorts of Grapes, whose juice, after fermenting, affords a noble rich liquor; these Grapes are always austere, and not so palatable. This is also agreeable to the constant practice of our cyder-makers in *England*, who observe, that the best eating Apples seldom make good cyder; whereas the more rough and austere sorts, after being pressed and fermented, afford a strong vinous liquor. And I believe it will be found true in all fruits, that where the natural heat of the sun ripens and prepares their juices, so as to render them palatable, whatever degree of heat these juices have more, either by fermentation, or from any other cause, will ren-

der them weaker and less spirituous. Of this we have many instances in fruits; for if we transplant any of our summer or autumn fruits, which ripen perfectly in *England* without the assistance of art, into a climate a few degrees warmer, these fruits will be mealy and insipid; so likewise if we bake or stew any of these fruits, they will be good for little, losing all their spirit and flavour by the additional heat of the fire; and such fruits as are by no means eatable raw, are hereby rendered exquisite, which, if transplanted into a warmer climate, have, by the additional heat of the sun, been also altered so as to exceed the most delicious of our fruits in this country.

From whence it is plain, that those Grapes which are agreeable to the palate for eating, are not proper for wine; in making of which, their juices must undergo a strong fermentation; therefore since we have in *England* been only propagating the most palatable Grapes for eating, and neglected the other sorts, before we plant vineyards, we should take care to be provided with the proper sorts from abroad, which should be chosen according to the sort of wines intended to be imitated; though I believe the most probable sort to succeed in *England* is the *Auvernat*, or true *Burgundy* Grape, (which is rarely found in the *English* vineyards, though it is a common Grape in the gardens against walls). This sort of Grape is most preferred in *Burgundy*, *Champaign*, *Orleans*, and most of the other wine countries in *France*; and I am informed, that it succeeds very well in several places to the north of *Paris*, where proper care is taken of their management; so that I should advise such persons as would try the success of vineyards in *England*, to procure cuttings of this Grape; but herein some person of integrity and judgment should be employed to get them from such vineyards where no other sorts of Grapes are cultivated, which is very rare to find, unless in some particular vineyards of those persons who are very exact to keep up the reputation of their wines, nothing being more common than for the *Vignerons* to plant three or four sorts of Grapes in the same vineyard, and at the time of vintage to mix them all together; which renders their wines less delicate, than in such places where they have only this one true sort of Grape. And here I would caution every one against mixing the juice of several Grapes together, which will cause the wine to ferment at different times, and in different manners.

The cuttings being thus provided (for I would always prefer these to layers, or rooted plants, for the reasons given at the beginning of this article) about the beginning of *April* is the best season for planting, when it will be proper to put the lower ends of the cuttings in water about three inches, setting them upright for six or eight hours before they are used; then at the center of every cross mark already made by a line, to the distance the Vines are designed, should be a hole made with a spade, or other instrument, about a foot deep; into each of which should be put one strong cutting, placing it a little sloping; then the hole should be filled up with earth, pressing it gently with the feet to the cutting, and raising a little hill to each about three inches, so as just to cover the uppermost eye or bud, which will prevent the wind and sun from drying any part of the cuttings, and this upper eye only will shoot; the under ones, most of them, will push out roots, so that this shoot will generally be very strong and vigorous.

After they are thus planted, they will require no other care until they shoot, except to keep the ground clear from weeds, which should be constantly observed; but as the distance between the rows of Vines is very great, so the ground between them may be sown or planted with any kind of esculent plants, which do not grow tall, provided there is proper distance left from the Vines, and care taken that

the Vines are not injured by the crops, or in the gathering, and carrying them off the ground; and this husbandry may be continued two or three years, till the Vines come to bearing; after which time there should be no sort of crop put between them in summer, because the cleaner the ground is kept between the Vines from weeds or other plants, the more heat will be reflected to the Grapes; but after the Grapes are gathered, there may be a crop of Coleworts for spring use planted between the rows of Vines, and the cultivating of these will be of use to the Vines, by stirring of the ground; but as to watering, or any other trouble, there will be no occasion for it, notwithstanding what some people have directed, for in *England* there is no danger of their miscarrying by drought. When the cuttings begin to shoot, there should be a stick of about three or four feet long stuck down by each, to which the shoot should be fastened, to prevent their breaking or lying on the ground; so that as the shoots advance, the fastening should be renewed, and all small lateral shoots (if there are any such produced) should be constantly displaced, and the ground between the Vines always kept clean. This is the whole management which is required the first summer.

But at *Michaelmas*, when the Vines have done shooting, they should be pruned; for if they are left unpruned till spring, their shoots being tender (especially toward their upper parts) will be in danger of suffering if the winter should prove severe.

This pruning is only to cut down the shoots to two or three eyes; and if, after this is done, the earth be drawn up in a hill about each plant, it will still be a greater defence against frost.

At the beginning of *March* the ground between the Vines should be well dug to loosen it, and render it clean; but you should be careful not to dig deep close to the Vines, lest thereby their roots should be cut or bruised; and at the same time the earth should be again laid up in a hill about each plant; but there must be care taken not to bury the young eyes of the former year's shoot, which were left to produce new wood.

At the beginning of *May*, when the Vines are shooting, there should be two stakes fixed down to the side of each plant, which must be somewhat taller and stronger than those of the former year; to these the two shoots (if so many are produced) should be fastened, and all the small trailing or lateral shoots should be constantly displaced, to strengthen the shoots; the ground should also be kept very clear from weeds as before.

The autumn following these Vines should be pruned again in the following manner; those of them which have produced two strong shoots of equal vigour, must be cut down to three eyes each; but in such as have one strong shoot and a weak one, the strong one must be shortened to three eyes, and the weak one to two; and such Vines as have produced but one strong shoot, should be shortened down to two eyes also, in order to obtain more wood against the succeeding year.

In the spring, about the middle of *March*, the ground between the Vines should be again dug, as before, and two stakes should be placed down by the side of all such Vines as have two shoots, at such distance on each side of the plant as the shoots will admit to be fastened thereto, and the shoots should be drawn out on each side to the stakes, so as to make an angle of about forty-five degrees with the stem; but by no means should they be bent down horizontally, as is by some practised, for the branches lying too near the earth, are generally injured by the damps which arise from thence, but especially when they have fruit, which is never so well tasted, nor so early ripe upon those branches, as when they are a little more elevated.

In *May*, when the Vines begin to shoot, they must be carefully looked over, and all the weak dangling shoots should be rubbed off as they are produced; and those shoots which are produced from strong eyes, should be fastened to the stakes to prevent their being broken off by the wind.

This management should be repeated at least every three weeks, from the beginning of *May* to the end of *July*; by which means the shoots which are trained up for the succeeding year, will not only be stronger, but also better ripened and prepared for bearing, because they will have the advantage of sun and air, which is absolutely necessary to prepare their juices; whereas, if they are crowded by a number of small dangling weak branches, they will shade and exclude the rays of the sun from the other shoots, and so by detaining the moisture a longer time amongst the branches, occasion the vessels of the young wood to be of a larger dimension; and hereby the crude juice finds an easy passage through them, so that the shoots in autumn seem to be mostly pith, and are of a greenish immature nature; and wherever this is observed, it is a sure sign of a bad quality in the Vines.

The soil also should be constantly kept clean, because, if there are any vegetables (either weeds or plants of other kinds) growing between the Vines, it will detain the dews longer, and by their perspiration occasion a greater moisture than would be, if the ground were entirely clear; so that those who plant other things between their rows of Vines, are guilty of a great error.

In autumn the Vines should be pruned, which season I approve of rather than the spring (for reasons before given) and this being the third year from planting, the Vines will now be strong enough to produce fruit, therefore they must be pruned accordingly. Now suppose the two shoots of the former year, which were shortened to three eyes, have each of them produced two strong branches the summer past, then the uppermost of these shoots upon each branch should be shortened down to three good eyes (never including the lower eye, which is situate just above the former year's wood, which seldom produces any thing, except a weak dangling shoot); and the lower shoots should be shortened down to two good eyes each; these being designed to produce vigorous shoots for the succeeding year, and the former are designed to bear fruit; but where the Vines are weak, and have not produced more than two or three shoots the last season, there should be but one of them left with three eyes for bearing; the other must be shortened down to two, or if weak to one good eye, in order to obtain strong shoots the following summer; for there is nothing more injurious to Vines than the leaving too much wood upon them, especially while they are young; or the overbearing them, which will weaken them so much, as not to be recovered again to a good state in several years, though they should be managed with all possible skill.

In *March* the ground between the Vines should be well dug as before, observing not to injure their roots by digging too deep near them; but where there are small horizontal roots produced on or near the surface of the ground, they should be pruned off close to the places where they were produced; these being what the *Vignerons* call day-roots, and are by no means necessary to be left on: after having dug the ground, the stakes should be placed down in the following manner: On each side of the Vine should be a stake put in at about sixteen inches from the root, to which the two branches, which were pruned to three eyes, each for bearing, should be fastened, (observing, as was before directed, not to draw them down too horizontally); then another taller stake should be placed down near the foot of the Vine, to which the two shoots which were pruned down to two eyes, should be fastened, provided they are long enough

enough for that purpose; but if not, when their eyes begin to shoot, these must be trained upright to the stakes, to prevent their trailing on the ground, hanging over the fruit-branches, or being broke by the wind.

In *May* the Vines should be carefully looked over again, at which time all weak lateral branches should be rubbed off as they are produced; and those shoots which show fruit must be fastened with bafs to the stakes, to prevent their being broken, until they are extended to three joints beyond the fruit, when they should be stopped; but the shoots which are designed for bearing the following season should be trained upright to the middle stake, by which method the fruit-branches will not shade these middle shoots, nor will the middle shoots shade the fruit, so that each will enjoy the benefit of the sun and air.

This method should be repeated every three weeks, from the beginning of *May* to the middle of *July*, which will always keep the shoots in their right position, whereby the leaves will not be inverted, which greatly retards the growth of the fruit; and by keeping the Vines constantly clear from horizontal shoots, the fruit will not be crowded with leaves and shaded, but will have constantly the advantage of the sun and air equally, which is of great consequence; for where the fruit is covered with these dangling shoots in the spring, and are afterwards exposed to the air, either by divesting them of their leaves, or else displacing their branches entirely, as is often practised, the fruit will become hard, and remain at a perfect stand for three weeks, and sometimes will never advance afterward, as I have several times observed; therefore there cannot be too much care taken to keep them constantly in a kindly state of growth, as the *Vignerons* abroad well know, though in *England* it is little regarded by the generality of gardeners, who, when their Grapes suffer by this neglect, immediately complain of the climate, or the untowardness of the season, which is too often a cover for neglects of this nature. And here I cannot help taking notice of the absurd practice of those, who pull off their leaves from their Vines, which are placed near the fruit, in order to let in the rays of the sun to ripen them, not considering how much they expose their fruit to the cold dews, which fall plentifully in autumn, which, being imbibed by the fruit, greatly retard them; besides, no fruit will ripen so well when entirely exposed to the sun, as when they are gently screened with leaves, which are absolutely necessary to prepare the juices before they enter the fruit, the gross parts of which are perspired away by the leaves, the fruit must either be deprived of nourishment, or else some of the gross particles will enter with the more refined parts of the juice, and thereby render the fruit worse than it would otherwise be, were the leaves permitted to remain upon the branches; for if the weak dangling shoots are constantly displaced as they are produced, the fruit will not be too much shaded by the leaves that are upon the bearing branches.

When the fruit is ripe, if the stalks of the bunches are cut half through a fortnight before they are gathered, it will cause the juice to be much better, because there will not be near so great a quantity of nourishment enter the fruit, whereby the watery particles will have time to evaporate, and the juice will be better digested. This is practised by some of the most curious *Vignerons* in the south of *France*, where they make excellent wine. But if after the fruit be cut, it is hung up in a dry room upon strings, so as not to touch each other, for a month before they are pressed, it will also add greatly to the strength of the wine, because in that time a great quantity of the watery parts of the juices will evaporate. This is a constant practice with some persons who inhabit the *Tirolese*, on the borders of *Italy*, where is made a most delicious rich wine, as hath been attested by

Dr. Burnet in his travels; and I have heard the same from several gentlemen who have travelled that road since.

But with all the care that can possibly be taken, either in the culture of the Vines, or in making the wine, it will not be near so good while the vineyard is young, as it will be after it has been planted ten or twelve years; and it will be constantly mending, until it is fifty years old, as is attested by several curious persons abroad, as also by the most skilful wine-coopers at home, who can tell the produce of a young vineyard from that of an old one, after it is brought to *England*, by the colour of the wine. This difference is very easily accounted for, from the different structure of the vessels of the plants; those of the young Vines being larger, and of a looser texture, easily admit a larger quantity of gross nourishment to pass through them; whereas those of old Vines, which are more woody, are more closely constricted, and thereby the juice is better strained in passing through them, which must consequently render it much better, though the Grapes from a young vineyard will be larger, and afford a greater quantity of juice, so that people should not be discouraged if their Vines at first are not so good as they would wish; since afterward, when the vineyard is a few years older, the wine may answer their expectation. As to the fermenting and managing the wine, that is treated of particularly under the article *WINEs*, to which the reader is desired to turn.

The vineyard being now arrived to a bearing state, should be treated after the following manner: First, in the pruning there should never be too many branches left upon a root, nor those too long, for although by doing of this there may be a greater quantity of fruit produced, yet the juice of these will never be so good as when there is a moderate quantity which will be better nourished, and the roots of the plants not so much weakened; which is found to be of so bad consequence to vineyards, that when gentlemen abroad let out vineyards to *Vignerons*, there is always a clause inserted in their leases, to direct how many shoots shall be left upon each Vine, and the number of eyes to which the branches must be shortened; because were not the *Vignerons* thus tied down, they would overbear the Vines, so that in a few years they would exhaust their roots, and render them so weak as not to be recovered again in several years; and their wine would be so bad, as to bring a disreputation on the vineyard, to the great loss of the proprietor.

The number of branches which the *Italians* generally agree to leave upon a strong Vine are four; two of the strongest have four eyes, and the two weaker are shortened down to two eyes each; which is very different from the common practice in *England*, where it is usual to see six or eight branches left upon each root, and those perhaps left with six or eight eyes to each; so that if these are fruitful, one root must produce near four times the number of bunches which the *Italians* do ever permit, and so consequently the fruit will not be so well nourished, and the roots will also be greatly weakened; as is the case of all sorts of fruit trees, when a greater number of fruit is left on than the trees can nourish.

The next thing is, constantly to keep the ground perfectly clean between the Vines, never permitting any sort of plants or weeds to grow there. The ground should also be carefully dug every spring, and every third year have some manure, which should be of different sorts, according to the nature of the ground, or which can be most conveniently procured.

If the land is stiff, and inclinable to bind on the surface, then sea sand, or sea coal ashes, are either of them very good manure for it; but if the ground be loose and dry, then a little lime mixed with dung is the best manure for

it. This must be spread thin upon the surface of the ground before it is dug, and in digging should be buried equally in every part of the vineyard. These are much preferable to that of all dung for Vines, so that it will be worth the expence to procure either of them; and as they require manuring but every third year, where the vineyard is large it may be divided into three equal parts, each of which may be manured in its turn, whereby the expence will be but little every year; when the whole is manured together it will add to the expence, and in many places there cannot be a sufficient quantity procured to manure a large vineyard in one year.

This digging and manuring should always be performed about the middle of *March*, at which time all the superficial or day-roots, as they are called, must be cut off, but the larger roots must not be injured by the spade, &c. therefore the ground close to the stem of the Vines must not be dug very deep. After this is done, the stakes should be placed down, one on each side the Vines, at about sixteen inches from their stems, to which the longest bearing branches should be fastened, and one stake close to the stem, to which the two shorter branches should be trained upright, to furnish wood for the succeeding year.

In the summer they must be carefully looked over, as before, rubbing off all weak dangling shoots, and training the good ones to the stakes regularly as they are produced, and those of them which have fruit should be stopped in *June*, about three joints beyond the bunches, but the upright shoots, which are designed for bearing the following year, must not be stopped till the middle of *July*, when they may be left about five feet long; for if they are stopped sooner in the year, it will cause them to shoot out many dangling branches from the sides of the eyes, which will not only occasion more trouble to displace them, but also will be injurious to the eyes or buds.

N. B. All this summer dressing should be performed with the thumb and finger, and not with knives, because the wounds made by instruments in summer do not heal so soon as when stopped by gently nipping the leading bud, which, if done before the shoot is become woody, may be effected with great ease, being very tender while young.

When a vineyard is thus carefully dressed, it will afford as much pleasure in viewing it as any plantation of trees and shrubs whatever, the rows being regular; and if the stakes are exactly placed, and the upright shoots stopped to an equal height, there is nothing in nature which will make a more beautiful appearance; and during the season that the Vines are in flower they emit a most grateful scent, especially in the morning and evening; and when the Grapes begin to ripen, there will be fresh pleasure arising in the viewing of them.

But as the beauty of vineyards arises from the regular disposition of the branches of the Vines, great care should be taken in their management to train them regularly, and to provide every year for new wood to bear the succeeding year; because the wood which has produced fruit is commonly cut quite away after the fruit is gathered, or at least is shortened down to two eyes, to force out shoots for the next year; where there is not a sufficient number of branches upon the Vine of those trained upright, so that in summer, when the Vines are in perfection, there should be six upright shoots trained for the next year's wood, and three or four bearing branches with fruit on them; more than these ought never to be left upon one Vine, for the reasons before given.

N. B. The *Auvernat*, or true *Burgundy* Grape, is valued in *France* before any other sort, because the fruit never grows very close upon the bunches, therefore are more equally ripened; for which reason it should also be pre-

ferred in *England*; though in general those sorts are most esteemed with us that have always close bunches, which is certainly wrong; for it may be observed, that the Grapes on such bunches are commonly ripe on one side and green on the other, which is a bad quality for such as are pressed to make wine.

I shall now subjoin a few sorts of Vines, which are preserved in some curious gardens, more for the sake of variety than the value of their fruit: these are,

1. *VITIS foliis cordatis dentatis subtus villosis, cirrbis racemiferis. Flor. Zeyl. 99.* Wild Indian Vine, with round berries.
2. *VITIS foliis cordatis subtrilobis dentatis subtus tomentosis. Lin. Sp. Plant. 203.* Wild Virginia Grape.
3. *VITIS foliis cordatis dentato-ferratis utrinque nudis. Lin. Sp. Plant. 203.* The Virginia Fox-grape.
4. *VITIS foliis quinatis, foliolis multifidis. Hort. Cliff. 74.* Vine with jagged leaves, commonly called the Parsley-leaved Grape.
5. *VITIS foliis supradecompositis, foliis lateralibus pinnatis. Lin. Sp. Plant. 203.* Climbing Virginia shrub with Parsley leaves, sending out tendrils. This is the *Reynardsonia*. *Rand. Ind. Hort. Chelf.* Falsly called the Pepper-tree.

The first sort grows naturally in both *Indies*. The stalks of this are woody, and send out many slender branches, which are furnished with tendrils, by which they fasten themselves to the neighbouring trees, and are thereby supported. The leaves are heart-shaped, indented on their edges, and hairy on their under side. The flowers are disposed in bunches, like those of the other species, and are succeeded by round berries or Grapes, of an austere taste.

The second sort hath ligneous stalks which send out many branches, that fasten themselves by tendrils to any neighbouring support. The leaves of this are large, and for the most part divided into three lobes which are indented on their edges. The under side of the leaves is covered with a white down. The fruit is disposed in bunches like the other Grapes. The berries are round and black; the juice has a rough flavour.

The third sort has heart-shaped leaves, which are indented on their edges, and are smooth on both sides. The plants climb on trees by the help of their tendrils, like those of the other sorts. The fruit is disposed in bunches. The berries are black, and their juice has a flavour resembling the scent of a fox, from whence the inhabitants have given it the title of Fox-grape.

The fourth sort is supposed to grow naturally in *Canada*, but it has been long cultivated in the *European* gardens for its fruit; but as it has little flavour, and ripens late in autumn, so it has been almost banished the *English* gardens, where at present there are only a few plants preserved for the sake of variety. The stalks and branches of this are like those of the common Grape, but the leaves are cut into many slender segments. The Grapes are round and white, and are disposed in loose bunches.

The fifth sort is by *Dr. Linnæus* ranged under this genus of *Vitis*, but the characters of this plant are not sufficiently known in *Europe*, to determine the proper genus to which it belongs, for the plant seldom produces flowers here, and has never produced any fruit in *England*, for which reason I have ranged it under the same genus, upon *Dr. Linnæus's* authority.

The stalk of this plant is ligneous, and sends out many slender branches furnished with tendrils, which fasten themselves to any neighbouring plants for support, and are garnished with leaves composed of many smaller winged leaves, so that they are divided somewhat like those of common Parsley; they are of a lucid green on their upper side, but are much paler on their under. The flowers spring from
the

the wings of the stalks in loose bunches; they are very small, white, and are composed of five small petals, which expand and soon fall off; these are not succeeded by any fruit in *England*, but the berries which I have received from *America* had generally three seeds in each.

The first sort being a native of warm countries, will not live in *England* without artificial heat; it is easily propagated by seeds, when they are brought from the countries where the plants grow naturally, for they do not produce any here; these must be sown in small pots, which should be plunged into a hot-bed of tanners bark. When the plants come up and are fit to remove, they should be each transplanted into a separate small pot filled with light earth, and plunged into a fresh hot-bed of tanners bark, shading them from the sun till they have taken new root; then they must be treated in the same way as other tender exotick plants from the same countries, always continuing them in the stove, otherwise they will not thrive. These plants cast off their leaves every winter.

The second and third sorts grow in great plenty in the woods of *America*, where, I have been informed, are many other sorts, which produce fruit very little inferior to some of the fine sorts which are cultivated in *Europe*; notwithstanding which, it is generally thought impossible to make wine in *America*; but this, I dare say, must proceed from a want of skill, rather than any bad quality in the soil or climate; so that instead of planting vineyards on their loose rich lands (as hath been generally practised by the inhabitants of those countries), if they would plant them upon rising ground, where the bottom was rocky or hard near the surface, I dare say they would have very good success; for the great fault complained of in those countries is, that the Grapes generally burst before they are fully ripe, which must certainly be occasioned by their having too much nourishment; therefore, when they are planted on a poorer soil, this will be in part remedied. Another cause of this may proceed from the moisture of the air (occasioned by the perspiration of trees, &c.) which being imbibed by the fruit, may break their skins. This cannot indeed be prevented, until the country is better cleared of the timber; but, however, this should caution people not to plant Vines in such places where there are great quantities of woods, because of this effect which it hath on the Grapes. But to return:

These two Vines are preserved in the gardens of those who are curious in botany, but I have not seen either of them produce fruit in this country. They may be propagated by layers in the same manner as the common Grapes, which will take root in one year, and may be taken off, and transplanted where they are to remain, which should be against a warm wall; because if they are exposed to much cold in winter, they are often destroyed, especially while they are young.

The pruning and management is the same with any other sorts of Grapes, but only they should have fewer shoots, and those shortened down very low, otherwise they will make very weak shoots the following year, and never arrive to any considerable strength, so will not be capable of producing any fruit.

The fourth sort is planted against walls, and treated in the same way as the common Vines, and may be propagated by cuttings or layers in like manner.

The fifth sort is preserved in some gardens for the sake of variety, but as it rarely produces flowers in *England*, so it has not much beauty; it is a native in *Virginia* and *Carolina*. From both of these countries I have received the seeds. As this sort does not produce seeds here, it is generally propagated by laying down the young branches, which will put out roots in one year fit to remove, when

they may be taken off, and transplanted where they are to remain. These require support; and as their young branches are tender and liable to be killed by frost, so if they are planted against a wall or pale, exposed to the south, they will succeed much better than when they are fully exposed to the open air, and supported by props. The young shoots of these plants should be shortened down to two or three buds in the spring, which will cause the shoots of the following summer to be much stronger, and when they are regularly trained against the wall or pale, they will produce flowers in warm seasons.

This plant is very apt to push out suckers from the root, by which it is often propagated, but the plants so raised are very subject to send out suckers again, whereby they are robbed of their nourishment, and do not thrive so well as those which come from layers.

VITIS IDÆA. See Vaccinium.

VITIS SYLVESTRIS. See Clematis.

ULEX. *Lin. Gen. Plant.* 786. Furze, Gorse, or Whins.

The Characters are,

The flower has a two-leaved empolement; it has five petals, and is of the butterfly kind. The standard is large, erect, oval, heart-shaped, and indented at the point. The wings are shorter and obtuse. The keel is composed of two obtuse petals, whose borders are joined at bottom; it has ten stamina, nine joined, and one separate, terminated by single summits, with an oblong cylindrical germen, supporting a rising style, crowned by a small obtuse stigma. The germen afterward turn to an oblong turgid pod with one cell, opening with two valves, inclosing a row of kidney-shaped seeds.

The Species are,

1. ULEX foliis villosis acutis spinis sparsis. *Lin. Sp. Plant.* 741. Ulex with acute-pointed hairy leaves, and sparsed spinous. The common Furze, Whins, or Gorse.

2. ULEX foliis obtusis solitariis, spinis simplicibus terminalibus. *Flor. Leyd. Prod.* 372. African Furze, or Whins, with single blunt leaves ending with spinous.

The common Furze, Gorze, or Whins; as it is called in the different counties in *England*, is so well known as to need no description.

There are two or three varieties of this, which are frequently met with on the commons and heaths, in most parts of *England*; but as they are not specifically different they are not worth enumerating here, especially as they are plants which are seldom cultivated.

These plants propagate themselves very plentifully by seeds, so that when they are established in a spot of ground they soon spread over the place; for as the seeds ripen, the pods open with the warmth of the sun, and the seeds are cast out with an elasticity to a great distance all round, and these soon vegetate; whereby the ground is filled with young plants, which are not easily destroyed when they are well rooted in the ground.

Some years ago the seeds of this plant were sown to form hedges about fields, where, if the soil was light, the plants soon became strong enough for a fence against cattle; but as these hedges in a few years became naked at the bottom, and some of the plants frequently failed, there became gaps in the hedges, therefore the raising of them for that purpose has been of late years little practised. But there are some persons who have sown the seeds of this plant upon very poor, hungry, gravel or sandy land, which has produced more profit than they could make of the ground by any other crop, especially in such places where fuel of all sorts is dear; for this Furze is frequently used for heating ovens, burning lime and bricks, and also for drying malt. And in some places where there has been a scarcity of fuel, I have known poor land, which would have let for two shillings per acre, which has been sown with Furze, produce one

found *per acre per ann.* so that there has been a considerable improvement made by this plant. But this is not worth practising in such countries where fuel of any kind is cheap, or upon such land as will produce good Grass or Corn; therefore it is only mentioned here to shew, that poor lands may be so managed, as to bring an annual profit to their proprietors.

The second sort is a native of the country near the *Cape of Good Hope*, where it usually grows to the height of five or six feet; but in *Europe*, where it is preserved as a curiosity in some gardens, it seldom rises so high. The stalk is ligneous and hard, covered with a greenish bark when young, but it afterwards becomes greyish. The branches are slender and ligneous, the leaves are single, obtuse, and the shoots terminate with spines. This has been several years in the *English* gardens, but has not produced any flowers.

This plant is too tender to live in the open air, through the winter in *England*, therefore it is preserved in green-houses, with the hardier sorts of exotick plants, which do not require any artificial heat to preserve them.

It is very difficult to propagate either by layers or cuttings, for the layers are generally two or three years before they have sufficient root to transplant, and the cuttings do very rarely take root; and as the plant does not produce seeds in *Europe*, it is very rare in the *European* gardens. It is a plant of no great beauty, but, as it is an ever-green, it is admitted into the gardens of those who are curious in botany for the sake of variety.

ULMARIA. See Spiræa.

ULMUS. *Tourn. Inst. R. II. 601. tab. 372.* The Elm-tree.

The Characters are,

The flower has a rough permanent empalement of one leaf, cut into five points, and coloured within; it has no petals, but has five awl-shaped stamina, twice the length of the empalement, terminated by short erect summits having four furrows, and an orbicular erect germen supporting two styles which are reflexed, and crowned by hairy stigmas. The germen afterward turns to a roundish, compressed, bordered capsule, including one roundish compressed seed.

The Species are,

1. ULMUS foliis oblongis acuminatis, duplicato serratis, basi inæqualibus. Elm with oblong acute-pointed leaves, which are doubly sawed on their edges, and unequal at their base; the common rough, or broad-leaved Witch Elm.

2. ULMUS foliis oblongo-ovatis inæqualiter serratis, calycibus foliaceis. Elm with oblong oval leaves which are unequally sawed, and have leafy empalements to the flowers; the Witch Hazel, or very broad leaved Elm; by some unskillful persons called the *British* Elm.

3. ULMUS foliis ovatis acuminatis duplicato-serratis, basi inæqualibus. Elm with oval acute-pointed leaves which are doubly sawed, and unequal at their base; the small-leaved or *English* Elm.

4. ULMUS foliis ovatis glabris, acutè serratis. Elm with oval smooth leaves, which are sharply sawed on their edges; the smooth-leaved Witch Elm.

5. ULMUS foliis ovatis acuminatis rugosis, inæqualiter serratis, cortice fungoso. Elm with oval, acute pointed, rough leaves, which are unequally sawed, and a fungous bark; the *Dutch* Elm.

6. ULMUS foliis oblongo-ovatis glabris acuminatis duplicato-serratis. Elm with oblong, smooth, acute pointed leaves, which are doubly sawed; the smooth narrow-leaved Elm; by some called the upright Elm.

The first sort is very common in the north-west counties of *England*, where it is generally believed to grow naturally in the woods; this grows to a very large size. The bark

of the young branches is smooth and very tough, but that of the old trees cracks and is rough. The branches spread, and do not grow so erect as those of the third sort. The leaves are rough, and are doubly sawed on their edges. Their base is unequal, standing on short foot stalks. The flowers come out in *March* upon the slender twigs in clusters, of a deep red colour, and are succeeded by oval bordered capsules, containing one roundish compressed seed, which ripens in *May*. The wood of this tree is very good for all the purposes of any kind of Elm, and the trees grow to a very large size, but the leaves do not come out till late in the spring, so there are few persons who plant these trees for ornament.

The second sort grows naturally in some of the northern counties of *England*, where it is frequently called Witch Hazel, from the resemblance of the young shoots and leaves to those of Hazel. This grows to a tree of great magnitude. The bark of the young shoots is very smooth and tough; it is of a yellowish brown colour, with spots of white. The leaves are oval, unequally sawed on their edges. The flowers grow in clusters toward the end of the twigs; they have long leafy empalements of a green colour, appearing in the spring before their leaves, and the seeds ripen the latter end of *May*. The wood of this tree is not so good for use as that of the first sort. Formerly, when long bows were in use, many of them were made of the boughs of this tree.

The third sort is commonly known in the nursery-gardens by the title of *English* Elm, which is far from being a right appellation; for it is not a native of *England*, and is only found in plantations where the young trees were procured from the neighbourhood of *London*. Where this tree grows naturally is not easy to determine; some persons have supposed it was brought from *Germany*. As this tree is well known it requires no description. The flowers of this are of a purplish red colour, and generally appear the beginning of *March*, but I could never observe any seeds upon this sort.

The fourth sort is very common in several parts of *Hertfordshire*, *Essex*, and other north-east counties of *England*; this grows to a large tree, and is much esteemed. The branches spread out like those of the first sort. The leaves are sharply sawed on their edges; they are smoother than most of the other sorts, and do not appear till the middle or latter end of *May*, so the trees are seldom planted for ornament.

The fifth sort is well known by the title of *Dutch* Elm; this was brought from *Holland* the beginning of king *William's* reign, and was for some time a fashionable tree, and has been recommended for its quick growth; it was some years ago in request for forming hedges in gardens, for which purpose it was one of the most improper trees that could be chosen; for they made very strong irregular shoots, which are distant from each other. The leaves were very large and rough, and the branches covered with a fungous rough bark, which was disagreeable, so that when the hedges were sheared, they appeared naked and disagreeable the whole summer after. The wood of this tree is good for nothing, so it is almost banished this country.

The sixth sort is found growing in hedge-rows in several parts of *England*. The branches of this sort have a smooth grayish bark, and grow erect. The leaves are narrower, and more pointed than those of the *English* Elm, and are smoother; they are later in coming out in the spring than those, but continue longer in autumn; this has been by some called the *Lis* Elm.

There are some other varieties of this tree which are preserved in the nursery-gardens, but their difference is not remarkable

markable enough to deserve notice; therefore they are omitted, as are also those with variegated leaves, of which there are several varieties propagated in the nurseries about London; these are by some persons esteemed.

All the sorts of Elm may be either propagated by layers or suckers taken from the roots of the old trees, the latter of which is generally practised by the nursery-gardeners; but as these are often cut up with indifferent roots they often miscarry, and render the success doubtful; whereas those which are propagated by layers are in no hazard, and always make better roots, and come on faster than the other, and do not send out suckers from their roots in such plenty, for which reason this method should be more universally practised. And since a small compass of ground filled with stools of these plants will be sufficient to furnish a nursery of a considerable extent, annually, with layers to be transplanted, it is richly worth every person's while, who would cultivate these trees, to allot a spot of ground for this purpose.

The best soil for such a nursery is a fresh Hazel loam, neither too light and dry, nor over moist and heavy; this ground should be well trenched, and if a little rotten dung is buried therein it will be of service; in doing of this great care should be taken to pick out all roots of pernicious weeds, which, if left in the ground, would be very injurious to the layers, and cannot afterwards be so easily rooted out; then having laid the ground level, the plants must be planted at about eight feet asunder each way. The best season for this work is in autumn, as soon as the leaves begin to decay, that they may take root before the dry weather in the spring comes on, whereby a great expence of watering them will be saved; for if they are well settled in the ground before the dry weather, they will require little more than to mulch their roots to keep the earth from drying.

These plants should be permitted to grow rude two years, during which time the ground between should be carefully cleaned and dug every spring, by which time they will be well rooted, and have made pretty strong shoots, so that they may be laid in the ground. The manner of performing this being already described in the article *LAYERS*, I shall forbear repeating it in this place.

When these layers are well rooted, which will be in one year, they should be taken off, and transplanted out into a nursery, which should be upon a good soil, and well prepared (as before for the stools). The plants should be planted in rows four feet asunder, and two feet distance plant from plant in rows. This should be done in autumn, as soon as the leaves begin to decay, and if there is some mulch laid upon the surface of the ground about their roots, it will preserve them from being hurt by frost in winter, and from drying winds in spring, and thereby secure them from all hazard.

In this nursery they may remain four or five years, observing constantly to dig the ground between them every spring, and to trim them up to stems, which will promote their growth, and render them strong enough to transplant out where they are to remain in the time before-mentioned.

These trees are very proper to plant in hedge rows, upon the borders of fields, where they will thrive much better than when planted in a wood or close plantation, and their shade will not be very injurious to whatever grows under them; but when these trees are transplanted out upon banks after this manner, the banks should be well wrought and cleared from all other roots, otherwise the plants, being taken from a better soil, will not make much progress in these places. About *Michaelmas* will be a good time for this work for the reasons before assigned, but when

they are planted there should be some stakes fixed in by them, to which they should be fastened to prevent their being displaced by the winds, and part of their heads should be taken off before they are planted, which will also be of use in preventing their being easily overturned by winds, but by no means should their leading shoot be stopped, nor the branches too closely cut off; for if there are not some shoots left on to draw and attract the sap, they will be in danger of miscarrying.

These trees are also proper to plant at a distance from a garden or building, to break the violence of winds; for which purpose there is not any tree more useful, for they may be trained up in form of a hedge, keeping them cut every year, which will cause them to grow very close and handsome, to the height of forty or fifty feet, and be a great protection against the fury of winds; but they should not be planted too near a garden, where fruit trees, or other plants are placed, because the roots of the Elms run superficially near the surface of the ground to a great distance, and will intermix with the roots of the other trees, and deprive them of nourishment; nor should they be planted near gravel or Grass-walks, which are designed to be well kept, because the roots will run into them, and send forth suckers in great plenty, which will deface the walks, and render them unsightly.

But for large gardens, where shade is required, there is scarce any tree so proper for that purpose, being easy to remove when grown to a considerable size; so that a person who is willing to have his plantations for shade in a short time, may procure trees of near one foot circumference in their trunk, which will be in little danger of succeeding, provided they are removed with care. And these will take root and grow very well, though not so well as young plants, which is what few other sorts of trees will do; but then they should be such trees as have been thus regularly trained up in a nursery, and have good roots, and not such as are taken out of hedge-rows (as is by some practised), which seldom rise with any tolerable roots, and consequently often miscarry; and this has been the occasion of so many plantations of these trees failing; for though some of them may live a few years, yet few of them are of long duration, and they rarely increase much in their stems, but frequently grow hollow, their heart decaying first, so that they are supported only by their bark or shell for a few years, and the first severe winter, or very dry summer, they are generally destroyed.

But although I have said, that Elms which are trained up in a nursery may be removed with safety, at a larger size than most other trees, yet I would not have it understood, that by this I would recommend the planting of them when large; for if people would have a little patience when they plant, and never plant any of these trees which are more than five or six inches in girth of their stems, they will in a few years become better trees than any of those which are transplanted of a much larger growth, and will grow to a much larger size; besides, they are much more easily removed, and do not require to be so strongly supported, nor is there much danger of the young trees miscarrying; therefore it is much more eligible to make choice of young thriving trees (but not out of a better soil than that where they are to be planted), and never to plant any large trees, unless where a small number may be wanted for an immediate shade; and in such cases it is always proper to plant some young trees amongst the large ones, to succeed them when they fail.

In planting of these trees great care should be taken not to bury their roots too deep, which is very injurious to them, especially if they are planted on a moist loam or clay; in which case, if the clay is near the surface, it will be the

best way to raise the ground in a hill, where each tree is to be planted, which will advance their roots above the surface of the ground, so that they will not be in danger of rotting in winter with moisture.

When these trees are propagated by suckers taken from old trees, they are commonly laid into the ground in rows pretty close together in beds, where, in dry weather, they may be frequently watered to encourage their putting out roots. In these beds they are left commonly two years, by which time those that live will be rooted (though a great many of them generally die); then they are transplanted into the nursery, and managed as hath been directed for the layers.

There are some who raise the Witch Elm from seeds, which it generally produces in great plenty, and are ripe in May; these should be sown upon a bed of fresh loamy earth, and gently covered. In dry weather they should be watered, and if the bed is shaded from the violent heat of the sun, it will be of great service to the seeds (for I always observe the plants to come up better in the shade than when exposed to the sun). When the plants come up they should be carefully cleared from weeds, and after they have stood two years in the seed bed they will be fit to plant out into the nursery, where they must be managed as the former.

VOLKAMERIA. *Lin. Gen. Plant.* 706.

The Characters are,

It hath a ringent flower of one petal, whose tube is much longer than the empalement; the brim is cut into five parts. It has four long slender stamina, two being shorter than the other, with a four-cornered germen, having a long style crowned by a bifid stigma. The germen turns to a roundish berry with two cells, including a nut with two cells.

The Species are,

1. VOLKAMERIA *spinis petiolorum rudimentis. Lin. Sp. Plant.* 637. Prickly Volkameria.

2. VOLKAMERIA *ramis inermibus. Lin. Sp. Plant.* 637. Smooth Volkameria.

The first sort grows naturally in the *West India* islands, where it rises to the height of twenty feet, having many pliable branches which are much diffused, covered with a light smooth bark, garnished with oval, spear-shaped, lucid leaves placed opposite. The flowers come out from the side of the stalk, five or six standing on the same foot-stalk, almost in form of an umbel; they are in shape somewhat like those of the common Jasmine, but the tube is curved, and two of the stamina are longer than the other, so it comes under the class of ringent flowers. They have no scent, and are not succeeded by seeds in *England*, nor are the plants very free to flower here.

The second sort is also a native of both *Indies*; this rises higher than the former, the stem and branches are stronger, and grow more erect; the bark is very white; but have short crooked spines immediately under the foot-stalk of the leaves. The leaves frequently grow round the branches in clusters or whorls. The flowers are set upon long foot-stalks arising from the wings of the stalk, each supporting several flowers, which generally stand erect. They are shaped like those of the former, have no scent, nor are succeeded by seeds here.

As these do not produce seeds in *England*, so the plants are propagated by cuttings, which readily put out roots, when they are planted in pots and plunged into a moderate hot-bed, covering them close with hand glasses to screen them from the external air. The cuttings may be planted any time from the middle of *May* to the end of *July*; if they are planted later in the season, there will not be summer enough for them to get strong roots before the cold of autumn; nor sooner than *May*, because their shoots will not be hardened enough for planting.

When they have put out roots the plants should be carefully separated, and each planted into a separate small pot, and plunged into a gentle hot-bed, to get fresh roots in the pots; then they may be inured to the open air provided the weather is warm, and may remain abroad in a sheltered situation until the nights begin to be cold, when they must be removed into the house, for cold will soon destroy them.

In winter these plants will require some warmth, so should be placed in a stove where the air is never greatly warmed, because in heat they are very subject to shoot and grow weak; but in a common green-house they will not live through the winter.

URENA. *Hort. Elth.* 319. *Lin. Gen. Plant.* 754. Indian Mallow.

The Characters are,

It hath a malvaceous flower with a double empalement, the outer being of one leaf slightly cut at the brim into five parts, but the inner is five-leaved, permanent, and cut to the bottom. The flower is composed of five leaves which are oblong, and blunt at their extremity, but narrow at their base, where they coalesce. In the center there are many stamina which are joined, and form a column at their base, but spread open above. It has a roundish five-cornered germen with a single style, and ten hairy reflexed stigmas. The germen changes to a pentagonal fruit which is burry, and divides into five cells, each having one angular seed.

The Species are,

1. URENA *foliis angulatis. Hort. Cliff.* 348. Indian Mallow with angular leaves.

2. URENA *foliis inferioribus angulatis, superioribus trilobis quinquelobisque acutè serratis.* Urena with angular lower leaves, the upper ones divided into three or five lobes which are sharply sawed; or Indian shrubby Vervain Mallow from *Bengal*.

3. URENA *foliis sinuato-multifidis villosis. Flor. Zeyl.* 257. Urena with sinuated hairy leaves having many points.

The first sort grows naturally in *China*; this rises with an upright stalk two feet high, which becomes ligneous toward the autumn. It sends out a few side branches which are taper, stiff, and have a dark green bark, garnished with roundish angular leaves, standing upon pretty long foot-stalks, of a dark green on their upper side and pale on their lower. The flowers come out single from the wings of the stalk, sitting close to it; they are shaped like those of the Mallow, but are small, and of a deep blush colour; these are succeeded by roundish capsules, armed with prickly hairs, divided into five cells, each containing one kidney-shaped seed.

The second sort grows naturally on the coast of *Malabar*, from whence I received the seeds; this rises with a ligneous stalk three feet high, dividing into four or five branches, which have a grayish bark, garnished with leaves of different forms; those on the lower part are angular, those above are cut some into three, and others have five angular obtuse lobes, of a dark green on their upper side, but pale on their under, sharply sawed on their edges, and stand upon long foot stalks. The flowers come out singly from the wings of the stalk; they are shaped like those of the other, but are larger. The petals are narrower at their base, and have deep red bottoms.

The seeds of the third sort came from *Malabar*; the stalks of this are hairy, and divide into many branches: it rises about two feet high, and is garnished with oblong leaves, divided into three obtuse lobes to the midrib. The lobes are indented in several parts; they are of a light green on both sides, and hairy. The flowers sit close to the stalks singly at the wings; they are shaped like those of the former, but are of a pale blush colour, with a deep red bottom.

These plants are propagated by seeds, which should be sown on a hot-bed early in the spring; and when the plants are fit to remove they should be transplanted into pots, and plunged into a fresh hot-bed to bring them forward, and afterward they must be treated in the same manner as hath been directed for the tender sorts of Hibiscus, to which the reader is desired to turn. If the plants are brought forward in the spring, and afterward placed in the stove, or under a deep frame, they will ripen seeds the first season; but if they should not, they may be preserved through the winter in the stove, and will ripen their seeds the following season, after which the plants seldom continue.

URTICA. *Tourn. Inst. R. H.* 534. *tab.* 308. The Nettle.

The Characters are,

It has male and female flowers at remote distances, sometimes on the same, and at others on separate plants. The male flowers have empalements composed of four roundish concave leaves, and have a pitcher-shaped nectarium in the center of the flower, and four awl-shaped spreading stamina terminated by summits with two cells. The female flowers have an oval permanent empalement with two valves; they have neither petals nor stamina, but an oval germen, without any style, crowned by a hairy stigma. The germen afterward turns to an oval compressed seed, which ripens in the empalement.

The Species are,

1. URTICA foliis oppositis cordatis, racemis geminis. *Lin. Sp. Plant.* 984. Nettle with heart-shaped leaves which are placed opposite, and double spikes of flowers; the great stinging Nettle.
2. URTICA foliis oppositis ovalibus. *Lin. Sp. Plant.* 984. Nettle with oval leaves which are placed opposite; smaller stinging Nettle.
3. URTICA foliis oppositis cordatis, amentis fructiferis globosis. Nettle with heart-shaped leaves placed opposite, and seed-bearing globular Katkins; commonly called Roman Nettle.
4. URTICA foliis oppositis ovato-lanceolatis, subintegerrimis, amentis fructiferis globosis. Nettle with oval spear-shaped leaves, which are almost entire, and placed opposite, and globular seed-bearing katkins; commonly called Spanish Marjoram.
5. URTICA foliis oppositis tripartitis incisiss. *Hort. Upsal.* 282. Nettle with leaves placed opposite, which are cut into three parts.
6. URTICA foliis oppositis oblongis, amentis cylindricis solitariis indivisis. *Lin. Sp. Plant.* 984. Nettle with oblong leaves which are placed opposite, and single, cylindrical, undivided katkins.
7. URTICA foliis oppositis ovato-lanceolatis acuminatis crenatis, amentis cylindricis indivisis. Nettle with oval, spear-shaped, acute-pointed, crenated leaves, which are placed opposite, and cylindrical undivided katkins.
8. URTICA foliis alternis cordato-ovatis, amentis racemosis distichis erectis. *Hort. Cliff.* 441. Nettle with oval heart-shaped leaves, which are placed alternate and erect, branching, double katkins.
9. URTICA foliis alternis orbiculato utrinque acutis subtus tomentosis. *Hort. Cliff.* 441. Nettle with orbicular leaves, pointed at both ends, placed opposite, and woolly on their under side.

The first of these sorts is a very common weed upon the sides of banks, ditches, and other uncultivated places, where its roots will spread, and over-run the grounds, so that it should always be carefully extirpated from gardens; it is sometimes used in medicine, but may easily be procured from the fields at almost any season.

The second sort is also a very common weed in gardens and cultivated fields; but it being an annual plant, is not so difficult to eradicate as the former.

These plants are so well known as to need no description.

The third sort grows naturally in *Romney* marsh, and near *Yarmouth*; this is an annual plant which rises three feet high. The stalk is herbaceous, thick, of a purple colour, armed in every part with stinging hairs. The branches come out opposite. The leaves are heart-shaped, ending in acute points, deeply sawed on their edges, and stand opposite upon long foot-stalks; these are also armed with stinging hairs on both sides. The male and female flowers come out from the wings of the leaves, at the same joint on each side the stalk; the male standing above the female, upon long slender foot-stalks or katkins, placed very loosely. The female flowers have shorter foot-stalks, and are in globular heads; these are succeeded by smooth shining seeds like those of the flax.

There is a variety of this growing naturally in the *Balearick* islands, which was discovered by Mr. *Salvadore*, an apothecary in *Barcelona*, who sent the seeds to *England*, which were sown in the *Chelsea* garden, but the plants, when cultivated, approached so near to the last mentioned sort, in every part except the colour of the stalk, as to make it doubtful of its being a distinct species.

The fourth sort grows naturally in *Spain* and *Italy*; this is also an annual plant, whose stalks are much slenderer than those of the former, and seldom branch. The leaves are placed by pairs, upon very slender foot-stalks; they are oval, spear-shaped, and for the most part entire, and have male and female flowers springing from the wings of the leaves, which are shaped like the former, the whole plant being armed with stinging hairs.

These plants may be easily propagated, by sowing their seeds in *March* upon a bed of light earth; and when the plants are come up they should be transplanted into beds, or the borders of the pleasure garden, interspersing them amongst other plants, that they may not be easily discovered by persons whom there is a design to deceive, by gathering a sprig for them to smell to. After the plants have taken root they will require no farther care, but only to keep them clear weeds.

The seeds of the third sort are sometimes used in medicine.

The fifth sort grows naturally in *Tartary*; this has a perennial root, from which spring up many square stalks, which rise five or six feet high, garnished with oblong leaves, deeply cut into three lobes, which are acutely indented on their edges; these stand opposite upon long foot-stalks. The flowers are produced from the wings of the leaves in long cylindrical katkins; the male are produced on the lower part of the stalk, and the female on the upper; the latter are succeeded by seeds like those of flax, inclosed in the three-cornered empalement of the flower.

This plant is easily propagated either by seeds or parting of the roots, and will thrive in most soils or situations.

The sixth sort grows naturally in *Canada* and other parts of *North America*; it is an annual plant, with a lucid herbaceous stalk, which divides into several branches, garnished with oblong sawed leaves, having three longitudinal veins; they are placed opposite upon pretty long foot-stalks. The flowers are produced from the wings of the stalks in single katkins, which are not divided; they appear late in the year, and unless the autumn is very favourable, the seeds will not ripen in *England*.

The seventh sort grows naturally in *North America*; this has a perennial root, from which spring out many stalks from two to three feet high, garnished with oval spear-shaped leaves, placed opposite, standing upon long foot-stalks; they are crenated on their edges, and end in acute points. The flowers come out from the wings of the leaves in long, cylindrical, undivided katkins; the seeds do not ripen in *England*.

The eighth sort grows naturally in *Canada* and *Virginia*. The root is perennial; the stalks rise two feet high; the leaves are oval, heart-shaped, and stand alternately upon the stalks; the flowers come out in branching katkins from the wings of the stalks, but are not succeeded by seeds in this country.

The two last sorts are common in many *English* gardens, where they are preserved more for the sake of variety than for any beauty. They may be propagated by parting their roots in the spring, and planted in almost any soil or situation, and will endure the severest cold of this climate in the open air.

The ninth sort grows naturally in *China*, where it is titled *Peama*; this is a perennial plant, sending up many stalks from the root, which rise three or four feet high, garnished with oval leaves, drawing to points at both ends, sawed on their edges, of a deep green on their upper side, but very white on their under, and have five longitudinal veins; they are placed alternately, and stand upon very long slender foot stalks. The flowers spring from the wings of the stalk in loose katkins; these are not succeeded by seeds in *England*.

This may also be propagated by parting of the roots, which should be done in the spring, for at that season this plant is in its least vigour, the winter being the time when it is most flourishing.

The plants must be planted in pots filled with light earth, and as they are too tender to thrive without artificial heat in *England*, they should be kept in a temperate stove, and only exposed to the open air for three months in the heat of summer.

UVA. URSI. See *Arbutus*.

VULNERARIA. See *Anthyllis*.

UVULARIA. *Lin. Gen. Plant.* 373.

The Characters are,

The flower has no empalement; it has six oblong, erect, spear-shaped petals, and six awl-shaped stamina, terminated by oblong, erect, four-cornered summits; it has an oblong, obtuse, three-cornered germen, supporting a style longer than the stamina, crowned by a triple, obtuse, spreading stigma. The germen af-

terward turns to an oblong obtuse capsule, with three lobes and as many cells, filled with flat orbicular seeds, ranged in a double order.

The Species are,

1. UVULARIA *foliis amplexicaulibus*. *Lin. Sp. Plant.* 304. Uvularia with leaves embracing the stalk.

2. UVULARIA *foliis perfoliatis*. *Amœn. Acad.* 2. p. 3. Uvularia with perfoliate leaves.

The first sort grows naturally in *Bohemia* and *Saxony*. The root is perennial, but the stalk is annual; it rises about two feet high, sending out one or two branches from the lower part, garnished with oblong smooth leaves, ending in acute points, whose base embrace the stalks. The flowers come out singly from the bosom of the leaves upon long slender foot-stalks; they are composed of six oblong naked petals, of a yellowish colour; these hang downward, but are rarely succeeded by seeds here.

The second sort grows naturally in *North America*; this has a perennial root and an annual stalk. The root is composed of many thick fleshy fibres, from which spring up several stalks, which for the most part divide into two at a small height from the ground, and are garnished with oblong, smooth, pointed leaves, which are broad at their base, surrounding the stalk in such a manner, as if the stalk run through them. The flowers are composed of six oblong yellow petals, ending in acute points; these stand upon slender foot-stalks, which arise from the bosom of the leaves, and hang downward, but are not succeeded by seeds in *England*.

They are both very hardy plants, and will live in the full ground; but as the flowers have not much beauty, so they are only cultivated for the sake of variety; they are propagated by parting of their roots. The best season for removing them is about *Michaelmas*, when their roots may be separated, and planted in the borders of the flower-garden; but this should only be done every third year, for if they are often removed, the plants will not thrive so well or flower so strong, as when they stand two or three years unremoved; they delight in a soil not too wet or stiff, but a gentle Hazel loam.

W.

W A C

WACHENDORFIA. *Burman.*

The Characters are,

The flowers are ranged alternately in clusters on the side of the stalk, each cluster having acute-pointed spathæ; each flower has six oblong petals, the three upper are erect, spread open, and are joined at bottom; two on the side spread open like wings; the lower forms a kind of keel; it has a protuberant nectarium on each side the upper petal, with three awl-shaped stamina, which decline, terminated by horizontal summits, and an oval three-cornered germen, supporting one awl-shaped style, crowned by a single stigma. The germen afterward turns to an oval, three-cornered, hairy capsule, with three cells, containing three oval seeds.

The Species are,

1. WACHENDORFIA *scapo simplici*. *Lin. Sp. Plant.* Wachendorfia with a simple stalk.

W A C

2. WACHENDORFIA *scapo polystachio*. *Lin. Sp. Plant.* Wachendorfia with stalks sending out many flower stems.

These plants grow naturally at the *Cape of Good Hope*; the roots of both have many strong fibres springing from a fleshy head; out of these heads arise several plaited leaves; those of the first are much smaller than the second sort; from the center arises the flower-stalk, which in the first sort is strait, simple, and about a foot and a half high, garnished with white flowers, disposed in loose spikes; but the stalk of the second sort rises more than three feet high, sending out alternately clusters of flowers, each cluster being covered with a spatha, which withers and remains on the stalk till it decays. The flowers of this are larger than those of the first sort, and are of an herbaceous white, inclining to yellow. The petals are divided into six parts almost to the bottom; they have each three stamina and

one style, which sits on the germen, crowned by horizontal summits. The germen afterward becomes an oval three-cornered capsule, having three cells, containing three oval seeds.

These plants are usually propagated by offsets, which come out from the side of their roots, because their seeds do not often come to perfection in *England*; but when they do, if they are sown in pots soon after they are ripe, and the pots placed in a garden-frame in the autumn to screen the seeds from frost, the plants will come up the following spring; and when they are strong enough to remove, they should be each planted in a separate small pot, and may be exposed abroad till the autumn; then they should be placed under a frame to screen them from frost, for they will not live in the open air through the winter in *England*. The second year the plants will flower, and if the season is warm, the seeds will ripen in autumn.

The offsets which are taken from the old roots, must be planted in separate pots, and after they have taken root, should be treated in the same way.

WALKERIA.

The Characters are,

The empalement of the flower is of one piece, cut half way into five segments, which are reflexed; the corolla of the flower is of one petal, deeply divided into five segments, which are concave; it has five incurved stamina, which are shorter than the petal, crowned by oval summits, and a conical germen without any style, crowned by a small blunt stigma. The germen afterward turns to a conical capsule, divided into five cells, each containing one angular seed.

The title of this genus is given in honour of Doctor Richard Walker, Vice-Master of Trinity-College in Cambridge, who is a great lover of botany, and has lately established a botanick garden in Cambridge, for the public use of the university.

We have but one species of this genus, the seeds of which were brought from the *East-Indies*, but from what particular part we are not acquainted.

It is an annual plant, whose branches are diffused and trail upon the ground, garnished with roundish leaves about the size of those of Chickweed, but of a thicker consistence, and of a bluish colour, standing upon short foot-stalks: the flowers come out from the wings of the stalk at each joint, having very short foot-stalks; the flower is of one petal, shaped like those of the Winter Cherry, but of a fine blue colour; these are each succeeded by conical capsules, divided into five cells, each containing one angular seed.

It is propagated by seeds, which must be sown upon a hot-bed early in the spring; but as the seeds do frequently lye long in the ground, so it is the surest way to sow them in small pots, and plunge them into a hot-bed, because if the plants do not rise in due time, the pots may be removed to another hot-bed, which will cause the seeds to vegetate. When the plants come up, and are strong enough to remove, they should be planted into separate small pots, and plunged into a hot-bed of tanners bark, shading them until they have taken root again; after which time they should have a large share of fresh air admitted to them in warm weather, and duly watered. The beginning of *July* they will flower, and the seeds will ripen in autumn; but if the plants should come up late in summer, and not perfect their seeds, if the pots are removed in autumn, and plunged into the tan-bed in the stove, the plants may be preserved through the winter, so will flower early the next summer, and thereby good seeds may be obtained; but when the plants come up early, and produce good seeds the same year, they seldom continue longer.

WALKS are made either of gravel, sand, or Grass; these three sorts of walks are the most common in *England*, but where gravel or sand cannot be procured, they are

sometimes laid with powdered coal, sea-coal ashes, and sometimes of powdered brick, but these are rarely used, when either gravel or sand can be procured; however, where sea-coal ashes can be had, it is preferable to the powdered coal or bricks, because they bind very hard, and never stick to the feet in frosty weather, which is a good quality, but the darkness of its colour has been an objection to the use of it in gardens; however, for wilderness-walks I think it is preferable to most other materials, but I shall proceed to give directions for the making of the several sorts of walks, and first of the gravel-walks.

In order to the laying of walks in gardens, when they are marked out, the earth should be taken away to a certain depth, that the bottom of them may be filled with some lime-rubbish, or coarse gravel, flint stones, or other rocky materials, which will be serviceable to prevent weeds from growing through the gravel, and also to keep away worm-casts. This bottom should be laid ten inches or a foot thick, over which the coat of gravel should be six or eight inches; which gravel should be fine, but yet not screened, because that spoils it. This should be laid on a heap, rounding, that the larger rough stones may run down on the sides, which being every now and then raked off, the gravel by that means will be sufficiently fine.

After the gravel has been laid to the thickness above-mentioned, then the walks must be exactly levelled, and raked true from all great drips, as well as little holes. By this means most of the stones of the walks will be raked under your feet, which should rather be gently sprinkled back again, over the last length that is raked, than buried (as is the practice of many gardeners); for by this means the walk will lie much harder, and the coarsest stones will very much contribute to its firmness.

There is also a great fault committed frequently, in laying walks too round, and some to that degree, that they cannot be walked on with that ease and pleasure that ought to be.

The common allowance for a gravel-walk of five feet breadth, is an inch rise in crown; so that if a walk be twenty feet wide, according to this proportion, it will be four inches higher in the middle than on each side, and a walk of twenty-five feet will be five inches, one of thirty feet six inches, and so on.

When a walk has been thus carefully laid, trodden down, and raked, or rather, after every length or part of it (which commonly is about fifteen feet each), then it should be rolled well, both in length and also cross-ways. The person who rolls it, should wear shoes with flat heels, that he may not make holes in the walks, for when these are once made in a new walk, it will not be easy to roll them out again.

In order to lay gravel-walks firm, it will be necessary to give them three or four water-rollings, that is, they must be rolled when it rains so very fast, that the walks swim with water; this will cause the gravel to bind, so that when the walks come to be dry, they will be as hard as terrace.

Iron-mould gravel is accounted the best for binding, or gravel with a little binding loam amongst it; which latter, though it be apt to stick to the heels of shoes in wet weather, yet nothing binds better in dry weather.

When the gravel is over-sandy or sharp, loam is frequently mixed with it, which, if they be cast together in heaps, and well mixed, will bind like a rock; whereas loose gravel is as uncomfortable and uneasy to walk on, as any other fault in a walk can render it.

The best gravel for walks is such as abounds with smooth pebbles (as is that dug at *Black beath*), which, being mixed with a due proportion of loam, will bind like a rock, and is never injured by wet or dry weather, and the pebbles being smooth, are not so liable to be turned up, and loosened

by the feet in walking, as are those which are angular and rough; for where walks are laid with such gravel as is full of irregular stones, they appear unsightly in a day's time after rolling, because the stones will rise upon the surface whenever they are walked upon, but the smooth pebbles will remain handsome two or three days without rolling.

Gravel-walks are not only very necessary near the house, but there should always be one carried quite round the garden, because, being soon dry after rain, they are proper for walking on in all seasons; but then these should be narrow, and those adjoining to the house ought to be large and magnificent, proportionable to the grandeur of the house and garden. The principal of these walks should be elevated, and carried parallel with the house, so as to form a terrace; this should extend itself each way, in proportion to the width of the garden; so that from this there may be a communication with the side-walks, without going on the Grass, that there may be a dry walk continued quite through the gardens; but there is not a more ridiculous sight, than that of a strait gravel-walk leading to the front of the house, intersecting the Grass, so as to make it appear like the stiff formal Grass-plats frequently made in little court-yards by persons of low taste.

Grass-walks in gardens were formerly in great esteem, and looked upon as necessary ornaments to a garden; but of late years they have justly been banished by every person of true taste, for those narrow slips of Grass were very unsightly, and far from being ornamental, and for the most part useless, being generally too damp for persons of tender constitutions to walk upon; and whenever they were constantly used, they became bare in the places frequently trodden, so were rendered more unsightly; and as the intention of walks in gardens is to have at all seasons a dry communication throughout the garden, for exercise and recreation, Grass-walks were very improper, because every shower of rain made them so wet, as not to be fit for use a considerable time, and the dews render them too damp for use either in the morning or evening; and if the Grass of walks is not very fine and short, like that of the downs, it will be very troublesome to walk upon; besides, whenever the ground is so dry, as that persons may with safety walk upon Grass, the lawns and other parts of verdure in gardens are better adapted for use, than any of those formal stiff walks, which were so much esteemed in the last age.

Having given directions for the making of gravel-walks, I shall come next to treat of sand walks, which are now very frequently made in gardens, as being less expensive in the making, and also in keeping, than the former; and in very large irregular gardens, which are such as most persons esteem, this is a very great article; for as the greatest part of the walks which are made in gardens, are carried about in an irregular manner, it would be very difficult to keep them handsome, if they were laid with gravel, especially where they are shaded by trees, for the dripping of the water from their branches, in hard rains, is apt to wash the gravel in holes, and render the walks very unsightly; and when these wood-walks are of Grass, they do not appear sightly, nor are they very proper for walking on; for after rain they continue so long damp as to render them unfit for use, and the Grass generally grows spiry and weak for want of air, and by the continual dropping of the trees, will by degrees be destroyed; therefore it is much better to lay these walks with sand, which will be dry and wholesome; and whenever they appear mossy, or any weeds begin to grow on them, if they are scuffled over with a *Dutch* hoe in dry weather, and then raked smooth, it will destroy the weeds and moss, and make the walks appear as fresh and handsome as if they had been new laid.

In the modern way of laying out gardens, the walks are

carried through woods and plantations, so that these are shady and convenient for walking in the middle of the day. These are usually carried about, winding as much as the ground will admit of, so as to leave a sufficient thickness of wood to make the walks private; and that the persons who are walking in one part of them, may not be seen by those who are in any of the other parts. Where these walks are contrived with judgment, a small extent of ground will admit of a great many turns, so that a person may walk some miles in a small garden. But these turns should be made as natural as possible, so as not to appear too much like a work of art, which will never please so long as the former.

The breadth of these walks must be proportioned to the size of the ground, which in a large extent may be eight or ten feet wide; but in small gardens five or six feet will be sufficient. As the walks are designed to wind as much as the ground will allow, so this width will be sufficient, because the wider they are, the greater must be the turns, otherwise the walks will not be private for any distance. Besides, as it will be proper to line the sides of these walks with Honeysuckles, Sweet-briar, Roses, and many other sweet-flowering shrubs, so the tall trees should be placed at least five or six feet from the walk, to allow room for these. But as I shall particularly treat of the method of laying out wildernesses, and planting of them, in such a manner as to render them as nearly resembling a natural wood as possible, under its proper head, I shall add nothing more in this place, except a few common directions for making of these sand-walks.

When the ground is traced out in the manner as the walks are designed, the earth should be taken out of the walks, and laid in the quarters. The depth of this must be proportioned to the nature of the soil, for where the ground is dry, the walks need not be elevated much above the quarters, so the earth should be taken out four or five inches deep in such places; but where the ground is wet, the bottom of the walks need not be more than two inches below the surface, that the walks may be raised so high, as to throw off the wet into the quarters, which will render them more dry and healthy to walk on.

After the earth is taken out of the intended depth, the bottom of the walks should be laid with rubbish, coarse gravel, or whatever of the like nature can be most readily procured. This should be four, five, or six inches thick, and beaten down as close as possible, to prevent the worms from working through it; then the sand should be laid upon this about three inches thick, and after treading it down as close as possible, it should be raked over to level and smooth the surface. In doing of this, the whole should be laid a little rounding to throw off the wet, but there will be no necessity of observing any exactness therein; for as the whole ground is to have as little appearance of art as possible, the rounding of these walks should be as natural, and only so contrived as that the water may have free passage from them.

The sand with which these walks are laid should be such as will bind, otherwise it will be very troublesome to walk on them in dry weather; for if the sand be of a loose nature, it will be moved with strong gales of wind, and in dry weather will slide from under the feet. If, after these walks are laid, they are well rolled two or three times, it will settle them, and cause them to be firm. If the sand is too much inclinable to loam, it will also be attended with as ill consequence as that which is too loose, for this will stick to the feet after every rain; so that where sand can be obtained of a middle nature, it should always be preferred.

In some countries where sand cannot be easily procured, these walks may be laid with sea-shells well pounded, so as to reduce them to a powder, which will bind extremely well,

well, provided they are rolled now and then; but where none of these can be easily procured, sea-coal ashes, or whatever else can be gotten, which will bind and be dry to the feet, may be used for this purpose; and where any of these can only be had in small quantities, the walks should have a greater share of rubbish laid in their bottom, and these spread thinly over them; and in most places rubbish, rough stones, or coarse gravel, may be easily procured.

WALLS are absolutely necessary in gardens, for the ripening of all such fruits as are too delicate to be perfected in this country without such assistance. These are built with different materials; in some countries they are built of stone, in others with brick, according as the materials can be procured best and cheapest.

Of all materials proper for building walls for fruit-trees, brick is the best, in that it is not only the handsomest, but the warmest and kindest for the ripening of fruit; besides that, it affords the best conveniency of nailing, for smaller nails will serve in them than in stone walls, especially if the joints are not too large; and brick walls, with copings of free-stone, and stone pilasters or columns, at proper distances, to separate the trees, and break off the force of the winds, make not only the most beautiful, but the most durable walls.

In some parts of *England* there are walls built both of brick and stone, which have been very commodious. The bricks of some places are not of themselves substantial enough for walls, nor are they any where so durable as stone; and therefore some persons, that they might have walls both substantial and wholesome, have built double ones, the outside being of stone and the inside brick, or a stone wall lined with brick; but when these are built, there must be great care taken to bind the bricks well into the stone, otherwise they are very apt to separate one from the other, especially when hard frost comes after much wet; which swells the mortar, and frequently throws down the bricks, when the walls are only faced with them and not well tied into the stone.

Where the walls are built entirely of stone, there should be trellises fixed up against them, for the more convenient fastening the branches of the trees; the timbers of these espaliers need not be more than an inch and a half thick, and about two inches and a half broad; these should be fixed cross each other, at about four inches distance; for if they are at a much greater distance, it will be difficult to fasten the shoots of the trees properly. As this trellis will be laid close to the wall, the branches of the trees will lie about two inches from the wall, in which position the fruit will ripen better than when it lies close to the wall; so that there should always be these espaliers framed against them, which will render these walls very good for fruit-trees, which, without the espaliers, seldom are found to answer the purpose of ripening the fruits well, besides the inconvenience of having no good fastening for the branches of the trees.

There have been several trials made of walls built in different forms; some of them having been built semicircular, others in angles of various forms, and projecting more towards the north, to screen off the cold winds; but there has not been any method as yet, which has succeeded near so well, as that of making the walls strait and building them upright.

The fairest trial which I have seen made of circular walls was at *Goodwood* in *Suffex*, the seat of the duke of *Richmond*, where, in the middle of two south walls, there were two large segments of circles, in which there were the same sorts of fruit-trees planted, as against the strait parts of the walls; but there never was any fruit upon the trees in the circular part of the walls which came to maturity,

nor were the trees of long continuance, being blighted every spring, and in a few years were totally destroyed; and when the branches of those trees, which grew upon the strait part of the walls, had extended themselves so far as to admit of their being led into the circular parts of the walls, they were constantly blighted and killed.

When the trees which had been planted in the circular parts were destroyed, the walls were filled with Vines; but the Grapes of the same sort were a full month later than those growing against the strait parts of the walls; so that they rarely ripened, which occasioned their being rooted out, and figs were afterwards planted, but the fruit of these succeeded little better; nor can it be supposed, that any trees or plants will thrive so well in these circles, where there is a constant draught of air round them, which renders the situation much colder than the open free air.

I have also seen, at Mr. *Le Cour's* garden in *Holland*, some walls built in angles of different forms; but these succeeded no better than the circles before mentioned; for I did not find one tree in health against the walls, nor did they produce fruit.

There are several other schemes which have been proposed by different persons, for the building of walls to accelerate the ripening of fruits; among which there was a very ingenious book written some years ago, intitled, *Fruit-walls improved, by inclining them to the horizon*; in which the author has shewn, by calculation, that there will be a much greater number of the rays of the sun fall upon such walls, than upon those which are built perpendicular; and from thence has drawn calculations, that walls so built will be of great service in the accelerating of fruit; and he has taken the trouble of calculating the different inclinations, which such walls should have in the different climates, in order to receive the greatest number of the sun's rays. This theory seems to have all the demonstration necessary for its support, but upon trial has not succeeded in the least; for as these walls must be built against banks of earth, the damps which arise from the ground overbalance the advantage of the sun's rays; besides, these sloping walls being much more exposed to the cold dews in the night, the fruit will be more chilled thereby; and in the spring the morning frosts will prove much more destructive to the tender blossoms of the fruit-trees, as they will be more exposed to them than against an upright wall; add to this their being much more exposed to the winds and the rain, and it will be found, by comparing the advantages proposed from these walls, with the disadvantages to which the fruit-trees will be exposed, that upright walls will have the preference; for it is not the strongest rays of the sun, in the heat of summer, which are so much wanting for ripening of fruit, as the continuance of a moderate share of warmth; and, above all, the having of the sun in a morning, to dry off the cold dews of the night early, is of the greatest use; and in this respect the upright walls are much preferable to the sloping, as they will have the direct rays of the sun in the morning, which will be oblique on the other.

There are some persons who recommend the painting of walls black, or of a dark colour, as they suppose the dark colour will imbibe more of the sun's rays, so will retain the warmth longer; this also answers better in theory than in practice; for although it must be allowed, that a black wall is warmer to the touch than a common brick wall, yet, as the fruit generally is situated at a small distance from the wall, it receives no benefit from the warmth of the wall, but it is the reflected heat which accelerates the ripening of fruit; therefore I would advise every one to make fair trials of these things before they put them in practice, and not take upon trust what they may be told by persons, who are

too sanguine in recommending to others schemes, which they have adopted upon very slight principles, or perhaps upon a single trial; this painting of the walls is recommended by the same person who wrote upon inclining walls, and he has proposed this upon the same principles; but the introducing of these schemes should be avoided, until there have been sufficient trials made to warrant their use.

Where persons are willing to be at the expence in the building of their walls substantial, they will find it answer much better than those which are slightly built, not only in their duration, but also in their warmth; therefore a wall two bricks thick, will be found to answer better than one brick and a half; and if in the building of garden walls they are grouted with soft mortar, to fill and close all the joints, the walls will be much stronger, and the air will not so easily penetrate through them, as it does through those which are built in the common way.

According to the modern taste in gardening, there are very few walls built round gardens, which is certainly very right; not only with regard to the pleasure of viewing the neighbouring country from the garden, but also in regard to the expence, therefore the quantity of walling should be proportioned to the fruit consumed in the family; but as it will be necessary to inclose the kitchen-garden, for the security of the garden stuff, so, if that be walled round, it will contain as much fruit as will be usually wanted in the family, because the kitchen-garden is always proportioned to the number of persons maintained; but if the quantity of walling which surrounds the kitchen-garden, should be judged too little for the supply of fruit, there may be a cross wall built through the middle of the kitchen-garden; or, where the size of the garden will admit, there may be two cross walls built; but this must not be done, where there is not room to place the walls at least eighty or one hundred feet asunder, and if they are allowed a much greater distance it will be better; and as the kitchen garden should always be placed out of sight from the house, the walls may be hid by plantations of shrubs at some little distance.

The best aspect for walls in *England* is, to have one point to the eastward of the south; for these will enjoy the benefit of the morning sun, and will be less exposed to the west and south-west winds (which are very injurious to fruits in *England*) than those walls which are built due south. I know there are many persons who object to the turning of walls the least point to the east, on account of the blights which they say come from that quarter in the spring; but from many years experience and observation I can affirm, that blights as often attack those walls which are open to the south-west, as those which are built to any other aspect; and I believe, whoever will be at the trouble to observe for seven years, which aspected walls suffer most from blights, will find those which are built with a point to the eastward of the south, as seldom blighted as those which are turned to any other aspect; therefore, in the contrivance of a kitchen garden, there should be as great length of these walls built as the situation of the ground will admit.

The next best aspect is due south, and the next to that south east, which is preferable to the south-west for the reasons before assigned; but as there will, for the most part, be south-west and west walls in every garden, these may be planted with some sorts of fruit, which do not require so much heat to ripen them as those designed for the best walls; but wherever there are north walls, those will only be proper for baking Pears, Plums, and Morello Cherries for preserving; or some Duke Cherries may be planted against these walls, to continue them longer in the season, which will be found useful in supplying the table till Peaches, Nectarines, and Plums are ripe.

Where persons are very curious to have good fruit they erect a trellis against their walls, which projects out about two inches from them, to which they fasten their trees; which is an excellent method, because the fruit will be at a proper distance from the walls, so as not to be injured by them, and will have all the advantage of their heat; and by this method the walls will not be injured by driving nails into their joints, which, by every year being drawn out, draws out the mortar from between the bricks, and thereby makes holes, in which snails and other vermin will harbour and destroy the fruit, and also impair the wall.

These trellises may be contrived according to the sorts of fruit which are planted against them. Those which are designed for Peaches, Nectarines, and Apricots (which, for the most part, produce their fruit on the young wood), should have their rails three, or, at most, four inches asunder every way; but for the other sorts of fruit, which continue bearing on the old wood, they may be five or six inches apart; and those for Vines may be eight or nine inches distance. For as the shoots of Vines are always trained at a much greater distance than those of any other sort of fruit, the trellises for these need not be near so close, especially as those for Peaches and Nectarines, whose shoots are generally shortened to about five or six inches or less; so that if the rails are not pretty close, many of the short branches cannot be fastened to them.

These trellises may be made of any sort of timber, according to the expence which the owner is willing to bestow; but fir is most commonly used for this purpose, which, if made of yellow deal, well dried and painted, will last many years; but if any person will go to the expence of Oak, it will last sound much longer; but those who are unwilling to be at the expence of either, a trellis may be made of Ash-poles, in the same manner as is practised in making espaliers for counter borders, with this difference only, that every fourth upright rail or post should be stronger, and fastened with iron hooks to the wall, which will support the whole; and as these rails must be laid much closer together than is generally practised for espaliers, these strong upright rails or posts will not be farther distant than four or five feet from each other. To these the cross rails which are laid horizontally should be well nailed, which will secure them from being displaced, and also strengthen the trellises; but to the other smaller upright poles they need only be fastened with wire. To these trellises the shoots of the trees should be fastened with Osier-twigs, rope-yarn, or any other soft bandage, for they must not be nailed to it, because that will decay the wood work.

These trellises need not be erected until the trees are well spread, and begin to bear fruit plentifully; before which time the young trees may be trained up against any ordinary low espaliers, made of a few slender Ash poles, or any other slender sticks; by which contrivance the trellises will be new when the trees come to bearing, and will last many years after the trees have overspread them; whereas, when they are made before the trees are planted, they will be half rotten before the trees attain half their growth.

When these trellises are intended to be made against new walls, it will be proper to fasten some strong iron hooks into the wall as it is built, at the distance which the upright posts are intended to be placed; because when these are afterwards driven into the wall, they displace the mortar in the joints, and injure the wall.

In the building of the walls round a kitchen garden, the insides, which are designed to be planted with fruit-trees, should be made as plain as possible, so that the piers should not project on those sides above four inches at most, and these should be placed about fourteen feet asunder, in such walls

walls as are designed for Peach and Nectarine trees; so that each tree may be planted exactly in the middle between the piers, which will render them more sightly, and be better for the trees; but where Apricots, Plums, or Cherries, are to be planted, the piers may be only ten feet asunder; and against every other pier the trees should be planted, which will allow them sufficient room to spread; as the trelase will project as forward as the piers, the branches of the trees may be spread as on a plain; but when the piers project no more on the inside of the garden, they should be built stronger on the outside, for the better supporting of the walls.

The usual thickness which garden walls are allowed, if built with bricks, is thirteen inches, which is one brick and a half, but this should be proportionable to the height; for if they are built twelve or fourteen feet high or more, as is sometimes practised, then the foundations of the walls should be carried up at least two bricks and a half thick, a foot or more above the level of the surface of the ground; then may be diminished on each side, to reduce them to the thickness of two bricks, which must be continued to the top of the walls; and the piers in these high walls should also be proportionably stronger than is commonly allowed to lower walls; for as these will be much more exposed to strong gales of wind, if they are not well built they will be in danger of being blown down; therefore the piers of these walls should be projected the length of a brick on their backside, and the thickness of a brick on their front; and if these are built about ten or twelve feet asunder, they will greatly strengthen the walls.

But there is no necessity for building walls higher than nine or ten feet, unless it be for Pears, which, if properly managed, will spread over a great compass of walling; but as only some of the latest winter Pears require the assistance of a wall, there need no more but that part of the wall, where these are designed, to be built higher; for Peaches and Nectarines never require a wall higher than nine or ten feet, provided they are rightly managed; because whenever they are carried to a greater height, the lower part of the wall is unfurnished with bearing branches; and although Apricots, Plums, and Cherries, will frequently grow higher, yet, if they are planted at a proper distance, and the branches trained horizontally from the bottom, they will not soon cover a wall of this height; and Vines may be kept as low as any sort of fruit, for when they are planted against low walls, they must be treated somewhat after the same manner as those in vineyards, which is, to cut off the greatest part of the wood which produced fruit the preceding year, and train in new shoots for the next year's bearing, which are rarely left a yard in length, therefore will not require very high walls.

If the Pears which are designed to be planted, are allowed a south-west aspect, on which they will ripen very well, then the wall to this aspect should be built fourteen feet high or more; for as these trees spread very far, when on free stocks, they should not be shortened and stopped in their growth, which will prevent their bearing. But I shall now proceed to give some directions for the building of hot-walls, to accelerate the ripening of fruits, which is now pretty much practised in *England*.

In some places these walls are built at a very great expence, and so contrived as to consume a great quantity of fuel; but where they are judiciously built, the first expence will not be near so great, nor will the charge of fuel be very considerable, because there will be no necessity of making fires more than three months, beginning about the middle or latter end of *January*, and ending by the middle of *May*, when there will be no want of fires, if the glasses are close shut every night, or in bad weather; for half an

hour's sun-shine on the glasses at that season, will sufficiently warm the air inclosed in the glasses, for the growth of any of our *European* fruits.

There are some persons who plant Vines, and other fruit-trees, by the sides of stoves, and draw some of their branches into the stove, in order to obtain early fruit, and very often train the Vines over the whole tan-bed; which is very wrong, where the stove is designed for the Ananas, because the air must be kept much warmer for them, than is required for Grapes or other fruits, so they can never succeed well together; for when there is only a sufficient quantity of air admitted for the growth of Grapes, the Ananas suffer for want of proper heat; and so, on the contrary, when the stove is kept up to the proper heat for the Ananas, it will be too hot for Grapes; therefore it will be proper to have the Vines on a particular wall by themselves, because these require to have a greater share of air admitted to them, when they begin to shoot, than most other sorts of fruit, so that it is by much the better method to have them separate.

The ordinary height of these hot walls is eight or nine feet, which will be sufficient for any of those sorts of fruits which are generally forced; for by forcing of the trees, they are commonly weakened in their growth, so that they will not grow so vigorously as those which are always exposed to the open air; and where there is not a quantity of walling planted sufficient to let one part rest every other year, the trees will never be very healthy, and will last but a few years. The quantity of walling to produce early fruit for a middling family, cannot be less than eighty or one hundred feet in length; therefore where a person is desirous to have the fruit in perfection, and the trees to continue in a good condition many years, there should be three times this quantity of walling built; so that by dividing it into three parts, there will be two years for the trees to recover their vigour between the times of their being forced; whereby a greater quantity of bearing wood may be obtained, and the fruit will be fairer and in larger quantities than when they are forced every year, or every other year; and as the glasses may be contrived so as to move from one to the other, the expence of building the walls so much longer, will not be very great, because the frames and glasses need not be more than for one year's fruit.

The foundations of these walls should be made four bricks and a half thick, in order to support the flues; otherwise, if part of them rest on brick work, and the other part on the ground, they will settle unequally, and soon be out of order; for wherever there happen any cracks in the flues, through which the smoke can make its escape, it will prevent their drawing; and if the smoke gets within the glasses, it will greatly injure the fruit. This thickness of wall need not be continued more than six inches above the ground, where should be the foundation or bottom of the first flue, which will raise it above the damps of the earth; then the walls may be set off four inches on each side, which will reduce it to the thickness of three bricks and a half, so that the back wall may be two bricks thick, which is absolutely necessary to throw the heat out more in front; for when the back walls are built too thin, the heat will escape through them. The wall in front next to the fruit will be only four inches thick, whereby there will be allowance of nine inches for the flues, which may be covered with twelve inch tiles; for if they have an inch and a half bearing on each side, it will be sufficient.

The ovens in which the fires are made, must be contrived on the backside of the walls, which should be in number proportionable to the length of the walls. The length usually allowed for each fire to warm is forty feet, though they will do very well for fifty; but I would not

advise the flues to be longer than this to each fire, because when the ovens are made at a great distance, there is a necessity of making the fires so much stronger to warm the walls, which will occasion the heat to be too violent near the fires. These ovens should be shedded over, to keep out the wind and rain, otherwise the fires will not burn equally. Some people make these sheds of timber, but it is much better to build them of brick, and tile them over; because the wooden sheds will in a few years decay, and afterwards will be a constant charge to keep in repair; and besides they may be in danger of firing, if great care is not constantly taken of the fires. As it is absolutely necessary to have ovens below the foundation of the first flues, there must be steps down into the sheds, to come to the mouth of the ovens to supply the fuel, therefore the sheds should not be narrower than eight feet in the clear; for as the steps will require four feet space, there should be at least four feet more for the person who attends the fire, to have room to turn himself to clear out the ashes and to put in the fuel. Where the length of walling requires two ovens, it will be proper to have them in the middle included in one shed, which will save expence and allow more room to attend the fires; for in this case the sheds must be at least ten feet long, and then they need not be more than six in breadth. The steps down into these should be at one end, so that the door opening into the sheds will not be opposite to the mouths of the ovens, therefore the fires will burn more regular; for whenever the doors are contrived to front the mouth of the ovens, if the winds set directly against them it will cause the fire to burn too fiercely, and the fuel will be soon consumed.

These ovens may be contrived in the same manner as those which are already described for stoves, wherefore I shall not repeat it again in this place; but must observe, that when the two ovens are joined together, there should be a partition wall at least three bricks thick between them, otherwise the fires will soon destroy it; and if there should be the least hole in the wall, through which the smoak of the two fires can communicate, it will prevent their drawing.

The lower flue, through which the smoak first passes from the fire, may be two feet and a half deep; therefore the back wall should be at least two and a half or three bricks thick, as high as to the top of this flue, then it may be set off to two bricks or two and a half thickness, which must be continued to the top of the wall. The second flue, which should return over the first, may be made two feet, the third a foot and a half, and the fourth one foot deep; which four flues, with their coverings, will rise near eight feet in height, so that there will be just room left for the fixing of the frames at the top to support the glasses under the coping of the wall: and these four returns will be sufficient to warm the air in the frames, for the smoak will have lost its heat by the time it has passed thus far.

In the carrying up of these walls there should be some strong iron hooks fastened at convenient distances, which should project one inch from the wall to which the trelase must be fastened, which is to support the trees. These hooks should be long enough to fasten into the back wall, for the wall in front, being but four inches thick, will not be strong enough to support the trelase; but in placing of them care should be taken not to lay them cross the middle of the flues, because they would obstruct the clearing them of soot whenever there should be occasion; so that the best way is to lay them just under the tiles which cover each flue at about three feet asunder, which will be near enough, provided the bars of the hooks are made sufficiently strong; but these should be flat, lest they obstruct the smoak. As the flues must be well plastered with loam on their inside, so likewise should the loam be spread under the tiles which

cover them, to the thickness of the hooks, that the flues may be very smooth. It will also be very proper to cover these flues on the side next the trelase with hop-bags, or some such coarse cloth, in the manner as hath been directed for the stoves, which will make them so tight that no smoak will find its way, which, without this covering, it is very apt to do through the joints of the walls, especially when they are so thin as these must be built; and this covering will also strengthen the wall of the flues, and join the whole work together. If at each end of these flues there are small arches turned in the back walls, in such a manner that there may be holes opened to clean the flues of soot whenever there is a necessity for it, the trouble will be much less than to open the flues in front; and there will be no damage done to the trees, nor will the flues be in the least injured by this, which they must be when they are opened in front.

The borders in front of these hot walls should be about four feet wide, which will make a sufficient declivity for the sloping glasses; and in these borders there may be a row of dwarf Peas planted to come early, or a row of dwarf kidney Beans, either of which will succeed very well; and if they are not planted too near the trees, will not do them much injury. On the outside of these borders should be low walls erected, which should rise three or four inches above the level of the borders, upon which the plate of timber should be laid on which the sloping glasses are to rest; and this wall will keep up the earth of the border, and also preserve the wood from rotting.

The glasses which are designed to cover these walls must be divided into two ranges; for as they must reach from the ground-plate (just above the level of the border) to almost the top of the wall they will be more than twelve feet long, which will be too great a length for single frames; which, when they are much more than six feet long, are too heavy to move, especially if the frames are made of a proper strength to sustain the glass. These frames should be contrived in such a manner, as that the upper row may slide down; and by making on one side three small holes in the wood work which supports the frames, at about a foot distance, and having a small iron pin to fix into them, the top glasses may be let down one, two, or three feet, according as there may be occasion to admit air. The lower row of glasses may be contrived so as to easily take out, but as they must lie sloping, and the upper row must bear on them, they cannot be contrived to slide upwards, nor indeed will there be any occasion for their moving, because it is much better to let the air in at the top than in the front of the trees.

The sloping timbers, which are to support the glass frames, must be fastened at bottom into the ground plate in the front of the border, and at the top into strong iron cramps fixed in the upper part of the wall for that purpose. These timbers should be made of Fir, which will not twist as Oak and some other wood will, where it is laid in such position. They must be made substantial, otherwise they will not last many years, especially as they are designed to be moveable. On the top of these should be fixed a strong board, under which the upper row of glasses should slide. The use of this board is, to secure the upper part of the glasses from being raised by the winds, and also to keep the wet from getting to the trees; therefore it should be joined as close as possible to the wall, and should project about two inches over the glass frames, which will be enough to throw the wet on the glasses, and likewise to secure them fast down.

The breadth of these frames for the glasses may be about three feet or a little more, according as the divisions of the length of the wall will admit; for a small matter in their width

width is of no consequence, provided they are not too wide to be easily moved; for when they are wider than a man can easily reach with his arms to manage, they will be very troublesome to carry from one place to another. The bars of these frames, which are to support the glasses, should be placed lengthwise of the frames; for when they are placed across, they stop the moisture which is lodged on the inside of the glasses, and cause it to fall in drops on the borders at every bar, which will be very injurious to any thing under them; and if it falls on the trees, will greatly damage them, especially when they are in blossom. The lead into which the glasses of these frames are fixed, should be very broad, and the joints well cemented; otherwise the wet will find an easy passage through, and do great damage to the fruit.

At each end of the range of glasses, there will be an angular space between the glasses and the wall, which must be closely stopped to prevent the air from getting in, which might greatly injure the fruit. These are by some persons closely boarded up; but if they are closed with glasses, so contrived as to open to let in air at proper times, it will be of great advantage; because when the wind may be too strong against the front glasses, one or both of these end glasses may be opened, according to the warmth of the air inclosed, which will be often very useful to cool the air, and to admit a small quantity of fresh air to the fruit.

The sorts of fruit which are usually planted for forcing, are Cherries, Plums, Peaches, Apricots, and Nectarines; but the last-mentioned seldom succeed well, nor will the trees continue long, so is scarce worth planting against hot walls. As for the Vines, I would propose they should be planted by themselves against a particular wall; for as they will require more air to be admitted to them when they begin to shoot, than any of the above-mentioned fruits, they will not succeed, if they are included in the same frame; but the others will do very well in the same border, and require the same temperature of warmth. The best of these sorts to plant against hot walls, are those here mentioned:

Cherries.

The Early May, and May Duke.

Plums.

The Early Black Damask, or Morocco.

The Great Damask Violet of *Tours*.The *Drap d'Or*.

Peaches.

The Red Nutmeg.

The Red *Magdelain*.The *Montauban*.

Nectarines:

Fairchild's Early Nutmeg.The *Elruge*.

Apricot.

The *Masculine*.

These being the sorts which ripen early, are the most proper to plant against these walls, although they are not so valuable as some other sorts of these fruits; yet, as they naturally ripen three weeks or a month earlier in the season, they will be very early ripe when they are brought forward by artificial warmth.

In the preparing of the borders for planting these fruit-trees, there should be the same care taken as for those against open borders; which, being fully treated of in another part of this work, I shall not repeat here. There must also be the same care in training up the trees when they shoot; but the trellises need not be made against these walls, until the trees are grown large enough to spread, and produce a great quantity of fruit; till which time they

may be supported by any low ordinary trellis, which will do very well till the time that the trees will have strength enough to force, which will not be until the fourth or fifth year after planting, according to the progress they have made; for if they are forced too young, it will weaken them so much, as that they seldom make vigorous trees afterwards; besides, the quantity of fruit which such young trees produce, is not worth the expence and trouble of forcing; for the quantity of fuel used, and the trouble, will be the same for small trees, which are not capable of producing more than six or eight fruit each, as for those trees which may produce three or four dozen; so that the greater time the trees have to grow before they are forced, the better they will pay for the trouble and expence.

When the trees have acquired strength enough to produce a quantity of fruit, that part which is designed to be forced the following spring, should be carefully pruned early in autumn; when the very weak shoots must be either entirely cut out, or pruned very short, because these, by being forced, will for the most part decay; and though some of them may be full of flower-buds, yet these shoots being weak, cannot nourish them; so that the flowers having exhausted all the sap, the shoots die soon after, and rarely produce any fruit, or at least do not bring them to perfection. The other more vigorous shoots should also be shortened to a proper length, after the same manner as is directed for those trees in the open air; with this difference only, *viz.* that these which are designed for forcing, should not have their shoots left so long, because the forcing of them will weaken them; and consequently, should there be as great a length of branches, there will probably be a greater number of fruit on them; because, as these will be screened from the open air, they will not be liable to blasts, or the injuries of frost; and the having too many fruit on the trees, will render them small, and also too much weaken the trees; then the shoots should be all regularly fastened to the trellis, at a proper distance from each other; so that when the branches shoot the following spring, they may not over-hang each other. The reason for my advising these trees to be pruned so early in the season, is, that those branches which are left on, may enjoy the whole nourishment of the sap; so that the buds will become very turgid during the winter season, and will be prepared to open when the fires are set to work.

The time for beginning to make the fires is about the middle or latter end of *January*, according as the season is more or less favourable; for if the trees are forced too early into flower, they will be in some danger of miscarrying, if the weather should prove severe; so that it is by much the surest method to begin about the time here directed, because there will be a necessity of admitting fresh air to the trees when they are in flower, which cannot be done with safety when they flower in very bad weather. And those trees which are forced into flower by the middle of *February*, will ripen their fruit as early as most people will desire to eat them; for the Cherries will ripen early in *April*, and the Apricots by the beginning of *May*; and soon after the Plums, Peaches, and Nectarines will be ripe.

There are some persons who plant Strawberries in their borders before the fruit-trees, in order to have early fruit, which often succeed very well; but wherever this is practised, great care should be taken to keep them from spreading over the border, because these plants will exhaust the principal goodness of the earth, and thereby injure the trees; so that when it is designed to have Strawberries in these borders, I would advise, that the roots should be either planted in pots, or singly at a good distance on a shady border of loamy earth, one year before they are designed to be forced; during which time the runners should be diligently

ligerly pulled off, to encourage the main roots for fruiting; and at *Michaelmas* these plants may be transplanted with large balls of earth to their roots, into the borders, before the fruit-trees which are to be forced the following spring, so that they may have time to get new root before that season; and if these plants are carefully watered when they begin to shew their flower-buds, they will produce a good quantity of fruit, which will ripen the latter end of *April*, or the beginning of *May*; but then I would also advise, that these plants be taken away as soon as they have done bearing, that they may not rob the trees of their nourishment.

Since I have mentioned this method of having early Strawberries, I shall take the liberty to insert another method, which is often practised to obtain this fruit early in the spring, though it doth not so properly come under this article; which is, to train up the plants either in pots or borders, after the manner before directed, for at least one year or more; then, about the beginning of *February*, there should be a moderate hot-bed prepared, in length proportionable to the number of plants designed to be forced, and the breadth should be proportionable to the width of the frames which are designed to cover them. These frames may be such as are used for common hot-beds, to raise early Cucumbers, &c. This hot-bed must be covered with fresh loamy earth about eight inches thick, into which the Strawberry plants should be placed, with large balls of earth to the roots, as close as they can conveniently be planted (for as they must be kept clear from runners, they will not spread much during the time they remain in the bed, which will be no longer than until their fruit is gone). Then they should be gently watered to settle the earth to their roots, which must be frequently repeated as the earth becomes dry, otherwise they will produce but few fruit. While the nights continue cold, the glasses of the hot-bed should be covered with mats, to preserve a kindly warmth in the beds; but in the day-time, when the weather is favourable, the glasses should be raised to admit fresh air to the plants; for if they are too much drawn (especially when they begin to flower), they will not produce much fruit. If the season should continue long cold, and the heat of the beds should decline, it will be proper to lay some fresh hot dung round the sides of the beds to renew their heat, being always careful not to make them too hot, for that will scorch their roots, and prevent their fruiting. If the plants which are planted in these beds are strong, and in a good condition for bearing, and care is taken in transplanting of them to preserve good balls of earth to their roots, as also to keep a due temperature of warmth in the beds; they will produce ripe fruit by the end of *April*, or the beginning of *May*, in plenty, and will continue bearing until some of those in the open air come in to succeed them.

The best kind of Strawberries to plant for forcing, is the Scarlet, for the Hautboys grow too rampant for this purpose.

But to return to the subject of hot walls; what I have here inserted concerning the forcing of fruits, has been only to obtain these fruits earlier in the season, than they would naturally ripen against common walls. But in some parts of *England*, where most of our good kinds of fruit seldom ripen, it might be very well worth while to build some of these walls, to obtain good fruit from the best kinds of Peaches, Plums, &c. especially in such places where fuel is plenty, because there the expence will not be great after the first building of the walls. For I would not propose to have coverings of glass, excepting for a small proportion of the walls; the rest may have frames of canvas, to shut over them, in the same manner as the glasses are contrived, which will succeed very well, where proper care is taken;

for as there will not be occasion to cover these trees until the beginning of *March*, at which time also the fires must be made, so, before the trees are in flower, the weather may be frequently warm enough to open the covers to admit sun and air to the trees in the middle of the day; for if these covers are kept too closely shut, the shoots of the trees will draw very weak, and their leaves will turn pale, for want of light and air. And as the design of these contrivances is only to bring the trees into flower three, or, at most, four weeks earlier than they would naturally come against common walls, there will be no necessity of making very large fires, or keeping the covers too closely over the trees.

Instead of canvas for these covers, oiled papers may be used, which should be done in the manner directed for raising of Melons, by passing as many sheets of paper together, as will fit the frames on which they are to be fixed; and when the paste is dry, the paper should be fastened into the frames, and then the oil rubbed over on the outside with a brush, which will soak through the paper, and when the paper is dry, the cover may be used. This paper will last very well one season, and the expence of repairing it will not be very great; wherefore these are to be preferred to the canvas, because all sorts of plants will thrive much better under them than they will under canvas, or any other close covering, which will not admit the rays of light so well through to the plants.

The frames designed for either canvas or paper may be made much slighter than those for glass, because these being very light, will not require so much strength to support them; and if these are well painted, and every year, when their use is over, carried into shelter, they will last a long time, for they will not be wanted abroad longer than three or four months, *viz.* from the beginning of *March* to the middle of *June*; for after this time the fruit will not require any covering, the trees being then full of leaves, and the young shoots will by that time have made such progress, as to become a good defence for the fruit; but these covers should not be too suddenly taken away, but by degrees the trees should be inured to the open air, otherwise the change will be too great, and may occasion most of the fruit to fall off, especially if cold nights should follow.

By this method gentlemen may be supplied with most of the best kinds of fruit, in the northern parts of *England*, where, without some such care, they cannot expect much good fruit in their gardens. And as coal is in great plenty in those places, the expence will be very little; therefore I am surpris'd that most of the gentlemen, who live in the north, do not put this method in practice. That there are some of these walls built in the north is well known, but then they are chiefly designed to produce a little early fruit, more for curiosity than any real use; and these walls are, for the most part, so ill contrived, that four times the fuel is expended, as will be requisite when the walls are built after the manner here directed; and where the heat is not pretty equally distributed through every part of the wall, some of the trees will have too much heat, while others will have little benefit from the fires.

Where the walls are planted with the best kinds of fruit, which are designed to ripen in perfection, if the autumns should prove cold, or very wet, before the fruit be ripe, it will be proper to put the covers over the trees; and if there are some slow fires made to dry off the damps, it will be of great use to prevent the fruit from growing mouldy, and to hasten their ripening; but when this is practis'd, the covers should be taken off whenever the weather will admit of it, that the fruit may enjoy the benefit of the free air, without which they will be insipid or ill-tasted.

Although in the former directions for forcing trees, in order to have early fruit, I have advised, that such trees should have one or two years rest, in order to recover vigour; yet that is not to be understood of these trees, which are only designed to be brought forward enough to produce their fruit in perfection; for as the fires are not designed to be made till the beginning of *March*, the trees will not be weakened thereby, because they will be inured to the open air long before their fruit is ripe, and will have time to ripen their shoots, and form their buds, for the next year's bearing; therefore these trees may be thus forced every year, without doing them much injury, provided they are carefully managed.

There are some persons near *London* who make it their business to raise early fruit to supply the markets, which they perform by the heat of dung only, having no fire-walls in their gardens. The method which these people follow is to have a good quantity of new dung laid in a heap to warm (after the same manner as is practised for making of hot-beds). When this dung is in a proper temperature of heat, they lay it close on the backside of their fruit-wall, about four feet thick at the bottom, and sloping to about ten inches or a foot thick at the top. This dung should be gently beat down with a fork to prevent the heat going off too soon; but it should not be trodden down too hard, lest that should prevent its heating. The outside of the dung should be laid as smooth as possible, that the wet may run off more easily; and if there is a covering of thatch, as is sometimes practised, it preserves the dung from rotting too soon, whereby the heat is continued the longer. The time for laying this dung to the back of the wall, is the same as for making the fires, *i. e.* about the middle or end of *February*. The first parcel of dung will continue warm about a month or five weeks, when there should be a supply of new dung prepared, and the old taken quite away, or mixed up with this new dung, to renew the heat, which, if it works kindly, will be sufficient to last the season. These walls are covered with glasses or oiled paper, in the same manner as the fire-walls, and the trees must be treated the same way; but there must be more care taken to open the glasses against these walls, whenever the weather will permit, otherwise the steam of the dung will occasion a great dampness through the wall, which, if pent in about the trees, will be very pernicious to them, especially at the time they are in flower.

By this method some gardeners have forced long walls, filled with old well-grown fruit-trees, which have produced great quantities of fruit annually, which has well answered their expence; but, as in many parts of *England*, it will be very difficult to procure a sufficient quantity of new dung for this purpose, the fire-walls are most useful, and least expensive.

WALL FLOWER. See *Cheiranthus*.

WALNUT. See *Juglans*.

WALTHERIA. *Lin. Gen. Plant.* 741.

The Characters are,

The flower has a cup-shaped permanent empalement of one leaf, cut into five points at the brim; it has five heart-shaped petals and five stamina, joined in a cylinder, terminated by loose summits, and an oval germen, supporting a single style, crowned by a bifid stigma. The germen turns to an oval capsule with one cell, inclosing one obtuse seed.

The Species are,

1. WALTHERIA *foliis oblongo-ovatis serratis, floribus confertis, pedunculis longissimis axillaribus*. Waltheria with oblong, oval, sawed leaves, and flowers growing in clusters upon very long foot-stalks, at the wings of the branches.

2. WALTHERIA *foliis ovatis serratis nervosis, floribus confertis alaribus sessilibus*. Waltheria with oval, sawed, veined

leaves, and clustered flowers sitting close at the wings of the stalk.

The first sort grows naturally in both *Indies*; this rises with a shrubby branching stalk to the height of eight or ten feet, covered with soft hairs. The leaves are placed alternately upon long foot-stalks; they are hairy and soft, having several longitudinal veins. From the wings of the branches arise the foot-stalks, terminated by clusters of very small yellow flowers, which just peep out of their hairy soft empalements; under each cluster is placed a small leaf of the same shape with those below. The flowers are succeeded by a single seed, wrapped in the empalement of the flower.

The second sort grows naturally at *Campeachy*, from whence the seeds were sent me. The stalks of this are ligneous; they rise six or seven feet high, dividing into several branches, which are less hairy than those of the former sort. The leaves are oval, of a yellowish green colour, sawed on their edges, and hairy, but are not so soft as those of the former, having many veins running from the midrib, standing upon long foot-stalks. The flowers are very small, yellow, and are collected into round clusters, having very short foot-stalks close to the wings of the leaves.

These plants are propagated by seeds, which must be sown on a hot-bed; and when the plants are fit to transplant, they must be each planted into a separate small pot, and plunged into a fresh hot-bed, and afterward treated in the same manner as other tender plants from the same country, so must be kept in the bark-stove, otherwise they will not thrive in *England*. The second year the plants will flower, and produce good seeds; but they may be continued three or four years, if the plants are often shifted, and their roots pared, to keep them within compass; for if they are permitted to remain long undisturbed in the tan-bed, their roots will run out through the holes in the bottom of the pots, and extend to a great distance in the tan-bed; and when this happens, if their roots are torn, or cut off, the plants seldom survive it. When the plants root into the tan, they grow very luxuriant, and cannot be kept within reasonable compass; but on their roots being disturbed, their branches will hang, and their leaves shrivel up, and drop off; therefore, to keep these plants within bounds, they should be drawn up out of the tan, at least once in six weeks, during the summer season, and the plants shifted out of the pots once in three months; with this management the last sort may be continued several years, but the first seldom lives longer than two years.

WARNERIA. Yellow Root.

The Characters are,

The flower has no empalement; it has three roundish petals, which fall off very soon, and a great number of awl-shaped stamina, terminated by oval summits, with several roundish germen, supporting a short style, crowned by a permanent bifid stigma. The germen afterward turns to a roundish fruit, composed of many acini like the Strawberry, each having one cell, including a single seed.

I have given the title of *Warneria* to this genus in honour to *Richard Warner, Esq.* of *Woodford* in *Essex*, who is a very curious botanist, and is possessed of a large collection of curious plants, of which he is very communicative to all lovers of plants. This title of the plant was given by me to it long before *Dr. Linnæus's* second volume of his *Systema Naturæ* was published, in which he has given to this plant the title of *Hydrastis*; the characters of which were sent him from *England*, but he had not seen the plant.

It grows naturally in *Persyvania*, from whence the roots were sent me by *Dr. Bensef*. The root is fleshy, of an irregular form, and a deep yellow colour, sending out one or two stalks about ten inches high; toward the bottom of these is one large, roundish, indented leaf, standing upon a

foot-stalk; the upper part of each stalk is garnished by a smaller leaf, of the same form as the lower, which embraces the stalk, which is terminated by single white flowers, composed of three petals, which drop off in a few hours after they expand, leaving a great number of stamina with the styles naked. The germen soon after swell, and compose a fruit very like that of the Dewberry, having many acini of a bright red colour when ripe, each acini including one seed.

This plant may be propagated by seeds, which should be sown in a pot of loamy earth soon after they are ripe, placing the pot in shade till autumn; when it may be put under a frame for the winter, the plants will appear in the spring; then should be placed in shade till their leaves decay, when the roots may be transplanted in a shady border, where they may remain to flower.

WATER is one of the most considerable requisites belonging to a garden: if a garden be without it, it brings a certain mortality upon whatsoever is planted. By waterings the great droughts in summer are allayed, which would infallibly burn up most plants, had we not the help of water to qualify the excessive heats; besides, as to noble seats, the beauty that water will add, in making *Jet d'Eau*, and cascades, which are some of the noblest ornaments of a garden.

The qualities of water.

Sir *Isaac Newton* defines water (when pure) to be a very fluid salt, volatile, and void of all savour and taste, and it seems to consist of small, hard, porous, spherical particles of equal diameters, and equal specific gravities; and also that there are between them spaces so large, and ranged in such a manner, as to be pervious on all sides.

Their smoothness accounts for their sliding easily over the surfaces of one another.

Their sphericity keeps them from touching one another in more points than one, and by both these their frictions, in sliding over one another, are rendered the least possible.

The hardness of them accounts for the incompressibility of water, when it is free from the intermixture of air.

The porosity of water is so very great, that there is at least forty times as much space as matter in it, for water is nineteen times specifically lighter than gold, and of consequence rarer in the same proportion, but gold will, by pressure, let water pass through its pores, and therefore may be supposed to have (at least) more pores than solid parts.

Dr. *Boerhaave* is of opinion, that if water could be had alone and pure, it would have all the requisites of an element, and be as simple as fire; but there has been no expedient hitherto found out for making it such.

Rain water, which seems to be the purest of all those we know of, is replete with infinite exhalations of all kinds, which it imbibes from the air; so that though it be filtered and distilled ever so often, yet there still remain fæces.

The purest of all waters we can any way arrive at, is that distilled from snow, gathered in a clear, still, pinching night, in some very high place, taking none but the outer, or superficial part thereof. By a number of repeated distillations thereof, the greatest part of the earth, and other fæces, may be separated from it; and this is what we must be content to call pure water.

Of the fluidity of water.

Water, says Dr. *Boerhaave*, is fluid, but the fluidity is not natural thereto; for naturally it is of the crystalline kind, and accordingly, wherever a certain degree of fire is wanting, there we see water become ice. That this ice is the proper effect of the want of heat, and not of any ad-

ditional spicula introduced into the water, as *Mariotte* and others contend, is evident enough, were it only hence, that on this supposition it could not penetrate the substance of all bodies, as we find it does, and even that of metals.

This water, in its state of solution, never remains at rest; its parts are in perpetual motion, as was first discovered by the *French* with the help of microscopes; and is farther confirmed by this, that if a little saffron be suspended in the middle of a vessel full of water, the saffron colour will in a little time form, as it were, a kind of atmosphere around, and at length be diffused through the whole water. Now this could no way be effected without a motion of the watery particles among each other. Add, that if you cast a quantity of the driest salt, in the coldest weather into water, it will soon be dissolved, which argues the continual motion of the particles of that element.

He adds, that he had more than once filled a large wide vessel with water, and narrowly watched with a good microscope, but could never perceive it without some sort of undulatory motion.

Water scarce ever continues two moments exactly of the same weight, but is always varying more or less, by reason of the air and fire contained in it. Thus, if you lay a piece of pure limpid ice in a nice balance, you will find it continue in equilibrio. The expansion of water in boiling, shews what effect the different degree of fire has on the gravity of water.

This uncertainty makes it difficult to fix the specific gravity of water, in order to settle its degree of purity; but this we may say in the general, that the purest water we can procure is, that which weighs 880 times as much as air.

However, neither have we any tolerable standard for air, for water being so much heavier than air, the more water is contained in air, the heavier of course must it be; as in effect, the principal part of the weight of the atmosphere seems to arise from the water.

Of all waters, the purest is that which falls in rain in a cold season, and a still day; and this we must be content to take for elementary water. The rain water in summer or when the atmosphere is in commotion it is certain, must contain infinite kinds of heterogeneous matter. Thus if you gather the water that falls after a thunder clap in a sultry summer's day, and let it stand and settle, you will find a real salt sticking at the bottom; but in winter, especially when it freezes, the exhalations are but few, so that the rain falls without much adulteration; and hence, what is thus gathered in the morning, is found of good use for taking away spots in the face, and that gathered from snow, against inflammations in the eye. Yet this rain-water, with all its purity, may be filtered and distilled a thousand times, and it will still leave some fæces behind it; so that to procure the purest water possible, a man must look for it in a spacious plain in the winter time, when the earth is covered with snow, and its pores locked up with frost.

The next in point of purity is spring-water. This, according to Dr. *Halley*, is collected from the air itself, which, being saturated with water, and coming to be condensed by the evening's cold, is driven against the cold tops of mountains, where, being farther condensed and collected, it gleets down or distills, as much as in an alembick.

Spring-water becomes the better by running, for during all its course, it is depositing what heterogeneous matters it contained; but while the river drives on its waters in an uninterrupted stream, all its salts, with all the vegetable and animal matters drained into it, either from exhalations, or from the ground it washes gradually, either sink to the bottom, or are driven to the shore.

But what water descends from springs on the tops of mountains, is generally pretty free from heterogeneous bodies.

Having treated of the properties of water philosophically, I shall next consider it as essentially necessary in gardens for use, as also of the beauty which water adds to gardens, where it can be obtained in plenty, if it is properly disposed; and first of its use.

In the kitchen-garden water is absolutely necessary, for without it there can be little expected; therefore in such places where there cannot be a supply of water obtained for basons or ponds, wells must be dug; and where the depth to the water is too great to be raised by pumps, there must be either machines for raising it contrived, or it must be drawn by hand; but in such places which are so unhappily situated, as to require machines for the raising of water from a great depth, there is but small encouragement to make kitchen-gardens, because the constant supplying of water in those dry situations, will be attended with great expence; and generally the produce of such land is of little worth, especially in dry seasons.

Where kitchen-gardens are supplied with water from wells, there should be a contrivance of large cisterns, into which the water should be raised, to be exposed to the sun and air some time before it is used; for the rawness of this water, when fresh drawn from wells, is not agreeable to the growth of vegetables; so that where large ponds are in the neighbourhood of these gardens, from whence the water can be led into them, that is by much the best for the growth of vegetables; next to this, river-water is to be preferred, especially from those rivers which run through or near large towns, where the water is fattened by the soil thrown into the rivers; but the water of some very clear rivers is as hard as that from the deepest springs, rising through gravel or sand; but the springs issuing through chalk, are generally much softer.

If good water can be obtained in plenty from the neighbourhood of the kitchen-garden, then there should be two or three basons made in different parts of the garden; so that no part of the garden should be too far distant from the water, for where the water is to be carried to a considerable distance, the expence of labour will be great, and there will be great danger of the plants suffering from their being but sparingly watered, labourers being very apt to flight their work, when attended with trouble, if they are not well looked after. The size of these basons should be in proportion to the quantity of water which will be required, or that they can be supplied with; but their depth should not be more than four feet, for when they are deeper, there is danger of persons being drowned, if by accident they should fall into them; besides water, when very deep, is not so well warmed and tempered by the sun and air as when it is shallow; therefore the water of shallow basons is best for the use of gardens.

In making of these basons, there must be particular regard had to the natural soil of the garden, for in loose sandy land there will require much care in making of the clay-walls so as to hold water; but where the ground is loamy, or inclining to clay, there will be little difficulty in making basons, and the clay-walls need not be so thick. Where the ground is loose, the clay-walls at the bottom should not be less than two feet thick, and those on the sides one foot and a half. The clay should be well wrought over and trod after it is taken from the pit, before it is used in building the wall. The true sign of good clay is, that it be close and firm, without any mixture of sand, and that it be tenacious and fat in handling; as for the colour, it is no matter whether it be green, yellow, blue, or red; but before the clay is brought to the place, the bason should be dug

out and formed, for if the clay is too long exposed to the sun and air, it will not be so fit for use, especially if it be laid in small parcels.

The best time of the year for making basons is in autumn, when the sun is declining, and the weather temperate; for in the spring of the year the east and north-east winds generally blow, which are drying; so that the clay-walls, which are not very carefully covered as fast as they are made, very often crack in many places, and these small cracks often grow wider, and the water will find a passage through them. The same inconveniency happens from the violent heat of the sun in summer; for when the clay dries fast, it will be very difficult (not to say impossible) to prevent its cracking, and these will let off the water; and if the clay-wall should not be well made at first, it will be very difficult to mend it after, besides the uncertainty there is in finding out the places through which the water finds a passage, which is seldom done without strictly examining every part of the clay.

When the ground is dug out level, where the bason is designed, the clay must be brought in, and laid very carefully in the bottom, being very careful that no dirt, or small stones, be mixed with the clay; and there must be some water thrown from time to time upon it, as it is closely trod by mens naked feet, and then it must be rammed very close: in the performance of this, there must be great care taken that every part of the clay is equally kneaded and rammed, without which there will be great danger of the water making its way through those parts of the clay which are not well wrought. After the bottom is finished with clay, there should be a stratum of coarse gravel laid over it about four or five inches thick, which will greatly secure the clay-wall, and render the water clear; but where the basons are large, so that the clay walls are long in making, the clay should be covered with moist litter, to prevent its drying, which may be taken off when the whole is finished, to lay on the gravel; but if part of the side-walls are finished before this is done, it will be the better, because there may be some water let into the bason as soon as the gravel is laid, which will prevent the clay from cracking; then the walls round the side of the bason must be carried up with the same care as hath been directed for the bottom, observing also to cover the clay first with litter while the work is carrying on, and afterward lay it with coarse gravel; and as the walls are finished round, the water may be let in, to secure the clay from drying or cracking.

When the whole is finished, the upper part of the walls must be laid with turf, which will secure them from being broken, and prevent the sun from penetrating the clay; but before this is done, there must be a stratum of sand laid upon the clay four or five inches thick, and upon this a thin stratum of good earth laid, for the Grass to take root in. The bed of sand will prevent the Grass from rooting into the clay; and this will also keep out the frost, which will penetrate the clay, where there is not a covering of sand to secure it, and by being frozen and swelled, and afterward drying, the clay is very apt to crack in many places. The turf on the side of the bason should be laid as far down as the water is apt to shrink, that no part of the clay may be wholly exposed to the weather, for the reasons before given.

Where these basons are made, there should be no trees growing near, for the roots of trees or shrubs will extend themselves to the clay-walls, and by penetrating them, will occasion fissures, through which the water will find an easy passage; and where tall trees are growing near basons or ponds, the shaking of the trees with violent winds is apt to loosen the clay-walls, and occasion cracks in them, therefore these cautions are necessary to be observed.

In some countries, where clay cannot be easily procured, the walls of these basons are frequently made of chalk, which is beaten into fine powder, and made into a sort of mortar; and with this the walls are made, by ramming and working it very hard and firm. These basons hold water very well where they can be well supplied with water, so as not to be too long dry, for when it so happens, the sun and wind dry the chalk, and cause it to crack, and these cracks commonly extend through the thickness of the walls, so as to let off the water.

There are others who build their walls with brick laid in terrass, which is a good method for such places where the ground is very loose and sandy, because the walls, when well built, will support the loose earth from falling or settling away from the sides; but where terrass is used, the walls should not be long dry and exposed, for the heat is apt to crack the terrass.

Some persons make a cement of powdered tile and lime, two thirds of the former to one third of the latter, being very careful in the mixing of it not to add too much water, but to labour it well in the beating, which is a principal thing to be observed. With this cement they cover the surface of the walls of basons about two inches thick, laying the plaster very smooth, and being very careful that no sticks, straws, or stones, are mixed with it; this plastering is commonly performed in dry weather, and as soon as it is finished, it is rubbed over with oil or bullocks blood, and the water let into the bason as soon as possible. This cement has the property of hardening under water, so as to be equal to stone, and will continue as long sound.

Whatever the materials are with which the walls are made, there must be great care taken that they are built so strong, as that they may resist the weight of the water; so that where the ground about the bason is not very solid, the walls should be thicker, and supported on the backside by buttresses of the same materials, placed at proper distances; or if the walls are made of clay, there should be planks supported by strong timbers, placed at proper distances to support the clay, otherwise there will be great danger of their being broken down, especially where the basons are large, so as that the winds have room to act upon the surface of the water, and drive it in large waves against the banks.

The directions here given are only for basons or reservoirs of water for use, so must not be supposed for large pieces of water for beauty; for where the ground is of a loose sandy nature, so as not to hold water, the expence of claying the bottom and sides will be too great, if the water is of a large extent; therefore it would be imprudent to attempt it in such places, but where there is a supply of water, and the ground is well adapted to hold it. There can be no greater beauty than that which water affords to a seat, provided it is properly disposed; therefore I shall give some general hints, by which persons may be directed in the forming of large pieces of water, so as to render them beautiful.

In those places where there is a command of running water, it will be a great additional beauty, because the water will always be much clearer, so more beautiful than still water; besides, if it moves with any degree of velocity, there may be one or more falls of water contrived, which will still add to the beauty. In the conducting of this water, the level of the ground must be carefully taken, for the great skill in the contriving of rivers, or other pieces of water, is in the saving of expence in the digging; therefore where the ground is naturally low, the water should be conducted through these low parts, and never endeavour to carry it through higher ground; for in such places the banks will be so high as to shut out the sight of the water,

to persons who stand at a little distance from it on either side, unless the water is very broad; and where it is so, the eye is thrown to a considerable distance over the surface of the water, by the steepness of the banks, therefore the slopes on the side of water should always be made as easy as possible; nor should they be made flat, with sharp edges on the top (as is too generally practised); for these stiff regular slopes are not near so pleasing as those which are made gently convex, for the eye will slide over these to the water, having no ridge to cut the sight, and at a small distance there will be no appearance of a cut, as will always be seen where the upper part of the slope is finished in a sharp angle; and the great skill is to contrive, that as much of the surface of the water may appear to the sight as possible.

In most of the old gardens, where there are pieces of water, there is nothing more common than to see them brought into regular figures, such as long strait canals, or basons, either round or polygonal; so that all the boundaries of the water are seen at one view, but these, however large may be their extent, are not near so pleasing as where the water is so conducted, as that the termination may be seen as little as possible; for when the water is lost from the sight by some gentle easy turns, the imagination may be led to suppose the surface of the water extended to a considerable distance; so that sometimes small pieces of water are so artfully contrived, as to make them appear very considerable.

As in the old stile of laying out gardens the water was generally wrought into regular strait canals, which corresponded with the strait walks, hedges, and regular lines of trees, which were then chiefly studied, so, as the taste altered from this stiff method of disposing gardens, to that which approached nearer to nature in the forming of rivers, or other large pieces of water, those who have succeeded best have always had great regard to the natural situation of the ground, so as to lead the water through the natural hollows, whereby the great expence of digging is saved; and by contriving to make the head in some narrow part of the ground, it may be done at a much less expence, and will be better secured than where the head is of great extent; therefore it is better either to shorten the extent of the water, or to carry it farther, according to the natural situation of the ground, than to terminate it where it may occasion great expence; and it is always observed, that where there is the greatest expence in the making of these large heads, the whole will appear less beautiful than where nature is chiefly consulted, for nothing can be more unsightly than those extensive heads which are sometimes made to pieces of water which rise six or eight feet, and sometimes much more, above the surface of the ground, whereby the water is hid from the sight, to those persons who are situated on that side of the head, and a large bank of earth shuts up the view; and sometimes these heads are so situated, as to appear in sight of the house, or from a principal part of the gardens, which is a very great absurdity.

Since the taste has been altered in the disposition of gardens, and a more natural method has been pursued by persons of judgment, there have been great improvements made in the distribution of water, so as to render it truly ornamental to the seats where they are placed; but there are some, who, by pretending to imitate or copy from these works, have erred as much in making so many short unnatural turns in their water, as those before-mentioned have done by their regular strait sides; for in what is usually termed Serpentine rivers, nothing is more common than to see a small surface of water twisted in so many short turns, as that many of them appear at one view; and these windings are often made like parts of circles, with such an air of stiffness, as to render them equally disagreeable with any

any the most studied figures, to persons of good taste. Another thing is also common to these unnatural pieces of water, which is, their being made of the same width in every part, which should always be avoided, for nothing is more beautiful than to see the water extend to a large surface in some places, and to have it in others more contracted; and this may be generally done at a much less expence than the other, where the natural site of the ground is well considered, which should be done with the utmost care, before any work of this sort is begun, for want of which many persons have repented after having been at great expence.

There is also another material thing to be observed, in the situation of large pieces of water, which is, never to extend them so near to the house, as that they may annoy it, by the damp, which the vapours exhaling from the water may occasion, especially when exposed to the wind, which will at times drive the vapours toward the house, and thereby render the habitation unhealthy, and destroy the furniture; therefore it is much better to walk out to see the water, than to sacrifice the habitation for the pleasure of seeing it from the house; nor should the water be so situated, as that the surface may be level with the floor of the house, for there is generally some moisture, which will percolate through the veins of the earth, enough to occasion so much damp, as to render the lower part of the house unwholesome; and where there is a considerable damp in the foundation of a house, part of it will ascend upward, and render the apartments so, therefore great care should be had as to this.

Where persons are not so happily situated, as to have the command of a constant running water, but yet from some neighbouring reservoirs or ponds can be supplied with it, there may be some agreeable pieces of water contrived, both for use and beauty, especially where there is a large supply, for otherwise it will be better to contract the design; for nothing can be more ridiculous than that of having either ponds or rivers designed, where they cannot be supplied with water in the dry seasons, when there is the greatest want of it, both for use and pleasure.

In those places where there is a great scarcity of water, there should be large reservoirs contrived, into which the water which descends from the hills and rising grounds may be led; so that a large body of water may be collected during the rainy season, for a supply in time of drought; these reservoirs, when large, may contain as much water as may be necessary for the use of the house and gardens; but these can rarely supply water enough for beauty, therefore in such situations it should not be attempted.

As water never appears so well, as when it is situated near woods, so in the contrivance of rivers, or pieces of water, they should be so placed as to have planting near, that the contrast between the wood and water may appear as perfect as possible; and in some places, where the water can be seen through the open groves, between the stems of large trees, it will add greatly to the beauty of the place; but where the water is designed to terminate, the head should be as much concealed as possible, by close plantations of ever-green trees, which may be faced with Alders and Weeping Willows, planted close on the sides of the water, so as that their branches may hang over; and if the water is contracted, and led through these trees with a gentle winding, it may seem to run much farther, and to communicate with a larger body of water at a distance; in the contriving of which, the greatest art is to make it appear as natural as possible; for the less art there appears in these things, the longer they will please, and the more they will be esteemed by persons of good judgment.

WATSONIA.

The title of this genus is given to it in honour of my

learned friend Dr. *William Watson*, F. R. S. whose knowledge in the science of botany justly demands this tribute.

The Characters are,

The flower has a permanent spatha (or sheath) which divides into two parts almost to the bottom; it is of one petal. The tube is long, a little curved, and swells at the upper part; the rim is cut into six obtuse segments, which spread open. It has three long slender stamina, which are terminated by prostrate oblong summits, and a roundish three-cornered germen, supporting a slender style a little longer than the stamina, crowned by three bifid stigmas. The germen afterward turns to a roundish three-cornered capsule, having three cells, opening with three valves, each containing three or four roundish seeds.

This has been titled by Dr. *Trew*, *Meriana flore rubello*, before he had been acquainted with the name which I had applied to it; but he has since informed me by a letter, that as I had raised the plants from seeds, he would suppress his title, and adopt mine, who he thought had the most right to give it; and that he rather chooses to do so, because the figure he has published of it was drawn from the plant in the *Chelsea* garden.

The Species are,

1. *WATSONIA foliis ensiformibus, floribus alternis.* *Watsonia* with sword-shaped leaves, and flowers placed alternately on the stalks.

2. *WATSONIA humilis foliis ensiformibus, floribus in thyrsis dispositis.* Dwarf *Watsonia* with sword-shaped leaves, and flowers disposed in a loose spike.

These plants grow naturally at the *Cape of Good Hope*, and were raised from seeds, which were brought from thence in the *Chelsea* garden. The description of the first sort:

The root is bulbous, compressed, and shaped like a kidney, covered with a fibrous brown skin. The leaves are sword-shaped, about a foot long, and an inch broad, ending in points; the two sides have sharp edges, but the middle is thicker, and has a prominent midrib; they are of a dark green colour, and rise immediately from the root. The stalk comes out from the root between the leaves, and rises a foot and a half high. The flowers are produced from the side, standing alternately at about an inch and a half distance from each other; they have each a spatha or sheath, composed of two leaves, which are joined at their base, where they are broad, but gradually lessen to their points. Before the flowers appear, they are of the same green colour with the stalk, and are divided, a small part of their length inclosing the flower, but afterward they are split almost to the bottom, and wither before the flowers decay, becoming dry, and wrap round the seed-vessel. The tube of the flower is an inch and a half long, narrow at the base, a little curved, swelling much larger above. The rim is divided into six obtuse segments, which spread open; the flower is of a red copper colour on the outside, but of a deeper red within; it has three stamina, which are incurved, terminated by oblong summits, of a dark brown colour, fastened in the middle to the apex of the stamina, lying prostrate. At the bottom of the tube of the petal is situated an oval three-cornered germen, supporting a slender style a little longer than the stamina, crowned by three bifid reflexed stigmas. The flowers generally appear in *May*, and the seeds ripen in *July*.

The second sort is much less than the first; the leaves are shorter, and not quite so broad; the flower-stalk seldom rises above a foot high, and the flowers are ranged closer upon the stalk; they are also of a deeper red colour.

These plants are propagated by offsets from the root, in the same manner as the *Crocus* or *Gladiolus*. The time for transplanting of the roots is in *August*, soon after the stalks decay; the larger roots must be each put into a separate pot filled with light fresh earth, and may be placed in

the open air till toward the end of *October*, when the leaves will begin to appear above ground, at which time it will be proper to remove them into shelter; for as this plant is a native of a warm country, it will require to be screened from frost.

The best way of treating these roots is to plunge the pots into an old bed of tanners bark, which has lost its heat, in *October*; this bed should be covered with a frame, the glasses of which should be drawn off every day in mild weather, that they may enjoy as much free air as possible, to prevent their drawing up weak; but they must be covered in bad weather, and screened from frost. The latter end of *April*, when they begin to put out their flower-stalks, the pots should be removed to an airy glass case, where they may stand to flower; and when the flowers are decayed, they should be placed in the open air to perfect their seeds.

The offsets and small roots may be planted three or four in a pot, according to their size, and should have the same treatment as the larger roots the first year, and by that time twelvemonth they will be strong enough to flower, so should have separate pots.

WILDERNESSES, if rightly situated, artfully contrived, and judiciously planted, are very great ornaments to a fine garden, but it is rare to see these so well executed in gardens as could be wished, nor are they often judiciously situated; for they are frequently so situated as to hinder a distant prospect, or else are not judiciously planted; the latter of which is scarce ever to be found in any of our most magnificent gardens, very few of their designers ever studying the natural growth of trees, so as to place them in such manner as not to obstruct the sight to the view; I shall therefore briefly set down what has occurred to me from time to time when I have considered these parts of gardens; whereby a person will be capable to form an idea of the true beauties, which ought always to be studied in the contrivance of wildernesses.

1. Wildernesses should always be proportioned to the extent of the gardens in which they are made, that they may correspond in magnitude with the other parts of the garden, for it is very ridiculous to see a large wilderness planted with tall trees in a small spot of ground; and, on the other hand, nothing can be more absurd than to see little paltry squares, or quarters of wilderness work, in a magnificent large garden.

Wildernesses should never be placed too near the habitation, because the great quantity of moisture, which is perspired from the trees, will cause a damp unwholesome air about the house, which is often of ill consequence. Nor should they be situated so as to obstruct any distant prospect of the country, which should always be preserved wherever it can be obtained, there being nothing so agreeable to the mind as an unconfined prospect of the adjacent country; but where the sight is confined within the limits of the garden from its situation, then there is nothing so agreeable to terminate the prospect, as a beautiful scene of the various kinds of trees judiciously planted; and if it is so contrived, that the termination is planted circularly with the concave toward the sight, it will have a much better effect than if it end in straight lines or angles, which are never so agreeable to the mind; therefore those lines should be broken.

The trees should also be adapted to the size of the plantation, for it is very absurd to see tall trees planted in small squares of a little garden; and so likewise, if in large designs the plantation has only small shrubs, it will have a mean appearance.

The walks must also be proportioned to the size of the ground, and not make large walks in a small wilderness nor too many walks, though smaller, whereby the greatest part of the ground is employed in walks; nor should the

grand walks of a large wilderness be too small, both of which are equally faulty. These walks should not be entered immediately from those of the pleasure garden, but rather be led into by a small private walk, which will render it more entertaining.

The old formal method of contriving wildernesses was to divide the whole compass of ground, either into squares, angles, circles, or other figures, making the walks correspondent to them, planting the sides of the walks with hedges of Lime, Elm, Hornbeam, &c. and the quarters within were planted with various kinds of trees promiscuously without order; but this can by no means be esteemed a judicious method, because first hereby there will be a great expence in keeping the hedges of a large wilderness in good order by shearing them, which, instead of being beautiful are rather the reverse; for as these parts of a garden should, in a great measure, be designed from nature, whatever has the stiff appearance of art, does by no means correspond therewith; besides, these hedges are generally trained up so high, as to obstruct the sight from the stems of the tall trees in the quarters, which ought never to be done.

In the next place the walks are commonly made to intersect each other in angles, which also shew too formal and trite for such plantations, and are by no means comparable to such walks as have the appearance of meanders or labyrinths, where the eye cannot discover more than twenty or thirty yards in length. These should now and then lead into an open piece of grass; and if in the middle part of the wilderness there is contrived a large opening, in the center of which may be erected a dome or banquetting-house, surrounded with a green plat of grass, it will be a considerable addition to the beauty of the place.

From the sides of the walks and openings the trees should rise gradually, above each other, to the middle of the quarters, where should always be planted the largest-growing trees which should appear to view, it will have a very different effect from the common method, where the trees are planted large and small without order.

In these plantations there may be planted next the walks and openings Roses, Honeyuckles, *Spiræa frutex*, and other kinds of low flowering shrubs; which may be always kept within compass; and at the foot of them, near the sides of the walks, may be planted Primroses, Violets, Daffodils, and many other sorts of wood flowers, to appear as in a natural wood. Behind these should be planted *Syringas*, *Cytisuses*, *Althæa frutex*, *Mezereons*, and other flowering shrubs of a middle growth, which may be backed with other flowering shrubs of a large growth.

In small gardens, where there is not room for these magnificent wildernesses, there may be some rising clumps of ever-greens, so designed as to make the ground appear much larger than it is in reality; and if in these there are some serpentine walks well contrived, it will greatly improve the places, and deceive those who are unacquainted with the ground as to its size.

In wildernesses there is but little trouble or expence after their first planting, which is an addition to their value; the only labour required is to keep the walks free from weeds. And in the quarters, if the weeds are hoed down two or three times in a summer, it will still add to their neatness. The trees should also be pruned to cut out all dead wood, or irregular branches, where they cross each other, and just to preserve them within due bounds; and, as was before observed, if the ground be slightly dug between the trees, it will greatly promote their vigour. This being the whole labour of a wilderness, it is no wonder they are so generally esteemed, especially when we consider the pleasure they afford.

SWEET WILLIAMS. *Sea Dianthus.*

WILLOW. *See Salix.*

WILLOW, the *French.* *See Epilobium.*

WIND is defined to be the stream or current of the air, together with such vapours as the air carries along with it, or it is a sensible agitation of the air, whereby a large quantity thereof flows out of one place or region to another.

The ancients made but four winds, according to the four cardinal points, but this was quickly looked upon as too gross a division. The following age added eight more to this number, which was thought too nice a subdividing, and therefore they reduced the last number to four, taking every other or middle wind, and adding them to the old account; but our sailors, who are far beyond the ancients for their skill in navigation, have divided the horizon into thirty-two equal parts, adding twenty-eight to the four cardinal winds; a thing useful in navigation, but of no great concern in natural philosophy, unless it be to give a hint, that the wind blows from all parts of the heavens.

Of the qualities of winds.

1. *A wind that blows from the sea is always moist; in summer it is cold, in winter warm, unless the sea be frozen up.* This is well demonstrated thus: There is vapour continually rising out of all water (as appears even hence, that a quantity of water, being left a little while in an open vessel, is found sensibly diminished), but especially if it be exposed to the sun's rays, in which case the evaporation is beyond all expectation. By this means the air incumbent on the sea becomes impregnated with a deal of vapour, but the winds blowing from off the sea, sweep these vapours along with them; and consequently are always moist.

Again, water in summer, &c. conceives less heat than terrestrial bodies, exposed to the same rays of the sun; but in winter sea water is warmer than the earth, covered with frost, snow, &c. Wherefore, as the air, contiguous to any body, is found to partake of its heat and cold, the air, contiguous to sea water, will be warmer in winter and colder in summer, than that contiguous to the earth: or thus; vapours raised from water by the sun's warmth in winter, are warmer than the air they rise in, as appears from the vapours condensing, and becoming visible, almost as soon as they are got out into the air. Fresh quantities of vapours, therefore, continually warming the atmosphere over the sea, will raise its heat beyond that over the land.

Again, the sun's rays reflected from the earth into the air in summer are much more than those from the water into the air. The air therefore over the earth, warmed by the reflection of more rays than that over water, is warmer. Hence sea winds make cloudy hazy weather.

2. *Winds which blow from the Continent are always dry, in summer warm, and cold in winter; for there is much less vapour arising from the earth than from water, and therefore the air over the Continent will be impregnated with much fewer vapours: add, that the vapours or exhalations raised by a great degree of heat out of the earth, are much finer and less sensible than those from water. The wind therefore, blowing over the Continent, carries but little vapour with it, and is therefore dry.*

Our northern and southerly winds, however, which are commonly esteemed the causes of cold and warm weather, Dr. Derham observes, are really the effects of the cold or warmth of the atmosphere: hence it is, that we frequently see a warm southerly wind on a sudden changed to the north, by the fall of snow or hail; and that in a cold frosty morning we see the wind north, which afterward wheels about toward the southerly quarters, when the sun has well warmed the air, and again in the cold evening turns northerly or easterly.

Some winds are drying, others are moist; some gather clouds, others disperse them; some are warm, others cold; but their influence is not one and the same in all places, for such winds as are warm in one country are cold in another; those that are wet with us are dry with other nations, and on the contrary.

The dry winds are such as carry but a few vapours along with them, and therefore lick off the moist particles from the bodies over which they pass; and thus in *Holland* the north and east winds, with the intermediate points, are drying, because the cold northern sea yields but few vapours in comparison of those that come from warmer parts of the ocean, but the westerly winds and others are moist, because they issue from warm and vaporous parts, the western wind seldom failing to send rain.

Such winds gather clouds which blow from the quarters where the vapours arise, which, in conjunction with the vapours of our own region, fill the air; and, on the contrary, those that bring little vapour along with them, and bear away that which hangs over us, bring fair weather.

Winds are either warm or cold, as the countries are from whence they blow; and therefore when a brisk wind blows from a cold quarter, it allays the heat of summer, which is very troublesome in still weather. Thus a quick blast of a pair of bellows will put out a flame, which a gentle blowing increases; for the quick blast drives all the flame to one side, where it is stifled by the force of the incumbent air for want of aliment, but a gentle wind augments the motion of the flame every way, and makes it seize on more parts of fuel.

Now, because all the heat or cold of wind proceeds from the heat or cold of the country where it blows, therefore the same winds are cold or hot every where. Beyond the line they are just the reverse of what they are with us; their cold winds are from the south, ours from the north; and as our south winds are warm, from no other reason but because they bring us an air heated by the sun; for the very same reason the north winds are warm to our antipodes.

From what has been said, it is evident that the sun is the cause of the wind, and motion the cause of the vapours.

Of WINE S, and vinous liquors.

WINE is a brisk, agreeable, and spirituous juice, drawn from vegetable bodies, and fermented.

Dr. *Boerhaave* characterizes wine, that the first thing that it affords by distillation be a thin, fatty, inflammable, &c. fluid, called a spirit; and in this it is distinguished from another class of fermented vegetable juices, *viz.* vinegars; which, instead of such spirit, yield for the first thing an acid, uninflamable matter.

In order to the making wines, it will be of great advantage to be well acquainted with the business of fermentation. This Dr. *Boerhaave* defines and explains as follows:

Fermentation is a change produced in vegetable bodies, by means of an intestine motion excited therein; the effect whereof is this, that the part which first rises from them in distillation is either a thin, fat, acrid, hot, transparent, volatile, and inflammable fluid, that will mix with water; or else a thin, acid, pellucid, less volatile, uninflamable liquor, capable of extinguishing fire.

The liquor, obtained by means of fermentation, is called thin, because none appears to be thinner than the spirit of fermented vegetables; acid, because it acts almost like fire, when applied to the tongue or other parts of the body; volatile, because there appears to be no liquor that is raised with greater ease; but it is this liquor being totally inflammable, and at the same time capable of mixing with water, that ultimately distinguishes fermentation from all other operations

rations in nature; for neither putrefaction, digestion, effervescence, nor any thing of that kind, will ever afford a liquor at once possessed of those qualities.

Putrefaction, indeed, as well as fermentation, is performed by means of an intestine motion; but the former will never produce either of the liquors above described, as the effect of fermentation; that is, neither a vinous nor acetous liquor.

We see then, that there are two different effects of fermentation, the production of an inflammable spirit, and an unflammable acid; and whatever operation will afford neither of these liquors, is improperly called fermentation; which therefore can only take place in the vegetable kingdom; for all the art in the world, so far as hitherto appears, will never gain such spirits from animals or fossils; and consequently never excite an actual and real fermentation in them; for fermentation is the single operation in nature, by which such spirits can be obtained.

2. Any vegetable liquor so fermented, as to afford the inflammable spirit above-mentioned for the first thing in distillation, we call wine; but if the liquor be so fermented, as first to afford the acid unflammable one, it is called vinegar; by which we mean every thin, acid, volatile, vegetable liquor, capable of extinguishing fire. So likewise, under the name of wine, we include beer or ale, mead and metheglin, cyder, perry, all sorts of artificial wines, and whatever liquors afford spirits possessed of the properties before set down.

The like is to be understood of vinegar, which is obtainable from all the same bodies that afford wine; so that we have either the wine or vinegar of all sorts of fruits, as of Grapes, Currants, Mulberries, Cherries, &c. all sorts of grain, as Barley, Wheat, Oats, &c. all sorts of pulse, as Beans, Peas, Tares, &c. all sorts of roots, as Turneps, Carrots, Radishes, &c. and in short, of all sorts of vegetable substances, even Grass itself.

3. All the bodies capable of being changed by fermentation, either into wine or vinegar, are said to be fermentable bodies; and because such a change can only be wrought, so far as we know at present, upon vegetables, these alone are accounted fermentable.

4. Any matter; which, being mixed with a fermentable body, increases its intestine motion, or excites or forwards the fermentation, is called the ferment; and, according to the doctrine before delivered, nothing can properly be called so, but what will produce either wine or vinegar.

These fermentable bodies may be reduced to the following classes.

The first class will consist of the meally seeds, *i. e.* all the grain, which, being fully ripe and well dried, may be reduced, by grinding, to a light meal or flour, that is neither clammy nor unctuous.

The second class consists of all the pulpy summer-fruits, which, when ripe, affect the tongue with the sense of acidity and sharpness, as Apples, Pears, Grapes, Gooseberries, &c. Under this class may be ranged all manner of bulbous pulpy roots growing in the ground, if they are first deprived of their volatile, alkaline salt, which is apt to determine them to putrefaction.

The third class takes in all the juicy parts of plants, as the leaves, flowers, stalks and roots, provided they are not too oily, or too alkaline; in which cases vegetables will rather putrefy than ferment.

The fourth class contains the fresh, expressed, and native juices of all kinds of vegetables; to which may be added all the native, saline liquors that distil from wounded plants, as the tears of the Vine, the Walnut, the Birch-tree, &c.

Under the fifth class come the most perfect of all the ve-

getable juices, *viz.* those that are unctuous, condensed, and elaborated by nature herself, such as honey, manna, sugar, and all other kinds of concocted juices capable of dissolving in water.

In order to fit any of the fermentable bodies for fermentation, there are several particulars requisite:

1. Maturity; the juice of unripe berries, as of Currants or Gooseberries, for instance, will scarce be brought to ferment at all; while it is very difficult to hinder their juice, when fully ripe, from falling spontaneously into fermentation.

Thus the juice of unripe Grapes, being incapable of fermenting, is a rough, acid liquor, called verjuice, that will for several years remain in the same unactive state; but after they come to maturity, it can no sooner be pressed into the vessel than it becomes a fermentable spirituous fluid.

2. Another requisite to prepare a body for fermentation is, that it should contain only a moderate proportion of oil; for if it either exceeds in the quantity, or be entirely destitute of oil, it will never be brought to ferment at all. Thus Almonds, Fennel-seeds, &c. are always deprived of their oil before they are attempted to be fermented.

3. The bodies intended for fermentation must not be too acid or austere; as is plain from the acid juices of unripe fruit which are greatly indisposed to ferment.

4. The last thing required to fit and prepare a body to undergo fermentation is the property of dissolving in water; for want of which all acid bodies, and such woods, roots, and herbs, as are dry and hard, become unfit for this operation; for unless the parts of these bodies are dissolved, the requisite intestine motion thereof will not ensue; but without such motion fermentation cannot subsist.

Hence honey itself can never be made to ferment, whilst it retains its native, thick consistence; but, being dissolved by heat, or let down with water, it immediately enters the state of fermentation. On the other hand, so violently as the juice of Grapes affects this state, yet if, immediately after it is expressed, it be reduced, by boiling, to the consistence of a jelly, it will lie quiet and never ferment at all, unless it be again diluted and let down with water.

Ferments are of two kinds; the natural or spontaneous, and those produced by fermentation.

The spontaneous or natural ferments are,

1. All the fresh expressed juices of fully ripened fruits, which easily run into fermentation.

2. Honey, manna, sugar, and the like thick and insipidated vegetable juices, which cause a strong fermentation.

3. The ferments produced by fermentation are, the fresh flowers or yeast of any fermenting vegetable juice or liquor, as of wine, beer, &c. By flowers or yeast is to be understood that light frothy matter, which covers the surface of the fermenting liquor in the nature of a tender crust; and which, being added to any other fermentable juices, will excite a fermentation in them.

4. The fresh *feces* or lees of any fermenting liquor, as of wine, ale, beer, &c. For all fermentation divides the liquor, which is the subject of it, into three parts, *viz.* the flowers or yeast, which possess the uppermost place; the operating or fermenting fluid, which lies in the middle; and the gross and seemingly exhausted matter, which, falling to the bottom of the vessel, is known by the name of lees, sediments, scum, or mother, that will, if raised again out of the liquor into which it was precipitated, cause it to work afresh.

Thus, when a hoghead of wine has done fermenting, and is fined down, if the vessel be any way shaken or disturbed, it will grow turbid again, and ferment anew, as vintners very well know. For as such as were the flowers in the act of fermentation, such is the mother after the action is over.

5. Acid paste, or bakers leaven, which is no more than any kind of meal brought into a close lump by means of water, after the same manner as common bread is made; for this being set in a warm place, during the space of four or five days it will first swell, then turn very acid, and at length become a ferment.

6. Those ferments which reside in, or stick to the sides of the casks that have contained fermenting liquors; for such casks will of themselves raise a fermentation in the liquors committed to them; and *Helmont* was of opinion they might be capable of doing this for ever.

Upon account of this inherent ferment it is, that old-seasoned vessels, or such as have been long employed by vintners or brewers, bear so great a price among them.

It is very remarkable, though a thing well known to brewers and vintners, that a new cask checks the fermentation of vinous liquors, and renders them weak and spiritless; for which reason they never choose to make use of such a cask before it is seasoned, as they call it, by having first contained some spirituous or fermented liquor or other; which being plentifully drank in by the wood, the original liquor comes to be deprived of a large proportion of its spirit, and more fermentable part; whence the remainder must needs taste flat and vapid.

This is certain, that even must itself will not easily ferment in a new pure vessel, but with the greatest facility, if put into one that has before contained fermenting juices; for the parts of the fermenting liquors, with which such a vessel must have been impregnated, presently rouse and determine it to action.

7. There are some ferments that appear to be heterogeneous, or which are improperly called Ferments; as the white of an egg beat into a froth, which is used when the liquor to be fermented proves too dilute or thin to sustain the operation. For in this case the fermentable parts of the fluid easily extricate themselves, and so fly off for want of something to detain and keep them in the body of the liquor; which therefore requires some viscid substance to be mixed with it, in order to prevent this avolation of its subtle parts. And this cannot be more commodiously effected, than by the white of an egg.

8. Of the like heterogeneous kind of ferments are all fixed and acid salts. Thus, if the liquor designed for fermentation be too acid to work kindly, the addition of an alkaline salt, as that of Vine branches, or any saponaceous substance, will, by taking off from the acidity, fit it for and so promote the operation; but if the liquor be of itself too alkaline, then tartar, or the like, ought to be added to it, to promote the fermentation.

But this does not happen, because either the acid or alkaline salt is an actual ferment, as some chymists have vehemently contended for the alkaline, because the salts employed respectively temper and take down the predominant acid or alkali, which before hindered the fermentation of the liquor.

And if such salts should in due quantities be mixed with any proper subject of fermentation, possessed of all the qualities before set down, as requisite to it, the operation would be entirely checked and prevented; so that alkaline bodies may as well be said to hinder as promote fermentation.

9. And lastly: Of the same sort are certain austere or rough tasted substances, as all harsh and green fruit, Pomegranate bark and flowers, the Tamarisk bark, Crab Apples, unripe Medlars, &c. which, when the liquor designed for the fermentation is too much broken in its parts, or dissolved in its texture, bind it together again by its astringent quality; so that though it was before too thin and aqueous, it is now reduced to a proper consistence for fermentation.

Thus, when must proves thin and watery, it will not fer-

ment kindly, unless some austere or astringent ingredient, as red Rose leaves, or the like, be added to it, to thicken and improve its consistence, and at the same time prevent the air it contains from making too easy an escape.

But when a liquor is too austere, or its roughness proves so great, that it cannot ferment, the addition of a fixed alkali, in a proper quantity, will remove the obstruction, and leave it at liberty to work.

So likewise when the operation is prevented by too large a proportion of acid in the liquor, the method is to throw chalk, Crabs-eyes, Bole Armoniaek, or the like, into it; but if it be too unctuous or oily, as is the case of some *Spanish* wines, salt of tartar is made choice of; and thus, as circumstances alter, different bodies are employed to stop or promote fermentation in liquors.

In order for fitting the subjects of the second class for fermentation, and making vinous liquors, *viz.* pulpy summer fruits, and the roots of bulbous plants, in case they prove crude or hard, they are to be first boiled in water, and afterwards bruised, which will dispose them for fermentation; but if such subjects are juicy, they may be directly ground to a pulp, or have their juice pressed from them; or if they are very succulent, there may be no occasion to bruise them, only directly to commit them to the press, and squeeze out all their juice.

But if the flesh or substance be strong and tough, it may be proper to rasp, shave, or cut them into small pieces, which will be of service in some bulbous roots, and make them yield their juice with the greater ease, and in greater plenty.

Prepared fruits seldom stand in need of any thing to make them ferment, for they generally begin to work of their own accord; but if the weather should prove exceeding cold, or the operation proceed but languidly, it may not be amiss to quicken it by adding a small proportion of a ferment, as a little yeast, the lees or mother of wine, or even a little new wine may serve the turn.

The subjects of the third class, *viz.* the succulent parts of plants, need only, in order to their fermentation, be beat to a thick kind of pulp, while they are fresh, and mixed with a proper proportion of rain water, that is just enough to dilute them, for if much water be employed, the spirit will be the weaker for it.

These require but very little ferment, or none at all, to make them work in the summer season, and no large proportion in the winter; but in case any at all be required, nothing will prove more serviceable than honey or sugar.

The subjects of the fourth and fifth classes, *viz.* the fresh native juices, and weeping liquors of vegetables, with the condensed and unctuous juices of the same, are to be diluted and let down with rain-water, to a due consistence, which is then thought to be obtained, when the compound liquor will just keep a new laid egg afloat; but some vegetable juices may naturally be of this very density or consistence, and in that case they will require no water at all. If any be thicker or denser, they ferment not so kindly, and if thinner or rarer, they afford but a weak spirit. Thus, in order to ferment sugar, treacle, or any common syrup, we first let down the matter with water, to the consistence above-mentioned; and then, if there be occasion, put yeast to it, to quicken the fermentation, and make it proceed kindly.

The subjects of the fourth class, *viz.* the prepared recent juices, and spontaneous tears of vegetables, are so far from requiring any ferment, that it often proves very difficult to restrain or check the fermentation they naturally fall into, especially if the season be warm and the juices rich; at most, if the weather should prove cold, they need only be set in a warm place to make them work.

The subjects of the fifth class, *viz.* the prepared or inspissated juices of vegetables, require no ferment at all in the summer, and but a small proportion in winter, to set them on working; less than an ounce of yeast to twenty pints of prepared liquor, will usually do for that purpose in the coldest season; but in hot countries, or sultry seasons, these prepared juices, and especially sugar, are of themselves apt to fall into a too violent fermentation; which therefore ought to be abated by the contrary means.

All the vegetable bodies of the several classes designed for fermentation, and prepared for it in the foregoing manner, ought, together with their ferments, to be committed to casks of oak already seasoned with the same kind of fermented liquor, or some other consisting of subtil and penetrating parts. Then those casks or vessels having their bung-holes lightly covered with a thin or single cloth, and being set in a warm place the liquor will ferment.

The mouths of the vessels are thus slightly covered over, that the air may have a free passage in and out of them, for they are here designed to serve as vent holes; and these vessels are ordered of wood, because fermentation is never observed to be so well carried on in those of glazed earth or glass, though, on account of their transparency, it is sometimes performed in the latter, that the phenomena may be better observed.

The preparatory business of fermentation hitherto described has been carried on by art, but nature must now perform the rest of the work; so that we are here only concerned to observe the phenomena which arise in the operation.

When therefore any fermentable body is prepared after the manner above delivered, and with its due proportion of a ferment committed to a large strong glass vessel standing in a warm place;

1. The whole body of the liquor soon begins to swell, heave, rarefy, and send up little bubbles to the top of the vessel, where they burst with an audible noise, and form into froth. Now the liquor which was before transparent grows opaque, and a violent uninterrupted intestine motion manifests itself therein.

2. The parts of the fermenting fluid appear incredibly elastic, and the motion of them exceeding violent. Indeed, by means of this property of fermentation, very terrifying and surprising actions may be performed. Thus if a hundred pints of musts were, on some warm day in autumn, to be confined close in a vessel of oak above an inch thick in the sides, and made ever so tight and strong with iron hoops, yet could not this prevent the working of the liquor; but in spite of so great a resistance it would burst the vessel with a report as loud as that of a cannon.

And therefore the way to preserve new wine in the state of must is to put it up in very strong, but small casks, firmly closed on all sides, by which means it will be kept from fermenting; and then it goes by the name of *stum*; but if it should happen to fall into fermentation, the readiest and only way to stop it is by the fume of sulphur, or something of the like nature.

Were it not for the knowledge of this property of burning sulphur, the wine merchants and vintners might frequently sustain great damages from the bursting of the vessels when the liquor is upon the fret, or, by some alteration in the air, or other accident, begins to ferment again; but the smoak of a little common brimstone, or a lighted match dipped in it, and held under a cask of wine that is just ready to burst its hoops, will calm its fury, and make it subside as suddenly as a spoonful of oil thrown into a large foaming copper of boiling sugar, takes down its heat, and prevents the mischief it might otherwise occasion.

3. A thick skin or crusty scurf forms itself on the sur-

face, through which the elastic or fermenting matter is continually breaking. This crust appears to be the principal cause of fermentation, for it keeps in, or prevents the spirituous part of the liquor from flying off; and if it be frequently broken, it puts a check to the fermentation, and will often entirely stop it if wholly taken away.

4. This skin or crust, which we now call flowers or yeast, gradually consumes and precipitates to the bottom of the liquor, in which case it is called by the name of *faeces* or mother; and after this, the fluid above it immediately becomes transparent again, ceases to hiss and bubble, has a very penetrating, pungent, spirituous, or vinous taste and scent, with a mixture of acidity and sweetness. And now the liquor, having undergone the operation of fermentation, is become wine.

The vapour arising from the liquor during its fermentation, ought not to be approached too near, or breathed in too great a quantity, because it is highly poisonous; and if it prove not mortal, may at least render the person apoplectic and paralytic. We have accounts in the *French* and *German* transactions, of people who were immediately struck dead, by receiving at the nose the fumes that issued from large vessels of wine in the state of fermentation.

And now if the liquor thus fermented be stopped down close, it will begin to feed upon and digest its own lees and mother, and at length consume them; in which case we commonly say the wine begins to ripen, and afterwards this mother shoots to the sides of the containing vessel, and there appears in the form of an essential salt which is then called tartar.

The space of time required for finishing the fermentation differs with the subject matter, the season of the year, the nature of the place, and other circumstances; but it is known to be perfectly performed by the several phenomena just now mentioned.

As soon as the flowers fall to the bottom, the vessel should be bunged down, otherwise the volatile part would fly off, and the fermented liquor become vapid and flat.

In this state it ought to stand for some weeks in a cool place, by which means it will grow stronger and more liquid; for during this time it imbibes and consumes its own *faeces*, which abound in subtle spirituous parts, and grows soft and loses of its acidity by throwing off its tartar.

And the longer it is thus suffered to stand, the more strength it gains, or the more spirit it will yield in distillation.

Thus, for instance, malt liquors newly brewed afford but a small quantity of inflammable spirit; but if suffered to remain for some weeks in the vessel, till they become fine and clean, they will yield much greater proportion; though, to avoid so great an apparatus of vessels as would then be required, malt liquors brewed, in order to make spirits, are seldom kept, but immediately after fermentation committed to the still. And hence we are furnished with a reason why all stale, vinous liquors are stronger, and inebriate sooner, than such as are new.

Some short general directions as to the making of Wines.

Wine is made of Grapes, by stamping them in a vat, or crushing and expressing the juice out of them in a press, and then fermenting, &c.

In the southern parts of *France* their method is, for red wines, to tread the Grapes, or squeeze them between their hands, and let the whole stand, juice and husks, till the tincture be in colour as they would have it, and then they press it; but for white wines they press the Grapes immediately.

When they have been pressed they tun the must and stop up the vessel, leaving the cask empty about the depth of half a foot, or better, to give room for its working.

At the end of ten days they fill this space with some other proper wine, that will not provoke it to work again, repeating this every ten days for some time: new wine spending itself a little before it is perfect.

About *Paris*, and in the northern parts of *France*, they let the marc and must stand two days and nights for white wines, and at least a week for claret wines, before they tun it, and while it continues working they keep it as warm as possible.

Some, upon stopping it up for good and all, roll the cask about the cellar to mix it with the lees, and after it has been settled a few days rack it off with great improvement.

To fine it down they put shavings of green beech into the cask; but they first take off all the rind, and boil them an hour in water to extract their rankness, and afterward dry them in the sun or an oven. A peck of these will serve for a hoghead of wine; they put it in a gentle working, and purify it in twenty-four hours; they also give it an agreeable flavour.

Some sweeten their wines with Raisins of the sun, trod in the vat with the Grapes, they having been first plumped by boiling; others by boiling half the must, scumming it, and tunning it up hot with the other.

Wine is distinguished, from the several degrees and steps of its preparation, into

1. *Mere-goute*, mother-drop, which is the virgin wine, or that which runs of itself out of the tap of the vat, before the Grapes are trodden.

2. The must, surmouft, or scum, which is the wine or liquor in the vat, after the Grapes have been trodden in the vat.

3. The pressed wine, or *Vin de Pressurage*, which is that squeezed with a press out of the Grapes half-bruised by treading.

4. *Boisson*, or draught wine. This is made of the husks left of the Grapes, which are called rape or marc, which, by throwing water upon, and pressing afresh, they make a liquor for servants.

Wines are also distinguished into

Vin doux, or sweet wine, which is that which has not yet worked nor boiled.

Bourou; that which has been prevented working by casting in cold water.

Wine of the *cuve*, or worked wine, *i. e.* that which has been let to work in the vat to give it a colour.

Vin cuit, *i. e.* boiled wine; that which has had a boiling before it worked, and which, by that means, still retains its native sweetness.

Vin passé, *i. e.* strained wine; that which is made by steeping dry Grapes in water, and letting it ferment of itself.

The goodness of wine consists in its being neat, dry, clear, fine, brisk, without any taste of the soil, of a clean steady colour; in its having a strength, without being heady; a body, without being four; and its keeping, without growing hard.

After wines have been made, they require to be managed according to their different state and circumstances. We shall therefore consider them under these four general heads following:

1. The natural purification or clarification of wines, whereby, of themselves, they pass from the state of crudity and turbulency to that of maturity, by degrees growing clear, fine, and potable.

2. The unseasonable workings, frettings, and other sicknesses, to which, from either internal or external accidents, they are afterward subject.

3. Their state of declination or decay, wherein they degenerate from their goodness and pleasantness, becoming palled or turning into vinegar.

4. The several artifices used to them in each of these states and conditions. As to the first, *viz.* the natural clarification of new wines, two things occur which deserve consideration; the manner how, and the cause by which, the same is effected.

As for the manner, it is to be observed that wine, while yet in the must, is usually put into open vessels, the abundance and force of the spirits, *i. e.* the more subtile and active parts therein contained being then so great, as not to endure being imprisoned in close ones; at which time it appears troubled, thick, and feculent, all parts of it being violently moved and agitated, so that the whole mass of the liquor seems to boil like water in a caldron over the fire.

This tumult being in some degree composed, and the *Gas sylvestre* (as *Van Helmont* calls it), or wilder spirit, sufficiently evaporated, they then pour the must into close vessels, there to be farther defecated by continuance of the same motion of fermentation, reserving the froth or flower of it, and putting the same into small casks hooped with iron, lest otherwise the force of it might break them.

This flower, thus separated, is what they call *stum*, either by transposition of the letters in the word must, or from the word *stum*, which in high *Dutch* signifies *mute*; because this liquor (as one may say) is hindered from that maturity, by which it should speak its goodness and wholesomeness.

This being done, they leave the rest of the wine to finish its own fermentation; during which it is probable, that the spirituous parts impel and diffuse the grosser and feculent parts up and down in a confused and tumultuous manner, until, all being disposed in their proper regions, the liquor becomes more pure in substance, more transparent to the eye, more piquant and gustful to the palate, more agreeable to the stomach, and more nutritive to the body.

The impurities, being thus separated from the liquor, are, upon chemical examinations, found to consist of salt, sulphur (each of which is impregnated with some spirits), and much earth, which, being now dissociated from the purest spirits, either mutually cohere, coagulate, and affix themselves to the sides of the vessels, in form of a stony crust, which is called tartar and argol, or sink to the bottom in a muddy substance, like the grounds of ale or beer, which is called the lees of wine. And this is the process of nature in the clarification of all wines, by an orderly fermentation.

As for the principal agent or efficient cause of this operation, it seems to be no other but the spirit of the wine itself; which, moving every way in the mass of the liquor, thereby dissolves that common tie of mixture, whereby all the heterogeneous parts thereof were combined and blended together; and having gotten itself free, at length abandons them to the tendency of their gravity and other properties, which, they soon obeying, each kind consorts with its like, and betaking themselves to their several places or regions, leave the liquor to the possession and government of its noblest principle, the spirit. For this spirit, as it is the life of the wine, doubtless is also the cause of its purity and vigour, in which the perfection of that life seems to consist.

From the natural fermentation of wines we pass to the accidental; from their state of soundness to that of their sickness, which is the second general head.

We have the testimony of experience, that frequently even those wines that are good and generous are invaded by unnatural and sickly commotions, or (as the wine coopers call them) workings; during which they are turbulent in motion, thick of consistence, unfavoury in taste, unwholesome in use, after which they undergo sundry alterations for the worse.

The causes of this may be either internal or external.

Among the internal, the chief place may be assigned to the excessive quantity of tartar or of lees, which contain much salt and sulphur, and continually send forth into the liquor abundance of quick and active particles, that, like stum, or other adventitious ferment, put it into a fresh tumult or confusion, which, if not in time allayed, the wine either grows rank or prickling, or else turns sour, by reason that the sulphur, being too much exalted above the rest of the elements or ingredients, predominates over the pure spirits, and infects the whole mass of liquor with sharpness or acidity; or else it comes to pass, that the spirits being spent and flown away in the commotion, the salt, dissolved and set afloat, obtains the mastery over the other similar parts, and introduceth rankness or ropiness.

Nay, if those commotions chance to be suppressed before, the wine is thereby much depraved, yet do they always leave such ill impressions, as, more or less, alienate wine from the goodness of its former state, in colour, consistence, and taste.

For hereby all wines acquire a deeper tincture, *i. e.* a thicker body or consistence, saeks and white wines changing from a clear white to a cloudy yellow; and claret losing its bright red for a dusky Orange colour, and sometimes for a tawney. In like manner they degenerate also in taste, and affect the palate with foulness, roughness, and rancidity, very unpleasant.

Among the external are commonly reckoned the too frequent or violent motion of wines after their settlement in their vessels, immoderate heat, thunder, or the report of cannon, and the admixture of any exotick body, which will not symbolize, or agree and incorporate with them; especially the flesh of vipers, which has been frequently observed to induce a very great acidity upon even the sweetest and fullest-bodied *Malaga* and *Canary* wines; or by putting new wines in a state of fermentation into vaults with old wines, in them more or less according to their different ages, but in all enough to make it turbid.

This brings us in the next place to the third previous thing considerable, *viz.* the palling or flatting of wines, and their declining towards vinegar, before they have attained to their state of maturity and perfection.

Of this the greatest and nearest cause seems to be their jejuneness and poverty of spirits, either native or adventitious:

Native, when the Grapes themselves are of a poor and hungry kind, or gathered unripe, or nipt by early frosts, or half starved in their growth by a dry and unkindly season, or too full of watery parts:

Adventitious, when the liquor, rich perhaps and generous enough at first, comes afterwards to be impoverished by loss of spirits, either by oppression, or by exhaustion.

The spirits of wine may be oppressed, when the quantity of impurities or dregs, with which they are combined, is so great, and their crudity, viscosity, and tenacity so stubborn, that they can neither overcome them, nor deliver them from their adhesion; but are forced to yield to the obstinacy of the matter on which they should operate, and so to remain unactive and clogged, as may be exemplified in the coarse wines of *Moravia*, which, by reason of their great austerity and roughness, seldom attain to a due exaltation of their spirits, but still remain turbulent, thick, and

in a state of crudity, and therefore easily pall; in which respect they are condemned by some *German* physicians as bad for generating the scurvy, and administering matter for the stone and gout, they yielding more of tartar than other wines.

The spirits of wine may be exhausted or consumed, either suddenly or gradually; suddenly, by lightening, which spoils wine, not by congelation or fixation of its spirits; for then such wines might be capable of being restored by such means as are apt to reinforce and volatilize the spirits again, contrary to what has been found by experience; but perhaps by disgregation, and putting them to flight, so as to leave the liquor dead, palled, and never to be revived by any supply.

Gradually, two ways, *viz.* by unnatural fermentation, of the ill effects of which something has already been said; or by heat from without, of which we have an instance in the making of vinegar; which commonly is done by setting the vessels of wine against the hot sun, which, beating upon the mass of liquor, and rarefying the finer parts thereof, gives wings to the fugitive spirits to fly away together with the purer and more volatile sulphur, leaving the remainder to the dominion of the salt, which soon debaseth and infecteth it with sourness.

This being the common manner of turning wine into vinegar, in all ages and all countries, it may be doubted whether spirit of wine may be drawn out of vinegar, notwithstanding it hath been delivered as practicable by *Sennertus* himself.

The times of the year when wines are observed to be most prone to ferment and fret, and then to grow qually (as it is called), that is, turbulent and foul, are *Midsummer* and *Allballowtide*, when our vintners are wont to rack them from their gross lees, especially *Rhenish*, which commonly grows sick in *June* if not racked; and they choose to do it in the wane of the moon, and fair weather, the wind being northerly.

Having thus succinctly recounted the most remarkable distempers of wines, guessed at their respective causes, and touched upon the times, it is proper to proceed to their usual remedies, such, at least, as may be collected from wine coopers and vintners; which is the fourth and last part proposed to be treated of.

To begin, therefore, with some of the artifices used to wines when yet in must: it is observable, that though to raising a fermentation in them at that time, there is not so much need of any additional ferment, as there is in the wort of ale, beer, hydromel, metheglin, and other sorts of drinks, familiar to us in *England*; because the juice of the Grape is replenished with generous spirits, sufficient of themselves to begin that work; yet it is usual in some countries to put quick lime either upon the Grapes, when they are pressing, or into the must; to the end that, by the force and quickness of its saline and fiery particles, the liquor may be both accelerated and assisted in working.

For the same reason, perhaps, it is that the *Spaniards* mix with their wines, while they are yet flowing from the press, a certain thing they call *gieffo*, which probably is a kind of gypsum or plaster, whereby the wines are made more durable, of a paler colour, and pleasanter taste; others put into the cask shavings of Fir, Oak, or Beech, for the same purpose.

Again; though the first fermentation succeeds generally well, so that the whole mass of liquor is thereby delivered from the gross lee; yet sometimes it happens either through scarcity of spirits at first, or through immoderate cold, that some part of those impurities remain confused and floating therein.

Now, in this case, wine-coopers put into the wine certain things to hasten and help its clarification; such as, being of gross and viscous parts, may adhere to the floating lee, and, sinking, carry it with them to the bottom; of which sort are iinglass and the whites of eggs, or such as, meeting with the grosser and earthly particles of the lee, disassociate and sink them by their gravity; of which kind are the powders of alabaster, calcined flints, white marble, roach allum, &c.

The *Grecians*, at this day, have a peculiar way of spurring nature, in fining and ripening their strongest and most generous wines; and this is done by adding to them, when they begin to work, a proportionate quantity of sulphur and allum; not (as is very probable) to prevent their fuming up to the head, and inebriating, according to the conjecture of that great man the lord of *St. Alban's*, for notwithstanding this mixture, they cause drunkenness as soon, if not sooner, than other wines; nor are men intoxicated by the vapours of wine flying up immediately from the stomach into the brain, but only to excite and promote fermentation, and hasten their clarification that ensues thereupon; the sulphur, perhaps, helping to attenuate and divide those gross and viscid parts, wherewith *Greek* wine abounds, and the allum conducting to the speedier precipitation of them afterwards. And a learned traveller relates, that some merchants put into every pipe of their *Greek* wine a gill, or thereabouts, of the chemical oil of sulphur, in order to preserve it the longer clear and sound; which, though it is very probable, because the sulphur is known to resist putrefaction in liquors, yet one would decline the use of wines so preserved, unless in time of pestilential infection.

But of all ways of the hastening the clarification and ripening of wine, none seems to be more easy, or less noxious, than that borrowed from one of the ancients by the lord chancellor *Bacon*; which is, by putting the wine into vessels well stopped, and letting it down into the sea.

That this practice was very ancient is manifest from that discourse of *Plutarch*, *Quest. Natur.* 27. about the efficacy of cold upon must; whereof he gives this reason, that cold, not suffering the must to ferment, by suppressing the activity of the spirits therein contained, conserveth the sweetness thereof a long time; which is not improbable, because experience teaches, that such as make their vintage in a rainy season cannot get their must to ferment well in a vault, unless they cause great fires to be made near the casks; the rain mixed with the must, together with the ambient cold, hindering the motion of fermentation, which arises chiefly from heat.

That the same is frequent at this day also, may be collected from what *Mr. Boyle* has observed in his *History of Cold*, on the relation of a *Frenchman*, viz. that the way to keep wine long in the must (in which the sweetness makes many to desire it) is to tun it up immediately from the press, and, before it begins to work, to let down the vessels, closely and firmly stopp'd, into a well or deep river, there to remain for six or eight weeks; during which time the liquor will be so confirmed in its state of crudity as to retain the same, together with its sweetness, for many months after, without any sensible fermentation.

But it may be objected, how can these two so different effects, the clarification of new wine, and the conservation of wine in the must, be derived from one and the same cause, the cold of the water?

But this may be conceived without much difficulty; for it seems not unreasonable, that the same cold which hinders must from fermenting, should yet accelerate and promote the clarification of wine after fermentation; in the first, by giving a check to the spirit, before it begins to move and act upon the crude mass of liquor, so that it can-

not in a long time after recover strength enough to work; in the latter, by keeping in the pure and genuine spirit, otherwise apt to exhale, and rendering the flying lee more prone to subside, and so making the wine much sooner clear, fine, and potable. Thus much concerning the helps of new wine.

The general and principal remedy for the preternatural or sickly commotions incident to wines after their first clarification, and tending to their impoverishment or decay, is racking, i. e. drawing them from their lees into fresh vessels.

Which yet being sometimes insufficient to preserve them, vintners find it necessary to pour into them a large quantity of new milk, as well to blunt the sharpness of the sulphureous parts now set afloat and exalted, as to precipitate them and other impurities to the bottom by adhesion.

But, taught by experience, that by this means the genuine spirits of the wine also are much flatted and impaired (for the lee, though it makes the liquor turbid, doth yet keep the wine in heart and conduce to its duration); therefore lest such wines should pall and die upon their hands, as of necessity they must, they draw them for sale as fast as they can vend them.

For the same disease they have divers other remedies, particularly accommodated to the nature of the wine that needs them: to instance a few;

For *Spanish* wines disturbed by a flying lee they have this receipt: Make a parell (as they call it) of the whites of eggs, bay salt, milk, and conduit water; beat them well together in a convenient vessel, then pour them into a pipe of wine (having first drawn out a gallon or two to make room), and blow off the froth very clean; hereby the tumult will in two or three days be compos'd, the liquor refined and drink pleasantly, but will not continue to do so long; and therefore they advise to rack it from the milky bottom after a week's settlement, lest otherwise it should drink foul and change colour.

If sacks or *Canary* wines chance to boil over, draw off four or five gallons; then putting into the wine two gallons of milk, from which the cream hath been skimmed, beat them till they are thoroughly mixed together, and add a pennyworth of roach allum, dried in a fire shovel and powdered, and as much of white starch; after this take the whites of eight or ten eggs, a handful of bay salt, and having beaten them together in a tray put them also into the wine, filling up the pipe again, and letting the wine stand two or three days, in which time the wine will recover to be fine and bright to the eye, and quick to the taste; but you must be sure to draw it off that bottom very soon, and spend it as fast as you can.

For claret, in like manner diltemper'd with a flying lee, they make use of this artifice:

They take two pounds of the powder of pebble-stones baked in an oven, the whites of ten or twelve eggs, a handful of bay salt, and having beaten them well together, in two gallons of the wine, they mix them with that in the cask, and after two or three days draw off the wine from the bottom.

The same parell serves also for white wines upon the fret, by the turbulency and rising of their lee.

To cure *Rhenish* of its fretting (to which it is most prone a little after *Midsummer*, as was before observed), they seldom use any other art but giving it vent, and covering the oaken bung with a tile or slate, from which they carefully wipe off the filth purged from the wine by exhalations; and after the commotion is by this means compos'd, and much of the fretting matter cast forth, they let it remain quiet for a fortnight, or thereabouts, and then rack it into a fresh cask, newly fumed with a sulphurated match.

As for the various accidents that frequently ensue and vitiate wine (after those before-mentioned reboilings, notwithstanding their suppression before they were incurable); you may remember they have all been referred to such as alter and deprave wines, either in colour or consistence, or taste or smell. Now for each of these maladies our vintners are provided of a cure.

To restore *Spanish* and *Austrian* wines grown yellow or brownish, they add to them sometimes milk alone, and sometimes milk, and isinglass well dissolved therein; sometimes milk and white starch; by which they force the exalted sulphur to separate from the liquor, and sink to the bottom, so reducing the wine to its former clearness and whiteness.

The same effect they produce with a composition of Iris-roots and salt-petre, of each four or five ounces, the whites of eight or ten eggs, and a competent quantity of common salt, mixed and beaten in the wine.

To amend claret decayed in colour, first they rack it upon a fresh lee, either of *Alicant* or red *Bordeaux* wine; then they take three pounds of Turnsole, and steep it all night in two or three gallons of the same wine, and having strained the infusion through a bag, they pour the tincture into a hoghead (sometimes they suffer it first to fine itself in a rundlet) and then cover the bung-hole with a tile, and so let it stand for two or three days, in which time the wine usually becomes well-coloured and bright.

Some use only the tincture of Turnsole.

Others take half a bushel of full ripe Elder-berries, pick them from their stalks, bruise them, and put the strained juice into a hoghead of discoloured claret, and so make it drink brisk, and appear bright.

Others, if the claret be otherwise found, and the lee good, overdraw three or four gallons; then replenish the vessel with as much good red wine, and roll it upon its bed, leaving it reversed all night; and then next morning they turn it again, so as the bung hole may be uppermost; which stopped, they leave the wine to fine.

But in all these cases they observe to set such newly recovered wines abroad the very next day after they are fined, and to draw them for sale speedily.

To correct wines faulty in consistence, *i. e.* such as are lumpish, foul, or ropy;

They generally make use of the powders of burnt allum, lime-chalk plaster, *Spanish* white, calcined marble, bay salt, and other the like bodies, which cause a precipitation of the gross and viscid parts of the wine then afloat: as for example;

For attenuation of *Spanish* wines that are foul and lumpish, having first racked them into a newly scented cask, they make a parell of burnt allum, bay salt, and conduit water; then they add to these a quart of Bean-flower, or powder of Rice; and if the wine be brown and dusky, milk, otherwise not; and beating all these well together with the wine, blow off the froth, and cover the bung with a clean tile or stone. Lastly, they rack the wine again after a few days, and put it into a cask well scented.

The manner of scenting casks is as follows:

They take four ounces of brimstone, one ounce of burnt allum, and two ounces of aqua vitæ; these may be put together in an earthen pan or pipkin, and hold them over a chafing dish of glowing coals, till the brimstone is melted and runs; then they dip therein a little piece of new canvass, and instantly sprinkle thereon the powders of Nutmegs, Cloves, Coriander, and Anise-seeds. This canvass they fire, and let it burn out in the bung-hole, so as the fume may be received into the vessel; and this is said to be the best scent for all wines.

To prevent the foulness and ropiness of wines, the old *Romans* used to mix sea-water with their must.

To cure the ropiness of claret, the vintners, as well *French* as *English*, have many remedies; of which these that follow are the most usual:

First they give the wine the parell, then draw it from the lee, after the clarification by that parell; this done, they infuse two pounds of Turnsole in good sack all night; and the next day, putting the strained infusion into a hoghead of wine with a spring funnel, leave it to fine, and after draw it for excellent wine.

Another is this: they make a lee of the ashes of Vine branches, or of oaken leaves, and pour it into the wine hot, and after stirring leave it to settle; the quantity of a quart of lee to a pipe of wine.

A third is only a spirit of wine, which, put into a muddy claret, serves to the refining it effectually and speedily; the proportion being a pint of spirit to a hoghead; but this is not to be used in sharp and eager wines.

When white wines grow foul and tawny, they only rack them on a fresh lee, and give them time to fine.

For the mending of wines that offend in taste, vintners have few other correctives, but what conduce to clarification; nor do they indeed much need variety in the case, seeing all unfavouriness of wines whatever proceeds from their impurities set afloat, and the dominion of others, their sulphureous or saline parts, over the finer and sweeter; which causes are removed chiefly by precipitation.

For all clarification of liquors may be referred to one of these three causes:

1. Separation from the grosser parts of the liquor from the finer.
2. The equal distribution of the spirits of the liquor, which always render bodies clear and untroubled.
3. The refining of the spirit itself.

And the two latter are consequents of the first, which is effected chiefly by precipitation, the instruments whereof are weight and viscosity of the body mixed with it; the one causing it to cleave to the gross parts of the liquor flying up and down in it; the other sinking them to the bottom.

But this being more than vintners commonly understand, they rest not in clarification alone, having found out certain specificks, as it were, to palliate the several vices of wines of all sorts, which make them disgustful. Of these I shall recite two or three of the greatest use and esteem amongst them.

To correct rankness, eagerness, and pricking of sacks, and other sweet wines, they take twenty or thirty of the whitest lime-stones, and slack them in a gallon of the wine; then they add some more wine, and stir them together in a half tub, with a parrelling staff; next they pour this mixture into the hoghead, and having again used the parrelling instrument, leave the wine to settle and then rack it.

This wine may probably be no ill drink for gross bodies and rheumatick pains, but injurious to good fellows of a hot and dry constitution and meagre habits.

Against the pricking of *French* wines they prescribe this easy and cheap composition: take of the powder of *Flanders* tile one pound, of roach allum half a pound, mix them and beat them well, with a convenient quantity of wine; then put them into the hoghead, as the former.

When their *Rhenish* wines prick, they first rack them off into a clean and strongly-scented cask or vat, then they add to the wine eight or ten gallons of clarified honey, with a gallon or two of skim milk, and, beating all together, leave them to settle.

Sometimes it happens, that claret loses much of its briskness and piquantness; and in such case they rack it upon a good lee of red wine, and put into it a gallon of Sloes or Bullace, which, after a little fermentation and rest, makes the wine drink brisk and rough.

To meliorate the taste of hungry and too eager white wines, they draw off three or four gallons of it, and infusing therein as many pounds of *Malaga* Raisins stoned, and bruised in a stone-mortar, till the wine has sufficiently imbibed their sweetness and tincture (which it will do in a day's time), they run it through an *Hippocras* Bag; then put it into a fresh cask well scented, together with the whole remainder of the wine in the hoghead, and so leave it to fine.

To help stinking wines, the general remedy is racking them from their old and corrupt lee; besides which, some give them a fragrant smell or flavour, by hanging in them little bags of spices, such as Ginger, Zedoary, Cloves, Cinnamon, Orris-roots, Cubeb, Grains of Paradise, Spike-nard, and other aromatics.

Others boil some of these spices in a pottle of good sound wine of the same sort, and tun up the decoction hot.

Others correct the ill flavour of rank-leed *French* wine with only a few Cinnamon canes hung in them.

Others again, for the same purpose, use Elder-flowers and tops of Lavender.

Having thus run over the Vintners Dispensatory, and described many of their principal receipts or secrets, for the cure of the acute diseases of wine, we shall come to the fourth head, which contains medicaments proper for their chronick distempers, *viz.* loss of spirits, and decay of strength.

Concerning these, therefore, it is observable, that as when wines are in preternatural commotions, from an excess and predomination of their sulphureous parts, the grand medicine is to rack them from the lees; so on the contrary, when they decline and tend towards palling, by reason of the scarcity of their spirits and sulphur, the most effectual preservative is to rack them upon other lees, richer and stronger than their own; that being from thence supplied with the new spirits, they may acquire somewhat more of vigour and quickness.

I say preservative; because there is, in truth, no restoring of wines after they are perfectly palled and dead, for nothing that is past perfection, and hath run its natural race once, can receive much amendment.

But besides reinforcing of impoverished wines, by new and more generous lees, there are sundry confections, by which also, as by cordials, the languishing spirits of many of them may be sustained, and, to some degree, recruited, of which the following are examples:

When sacks begin to languish (which doth not often happen, especially in this city, where it is drunk in plenty), they refresh them with a cordial syrup, made of most generous wine; sugar, and spices.

For *Rhenish* and white wines, a simple decoction of Raisins of the sun, and a strong-scented cask, usually serve the turn.

For claret inclining to a consumption, they prescribe a new and richer lee, and the shavings of Fir-wood, that the spirit, being recruited by the additional lee, may be kept from the exhaling by the unctuous spirit of the turpentine.

This artifice is used in *Paris* in the most delicate and thin-bodied wines of *France*, and is very probably the cause of that exceeding dulness and pain of the head, which always attends debauches with such wines.

Nor is it a modern invention, but well known to, and frequently used by the *Romans*, in the time of their greatest wealth and luxury; for *Pliny* (*Hist. Nat. lib. 14. cap. 2.*) takes singular notice of the custom of the *Italian* vintners, in mixing with their wines turpentine of several sorts.

The *Grecians* long before had their *vina picata* and *resinata*, as is evident by the commendation of such wines by *Plutarch*, and the prescription of them to women, in some cases, by

Hippocrates; and they were so much delighted with their *vinum pissites*, that they consecrated the Pitch-tree to *Bacchus*; but I shall next take some notice of the more disingenuous practices of vintners in the transmutation or sophistication, which they call trickings or compassings.

They transform poor *Rochelle* and *Coniac* white wines into *Rhenish*; *Rhenish* into sack; the lags of sack and malmseys into muscadels.

They counterfeit Raspie wine with *Fleur-de-llys* roots; *Verdea* with decoctions of Raisins; they sell decayed *Xeres*, vulgarly sherry, for *Lusenna* wine; in all these impostures deluding the palate so nearly, that few are able to discern the fraud, and keeping these arcana so close, that few can come to the knowledge of them.

As for their metamorphosis of white into claret, by dashing it with red, nothing is more commonly either done or known.

For their conversion of white into *Rhenish*, they have several artifices to effect it, among which this is the most usual:

They take a hoghead of *Rochelle* or *Coniac*, or *Nantz* white wine; rack it into a fresh cask strongly scented; then give the white parell; put into it eight or ten gallons of clarified honey, or forty pounds of coarse sugar, and, beating it well, leave it to clarify.

To give this mixture the delicate flavour, they sometimes add the decoction of the yellow *Clary*-flowers, or *Galitricum*, of which drugs there is an incredible quantity used yearly at *Dort*, where the staple of *Rhenish* wines was; and this is that drink with which the *English* ladies were wont to be so delighted, under the specious name of *Rhenish* in the must.

The manner of making adulterate bastard is thus:

Take four gallons of white wine, three gallons of old *Canary*, five pounds of bastard syrup; beat them well together, put them into a clean rundlet well scented, and give them time to fine.

Sack is made of *Rhenish*, either by a strong decoction of *Malaga* Raisins, or by a syrup of sack, sugar, and spices.

Muscadel is sophisticated with the lags of sack or *Malmsey* thus:

They dissolve it in a convenient quantity of *Rose-water*; of musk two ounces, of *Calamus Aromaticus* powdered one ounce, of *Coriander* beaten half an ounce, and while this infusion is yet warm, they put it into a rundlet of old sack or malmsey, and this they call a flavour for muscadel.

There are many other ways of adulterating wines in this city; but because they all tend to the above-mentioned alterations, and are not so general, I shall pass them over, and mention the observations of a certain curious author on this subject.

The mystery of wines consists in the making and meliorating of natural wines.

Melioration is either of sound or vicious wines. Sound wines are bettered,

1. By preserving.
2. By timely fining.
3. By mending colour, smell, and taste.

1. To preserve wines, care must be taken that after the pressing they may ferment well, for without good fermentation they become qually, *i. e.* cloudy, thick, and dusky, and will never fine themselves, as other wines do; and when they are fined by art, they must be speedily spent, or else they will become qually again, and then will not be recoverable by any art.

To preserve *Spanish* wines, and chiefly *Canary*, and therefore principally that which is *razie*, which will not keep long, they make a layer of Grapes and *Giesse*, whereby it acquires a better durance and taste, and a white colour, most pleasing to the *English*.

Razie wine is so called, because it comes from *Rhenish* Vine cuttings, sometimes renewed. The Grapes of this Vine are fleshy, yielding but a little juice.

The *French* and *Rhenish* wines are chiefly and commonly preserved by the ratch, thus used at *Dort* in *Holland*:

They take twenty or thirty pounds of brimstone, rack into it melted, as Cloves, Cinnamon, Mace, Ginger, and Coriander-seeds; and some, to save charges, use the reliques of the *Hippocras* Bag, and, having mixed these well with the brimstone, they draw through this mixture, long, square, narrow pieces of canvas, which pieces they light, and put into the vessel at the bung-hole, and presently stop it close: great care is to be had in proportioning the brimstone to the quantity and quality of the wine, for too much makes it rough. This smoking keeps the wine long white and good, and gives it a pleasant taste.

There is another way for *French* and *Rhenish* wines, *viz.* firing it. It is done in a stove, or else a good fire made round about the vessel, which will gape wide, yet the wine never runs out. It will boil, and afterwards may soon be racked.

Secondly, For timely fining of wines. All wines in the must are more opacous and cloudy. Good wine soon fines, and the gross lees settle quickly, and also the flying lee in time. When the grosser lees are settled, they draw off the wine; this is called racking. The usual times for racking are *Midsummer* and *Allhallowtide*.

The practice of the *Dutch* and *English* to rid the wine of the flying lees speedily, and which serves most for *French* and *Spanish* wine, is thus performed:

Take of isinglass half a pound; steep it in half a pint of the hardest *French* wine that can be got, so that the wine may fully cover it; let them stand twenty-four hours; then pull and beat the isinglass to pieces, and add more wine; four times a day squeeze it to jelly, and as it thickens add more wine. When it is full and perfectly jellied, take a pint or quart to a hoghead, and so proportionably; then overdraw three or four gallons of that wine you intend to fine, which mix well with the said quantity of jelly; then put this mixture to the piece of wine, and beat it with a staff, and fill it top full.

Note, That *French* wines must be bunged up very close, but not the *Spanish*; and that isinglass raises the lees to the top of strong wines, but in weaker precipitates them to the bottom.

They mend the colour of sound clarets by adding thereto red wine, tent, or *Alicant*; or by an infusion of Turnsole, made in two or three gallons of wine, and then putting it into the vessel, to be then (being well stopp'd) rolled for a quarter of an hour.

This infusion is sometimes twice or three times repeated, according as more colour is to be added to the wine; about three infusions of the Turnsole are sufficient; but then it must be rubbed and wringed.

Claret over-red is amended with the addition of white wines.

White wines coming over sound, but brown, are thus remedied:

Take of alabaster powder, overdraw the hoghead three or four gallons; then put this powder into the bung, and stir and beat it with a staff, and fill it top-full. The more the wine is stirred, the finer it will come upon the lee, that is, the finer it will be.

To colour sack-white: Take of white starch two pounds, of milk two gallons, boil them together two hours; when cold, beat them well with a handful of white salt, and then put them into a clean but sweet butt, beating them with a staff, and the wine will be pure and white.

One pound of the before mentioned jelly of isinglass takes

away the brownness of *French* and *Spanish* wines, mixed with two or three gallons of wine; according as it is brown and strong, more or less to be used. Then overdraw the piece of wine about eight gallons, and use the rod; then fill the vessel full, and in a day or two it will be fine, and be white, and mend if qually.

The first buds of *Ribes nigra*, *i. e.* black Currants, infused in wines, especially *Rhenish*, make it diuretick, and more fragrant in smell and taste, and so doth Clary.

The inconvenience is, that the wine becomes more heady: a remedy for which is Elder-flowers added to the Clary, which also betters the fragrancy thereof, as it is manifest in Elder-vinegar; but these flowers are apt to make the wine rosy.

To help brown *Malagas* and *Spanish* wines: Take powder of Oris-roots and Salt-petre, of each four ounces, the whites of eight eggs, to which add as much salt as will make a brine; put this mixture into wine, and mix them with a staff.

To meliorate muddy and tawny clarets: Take of rain-water two pints, the yolks of eight eggs, salt a handful; beat them well, let them stand six hours before you put them into the cask, then use the rod, and in three days it will come to itself.

To amend the taste and smell of *Malaga* wine: Take of the best Almonds four pounds, make an emulsion of them with a sufficient quantity of the wine to be cured; then take the whites and yolks of twelve eggs, beat them together with a handful of salt, put them into the pipe, using the rod.

To amend the smell and taste of *French* and *Rhenish* wines, which are foul: Take one pound of honey, a handful of Elder-flowers, an ounce of Orris-powder, one Nutmeg, a few Cloves to an auln of the wine, boil them in a sufficient quantity of the wine to be cured, to the consumption of half, and when it is cold, strain it, and use it with the rod; some add a little salt. If the wine be sweet enough, add one pound of the spirits of wine to a hoghead, and give the cask a strong scent. Spirit of wine makes any wine brisk, and fines it, without the former mixture.

A lee of the ashes of Vine branches, *viz.* a quart to a pipe, being beaten into wine, cures the ropiness of it, and so infallibly doth a lee of oaken ashes.

For *Spanish* rosy wine: Rack it from the lees into a new-scented cask, then take of allum one pound, of Orris-roots powdered half a pound, beat them well into the wine with a staff; some add fine and well-dried sand, put warm to the wine. If the wine besides prove brown, add three pottles of milk to a pipe: this cures rosy wine, before it begins to fret.

To amend and preserve the colour of clarets: Take red Beet-roots, *q. s.* scrape them clean, and cut them into small pieces; then boil them in *q. s.* of the same wine, to the consumption of the third part; scum it well, and when cool decant off what is clear, and use the rod.

Firing of wines in *Germany* is thus performed: They have in some vaults three or four stoves, which they heat very hot; others make fires almost before every vat; by this means the must fermenteth with that vehemency, that the wine appears between the staves; when this ebullition, fermentation, and working cease, they let the wine stand some days, and then rack it. This firing is only used in cold years, when the wine falls out green.

To set old wine a fretting, being deadish and dull of taste: Take of stum two gallons to a hoghead, put it hot upon the wine, then set a pan of fire before the hoghead, which will then ferment till all the sweetness of the stum is communicated to the wine, which thereby becomes brisk and pleasant.

Some use this stumming at any time; some in *August* only, when the wine hath a disposition to fret of itself, more or less stum to be added, as the wine requires.

The best time to rack wine is in the decrease of the moon, and when the wine is free from fretting, the wind being at north-east or north-west, and not at south, the sky serene, free from thunder and lightning.

Having thus given an account of the different practices of the vigneron, vintners, and wine-coopers, in the management of their several wines, I shall next offer a few things which have occurred to me from some observations and experiments, relating to the making of wines in *England*.

The Grapes being ripe, should be cut when they are perfectly dry, and carried into a large dry room, where they must be spread upon Wheat-straw, in such a manner as not to lie upon each other; in this place they may remain a fortnight, three weeks, or a month, according as there is conveniency, observing to let them have air every day, that the moisture perspired from the Grapes may be carried off. Then, having the presses and other things in order, you should proceed in the following manner: First, all the Grapes should be pulled off the bunches, and put into tubs, being careful to throw away such as are mouldy, rotten, or not ripe, which, if mixed with the others, will render the wine less delicate; and if the stalks of the bunches are pressed with the Grapes, there will be an austere juice come from them, which will render the wine acid and sharp; this, I fear, has spoiled a great quantity of wine which was made in *England*, which, if otherwise managed, might have proved very good; for we find in *France*, and other wine countries, where persons are desirous of having good wine, they always pick the Grapes from off the stalks before they are pressed, though indeed the common vigneron, who have more regard to the quantity than the quality of their wines, do not practise this. But as in *England* we labour under the inclemency of climate, we should omit nothing of art which may be necessary to help the want of sun.

The Grapes being thus carefully picked off, should be well pressed, and if it is designed for red wine, the husks and stones should be put into the liquor; and if the seeds or stones of the Grapes are broken in the press, the wine will have more strength, which must be put into a large vat, where the whole should ferment together five or six days; after which the wine should be drawn off, and put into large casks, leaving the bung-hole open to give vent to the air which is generated by the fermentation. But it must be remarked, that after the wine is pressed out, and put into the vat with the husks, if it does not ferment in a day or two at most, it will be proper to add a little warmth to the room by fires, which will soon put it into motion; and for want of this it often happens, where people press their wine, and leave it to ferment in open cold places, that the nights being cold, check the fermentation, and so cause the wine to be foul, and almost ever after upon the fret. This husbandry is much practised upon the *Rhine*, where they always have stoves placed in the houses where the wine is fermented, wherein they keep fires every night, if the season is cold, while the wines are fermenting.

If white wine is desired, then the husks of the Grapes should not remain in the liquor above twelve hours, which will be long enough to set it a fermenting; and when it is drawn off, and put into other vessels, it should not remain there above two days before it is drawn off again; and this must be repeated three or four times, which will prevent its taking any tincture from the husks in fermenting.

When the greatest fermentation is over, the wine should be drawn off into fresh casks, which must be filled to the top, but the bung-hole should be left open three weeks or

a month, to give vent to the generated air, and that the scum may run over; and as the wine subsides in the casks, they should be carefully refilled with wine of the same sort from a store-cask, which should be provided for that purpose; but this must be done with much care, lest, by hastily refilling the casks, the scum, which is naturally produced upon all new wines, should be broken thereby, which will mix with the wine, and foul it, causing it to take an ill taste; therefore it would be proper to have a funnel, which should have a plate at the small end, bored full of little holes, that the wine may pass through in small drops, which will prevent its breaking the scum.

After the wine has remained in this state a month or six weeks, it will be necessary to stop up the bung-hole, lest, by exposing it too much to the air, the wine should grow flat, and lose much of its spirit and strength; but it must not be quite stopped up, but rather should have a pewter or glass tube, of about half an inch bore, and two feet long, placed in the middle of the bung-hole. The use of this tube is to let the air, which is generated by the fermentation of the wine, pass off, because this being of a rancid nature, would spoil the wine, if it were pent up in the cask, and in this tube there may always remain some wine, to keep the cask full, as the wine subsides; and, as it shall be necessary, the wine in the tube may be easily replenished. For want of rightly understanding this affair, a great quantity of the choicest wines of *Italy*, and other countries, have been lost. A great complaint of this misfortune I received from a very curious gentleman in *Italy*, who says, *Such is the nature of this country wines in general (nor are the choicest Chianti's excepted), that at two seasons of the year, viz. the beginning of June and September, the first when the Grapes are in flower, and in the other when they begin to ripen, some of the best wines are apt to change, especially at the latter season; not that they turn eager, but take a most unpleasant taste, like that of a rotten Vine leaf, which renders them not only unfit for drinking, but also to make vinegar of, and is called the Settembrine. And what is most strange is, that one cask, drawn out of the same vat, shall be infected, and another remain perfectly good, and yet both have been kept in the same cellar.*

As this change happens not to wines in staves (though that will turn eager), I am apt to attribute it to some fault in refilling the cask, which must always be kept full, which, either by letting alone too long, till the decrease be too great, and the scum there naturally is on all wines, thereby being too much dilated, is subject to break, or else, being broken by refilling the cask gives it that vile taste. But against this there is a very strong objection, i. e. that this defect seizes the wine only at a particular season, viz. September; over which if it gets, it will keep good many years, so the case is worthy the enquiry of naturalists, since it is evident that most wines are more or less affected with this distemper, during the first year after making.

Upon receiving this information from *Italy*, I consulted the Rev. Dr. Hales of *Teddington*, who was then making many experiments on fermenting liquors, and received from him the following curious solution of the cause of this change in wine, which I sent over to my friend in *Italy*, who has tried the experiment, and it has accordingly answered his expectation, in preserving the wine, which was thus managed, perfectly good. He has also communicated the experiment to several vigneron in several parts of *Italy*, who are repeating the same, which take in Dr. Hales's words:

From many experiments which I made the last summer, I find that all fermented liquors generate air in large quantities, during the time of their fermentation; for, from an experiment made on twelve cubick inches of Malaga Raisins, put into eighteen cubick inches of water the beginning of March, there were 411 cubick inches of air generated by the middle of April; but afterwards, when the fermentation was over, it reformed a great quantity of

this air; and from forty-two cubick inches of ale from the tun (which had fermented thirty-four hours before it was put into the bolt-head) had generated 639 cubick inches of air from the beginning of March to the middle of June; after which it re- sorbed thirty-two cubick inches of air; from whence it is plain, that fermented liquors generate air, during the time of their fermentation, but afterwards they are in an imbibing state, which may perhaps account for the alteration of the nice Italian wines; for wine, during the first year after making, continues fermenting more or less, during which time a great quantity of air is generated, until the cold in September put a stop to it, after which it is in an imbibing state. Now the air thus generated is of a rancid nature (as the Grotto del Cano), and will kill a living animal, if put into it. So that if, during the fermentation of the wine, there are two quarts of this rancid air generated, which is closely pent up in the upper part of the vessel, when the cold shall stop the fermentation, the wine, by absorbing this air, becomes foul, and acquires this rancid taste; to prevent which, I would propose the following experiment:

Suppose the vessel A filled with wine, in the bung-hole of this vessel b, I would have a glass tube of two feet long, and about two inches bore, fixed with a pewter socket closely cemented, so as that there may be no vacuities on the sides; and into this tube should be another, of about half an inch bore, closely fixed; the lower tube should always be kept about half full of wine, up to X, which will supply the vessel, as the wine therein shall subside; so that there will be no room left in the upper part of the vessel to contain any generated air, which will pass off through the upper small tube, which must be always left open for this purpose; and the tube being small, there will be no danger of letting in too much air to the wine.

As the wine in the lower tube shall subside, it may be refilled by introducing a slender funnel through the small tube, down to the scum upon the surface of the wine in the larger tube, so as to prevent its being broken, by the wine falling too violently upon it. This experiment, being tried with glass tubes, will give an opportunity to observe what impression the different states of the air have upon the wine, by its rising or falling in the tubes; and if it succeeds, it may be afterwards done by wooden or metal tubes, which will not be in danger of breaking.

This curious experiment, having succeeded wherever it has yet been tried, will be of great service in the management of the wines, there being many useful hints to be taken from it, particularly with regard to fermenting wines; for, since we find that wines too long fermented (especially those which are produced in cool countries) seldom keep well, so, by letting them stand in a cool place, the fermentation will be checked, which is agreeable to the practice of the *Champagnois*, who keep the wines in winter in cellars above ground; but when the weather grows warmer in spring, they then carry them down into their vaults, where they are cooler than in the cellars; and this method of removing their wines from the cellars to the vaults, and back again into the cellars, as the seasons of the year shall require, is found of great service in preserving the wines in perfection; for these wines being weak (when compared with those produced in more southern countries), have not body enough to maintain them, if they are permitted to ferment all the succeeding summer, which the heat of the season will promote where the wine is exposed to its influence; and this surely must be worth the trial by those who make wine in this country, since it is the practice of the northern countries, which is the most proper for our imitation, and not that of the most southern.

But after the wine has passed its fermentation in the vat, and is drawn off in the casks, it will require something to feed upon; so that you should always preserve a few bunches of the best Grapes, which may be hung up in a room for

that purpose, until there be occasion for them; when they should be picked off the stalks, and two or three good handfuls put into each cask, according to their several sizes; for want of this, many times people make use of other things, which are by no means so proper for this purpose.

The vigneron of different countries do also put various sorts of herbs into the vat, when the wine is fermenting, to give it different flavours. Those of *Provence* make use of Sweet-marjoram, Balm, and other sorts of aromack herbs; and upon the *Rhine* they always put some handfuls of a peculiar kind of Clary into the vats, from whence arise the different flavours we observe in wines, which, it is possible, were made in the same manner, and from the same sorts of Grapes. How far this might be thought worth practising in *England*, a few experiments would inform us; though it is to be questioned, whether these herbs mend the wine, because it seems to obtain amongst the Vignerons, purely to alter the flavour of their wines, in order to render them agreeable to the palate of their particular customers; but, however this be, it is yet certain, that there is some art used to alter the flavour of the wine, in most of the different wine countries of *France*, for it is the same sort of Grape which the curious always plant in *Orleans*, *Champagne*, and *Burgundy*; and how different these wines are in their flavour and quality, every one who is acquainted with them well knows; and this difference can never be effected by the situation of the places, since there is no very great difference in the heat of those countries; nor do I believe their different ways of making the wine can alter their flavour so much, especially those of *Orleans* and *Burgundy*, where there is little difference in their management; but in *Champagne* there is this difference from the rest, that they always cut their Grapes in a morning, before the dew is gone off, or in cloudy weather; whereas the vigneron of all the other places, never cut any till they are perfectly dry, which may occasion a great alteration in the wine.

The method commonly practised to give the red colour to wine, is to let it ferment a few days upon the skins, which they always observe to press two or three times, in order to make them discharge their contents; but where a deep-coloured rough wine is desired, there they put a quantity of a certain sort of Grape, whose juice is red, into each vat; this is well known in *England* by the name of *Claret Grape*; the leaves of this Vine always change to a deep purple colour as the fruit ripens, and the Grapes are of a fine blue colour, with a flue over them like fine Plums; but the juice of them is very austere, especially if they are not very ripe.

This red wine will not require to be drawn off into casks more than at first from the vat, for it may remain in the same vessel until it is fit to bottle off, which, I think, should not be done till the wine is two years old; the greater quantity of wine there is in each vessel, the more force it will have, and so consequently be in less danger of suffering from the injuries of weather, especially if the before-mentioned method be practised; but where there are large quantities of wine preserved in close vaults, people should be very cautious how they at first enter them, after they have been shut up for some time; because the air of this vault will become rancid from the mixture of the generated air proceeding from the wines, which has often killed people who have incautiously entered them.

WINTER. [*Prognosticks of a hard winter.*] The lord Bacon gives these as signs or forerunners of a hard winter.

If stone or wainscot, that has been used to sweat (as it is called), be more dry in the beginning of winter, or the drops of eaves of houses come down more slowly than they used to do, it portends a hard and frosty winter. The reason is, that it shews an inclination in the air to dry weather,

weather, which, in the winter time, is always joined with frost.

Generally a moist and cool summer betokens a hard winter likely to ensue. The reason is, that the vapours of the earth, not being dissipated by the sun in the summer, do rebound upon the winter.

A hot and dry summer, especially if the heat and drought extend far in *September*, betokens an open beginning of winter, and cold to succeed towards the latter part of the winter, and in the beginning of the spring; for all that time the former heat and drought bear the sway, and the vapours are not sufficiently multiplied.

An open and warm winter portends a hot and dry summer; for the vapours disperse into the winter showers, whereas cold and frost keep them in, and transport them into the late spring and summer following.

When birds lay up Haws and Sloes, and other stores, in old nests and hollow trees, it is a sign of a hard winter approaching.

If fowls or birds, which used at certain seasons to change countries, come earlier than the usual time, they shew the temperature of the weather, according to that country from whence they came; as the winter birds, fieldfares, snipes, woodcocks, &c.

If they come earlier, and out of the northern countries, they intimate cold winters likely to ensue with us. And if it be in the same country, they shew a temperature of season, like that of the season in which they come; as bats, cuckoos, nightingales, and swallows, which come towards summer if they come early, it is a sign of a hot summer to follow. Cold dews and morning rains, about *Bartholomew-tide*, and hoar frost in the morning about *Michaelmas*, foretel a hard winter.

WOODS and groves are the greatest ornaments to a country seat, therefore every seat is greatly defective without them; wood and water being absolutely necessary to render a place agreeable and pleasant. Where there are woods already grown to a large size, so situated as to be taken into the garden or park, or so nearly adjoining, as that an easy communication may be made from the garden to the wood; they may be so contrived by cutting of winding walks through them, as to render them the most delightful and pleasant parts of a seat (especially in the heat of summer), when those walks afford a goodly shade from the scorching heat of the sun.

As I have already treated of the use and beauty of wildernesses, and have giving directions for the making and planting of them, I shall not enlarge much upon that head in this place; therefore I shall only give some short instructions for the cutting and making of these wood walks, in those places where persons are so happy as to have any grown woods so situated as to be near the habitation, and are either taken into the garden, or walks made from the house or garden leading to them; as also how to plant or decorate the sides of these walks with shrubs and flowers, so as to render them agreeable and pleasant; and then I shall more fully treat of the method to raise and improve woods, so as to be of the greatest advantage to the possessor, and a publick benefit to the nation.

Where persons have the convenience of grown woods near their habitation, so as that there may be an easy communication from one to the other, there will be little occasion for wildernesses in the garden; since the natural woods may be so contrived, as to render them much pleasanter than any new plantation can possibly arrive to within the compass of twenty years, where the trees make the greatest progress in their growth; and in such places where their growth is slow, there cannot be expected shade equal to the grown woods in double that number of years; but there is not on-

ly the pleasure of enjoying a present shade from these woods, but also a great expence saved in the planting of wildernesses, which, if they are large, and the trees to be purchased, will amount to no small sum.

If the wood is so situated, as that the garden may be contrived between the house and that, then the walk into the wood should be made as near to the house as possible, that there may not be too much open space to walk through in order to get into the shade; if the wood is of small extent, then there will be a necessity for twisting the walks pretty much, so as to make as much walking as the compass of ground will admit; but there should be care taken not to bring the turns so near each other as that any two walks may be exposed to each other, for want of a sufficient thickness of wood between; but where the wood is large, the twists of the walks should not approach nearer to each other than fifty or sixty feet; or in very large woods they should be at a greater distance; because, when the under wood is cut down, which will be absolutely necessary every tenth or twelfth year, according to its growth, then the walks will be quite open until the under wood grows up again, unless a border of shrubs, intermixed with some ever greens, is planted by the sides of the walks; which is what I would recommend, as this will greatly add to the pleasure of these walks.

These wood walks should not be less than eight or nine feet broad in small woods; but in large ones fifteen feet will not be too much, and on each side of the walks. The border of shrubs and ever-greens may be nine or ten feet broad; which may be so managed, as to shut out the view from one part of the walk to the other at those times when the under wood is cut down; at which times there will be an absolute occasion for such plantations, and at all times they will afford great pleasure by adding to their variety, as also by their fragrant odour.

The former method, which was practised in cutting these walks through woods, was to have them as strait as possible; so that there was much trouble to make fights through the woods, for direction how to cut them; but where this was practised, every tree which stood in the line, good and bad, was cut down, and many times boggy or bad ground was taken into the walks, so that an expence of draining and levelling was necessary to render them proper for walking on; besides this, there were many other inconveniencies attending these strait cuts through woods, as, first, by letting in a great draught of air, which in windy weather renders the walks unpleasant; and these cuts will also appear at a great distance from the woods, which will have a very bad effect; therefore the modern practice of twisting the walks through woods is to be preferred. In the cutting of these walks there should be particular care taken to lead them over the smoothest and soundest part of the ground, as also to avoid cutting down the trees; so that whenever these stand in the way, it will be better to lead the walk on one side than to have the tree stand in the middle; for although some persons may contend for the beauty of such trees which are left standing in walks, yet it must be allowed, that unless the walk is made much broader in those places than in the other, the trees will occasion obstructions to the walkers or riders, especially when several persons are walking together, so that it will be much better to have the walks entirely clear from trees; and where any large spreading tree stands near the walk, to cut away the small wood so as to make an opening round the trees, where there may be some seats placed for persons to rest under the shade. The turns made in these walks should be as easy and natural as possible; nor should there be too many of them, for that will render the walking through them disagreeable; therefore the great skill in making of these

these walks is, to make the turns so easy as not to appear like a work of art, nor to extend them strait to so great length, as that persons who may be walking at a great distance may be exposed to the sight of each other; both these extremes should be avoided as much as possible, since they are equally disagreeable to persons of true taste. When a wood is properly managed in this way, and a few places properly left like an open grove, where there are some large trees so situated as to form them, there can be no greater ornament to a fine seat than such a wood.

We shall now treat of the culture of woods for profit to the possessor, and publick benefit of the nation.

The great destruction of the woods and forests which has been of late years made in this country, should alarm every person who wishes well to it; since there is nothing which seems more fatally to threaten a weakening, if not a dissolution, of the strength of this once famous and flourishing nation, than the notorious decay of its timber: and as this devastation has spread through every part of the country, so unless some expedient be seriously and speedily resolved on, to put a stop to this destruction of the timber, and also for the future increase of it, one of the most glorious bulwarks of this nation will, in a few years, be wanting to it.

And as there are small hopes of this being remedied by those entrusted with the care of publick woods, since their private interest is so much advanced by the destroying the timber, which they were appointed to preserve; therefore, unless private persons can be prevailed on to improve their estates, by encouraging the growth of timber, it is greatly to be feared, that in an age there will be a want of it for the supply of the navy; which, whenever it happens, must put a period to the trade of this country.

It has been often urged, by persons whose judgment in other affairs might be depended on, that the great plantations, which for several years past have been carried on in several parts of this kingdom, will be of publick benefit by the propagation of timber; but in this they are greatly mistaken, for in most of the plantations which have been made for years past, there has been little regard had to the propagation of timber, present shade and shelter have been principally considered; and in order to obtain these soon, great numbers of trees have been taken out of woods, hedge rows, &c. which, if they had remained in their first situation, might have afforded good timber, but by being transplanted large, are absolutely rendered unfit for any use but fuel; so that the great quantity of plantations which have been made, I fear, will rather prejudice than be of use to the improvement of timber; nor is there any other method of increasing the useful timber of this country, than by sowing the seeds in the places where they are to remain, or in such situations where there are plenty of Oaks in the neighbourhood; if the ground is properly fenced, to keep out cattle and vermin, the Acorns which drop from those trees will soon produce plenty of young trees, which, if properly taken care of, will soon grow to be large.

The two most substantial timbers of this country are the Oak and Chestnut; though the latter has been of late years almost entirely destroyed in *England*, so that there are scarce any remains of trees of size in the woods at present; but there can be no doubt of this tree having been one of the most common trees of this country, as may be proved by the old buildings in many parts of *England*, in which the greatest part of the timber is Chestnut. But as I have already treated largely of the method of propagating both these trees for profit, under their respective titles, I shall not repeat it here. Next to these, the Elm is esteemed as a profitable timber; but of these there are few cultivated in woods, especially in the south part of *England*, where they chiefly grow in hedge rows, or plantations near houses;

but in the north-west part of *England*, there are numbers of very large trees of the Witch Elm growing in parks, and some in woods, as if that tree was a native of this country, which has been much doubted; though as this tree propagates itself by seeds, it may be deemed an indigenous plant in *England*.

The Beech is another tree common in the woods, especially upon the chalky hills of *Buckinghamshire*, *Kent*, *Suffex*, and *Hampshire*, where there are some very large woods entirely of this sort; some of which have been of long standing, as appears by the age of the trees; but whether this tree is a native of this country, has been a point often disputed.

The Ash is a very profitable tree, and of quick growth; so that in less than an age, the trees will arrive to a large size from the seeds, therefore a person may hope to reap the profits of his labour, who sows the seeds; but this is not a beautiful tree to stand near a habitation, being late in the spring in putting out its leaves, and the first that sheds them in autumn; nor is a friendly tree to whatever grows near it, the roots drawing away all the nourishment of the ground, whereby the trees or plants which grow near are deprived of it; so that where the Ash tree grows in hedge rows, the hedges in a few years are entirely destroyed; and if they are in pasture-grounds, and the cows browse on them, the butter made with their milk will be bad; for which reason the Ash should be sown separate in lands which are inclosed, where cattle are not permitted to come, and at a distance from the habitation.

Upon sandy or rocky soils, the *Scotch* Pine will thrive exceedingly, and turn to great advantage to the planter, provided the plants are planted young, and treated in the manner directed in the article *Pinus*, to which the reader is desired to turn to avoid repetition.

There are also several aquatick trees, which are very profitable to those who have low marshy lands, where the harder kinds of timber will not thrive; these are the Poplars of several sorts, the Willow, Alder, &c. but as these, and all the other kinds of trees, have been fully treated of, both as to their propagation and uses, and also an account of the different soils in which each will thrive best, under their respective titles, the reader is referred to them for farther information; and I shall next treat of the general management of woods, of whatever kinds of trees they are composed.

Where there are young woods, great care must be taken of the fences; for if cattle should get in among the trees, they will, in a short time, do infinite damage to them, by browsing on the branches, or barking the trees; and during the first ten years of their growth, they should be secured from hares and rabbits, otherwise, in severe frost, when the ground is covered with snow, whereby they are deprived of other food, they will get into the woods, and eat off the bark from the young trees, and gnaw all the branches within their reach; so that in a few days, where there are plenty of these animals, there may be such destruction made among the young trees, as cannot be retrieved, but by cutting them down to the ground, which will be a loss of several years; therefore those persons who have the care of young woods, should be very diligent in frosty weather in looking over the trees, and stopping the holes in the fences, to keep out all vermin.

Another care to be taken of young woods, is the thinning the trees from time to time, as they increase in their growth; but in doing of this, there must be great caution used, for it should be gradually performed, so as not to open the trees too much, to let the cold air among them, which will greatly retard their growth; nor should the trees be left so close, as to draw each other up like may-poles,

poles, but rather observe a medium in this work, cutting down a few each year, according as there may be necessity for it, being careful not to permit those to stand, which may spoil the growth of the neighbouring trees, always observing to leave those trees which are the most promising.

The young trees in these woods should not be lopped or pruned, for the more they are cut the less they will increase in bulk; every branch which is cut off will rob the tree of its nourishment, in proportion to the size of the branch; therefore the hatchet should not be suffered to come into young woods, unless in the hands of skilful persons.

Where persons have more regard to the future welfare of the timber than their immediate profit, the under wood should be grubbed up as the trees advance, that the roots may have the whole benefit of the soil, and their stems enjoy the free air, without which their stems are generally covered with moss, and their growth greatly stunted; as may be observed in all such woods where there is any quantity of under wood remaining, in which places it is rarely found that the trees do ever grow to a large size; therefore where large timber is desired, the trees must have room to extend their roots and branches, without which it cannot be expected; but from a covetous temper, many people let their under wood remain as long as it will live; for as the timber increases, the under wood will be gradually decaying by the shade and drip of the large trees, so that by this method the timber suffers more in a few years than the value of the under wood; therefore by endeavouring to have both, neither of them can be so good as where they are separately preserved.

If persons who have estates would be careful to nurse up trees in their hedge rows, it would in time become a fortune to their successors; as hereby the timber growing in the hedges may be worth more than the freehold of the estate, which has often been the case with estates from which their possessors have cut down timber for fortunes for their younger children; the frequency of this should encourage persons to be a little more attentive to the growth and preservation of young woods, since the expence and trouble is not great, and the future profit very certain; besides, the pleasure of seeing trees of a man's own sowing make yearly advances, must be very great to those who have any relish for country amusements.

There are several persons who plant copses for cutting every ten or twelve years, according to their growth. These are usually planted in autumn, either with stools or young plants, which are drawn out of the woods; the latter should

always be preferred to the former. These copses are commonly planted with several sorts of trees, as Oak, Beech, Chestnut, Ash, Birch, Willow, &c. but the Ash and Chestnut are the most profitable, where they grow kindly, because the poles of Ash are very valuable; these also are good for hoops, so that there is no danger of having sale for these copse woods when they are fit for cutting; but where the copses are intended to remain, there should be no standard trees left for timber, because as the heads of the trees spread, and over-top the under wood, it will cause that to decay; and where the standards are left upon the stumps of the copse wood they will never grow to a large size, nor will the timber be so valuable as that produced immediately from a young root; therefore whoever will make the experiment, will be convinced that it is more for the advantage of both to keep them in distinct woods.

But where persons plant copses upon land free from trees, it will be the better method to sow the seeds, especially if Chestnut, Oak or Beech, are the trees intended; for although it is a prevailing opinion with the generality of persons, that by planting they save time, yet I am sure of the contrary; for if the seedling plants are kept clear from weeds, they will, in eight or ten years, out-grow those which are planted, and these unremoved copses will continue much longer in vigour than the other; so that for either timber or copse wood, the best method is to prepare the ground well, and secure the fences and sow the seeds, which is so far from losing, that in twenty years it will be found to gain time, which is what every planter wishes to do.

The usual time of felling timber is from *November to February*, at which time the sap in the trees is hardened; for when the sap is flowing in the trees, if they are cut down the worm will take the timber, and cause it to decay very soon; therefore if the durability of the timber is considered, the trees should always be cut in the winter months; but as the bark of the Oak is so valuable for tanning leather, there has been a law passed to oblige persons to cut these trees during the spring season, when the bark will readily peel off; by which the timber is rendered unfit for building either ships or houses, as it will be very subject to cast, rift, or twine, and the worm will soon take it; therefore it would be more for the publick benefit, if a law was enacted to oblige every person to strip off the bark of such trees, as are designed to be cut down in the spring, when the bark will run, leaving the trees with their branches standing till the following winter, which will be found to answer both purposes well.

XANTHIUM. *Tourn. Inst. R. H. 438. tab. 252.*
 Lesser Burdock.

The Character are,

It hath male and female flowers on the same plant. The male flowers have a common scaly empalement; they are composed of several tubulous funnel shaped florets, which are equal, and disposed in a hemisphere, cut into five segments at the top, and have each five very small stamina, terminated by erect parallel summits. The female flowers are situated under the male by pairs; they have no petals, or stamina, but they are succeeded by oblong, oval, prickly fruit, having two cells, each including one oblong seed, convex on one side, and plain on the other.

The Species are,

1. XANTHIUM caule inermi, aculeis fructibus erectis. Lesser Burdock with an unarmed stalk, and the spines of the fruit erect; or lesser Burdock.

2. XANTHIUM caule inermi, aculeis fructibus incurvis. Lesser Burdock with an unarmed stalk, and incurved spines to the fruit; or Canada Burdock.

3. XANTHIUM spinis ternatis. *Hort. Upsal. 283.* Lesser Burdock, having triple spines.

4. XANTHIUM caule inermi, aculeis fructibus, longissimis erectis simplicibus. Lesser Burdock with an unarmed stalk, and very long erect spines to the fruit which are single.

The first sort grows naturally in *Europe*, and also in *India*, from whence I have received the seeds; it has been found growing wild in a few places in *England*, but of late years it has not been seen in those places. It grew some years past in the road near *Dulwich* college. The stalk of this plant is round, spotted with black; it rises in good ground two feet high, sending out a few side branches. The leaves stand upon long slender foot-stalks. From the wings of the stalks arise the foot stalks of the flowers, which are produced in loose spikes, the male flowers growing at the top, and the female flowers under them; they are of an herbaceous colour, collected into roundish heads. The female flowers are succeeded by oblong oval fruit, closely armed with short erect spines.

This plant has been much esteemed by some physicians for the cure of scrophulous tumours, and also in leprosy, but is rarely now used.

The second sort grows naturally in *North America*. The stalks of this are much thicker, and rise higher than those of the first; the leaves are not hollowed at their base, nor are they divided so deeply on their sides as those of the first; they are unequally indented on their edges, and have three longitudinal veins. The flowers are produced in shorter and looser spikes. The fruit are much larger, and are armed with stronger spines which are incurved.

The third sort grows naturally in *Portugal* and *Spain*. The stalks of this rise three feet high, sending out many branches; these are garnished with oblong leaves which are indented on their edges, ending in acute prickles; of a dark green on their upper side but hoary on their under, having very short foot-stalks. The flowers come out from the sides

X A N

of the branches, two or three at each place, one of which is female, and is succeeded by oblong oval fruit, armed with slender sharp spines which are erect. The stalks and branches are armed with long, stiff, triple thorns on every side, which renders it dangerous to handle them.

The fourth sort was discovered by the late Dr. *Houssoun* in the year 1730, growing naturally at *La Vera Cruz*; this plant rarely grows more than six or seven inches high. The leaves are small, and shaped like those of the second sort; the flowers are produced in loose spikes at the top of the stalks; the fruit is as large as those of the second sort, but the spines are slender, single, and strait.

All these plants are annual. The first will come up from the seeds which fall in autumn, and requires no other care but to thin the plants where they are too close, and keep them clear from weeds; the second sort formerly was as easily cultivated, and came up from the self-sown seeds as readily, and rarely failed to ripen its seeds, but of late years the autumns have proved so bad, as that the seeds have not come to maturity.

The third sort will perfect its seeds some years on self-sown plants; but as they sometimes fail, the sure way is to raise the plants on a gentle hot-bed, and, after they have obtained strength, plant them on a warm border on a lean soil, which will stint the plants in their growth, and cause them to be more fruitful; for when they are planted in rich ground the plants will grow to a large size, and will not produce flowers till late in autumn, so the seeds will not ripen.

The fourth sort must be raised on a hot-bed in the spring, and the plants should be transplanted each into a small pot, and plunged into a fresh hot-bed to bring them forward. After they have obtained strength they should be inured to the free air gradually, and in *June* some of the plants may be turned out of the pots, preserving the ball of earth to their roots, and planted in a south border, where, if the season proves favourable, they will perfect their seeds.

XANTHOXYLUM. *Lin. Gen. Plant. 335.* The Tooth-ach-tree.

The Characters are,

The flower has no empalement, but has five oval petals, and five slender stamina, which are longer than the petals, terminated by furrowed summits; it has three germen, which are united at their base, having each a lateral style crowned by obtuse stigmas. The germen after-ward become so many capsules, each containing one roundish, hard, shining seed.

The Species are,

1. XANTHOXYLUM foliis pinnatis, foliolis lanceolatis serratis petiolatis. Tooth-ach-tree with winged leaves, having spear-shaped sawed lobes growing upon foot-stalks.

2. XANTHOXYLUM foliis pinnatis, foliolis oblongo ovatis integerrimis sessilibus. Tooth-ach-tree with winged leaves, having oblong, oval, entire lobes without foot-stalks, commonly called broad-leaved Tooth-ach-tree.

The first sort grows naturally in *South Carolina*, where it rises to the height of fifteen or sixteen feet. The stem is woody, covered with a whitish rough bark, armed with short thick spines; these grow to a large size as the trunk increases in bulk, so as to become protuberances terminating in spines. The leaves are sometimes placed by pairs, and at others they stand without order; they are composed of three, four, or five pair of spear-shaped lobes placed opposite, terminated by an odd one, of a deep green on their upper side, and of a yellowish green below, a little sawed on their edges, and stand upon short foot-stalks. At the end of the branches come forth the foot-stalks which sustain the flowers; these branch out, and form a loose panicle. The flowers are composed of five white petals, which are small, and having no cover, they are by some called the empalement; but being of a different colour from the leaves, I shall take the liberty to stile them petals. Within these are situated five stamina, which are terminated by reddish summits, and in the hermaphrodite flowers there are three styles fastened to the side of the germen. After the flower is past, the germen turns to a roundish four-cornered capsule, each containing one roundish, hard, shining seed. It is sometimes called Pellitory-tree.

This has been generally confounded with the prickly Yellow Wood or Yellow *Hercules* of Sir *Hans Sloane*, but is very different from that; for in the *West-Indies* it is one of their largest timber trees, and the specimens which I have received from *Jamaica*, are very different from those of *Carolina*. The leaves of the former are twice as large as those of the latter; the lobes of the leaves are almost three inches long, and an inch and a half broad; they sit close to the foot-stalk, and the leaves are equally winged, having no single lobe at the end. The flowers of this I have not seen, but the capsules have five cells, each containing one black, shining, hard seed.

The second sort grows naturally in *Pensylvania* and *Maryland*; this hath a woody stem, which rises ten or twelve feet high, sending out many branches toward the top; these have a purplish bark, and are armed with short thick spines standing by pairs. The leaves are unequally winged, and are composed of four or five pair of oblong oval lobes, terminated by an odd one; these stand close to the midrib, having no foot-stalks. The midrib is armed on the under side with some small spines. The upper side of the leaves is of a deep green, and their under of a pale green; they have a warm biting taste. The bark of the tree is used for curing the tooth-ach, from whence it has the name. The flowers grow in loose panicles like those of the former sort, and these are succeeded by fruit with five cells, each including one hard shining seed.

These plants are generally propagated by seeds, but as these never ripen in this country, they must be procured from those places where they naturally grow. When the seeds arrive in *England*, they should be sown in pots as soon as possible, for they do not grow the first year; and when they are kept out of the ground till spring, they frequently lie two years in the ground before the plants appear; therefore the pots should be plunged into the ground up to their rims, in an east-aspected border, where they may remain during the summer; this will prevent the earth in the pots from drying too fast, which it is very apt to do when the pots are set upon the ground in the sun. The only care to be taken of the seeds, is to keep the pots constantly clean from weeds, and in very dry weather refresh them now and then with water. In autumn the pots should be placed under a common hot-bed frame, where they may be screened from frost, or else plunged into the ground in a warm border, and covered with tan to keep out the frost, and the following spring they should be plunged into a hot-bed, which

will bring up the plants. When these appear, they must be frequently, but sparingly watered, and kept clean from weeds; and, as the summer advances, they should be gradually inured to bear the open air, into which they should be removed in *June*, placing them in a sheltered situation, where they may remain till autumn, when they must be placed in a hot-bed frame to shelter them in winter. The spring following, before the plants begin to shoot, they should be carefully taken up, and each planted into a separate small pot; these may be plunged into a gentle hot-bed, which will forward them greatly in putting out new roots. The after care must be to shelter them for a year or two in winter, until the plants have gotten strength; then in the spring, after the danger of frost is over, some of them may be turned out of the pots, and planted in the full ground in a sheltered situation, where the second sort will thrive very well, and resist the cold; but the first is not quite so hardy, so these may be planted against a south wall, where they will thrive very well. Some of the plants of this sort had been planted in the open air in the *Chelsea* garden, some years, where they had thriven and endured the cold without any covering; but the severe winter in 1740, destroyed them all. These plants may be increased by cutting off some of their strong roots, preserving their fibres to them, and planted in pots filled with light earth, plunging them into a moderate hot-bed, which will cause them to push out, and become plants; but these will not thrive so well, nor grow near so large as those which are raised from seeds; the roots will also put out suckers, whereby the plants may be increased.

XERANTHEMUM. *Tourn. Inst. R. H.* 499. *tab.* 284. Eternal flower.

The Characters are,

The flower is composed of hermaphrodite and female florets, which have one common scaly empalement. The hermaphrodite florets, which form the disk, are funnel-shaped, and cut into five points; the female florets, which compose the border or rays, are tubulous, and cut into five less equal points; the hermaphrodite florets have five short stamina, terminated by cylindrical summits, and a short germen, supporting a slender style, crowned by a bifid stigma. The germen afterward becomes an oblong seed, crowned with hairs, which ripens in the empalement.

The Species are,

1. XERANTHEMUM *foliis lanceolatis potentibus.* *Lin. Sp. Plant.* 857. Eternal-flower with spreading spear-shaped leaves; commonly called Parmica.

2. XERANTHEMUM *foliis lineari-lanceolatis utrinque tomentosis.* Eternal-flower with linear spear-shaped leaves, which are downy on their under side.

3. XERANTHEMUM *foliis lineari lanceolatis, capitulis cylindraceutis, semine maximo.* Eternal flower with linear spear-shaped leaves, cylindrical heads, and a very large seed.

4. XERANTHEMUM *fruticosum erectum, foliis lanceolatis, ramis unifloris subnudis.* *Lin. Sp. Plant.* 858. Shrubby erect Eternal flower with spear-shaped leaves, and almost naked branches bearing one flower.

5. XERANTHEMUM *caulibus frutescentibus provolutis, foliis tomentosis recurvatis.* *Lin. Sp. Plant.* 858. Eternal flower with shrubby trailing stalks, and downy recurved leaves.

6. XERANTHEMUM *ramis unifloris imbricatis, foliis obsoletis.* *Lin. Sp. Plant.* 859. Eternal-flower with branches terminated by one imbricated flower, and obsolete leaves.

The first sort grows naturally in *Austria*, and some parts of *Italy*, but has been long cultivated in the *English* gardens for ornament. Of this there are the following varieties; one with a large single white flower; the purple and white with double flowers, though these only differ in the colour and multiplicity of petals in their flowers, so are not mentioned

tioned as distinct species, yet where their seeds are carefully saved separate, they are generally constant.

These plants are annual; they have a slender, furrowed, angular, branching stalk, covered with a white down, rising two feet high, garnished with spear-shaped hoary leaves, sitting close to the stalk, which divides into four or five branches, garnished with a few leaves at their lower parts, of the same shape with the other, but less. The upper part of the branches is naked, and sustains one flower at the top, composed of several female and hermaphrodite florets, included in one common scaly empalement, of a silvery colour. The florets are succeeded by oblong seeds, crowned with hairs. The petals of these flowers are dry, so if they are gathered when perfectly dry, and kept from the air, they will retain their beauty a long time.

The second sort grows naturally in *Italy*. The stalks of this do not rise much more than a foot high, and do not branch so much as the former. The leaves are narrower, and the whole plant very hoary. The flowers are not half so large as those of the former, and the scales of their empalements are very neat and silvery.

The third sort grows naturally in the *Levant*; this rises about the same height as the first sort. The leaves are narrower, and are placed closer on the stalks to the top. In other respects the plants are very like, but the flowers are much less, of a paler purple colour, and have a cylindrical empalement. The seeds are very large, and seldom more than three or four in each head.

These flowers were formerly much more cultivated in the *English* gardens than at present, especially the two sorts with double flowers, which the gardeners near *London* propagated in great plenty for their flowers, which they brought to market in the winter season, to adorn rooms, to supply the place of other flowers, which are not easy to be procured at that season; for these being gathered when they are fully blown, and carefully dried, will continue fresh and beautiful many months; but as there are no other colours in these flowers but white and purple, the gardeners had a method of dipping them into various tinctures, so as to have some of a fine blue, others scarlet, and some red, which made a pretty variety; and, if they were rightly stained, and afterwards hung up till they were thorough dry, they would continue their colours as long as the flowers lasted. The stalks of the flowers were not set in water, but the pots or glasses were half filled with dry sand, into which the stalks were placed, and in these they would continue in beauty the whole winter.

These plants are propagated by seeds, which may be sown either in the spring or autumn on a border of light earth; but the latter season is preferable, for those plants which come up in autumn will flower sooner. The flowers will be doubler and much larger than those which are sown in the spring, and from these good seeds may be always obtained; whereas the spring plants many times fail in cold years, and in hot dry seasons the plants do not grow to any size.

When the plants come up, and are about two inches high, they should be pricked out into another border under a warm wall, pale, or hedge, at about four or five inches distance from each other, where the plants will endure the cold of our ordinary winters very well, and in the spring will require no farther care but to keep them clear from weeds, for they may remain in the same place for good. In *June* they will begin to flower, and the middle or latter end of *July* they will be fit to gather for drying; but a few of the best and most double flowers of each kind should be suffered to remain for seed, which, in about six weeks or two months time, will be ripe, and the plants will perish soon after; so that the seeds must be annually sown, in order to preserve the kinds.

The fourth sort grows naturally at the *Cape of Good Hope*. This rises with a shrubby stalk three or four feet high, dividing into four or five branches, whose lower parts are garnished with thick-pointed leaves on their under side, and are ranged without order. The upper part of the branches are naked, and are terminated by one large yellow flower, composed of many oblong acute-pointed rays in the border, and the middle or disk, which is prominent, is made up of hermaphrodite florets, which are of a splendid yellow colour.

The fifth sort grows naturally at the *Cape of Good Hope*. The stalks of this sort are very slender, ligneous, and trail upon the ground, garnished with small silvery leaves placed without order, which sit close to the stalks, and are reflexed. The flowers are produced from the wings of the branches, sometimes one, and at others two or three flowers arise at the same point; these have scaly empalements; their border or rays are composed of many female florets, of a white colour, and their middle of hermaphrodite florets; these are succeeded by oblong seeds crowned with hairs.

The sixth sort is a native of the country near the *Cape of Good Hope*; this has a shrubby branching stalk, which rises three or four feet high. The branches are slender, and like those of the *Spanish Broom*, but hoary; these have very small leaves resembling scales, which sit close to the branches; they are hoary, ending in acute points. The stalks are each terminated by one large silvery flower, having a stiff, dry, scaly empalement. The rays of the flower are composed of many dry female florets, and the disk or middle is made up of hermaphrodite florets.

As these plants do not ripen their seeds in *England*, they are propagated by cuttings, which, if planted on a bed of light earth, during any of the summer months, and shaded from the sun, will put out roots. When these have gotten sufficient roots, they should be carefully taken up, and planted into separate pots, and placed in the shade till they have taken fresh root; then they may be removed to a sheltered situation, where they may have more sun; and here they may remain till autumn, when they must be removed into shelter, for they are too tender to live abroad through the winter in *England*, though they do not require any artificial warmth. I have kept these plants in a common hot-bed frame all winter, exposing them always to the open air in mild weather, but covering them in frost; and these plants have been stronger, and have flowered better than those which were placed in the green-house; so that I would recommend this method of treatment as the best, for the plants are apt to draw up weak in a green-house, and that prevents their flowering; nor are the plants near so handsome as those which are more exposed to the open air.

In the summer time they should be placed abroad in a sheltered situation with other hardy exotick plants, and in dry weather they will require to be often watered, for they are pretty thirsty plants, but in winter it should be sparingly given to them. As these plants are not of long duration, there should be young plants propagated to succeed them, for if they live four or five years, it is full long enough, because after that age they become unsightly.

XIMENIA. *Plum. Gen. Nov. 6. tab. 21.*

The Characters are,

The flower has a small empalement of three leaves, which falls off; it has one bell-shaped petal, cut into three segments at the top, which turn backward; it has three short awl-shaped stamina, terminated by single summits, and a small oval germen, situated under the flower, supporting a very short style, crowned by a beaded stigma. The germen afterward turns to an oval fleshy berry, including an oval nut with one cell, containing one seed of the same form.

The Species are,

1. *XIMENIA foliis solitariis*. *Lin. Sp. Plant.* 1193. *Ximonia* with single leaves.

2. *XIMENIA foliis geminis*. *Lin. Sp. Plant.* 1194. *Ximonia* with twin leaves.

The first sort grows naturally in the islands of the *West-Indies*; it rises with a woody stalk twenty feet high, sending out several branches, which are armed with thorns, garnished with spear-shaped leaves, standing round the branches without order. The flowers are produced at the end of the branches; they have one bell-shaped petal cut almost to the bottom into three segments, which are rolled backward, and are hairy; within they are of a yellow colour, and are succeeded by an oblong, oval, fleshy fruit, shaped like a Plum, including a hard nut of the same form.

The second sort grows naturally in *Egypt*, where it becomes a tree of middling size. The stem is large and woody; the branches are slender and stiff; they have a green bark, and are armed with strong spines; the leaves come out by pairs; they are larger than those of the *Box-tree*, and end in points, but are of the like consistence and colour. The flowers come out on the side of the branches; they are shaped like those of *Hyacinth*, but are small, and of a white colour; these are succeeded by oblong black berries, including an oval nut, having one kernel or seed.

Both these sorts are propagated by seeds, which must be procured from the countries where they grow naturally; these should be sown in pots filled with light earth, and plunged into a hot-bed of tanners bark. If the seeds are fresh, the plants will appear in six weeks or two months. When these are about three inches high, they must be each carefully transplanted into a separate small pot filled with light earth, and plunged into a good hot-bed of tanners bark, where they must be shaded from the sun till they have taken new root; then they must be treated in the same manner as other tender plants from the warm countries. During the first summer they may be kept in the tan-bed under frames, where they will thrive better than in the stove; but in autumn, when the nights grow cool, they should be removed into the stove, and plunged into the tan-bed; and in this they should always be kept, observing to shift them into larger pots when they require it; and in summer, when the season is warm, they should have a large share of free air admitted to them. With this management the plants will thrive well, but they cannot be expected to flower very soon in this country.

XIPHION, or *XIPHIUM*. *Tourn. Inst. R. H.* 362. tab. 189. Bulbous Iris, or Flower-de-luce.

The Characters are,

The flowers have each a permanent spatha or sheath; they have six petals, the three outer broad, obtuse, and reflexed, and the inner erect, pointed, and joined to the other at their base; they have three awl-shaped stamina, which lie upon the reflexed petals, and are terminated by oblong depressed summits, and an oblong germen under the flower, supporting a short style, crowned by a tripartite stigma. The germen afterward becomes an oblong angular capsule with three cells, filled with roundish seeds.

The Species are,

1. *XIPHIUM foliis carinatis caule longioribus*. Bulbous Iris with keel-shaped leaves, which are longer than the stalk; *Persian Iris*.

2. *XIPHIUM foliis subulato-canaliculatis, caule brevioribus*. Bulbous Iris with channelled awl-shaped leaves, which are shorter than the stalk; Bulbous Iris with a blue Violet flower.

3. *XIPHIUM foliis subulato-canaliculatis, floribus majoribus*. Bulbous Iris with channelled awl-shaped leaves, and larger flowers; or broad-leaved Bulbous Iris.

4. *XIPHIUM foliis planis caule longioribus*. Bulbous Iris with plain leaves, which are longer than the stalk; or broad-leaved Bulbous Iris with a blue flower.

The first sort grows naturally in *Persia*, but has been many years cultivated in the *English* gardens for the beauty of its flowers; it has an oval bulbous root, from which come out five or six pale green leaves, which are hollowed like the keel of a boat, ending in points. Between these the flower-stalk arises, which is seldom above three inches high, supporting one or two flowers, which are included in spathæ (or sheaths); these have three erect petals called standards, which are of a pale sky-blue colour, and three reflexed petals called falls, which on their outside are of the same colour, but the lip has a yellow streak running through the middle, and on each side are many dark spots, with one large deep purple spot at the bottom. These flowers have a very fragrant scent, and generally appear in *February*, which renders them more valuable.

The second sort grows naturally in the warm parts of *Europe*. There are several varieties of this species; the most common sort is blue, but there is one with a yellow, and another with a white flower; one with a blue flower, having white falls, another with yellow falls, one with a Violet-coloured flower, having blue falls, with some others; but these are all supposed to be varieties, which have been produced by culture.

The root of this is bulbous; the leaves are hollow or channelled, ending in points, where their two sides meet; these are not so long as the flower-stalk, which rises between them, and is embraced by the base of the leaves. This supports two or three flowers, which are each inclosed in a separate sheath at the top of the stalk. The flowers are shaped like those of the first sort, but differ in their colour.

The third sort has much larger bulbous roots than either of the former. The leaves are shaped like those of the second sort, but are much larger; the flower-stalk is near twice the height of the second sort, and the flowers are more than double their size. This is by some supposed to be only a variety of the second, but I think it a distinct species, for I have many years raised a great number of the plants from seed, and have never found a single one degenerated to the second sort, and have raised many of the second sort from seeds, without one instance of a plant improving to the third.

There is a great variety of this species, which differ in the colours of their flowers. Some are of a deep blue, others of a light or sky-blue, some of a deep purple, and others with fine variegated flowers, which make a fine appearance during their continuance, which is not long, unless the season proves cold, or the flowers are shaded from the sun.

The fourth sort grows naturally in *Spain* and *Portugal*. The root of this has a dark-coloured coat, but is white within, and of a sweet taste. The leaves are eight or nine inches long, and more than an inch broad at their base; they are almost plain, but toward their base are hollowed like the keel of a boat, and end in points, being of a pale green on their upper side, and a little hoary on their under. The flowers stand upon naked foot-stalks, which arise from the root, and grow five or six inches high, sustaining two or three flowers at the top, which are each wrapped up in a separate sheath; these are shaped like those of the other sorts, and have a very agreeable odour.

There are four or five varieties of this species, which differ in the colour of their flowers; but the most common colour is blue.

They are all propagated by offsets from their roots, but to obtain new varieties, they must be propagated by seeds in the following manner.

Having

Having procured a parcel of seeds from good flowers, you should provide some flat pans or boxes, which must have holes in their bottoms to let the moisture pass off; these should have pieces of tile or oyster-shells laid over each hole to prevent their being stopped; then they must be filled with fresh, light, sandy earth, and the beginning of *September* the seeds should be sown thereon pretty thick, observing to scatter them as equally as possible; then cover them over about half an inch thick with the same light fresh earth, and place the boxes or pans where they may have the morning sun till eleven o'clock; and if the season should prove very dry, they must be now and then refreshed with water.

In this situation they may remain until the middle of *October*, when they should be removed into a warmer situation, where they may have the full sun most part of the day, and screened from severe frosts; in which place they must abide all the winter, observing to keep them clear from weeds and moss, which, at this season, are very apt to spread over the surface of the earth, in tubs, pans, or pots, when they are exposed to the open air.

In the spring the plants will appear above ground, when, if the season is dry, they must be now and then refreshed with water, and constantly kept clear from weeds; and as the season advances, and the weather becomes warm, they should be again removed into their former shady situation, where they may enjoy the morning sun only. When the leaves begin to decay (which will be in *June*), they must be cleared from weeds and dead leaves, and some fresh earth sifted over them about half an inch thick, still suffering them to abide in the same situation all the summer season; during which time they will require no farther care, but to keep them clear from weeds, until the beginning of *October*, when they must be again removed into a warm situation, and the surface of the earth lightly taken off, and some fresh earth sifted over them.

In this place they must remain all the winter, as before; and in the spring they must be treated as was directed for the former years.

When the leaves are decayed, the bulbs should be carefully taken up (which may be best done by sifting the earth through a fine sieve), and a bed or two of good light fresh earth should be prepared, into which the bulbs must be planted, at about three inches asunder each way, and three inches deep. These beds must be constantly kept clean from weeds and moss; and if the winter should prove severe, the bed should be covered with rotten tanners bark, or Pease haulm, to keep out the frost; and in the spring, just before the plants come up, the surface of the beds should be stirred, and some fresh earth sifted over them about half an inch thick, which will greatly strengthen the roots.

During the spring and summer, they must be constantly weeded; and at *Michaelmas* the earth should be again stirred, and some fresh sifted over the beds again, as before, observing in winter and spring still to keep the beds clean, which is the whole management they will require, and in

June following the greatest part of the roots will flower; at which time you should carefully look over them, and put down a stick by all those whose flowers are beautiful, to mark them; and as soon as their leaves are decayed, these roots may be taken up to plant in the flower-garden amongst other choice sorts.

But the nursery-beds should still remain, observing to keep them clear from weeds, as also to sift fresh earth over them, as was before directed; and the following season the remaining part of the roots, which did not flower the foregoing season, will now shew their blossoms; so that you may know which of them are worth preserving in the flower-garden, which should now be marked; and when their leaves are decayed, they must be taken up and planted with the other fine sorts, in an east-border of light fresh earth; but the ordinary sorts may be intermixed with other bulbous-rooted flowers in the larger borders of the pleasure-garden, where, during their continuance in flower, they will afford an agreeable variety.

But after these choice flowers are obtained from seeds, they may be increased by offsets, as other bulbous flowers are. The offsets should be planted in a separate border from the blowing roots, for one year, until they have strength enough to produce flowers, when they may be placed in the flower-garden with the old roots.

These bulbs need not be taken up oftener than every other year, which should always be done soon after their leaves decay, otherwise they will send forth fresh fibres, when it will be too late to remove them; nor should they be kept long out of the ground; two months is full enough; for when they are kept longer, their bulbs are subject to shrink, which causes their flowers to be weak the following year.

The *Persian Iris* is greatly esteemed for the beauty and extreme sweetness of its flowers, as also for its early appearance in the spring, it generally being in perfection in *February*, or the beginning of *March*, according to the forwardness of the season, at which time there are few other plants in beauty.

This may be propagated by seeds in the same manner as the other sorts; but the boxes in which they are sown, should be put under a garden-frame in winter, to shelter them from hard frost, because, while the plants are young, they are somewhat tender. From the seeds of this kind I could never obtain any varieties, their flowers being always the same.

These plants are also propagated by offsets, in the same manner as the other sorts; but their roots should not be transplanted oftener than every third year; nor should they be ever kept out of the ground long, because their roots will shrink and entirely decay when they are long above ground, so as not to be recovered again. This sort was formerly more common in the gardens near *London* than at present, which, I suppose, has been occasioned by the keeping the roots above ground too long, which destroyed them.

XYLON. See Bombax.

Y.

Y U C

YEW-TREE. See *Taxus*.
YUCCA. *Dillen. Gen. Nov. 5.* The Indian
Yucca, or *Adam's Needle*.

The Characters are,

The flower has no empalement; it is bell-shaped, composed of six large petals, whose tails are joined, and six short reflexed stamina, terminated by small summits, and an oblong three-cornered germen, which is longer than the stamina, having no style, crowned by an obtuse stigma with three furrows. The germen afterward turns to an oblong three-cornered capsule, divided into three cells, filled with compressed seeds, lying over each other in a double arrangement.

The Species are,

1. *YUCCA foliis integerrimis.* *Vir. Cliff. 29.* *Yucca* with entire leaves; commonly called *Adam's Needle*.

2. *YUCCA foliis crenulatis strictis.* *Lin. Sp. Plant. 319.* *Yucca* with narrow leaves, which are slightly crenated.

3. *YUCCA foliis crenatis nutantibus.* *Lin. Sp. Plant. 319.* *Yucca* with nodding crenated leaves.

4. *YUCCA foliis serrato-filamentosis.* *Lin. Sp. Plant. 319.* *Yucca* with sawed thready leaves.

The first of these plants is a native of *Virginia* and other parts of *North America*.

This sort seldom rises with a stem above two feet high, which is garnished with leaves almost to the ground. The leaves are broad, stiff, and have the appearance of those of the *Aloe*, but are narrower, of a dark green colour, ending in a sharp black spine. The plants frequently produce spikes of flowers, which rise from the center of the leaves. The stalks grow three feet high, branch out to a considerable distance, but the flowers are placed very sparsely on the branches, which renders it less beautiful than the flowers of the other kinds; they are white within, but each petal is marked with a purple stripe on the outside, bell-shaped, and hang downward.

The second sort rises with a thick, tough, fleshy stalk to the height of ten or twelve feet, having a head or tuft of leaves at the top; these are narrower and stiffer than those of the former sort, and are of a lighter green colour; their edges are slightly sawed, and their points end with sharp thorns. The flower-stalk rises in the center of the leaves, and is from two to three feet long, branching into a pyramidal form. The flowers grow close on the branches, and form a regular spike; they are of a bright purple colour on the outside, and white within, making a fine appearance. The plants of this do not flower so often as the other sort; and when they flower, the head decays, but one or two young heads come out from the side of the stalk, below the old one.

The third sort grows naturally in *South Carolina*. The stalks of this sort rise about three or four feet high; the

Y U C

leaves are narrow, of a dark green colour, and hang downward; they are sawed on their edges, and end in acute spines. I never saw the flowers of this sort, but have been informed they are white.

The threaded sort is not so common as the others in the *English* gardens; but as it is a native of *Virginia*, it might easily be procured in plenty from thence. The stalk and leaves are like those of the first sort, but the leaves are obtuse, and have no spine at their ends. From the side of the leaves come out long threads, which curl and hang down.

All these plants are either propagated by seed, when obtained from abroad, or else from offsets or heads taken from the old plants, after the manner of *Aloes*.

When they are raised from seeds, they should be sown in pots, and plunged into a moderate hot-bed, where the plants will come up in five or six weeks after; and when they are two or three inches high, they should be transplanted each into a separate small pot, and plunged into the hot bed, where the plants should have air and water in proportion to the warmth of the season, and the bed wherein they are placed.

In *June* they should be inured, by degrees, to bear the open air; into which they must be removed, to harden them before winter, placing them in a well-sheltered situation, where they may remain until the beginning of *October*, when they must be removed into the green-house, where they may be arranged amongst the hardier sorts of *Aloes*, and should be treated in the same manner as hath been already directed for them; to which the reader is desired to turn for further instructions.

When these plants have acquired strength, those of the common sort, and also the threaded, may be afterwards turned out into a warm border, where they will endure the cold of our ordinary winters very well; but the other sorts must be kept in pots, that they may be sheltered in winter; and if they are treated in the same way as the large *American Aloe*, they will thrive very well.

The offsets taken from the old plants should be laid in a dry place, for a week or ten days before they are planted, that their wounds may heal, otherwise they will be subject to rot with moisture.

As the second and third sorts do not put out offsets so plentifully as the first, in order to propagate them, the heads of the plants may be cut off in *June*; and after the wounded part is dry, the heads may be planted, which will soon take root, provided the pots are plunged into a moderate hot-bed; and this cutting off the heads will occasion the stems to put out suckers, which they seldom do without until they flower; so that by this method the plants may be obtained in plenty.

Z.

Z E A

ZANTHOXYLUM. See Xanthoxylum.

ZEA. Lin. Gen. Plant. 926. Turkey Corn.

The Characters are,

It has male and female flowers situated at remote distances on the same plant. The male flowers are disposed in a loose spike, having oval, oblong, chaffy empalements, opening with two valves, each inclosing two flowers; these have two short compressed nectariums, and three hair-like stamina, terminated by quadrangular summits, which open in four cells at the top. The female flowers, which are situated below the male, are disposed in a thick spike, inclosed with leaves; these have thick chaffy empalements with two valves. The flowers are composed of two short membranaceous broad valves, which are permanent, and a small germen with a slender style, crowned by a single stigma, which is hairy toward the point. The germen afterward turns to a roundish compressed seed, angular at the base, and half inclosed in its proper receptacle.

The Species are,

1. ZEA caule altissimâ, foliis latioribus pendulis, spicâ longissimâ. Indian Corn with the tallest stalk, broader hanging leaves, and the longest spike.

2. ZEA caule graciliore, foliis carinatis pendulis, spicâ longâ gracili. Indian Corn with slenderer stalks, keel-shaped hanging leaves, and a long slender spike.

3. ZEA caule humiliori, foliis carinatis pendulis, spicâ breviori. Indian Corn with a lower stalk, hanging keel-shaped leaves, and a shorter spike.

These three species have been generally supposed but one, and only accidental variations; but from long experience I can affirm, they are different, and do not alter by culture.

The first sort grows naturally in the islands of the West-Indies; this hath a very large strong stalk, which rises to the height of ten or twelve feet. The leaves are long, broad, and hang downward; they have a broad white midrib. The male flowers come out in branching spikes at the upper part of the stalks; these are eight or ten inches long. The female flowers come out from the bottom of the leaves on the side of the stalk; they are disposed in a close, long, thick spike, and are covered closely with thin leaves; out of the end of the covers hang a small long bunch of filaments or threads, which are supposed to receive and convey the farina of the male flowers to the germen of the female. When the seeds of this sort are ripe, the spikes or ears are nine or ten inches long, and sometimes a foot; but these rarely ripen in England.

I have not seen any variety of colours in this species, though it is very probable there are the same varieties in the colour of the grain, as in the other species; but as this is less common in Europe, we are not so well acquainted with it.

The second sort is cultivated in Italy, Spain, and Portugal. The stalks of this sort are slenderer than those of the former, and seldom rise more than six or seven feet high. The leaves are narrower than those of the first sort, and are hollowed like the keel of a boat, and their tops hang downwards. The spikes of male flowers are shorter than those of the first, and the ears or spikes of grain are slenderer,

Z E A

and not more than six or seven inches long. The grains of this sort do not come to maturity in England, unless the season proves very warm; and the grains are planted early in a warm soil and situation.

The third sort is cultivated in the northern parts of America, and also in Germany. The stalks of this are slender, and seldom rise more than four feet high. The leaves are shorter and narrower than those of the two former; they are hollowed like the keel of a boat, and their tops hang down. The spikes of male flowers are short, and the ears or spikes of grain are seldom more than four or five inches long. This sort ripens its grain perfectly well in England, in as little time as Barley, so may be cultivated here to advantage.

There are several varieties of the two last species, which differ in the colour of their grain. The most common colour is that of a yellowish white; but there are some with deep yellow, others with purple, and some with blue grains; and when the different colours are planted near each other, the farina will mix, and the ears will have grains of several colours intermixed; but when the grains of the different varieties are planted at a proper distance from each other, the produce will be the same with the grains which were sown.

These plants are seldom cultivated in England for use, but in Italy and Germany it is the food of the poor inhabitants; as it is also in many parts of North America, where it is treated in the following manner:

They first dig the ground well in the spring, and after having made it level, they draw a line across the whole piece intended to be planted; then they raise little hills at about three or four feet distance, into each of which they put two or three good seeds, covering them about an inch thick with earth; then they move the line four feet farther, continuing to do the same through the whole spot of ground; so that the rows may be four feet asunder, and the hills three or four feet distance. Six quarts of this seed is generally allowed to an acre of land, which, if the soil be good, will commonly produce fifty bushels of Corn.

In the planting of this Corn, where they observe to plant the grain of any one colour in a field by itself, and no other coloured grain stand near it, it will produce all of the same colour again, as hath been affirmed by many curious persons who have tried the experiment; but, if the rows are alternately planted with the grain of different colours, they will interchange, and produce a mixture of all the sorts in the same row, and frequently on one and the same spike; and some do affirm they will mix with each other, at the distance of four or five rods, provided there is no tall fence or building between to intercept them.

There is nothing more observed in the culture of this grain, but only to keep it clear from weeds, by frequent hoeing of the ground; and when the stems are advanced, to draw the earth up in a hill about each plant, which, if done, will greatly strengthen them, and preserve the ground about their roots moist for a considerable time.

When

When the Corn is ripe, they cut off the stalks close to the ground, and after having gathered off the spikes of grain, they spread the stalks in the sun, to harden and dry, which they afterward use in the same manner as Reeds in *England* for making fences, covering sheds, &c. for which purpose they are very useful to the inhabitants of warm countries; and when there is a scarcity of forage, they feed their cattle with them green, as fast as the Corn is gathered off.

The Corn is ground to flour, and the poorest sort of people in *America*, and also in *Italy* and *Germany*, make their bread of this flour; and in many of the warmer countries, the inhabitants roast the whole spikes, and dress them many different ways, making several dishes of it; but this grain seldom agrees with those who have not been accustomed to eat it; however, in times of scarcity of other grain, this would be a better substitute for the poor than Bean-flour, or other sorts, which have been used in *England*, and at all times will be found a hearty food for cattle, hogs, and poultry; so that in light sandy lands, where Beans and Peas succeed not well, this grain may be cultivated to answer both purposes to advantage.

If this grain is cultivated by the horse-hoeing husbandry, it may be done at less expence than in any other method; for this is one of the plants which is more particularly adapted to this husbandry.

The time for sowing this Corn, is about the same as for Barley; in light warm land it may be sown the latter end of *March* or the beginning of *April*, but in cold ground the middle or end of *April* will be early enough, for the grain is subject to rot in cold land, especially if the season proves wet. When the large sorts are planted in a garden for curiosity, their seeds should be sown upon a moderate hot-bed the beginning of *March*; and when the plants are fit to remove, they should be transplanted on another moderate hot-bed to bring them forward; but they must not be kept too closely covered, for that will draw them up weak; therefore, when the weather is mild, they should be inured to bear the open air; and the middle of *May*, they should be taken up with balls of earth to their roots, and transplanted into a warm border at three or four feet distance, carefully watering them if the weather proves dry, until they have taken new root; after which they will require no other care but to keep them clean from weeds. If the season should prove warm, these plants will ripen the Corn late in autumn.

ZINNIA. *Lin. Gen. Plant.* 1161.

The Characters are,

The common empalement of the flower is imbricated with scales, and permanent, of a cylindrical oval form. The flower is composed of several funnel-shaped hermaphrodite florets, having each five short stamina, whose summits coalesce; the ray is composed of several large, spreading, female, half florets, which are permanent. The hermaphrodite florets have an oblong bearded germen with a slender style, crowned by two short reflexed stigmas; these florets are succeeded by oblong single seeds with two horns, which ripen in the empalement.

The Species are,

1. ZINNIA foliis oblongis oppositis sessilibus, calycibus ovato-cylindricis, radii plurimis dentatis. Zinnia with oblong leaves sitting close to the stalk opposite, an oval cylindrical flower-cup, and many indented rays to the flower.

2. ZINNIA caule erecto hirsuto, foliis ovato-lanceolatis sessilibus, floribus terminalibus. Zinnia with an erect hairy stalk, oval spear-shaped leaves sitting close to the stalk, which is terminated by a flower.

The first sort grows naturally in *Peru*; it is an annual plant, which rises from two to four feet high; the lower part of the stalk becomes ligneous in autumn. The branches come out opposite, and are garnished with oblong leaves,

which vary both in form and size: some are broad at their base, and terminate in acute points; others are of an oblong oval; they are smooth without foot-stalks, and placed opposite. The flowers are produced singly upon pretty long foot-stalks, most of them terminating the branches; but sometimes they rise from the division of the branches. The empalement of the flower is of a cylindrical form, composed of scales, lying over each other imbricated, closely inclosing several hermaphrodite florets, which form the disk, surrounded by half florets or rays, which are large, spread open, and of unequal number: in some flowers there are but five, in others ten or more, of a yellow colour, but afterward change to a brown, remaining till the seeds are ripe.

The second sort grows naturally in *Louisiana*; this is also an annual plant. The stalk is more erect than that of the former, as are also the branches; they are covered with soft hairs, and are channelled; the leaves are placed opposite; they are oval, spear-shaped, having three longitudinal veins, and are hairy. The flowers terminate the branches; the ray or border, which is composed of female half florets, spread open, and are of a deep gold colour on the upper side when first open, but afterward change to a dark copper, but on the backside of a pale straw colour. The florets which compose the disk are tubulous, and have five stamina stretched out beyond the corolla, whose summits which are yellow are connected; the half florets which compose the border or ray are permanent, remaining till the seeds are ripe, which are of the same structure with those of the former sort.

Both these plants are propagated by seeds, which must be sown upon a moderate hot-bed in *March*. When the plants come up, they must have air admitted to them by tilting of the lights of the bed every day when the weather is not too cold, otherwise the plants will draw up weak: when the plants are about an inch high, they should be planted on another hot-bed to bring them forward; but they should not be treated too tenderly, for they are very subject to grow too luxuriant in branches; and the first sort will not produce many flowers, if the plants are not stunted in their growth while young, which may be effected by planting them in small pots to confine their roots, otherwise the seeds will not ripen in *England*.

The second sort is much more prolific of flowers than the first, so may be treated with less care: these, when they have been brought forward on the hot bed, may be inured gradually to bear the open air in *May*, and in *June* should be transplanted into the borders of the flower-garden, where they will continue flowering all the summer, and will perfect their seeds very well; but the plants of the first sort should be placed either in the stove or a glass-case to obtain good seeds.

ZIZIPHORA. *Lin. Gen. Plant.* 33. Field Basil.

The Characters are,

The flower hath a long, rough, cylindrical empalement, which is slightly cut into five parts at the brim. The flower is of the labiated kind, having a long cylindrical tube. The upper lip is oval, reflexed, and entire; the under lip (or beard) is divided into three equal segments; it has two spreading stamina, terminated by oblong summits, and a quadrifid germen, supporting a bristly style, crowned by a sharp-pointed inflexed stigma. The germen afterward turns to four oblong seeds, which ripen in the empalement.

The Species are,

1. ZIZIPHORA capitulis terminalibus, foliis ovatis. *Lin. Sp. Plant.* 21. Field Basil with heads terminating the stalks, and oval leaves.

2. ZIZIPHORA floribus lateralibus, foliis lanceolatis. *Lin. Sp. Plant.* 21. Field Basil with flowers growing on the sides of the stalk, and spear-shaped leaves.

3. ZIZI-

3. *ZIZIPHORA foliis lanceolatis, floribus terminalibus.* Hort. Cliff. 305. Field Basil with spear-shaped leaves, and flowers terminating the stalks.

The first sort grows naturally in *Virginia*; this is an annual plant, which has a four-cornered stalk, sending out side branches, which stand opposite; these are terminated by a cluster of small flowers, surrounded by oval leaves, ending in acute points. The flowers have a slender cylindrical empalement, out of which they just peep; they are purple, of the lip kind, and have but two stamina.

The second sort grows naturally in the *Levant*; this sends up many slender ligneous branches, which rise near a foot high, garnished with spear-shaped leaves, about the size of those of Summer Savory, and have a scent like them. The flowers are produced in whorls round the stalks, which are like those of the former sort.

The third sort grows naturally on the *Alps* and *Appennine* mountains. The stalks of this rise about six inches high, garnished with small spear-shaped leaves placed opposite. The flowers are produced in a cluster at the top of the stalks, which are of the same shape and colour as those of the first sort, and are surrounded with spear-shaped leaves.

These plants are all of them annual, so are propagated only by seeds.

The seeds may be sown in a border of light earth, either in spring or autumn. Those plants which come up in autumn, will abide through the winter, and will grow much larger than those which come up in the spring; though neither of them rise very high. The seeds should be sown where the plants are to remain; for they do not thrive well when they are transplanted, unless the earth remains to their roots. These have a pretty strong aromack scent, somewhat resembling Summer Savory; but as they are plants of little beauty, they are seldom cultivated but in botanick gardens for sake of variety.

The seeds of those plants which come up in autumn, will be ripe in *July* or *August*; but those of the spring plants will not ripen till the latter end of *August*, or the beginning of *September*, when, if the seeds are permitted to scatter, the plants will come up, and require no farther care, but to clear them from weeds, and thin them where they are too close.

ZIZIPHUS. Tourn. Inst. R. H. 627: tab. 433. *Rhamnus.* Lin. Gen. Plant. 235. The Jujube.

The Characters are,

The flower has no empalement; it has one funnel-shaped petal, which spreads open at the top, and is cut into four or five segments; it has five awl-shaped stamina, whose base are inserted to the petal, and are terminated by small summits, and an oval germen, supporting two slender styles, crowned by obtuse stigmas. The germen afterward becomes an oblong oval berry, inclosing a single nut of the same form, which has two cells, each containing an oblong seed.

The Species are,

1. *ZIZIPHUS aculeis geminatis rectis, foliis oblongo-ovatis serratis.* Jujube with strait thorns growing by pairs, and oblong, oval, sawed leaves; or the common Jujube.

2. *ZIZIPHUS aculeis geminatis, altero recurvo, foliis ovatis nervosis.* Jujube with twin spines, one of which is recurved, and oval veined leaves; or the wild Jujube.

3. *ZIZIPHUS aculeis solitariis recurvis, pedunculis, aggregatis, foliis cordato-rotundis nervosis, subtus tomentosis.* Jujube with single recurved spines, foot-stalks in clusters, and round heart-shaped veined leaves, which are downy on their under side.

4. *ZIZIPHUS aculeis geminatis rectis, foliis ovatis nervosis.* Jujube with double strait thorns, and oval veined leaves.

The first sort grows naturally in the warm parts of *Europe*; it has a woody stalk, which divides into many crooked

irregular branches, which are armed with strong strait thorns set by pairs at each joint. The leaves are two inches long and one broad, slightly sawed on their edges, and stand upon short foot-stalks. The flowers are produced on the side of the branches, two or three arising from the same place, which sit close; they are small, and of a yellow colour; these are succeeded by an oval fruit, about the size of a middling Plum, of a sweetish taste, and are clammy, including a hard oblong stone, pointed at both ends.

The fruit of this tree was formerly used in medicine; it is reckoned pectoral, and good for coughs, pleurisies, and hot sharp humours, but is now seldom to be found in the shops. In *Italy* and *Spain*, this fruit is served up at the table in deserts during the winter season, as a dry sweetmeat.

The second sort grows naturally about *Tunis* in *Africa*; this has slender woody stalks, which send out many weak branches, covered with a grayish bark, and armed with spines, which come out by pairs at each joint, one of which is longer than the other, and is strait; the other is short and recurved. The leaves are small, oval, and veined; they are half an inch long, and as much in breadth, sitting close to the branches. The flowers of this sort I have not seen, so can give no farther description of this plant.

The third sort grows naturally in *India*; this rises with shrubby stalks ten or twelve feet high, sending out many slender branches, which have a yellowish bark, and are armed with single recurved thorns at each joint. The leaves are round, heart-shaped, about two inches long, and as much in breadth, and are indented at the foot-stalk; they have three longitudinal veins, and are covered with a yellowish down on their under side. The flowers come out in clusters from the wings of the branches; they are small, and of a yellowish colour; these are succeeded by oval fruit about the size of small Olives, inclosing a stone of the same shape.

The fourth sort grows naturally in *Syria*, from whence I have received the seeds; this sends up several shrubby stalks from the root, which divide into slender branches; these are armed with strait spines, which are set by pairs at each joint. The leaves are small, oval, and veined, and are placed alternate, standing upon very short foot-stalks. The flowers are small, of a yellow colour, arising at the wings of the branches. The fruit is round, and about the size of Sloes.

These plants are preserved in the gardens of some curious persons only for the sake of variety, for they do not produce fruit in *England*. The first and fourth sorts, which are the most hardy, will scarce live through the winters in *England*, even when they are planted against south walls; in which situation I have kept the plants two or three years, when the winters have proved mild, but they were afterward killed by a sharp frost. They may be propagated by putting their stones into pots of fresh light earth, soon after their fruits are ripe; and in winter they should be placed under a common hot-bed frame, where they may be sheltered from severe frost. In the spring these pots should be plunged into a moderate hot-bed, which will greatly forward the growth of the seeds; and when the plants are come up, they should be inured to the open air by degrees, into which they must be removed in *June*, placing them near the shelter of a hedge; and in very dry weather they must be frequently refreshed with water.

In this situation they may remain till the beginning of *October*, when they must be removed either into the greenhouse, or placed under a hot-bed frame, where they may be defended from frost, but should have as much free air as possible in mild weather.

During the winter season they should be now and then refreshed with water; but after their leaves are fallen (as they

they always shed them in winter), they must not be over watered, which would rot the tender fibres of their roots, and cause the plants to decay.

In *March*, just before the plants begin to shoot, they should be transplanted each into a separate small pot, filled with light fresh earth; and if they are plunged into a moderate hot-bed, it will greatly promote their taking root; but in *May* they must be inured to the open air by degrees, into which they should be soon after removed.

Thus these plants should be managed while young, at which time they are tender; but when they are three or four years old, some of them may be planted in the full ground, against a warm wall or pale, where, if they have a dry soil, they will endure the cold of our ordinary winters pretty well, but in hard frosts they will require to be sheltered, so it will be proper to keep a plant or two in pots, which may be housed in winter.

These plants may be also propagated by suckers, which the old ones many times send forth from their roots; but these are seldom so well rooted as those produced from seeds, nor do they make so good plants, for which reason they are but rarely propagated that way.

The second sort is not so hardy as the first, so these plants must be kept in pots, and in the winter placed into the green-house, and treated in the same way as other hardy exotick plants, being careful not to over-water them at that season, but especially when they have shed their leaves.

This sort is propagated by seeds, which must be procured from the country where it naturally grows; these should be sown in pots filled with light earth, and plunged into a hot-bed of tanners bark, which will bring up the plants in about six weeks, if the seeds are good. When the plants begin to advance in height, they should be gradually hardened, and in *June* they may be placed in the open air in a sheltered situation; but in autumn they must be removed into shelter, where they must remain all the winter; and in the spring, before the plants begin to push out their leaves, they should be carefully transplanted each into a separate small pot, and plunged into a gentle hot-bed to forward their putting out new roots. In summer they must be exposed abroad, but in winter they must be housed.

The third and fourth sorts are tenderer than the former, so will not thrive in this country unless the plants are kept in a warm stove. These are propagated in the same way as the former, but the plants must be more tenderly treated, for they should not be wholly exposed abroad at any time of the year; in summer they must have a large share of air in warm weather, and in winter they must be kept in a warm stove.

ZYGOPHYLLUM. *Lin. Gen. Plant.* 474. *Fabago*. *Tourn. Inst. R. H.* 258. *tab.* 135. Bean Caper.

The Characters are,

The empalement of the flower is composed of five oval obtuse leaves. The flower has five obtuse petals, which are longer than the empalement, and are indented at their points; it has a closed nectarium, which includes the germen, composed of several scales or little leaves, to which the bases of the stamina are fastened; it hath ten awl-shaped stamina, terminated by oblong summits, and an oblong germen, supporting an awl-shaped style, crowned by a single stigma. The germen afterward becomes an oval five-cornered capsule with five cells, containing several roundish seeds.

The Species are,

1. ZYGOPHYLLUM *capsulis prismaticeo-pentandris*. *Hort. Upsal.* 103. Bean Caper with a prismatical capsule and five stamina.

2. ZYGOPHYLLUM *capsulis globoso-depressis*. *Lin. Sp. Plant.* 385. Bean Caper with globular depressed capsules.

3. ZYGOPHYLLUM *capsularum angulis compresso-membra-*

naccis. *Lin. Sp. Plant.* 385. Bean Caper with compressed membranaceous angles to the capsules.

4. ZYGOPHYLLUM *capsulis ovatis acutis*. *Lin. Sp. Plant.* 386. Bean Caper with oval acute-pointed capsules.

The first sort grows naturally in *Syria*; this has been long an inhabitant of some curious gardens in *England*. The root is thick, fleshy, and strikes deep into the ground, and will grow as thick as a man's arm when old. The stalks decay every autumn to the root, from which spring new shoots every year, in number proportional to the size of the root; they rise three or four feet high, sending out a few side branches; these are smooth, green, and jointed; they are garnished with smooth fleshy leaves like those of Purslane, two standing together upon the same foot-stalk, which is an inch long; they are of a bluish green colour. The flowers are produced from the wings of the stalk, two or three arising at the same joint upon short foot-stalks; they are composed of five roundish concave petals, of a reddish colour on their outside, and ten stamina, which are twice the length of the petals. The flowers are succeeded by oblong prismatical capsules with five sides, which have cells filled with roundish seeds. This sort flowers in *June* and *July*, and the seeds ripen in autumn.

The second sort grows naturally at the *Cape of Good Hope*. This rises with a thick woody stalk three or four feet high, sending out many branches, which are garnished with succulent leaves, placed by fours sitting close to them. From the wings of the stalks the flowers are produced upon pretty long slender foot-stalks; they are composed of five sulphur-coloured petals, which have a brown spot on each of their tails; these are succeeded by roundish depressed fruit, having five cells, each containing two roundish seeds. This plant continues flowering all summer and autumn, and the seeds ripen in winter.

The third sort grows naturally at the *Cape of Good Hope*; this has a shrubby stalk, which divides into many irregular jointed branches, which rise four or five feet high, and are garnished with thick succulent leaves, which are larger and more obtuse than those of the second sort; they are placed by fours at each joint, two on each side the stalk opposite. The flowers come out from the wings of the stalk upon slender foot-stalks; these have but four petals, which are broader than those of the second sort, but of the same colour, each having a brown spot at their tails. The fruit has four broad membranaceous wings to it, resembling the sails of a mill. This plant flowers most part of summer, but the fruit seldom ripens well in *England*.

The fourth sort is a native of the *Cape of Good Hope*. The stalks of this branch out greatly from the bottom; they are shrubby, jointed, and irregular. The leaves are of the consistence of those of Purslane; they are narrow at their tails, but oval toward their points, and are placed by fours at each joint like the former. The flowers come out from the wings of the stalk upon slender foot-stalks; they are of a pale yellow colour, each petal having a pretty large red spot at their tails. The fruit is oval, about three quarters of an inch long, having five deep furrows, and is divided into five cells, which are filled with roundish seeds. This plant flowers great part of the year, and the fruit ripens in autumn and winter.

The first sort is propagated only by seeds, which ripen very well in *England* in warm seasons; these may be either sown upon a moderate hot-bed in the spring, or on a warm border of light ground; those which are sown upon the hot-bed will come up in three weeks or a month; and about a month after, the plants will be fit to remove, when they should be each planted in a separate small pot, filled with fresh light earth, and plunged into a gentle hot-bed to promote their taking root, and shaded from the sun in the day time;

time; afterward they must be gradually hardened to bear the open air, to which they should be exposed all the summer; but in autumn, when their stalks begin to decay, they should be placed in a hot-bed frame to shelter them from the frost in winter, for while they are young they are a little tender. The spring following they may be turned out of the pots, and planted in a south border close to the wall, in a dry rubbishy soil, where they will endure the cold without covering. There is a plant of this kind in the *Chelsea* garden, which is near fifty years old, and has resisted the severest cold without any covering, and produces great plenty of flowers and fruit annually.

Those plants which come up in the full ground, will require no other care but to keep them clean from weeds, and thin them where they come up too close, giving them room to grow the first year; and when their stalks decay in autumn, the surface of the ground should be covered with tan to prevent the frost from penetrating to the roots, or in frosty weather, they may be covered with Straw or Peas haulm, which will answer the same purpose; and in the spring, the roots should be carefully taken up, planting them close to a warm wall, as was before directed.

The other three sorts are too tender to live through the winter in the open air in this country, so they must be kept in pots, and housed in autumn. These plants may be propagated either by seeds or cuttings.

The second and fourth sorts ripen their seeds pretty well in *England*, so these may be propagated by sowing them on a moderate hot-bed in the spring; and when the plants are

about an inch high, they should be each transplanted into a small pot filled with light earth, and plunged into a moderate hot-bed, shading them from the sun till they have taken new root; then as the season advances, they should be gradually hardened to bear the open air, into which they should be removed the latter end of *May*, placing them in a warm sheltered situation, where they may remain till autumn, when they should be placed in an airy dry glass-case, where they will succeed better than in a greenhouse; for they require a large share of air in mild weather, otherwise their shoots are apt to be weak and tender, so are often injured by damp air in winter; but they do not require any artificial heat. If they are screened from the frost, and have plenty of air, they will thrive very well.

The third sort seldom produces good seeds in *England*, so is propagated by cuttings, and the two others are generally increased in the gardens the same way, that method being very expeditious, though the seedling plants grow stronger, and rise to a greater height. These cuttings may be planted in a bed of light earth during any of the summer months; if these are covered close down with bell or hand-glasses, and shaded from the sun, they will put out roots in five or six weeks, and then they may be taken up carefully and potted, placing them in the shade till they have taken new root; after which they may be removed to a warm sheltered situation, and treated in the same way as those plants raised from seeds.

ZYLOSTEUM. See *Lonicera*.

F I G U R E S

Of the most BEAUTIFUL, USEFUL, and UNCOMMON

P L A N T S

DESCRIBED IN THE

GARDENERS DICTIONARY,

EXHIBITED ON

Three Hundred COPPER PLATES,

Accurately ENGRAVEN after DRAWINGS taken from NATURE.

WITH

The CHARACTERS of their FLOWERS and SEED-VESSELS, Drawn when they were in their greatest Perfection.

To which are added,

Their DESCRIPTIONS, and an ACCOUNT of the CLASSES to which they belong, according to *Ray's*, *Tournefort's*, and *Linnaeus's* Method of Classing them.

BY PHILIP MILLER, F. R. S.

Member of the Botanick Academy at *Florence*, and Gardener to the Worshipful Company of APOTHECARIES, at their Botanick Garden at *Chelfea*.

Printed for the Author, and Sold by JOHN RIVINGTON, A. MILLAR, H. WOODFALL, J. WHISTON and B. WHITE, J. HINTON, G. HAWKINS, W. JOHNSTON, T. LONGMAN, T. CASLON, C. RIVINGTON, J. DODSLEY, and M. RICHARDSON.

EXTRACT from the PREFACE.

THE Author, in the Execution of this Work, confined his Plan to those Plants only, which are either curious in themselves, or may be useful in Trades, Medicine, &c. including the Figures of such new Plants as have not been noticed by any former Botanists, by which all those Genera of Plants, which do not include any Species having one or other of these Properties, are omitted.

In the Execution of the Work no Expence has been spared to render it as perfect as possible: The Drawings were taken from the living Plants; the Engravings were most of them done under the Author's Inspection; and the Plants have been carefully coloured from the original Drawings, and compared with the Plants in their Perfection, wherever it could be done, as well with regard to the Leaves as Flowers, that so Gentlemen who are least conversant with the Plants described, should not be drawn into any Mistake relating to them; and the less, as he has taken their Descriptions from the living Plants.

To these Figures are added the Characters of the Genus, under which each Plant is ranged, and an Account of the Classes to which they belong, according to *Ray's*, *Tournefort's*, and *Linnaeus's* Methods of classing them; and also the several Titles which the different Writers on Botany have given to them, with References to the several Books wherein they are mentioned.

The *English* Names (of those Plants which have any) are subjoined to the *Latin* Titles, for the Benefit of such as are unacquainted with *Latin*, and to these are added the *French* Names from *Tournefort's* Institutions of Botany: And mention is also made of the Countries from whence the Plants have been brought to *England*, which will be of some Use to those who are inclinable to cultivate them. And where any of the Plants here figured are of Use in Medicine, or for other Purposes of Life, the Uses are here inserted, with the Times of their Flowering, and perfecting their Seeds: So that, although this Work was intended for an Appendix to the GARDENERS DICTIONARY, yet it may be reckoned a complete Performance of itself, independent of that.

The following is an Alphabetical List of the *English* Names of the PLANTS, engraved and described in the above-mentioned Work.

T H E

ENGLISH NAMES of the PLANTS

Engraved and Described in the above-mentioned W O R K.

A Cacia, without Thorns
 Acacia, the American
 Acacia, the Narrow-leaved
 Acacia, the False
 Adonis Flower
 Agave
 Agrimony
 Agrimony, the Waterhemp
 Alkanet
 Almond-tree
 Aloe, African
 Amaranthus, spiked
 Amaryllis
 Anemomy
 Arctotis
 Arsmart
 Arum
 Astarabaca common
 Asparagus
 Asphodel
 Balsamine, Female
 Barbadoes Cherry
 Barberry Bush
 Barrenwort
 Bacteria
 Bastard Lychnis
 Bastard Asarum
 Baulm, the Turkey
 Bean Caper
 Bear's Breech
 Bear's Ear
 Bindweed
 Bird Cherry
 Bird's Eye
 Bird's Foot Trefoil
 Birthwort
 Bishop's Weed
 Bitter Vetch
 Bladder Pea
 Bladder Sena
 Blue Bottle
 Borage
 Boxthorn
 Boxthorn
 Briony white
 Broom
 Broom, the Green
 Browallia
 Bugloss
 Bulbocodium
 Burdock
 Calve's Snout
 Cammock
 Campion
 Cassidony

Cassioberry
 Catchfly
 Caterpillar
 Celandine
 Centaury
 Chaste-tree
 Cheese-Runnet
 Chelone
 Cherry
 Chesnut
 Chickling Pea
 Chickweed, Berry-bearing
 Chrysanthemum Hardseeded
 Climber
 Clethra
 Cnicus
 Colutea, joint-podded
 Colutea Shrubby, jointed-podded
 Columbine
 Convolvulus, Scarlet
 Corn Flag, Strange
 Corn Flag, greater Byzantine
 Corn Flag, African
 Corn Flag, African
 Corn Flag
 Cotton Weed
 Cowslip Chickweed
 Cranebill
 Crowfoot
 Crown Imperial
 Cuckow-Pint
 Cunonia, the Scarlet
 Custard Apple
 Daffodil Sea
 Daffodil Lily
 D'Ayena, Smooth
 Date Plum, Indian
 Dead Nettle
 Dianthus
 Diervilla
 Diosma
 Dittany, the White
 Dodartia
 Dogbane
 Dogbane upright
 Dogwood
 Dragon
 Dragon's Head
 Dropwort
 Dwarf Cistus
 Ebony-Mountain
 Elder
 Emony
 Eternal Flower
 Eupatorium of the Greeks

Felwort
 Fennel Flower
 Ferrara
 Field Basil
 Figwort
 Fir, or Spruce-tree
 Flax
 Fleabane
 Flower de Luce
 Flower Gentle
 Foxglove
 Fraxinella
 Fumitory, the podded
 Fumitory
 Furze
 Gentian
 Germander
 Gilliflower
 Globe Amaranthus
 Globe Thistle
 Goats Rue
 Golden Rod
 Goldylocks
 Groundsel
 Gundelia
 Hare's Ear
 Hartwort
 Hatchet-vetch
 Hawkweed
 Hawkweed, Greater
 Hawthorn
 Hellotrope
 Hellebore, the Bastard
 Hellebore, the White
 Hemp
 Henbane
 Holly-tree
 Honeyfuckle
 Honeyfuckle, the Upright
 Honeyly
 Honeywort
 Horse Chesnut, the Scarlet
 Hyacinth Eastern
 Hyacinth, the Tuberose
 Hydrangea
 Hypecoon
 Jasmine
 Jasmine, the Persian
 Jerusalem Sage
 Jersey Tea
 Immortal Flower
 Indian Fig
 Indigo Bastard
 Indigo
 St. John's Wort

ENGLISH NAMES of the PLANTS.

Ironwood	Nightshade, the Deadly	Spiræa
Judas-tree	None so pretty	Spotted Sanicle
Ixia	Oak	Staff-tree
Kingspear	Oil-feed	Star of Bethlehem
Knapweed	Orpine, the Lesser	Starwort Carolina
Knapweed	Othonna	Starwort American
Ladies Bedstraw	Ox-eye	Storax-tree
Ladies Slipper	Parsley, the Bastard	Strawberry
Larkspur, Great Bee	Pellitory of Spain	Strawberry-tree
Larkspur taller, perennial	Pentapetes	Sumach, the Venetian
Lavatera	Perriwinkle	Sun-flower, the Dwarf
Lavender Cotton	St. Peter's-wort	Swallow-wort
Laurel, the Rose, or Mountain	Pheasant's Eye	Sweetwilliam
Leopards-bane	Phlox	Tacamahac-tree
Lettuce	Phytolacca	Tamarisk
Lilac	Pine-tree	Tame Poison
Lily	Pink	Ttr agonia
Lily Asphodel	Piony	Thistle, the Torch
Lily Daffodil	Pipe-tree	Thistle, Melancholy
Lily, the Mexican	Pipperiſh Bush	Thistle, the Golden
Lion's Tail	Poke. or Pork Phyſic	Thistle, Woolly
London Pride	Poyanthes	Thorn, the Egyptian
Lungwort	Pomegranate	Toad-flax
Lupine	Poppy, the Prickly	Tobacco
Madwort	Poppy the Horned	Trefoil, the Bean
Magnolia	Primrose-tree	Trefoil, Carolina Shrub
Malabar Nut	Privet	Trefoil, Star-headed
Mallow, the Yellow Marsh	Punica	Triumfetta
Mallow, the Vervain	Quince	Trumpet-flower
Malpighia	Ranunculus	Tulip-tree, the Laurel-leaved
Mandrake	Ragwort foreign	Turnera
Mantle, Ladies	Raspberry	Turnſole
Maple-tree	Reitharrow	Tyger flower
Marigold	Rhubarb	Valerian, the Greek
Marigold, the Fig	Rocket, the Bastard	Venus Navel-wort
Martynia	Rock-Rose	Vetch Kidney
Maſtick tree, Indian	Rose	Vetch, the Chickling
Maudlin	Saffron	Vetch, the Horſe-shoe
Meadia	Sage	Vetchling
Meadow Rue	Sawwort	Wake-Robin
Meadow-sweet	Saxifrage	Warneria
Medlar	Self-heal	Water Apple
Melon, the Water	Senna, the wild	Watſonia
Mefembryanthemum	Senna, the Bladder	Watſonia, Dwarf
Milk-vetch	Senna, the Scorpion	Water Lily
Monarda	Senſitive Plant	Wayfaring-tree
Monk's Hood	Side-faddle Flower	Whin, Petty
Morea	Snake Gourd	White Satin
Moon Trefoil	Snakeweed	Widow-wail
Motherwort	Snapdragon	Wild Service
Moonwort	Solomon's Seal	Winter Cherry
Mullein	Sour Sop	Wolfsbane
Mullein, the Moth	Southernwood	Wood ſorrel
Myrtle	South-Sea Tea	Woundwort
Nettle-tree	Sowbread	Yellow Root
Nightshade	Spiderwort	Zerumbeth

This Work was published in Fifty Numbers, Price Five Shillings each, coloured, or Two Shillings and Six-pence plain: And as there may be many Persons who would be glad to be in Possession thereof, who do not chuse to purchase it altogether, on Account of the Price, it may be bought by a single Number once a Week or Month, or at such other Times as suits any Gentleman and Gardeners Conveniency to purchase it.
