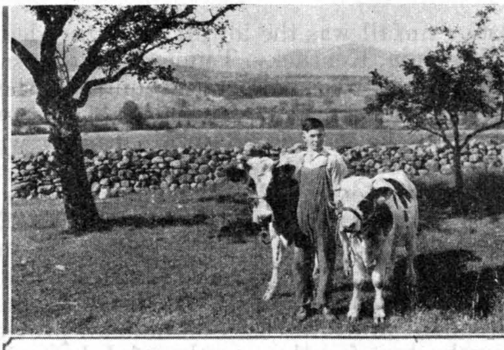
Secretary of Agriculture	ARTHUR M. HYDE.
Assistant Secretary	R. W. DUNLAP.
Director of Scientific Work	A. F. WOODS.
Director of Regulatory Work	WALTER G. CAMPBELL.
Director of Extension Work	C. W. WARBURTON.
Director of Personnel and Business Administration	W. W. STOCKBERGER.
Director of Information	M. S. EISENHOWER.
Solicitor	E. L. MARSHALL.
Weather Bureau	CHARLES F. MARVIN, *Chief.*
Bureau of Animal Industry	JOHN R. MOHLER, *Chief.*
Bureau of Dairy Industry	O. E. REED, *Chief.*
Bureau of Plant Industry	WILLIAM A. TAYLOR, *Chief.*
Forest Service	R. Y. STUART, *Chief.*
Bureau of Chemistry and Soils	H. G. KNIGHT, *Chief.*
Bureau of Entomology	C. L. MARLATT, *Chief.*
Bureau of Biological Survey	PAUL G. REDINGTON, *Chief.*
Bureau of Public Roads	THOMAS H. MACDONALD, *Chief.*
Bureau of Agricultural Economics	NILS A. OLSEN, *Chief.*
Bureau of Home Economics	LOUISE STANLEY, *Chief.*
Plant Quarantine and Control Administration	LEE A. STRONG, *Chief.*
Grain Futures Administration	J. W. T. DUVEL, *Chief.*
Food and Drug Administration	WALTER G. CAMPBELL, *Director of Regulatory Work, in Charge.*
Office of Experiment Stations	——————, *Chief.*
Office of Cooperative Extension Work	C. B. SMITH, *Chief.*
Library	CLARIBEL R. BARNETT, *Librarian.*

FOREWORD

FARMERS and research workers are partners in the task of shaping the agricultural industry to the most profitable and desirable ends. Each group must therefore maintain close contact with the other. This Yearbook, the fifth in a series of volumes similarly planned, is designed to facilitate that contact by reporting, in short popularly written articles, the results of research and service activities conducted by the United States Department of Agriculture. It deals also with the administrative responsibilities entrusted to the department under various Federal laws. ¶For farmers information about what the department is doing has a threefold value. First, it assists research, because the farm is the natural laboratory of the agricultural scientist; farmers who understand the method and purpose of scientific research are its most efficient support. Secondly, science discovers short cuts to the knowledge required in adapting agriculture to its constantly changing natural and economic environment. In a stable situation experience alone would eventually perfect an adequate technique. But no situation is stable. In a rapidly changing situation, like that with which farmers have had to deal since the war, blind groping is too slow and costly a method of initiating necessary modifications in farm practices. Science, through observation and experiment under controlled conditions, establishes principles whereby the risks of experimentation may be minimized. Thirdly, information about agricultural science is necessary to farmers, because without it the progress of knowledge may actually injure them. Nowadays scientific discoveries soon become known throughout the world. If not used in the country of their origin, they are used to its prejudice by competing countries. This is particularly true of the results of economic investigations. Changes on both the demand and the supply side of the agricultural markets throw certain types of farming or combinations of crops into the discard and put a premium on others. Timely notice of these changes is indispensable to farmers who wish to direct their efforts into profitable channels and thus to avoid useless struggles. ¶In the articles which comprise the section of this Yearbook entitled "What's New in Agriculture," the reader will find brief accounts of many of the research projects in which the department is engaged. More detailed information may be obtained in other department publications, through correspondence with members of the department's staff, or by consulting extension agents. ¶As usual, the volume contains the Annual Report of the Secretary to the President and a compilation of the principal agricultural statistics. Nonagricultural readers will find much of interest in the Yearbook, because the department has manifold activities of importance to everyone.

ARTHUR M. HYDE,
Secretary of Agriculture.

CONTENTS



THE YEAR IN AGRICULTURE

THE SECRETARY'S REPORT TO THE PRESIDENT

WASHINGTON, D. C., *November 15, 1930.*

To the PRESIDENT:

THE 1930 DROUGHT

The worst drought ever recorded in this country prevailed during much of the 1930 crop-growing season and greatly reduced farm production. Widespread droughts occurred in 1881, 1894, 1901, 1911, 1916, and 1924. These, however, did not equal the drought of the present year in duration, in the extent of the areas covered, in deficiency of precipitation, or in severity. In 1881 June was very dry in the Southwest, and July and August in the central valleys and in the East. Droughty conditions in 1894, though severe, were confined to the central valleys and the Northwest. In 1901 the central valleys, especially the western Corn Belt, suffered most. In 1911, the greatest shortage in precipitation occurred rather early in the season. The droughts of 1916 and 1924 covered comparatively small areas.

Up to the 1st of September, 1930, an area in the Middle Atlantic States, comprising mainly Maryland, Virginia, and West Virginia, had deficient precipitation every month from December, 1929. Over much of the interior of the country, especially in the Ohio and middle Mississippi Valleys, the drought persisted for six months, from the 1st of March to the 1st of September. For the spring season, March to May, the driest States were those in the Potomac, Ohio, and middle Mississippi Valleys. In June the drought area extended to the South Central States, especially those in the lower Mississippi Valley. In July the drought was severe in most States east of the Rocky Mountains. August was deficient in precipitation in most sections until about the middle of the month. Thereafter scattered rains partly relieved conditions over an area comprising principally South Dakota, Nebraska, and much of Kansas. Toward the end of August, however, the drought was intensified in some Northern and Southeastern States that had not previously been severely affected.

Precipitation in the spring (March to May) was the lowest of record in West Virginia, Kentucky, Indiana, Illinois, and Missouri. Only Florida and Nebraska had a rainfall equal to the normal rainfall for the entire area east of the Rocky Mountains. The summer

(June to August) rainfall was the lowest ever recorded in Maryland, Virginia, West Virginia, Kentucky, Tennessee, Arkansas, and Mississippi. In 15 States east of the Rocky Mountains, the average was little more than half the normal. In general, July was the driest and hottest month of the season. Rainfall in July was deficient in all States east of the Rocky Mountains, except New England and Georgia. The deficiency exceeded all previous records in Maryland, Virginia, West Virginia, Ohio, Kentucky, Illinois, Missouri, and Arkansas, and averaged only about one-third of the normal. Some other important agricultural States had the driest July in more than 30 years. On the other hand most of the Rocky Mountain area had an unusually abundant rainfall. In Colorado all previous high rainfall records were broken for the months of July and August combined. In Wyoming the August rainfall exceeded the previous maximum for that State by more than 50 per cent.

River stages showed the severity of the drought. Low river stages are not unusual for July and August in the Missouri Basin above Pierre, S. Dak., and that part of the upper Mississippi Basin above the Iowa-Minnesota line. In the remainder of the drainage area of the Mississippi River system, however, and on the Atlantic slope of Pennsylvania, Maryland, Virginia, and North Carolina, the dry weather was plainly reflected in low-water stages. Many of the small streams in the Missouri Basin became dry. In the rest of the drought area all streams were either as low as they had ever been in August, or were very close to the low record.

Wells failed; water for stock was scarce; and in some places sewage disposal became an acute problem. Hydroelectric plants on large streams did not suffer, but some plants on the smaller streams had to shut down. Navigation on rivers controlled by locks, dams, and so forth was not interrupted, but on the Mississippi, especially north of Cairo, low water made it necessary materially to decrease the length of tows. This was a serious interruption to navigation.

What caused the drought is a question that can not as yet be answered. All that can be said is that there was a prolonged stagnation of the air over nearly the whole continental extent of the United States. In ordinary years this great blanket of atmosphere overlying the continent is in more or less active circulation. Cool air from the polar regions moves southward from time to time. This circulation was especially absent this summer. Warm air from the tropical latitudes moves northward at intervals. Air from the oceans and from the Gulf of Mexico moves inland. There is a more or less active and continuous interchange of these different air masses which causes the favorable conditions that usually prevail. This interchange did not occur for a long time during the present great drought. Occasional showers and thunderstorms here and there seemed only to dry out the overlying air masses. Only a part, at best, of the water thus precipitated is evaporated back into the free air. With little or no new moisture borne in by winds from the oceans, each successive inland shower, coupled with the stagnation and absence of general rain-causing processes, tended further to deplete the moisture supply and intensify the drought. The lack of precipitation permitted the culmination of excessive temperatures, which are normally at their maximum over most of the United States about the last week of July.

EFFECTS OF THE DROUGHT

Only in North Dakota, Montana, Oklahoma, Texas, and New Mexico, did the drought come early enough to reduce seriously the yields of wheat, oats, or barley. These crops, taking the country as a whole, yielded somewhat more than the usual average. Irrigated crops, such as sugar beets and some fruits largely grown outside the drought area, also produced well. Practically all nonirrigated crops growing late in the season, however, were affected, particularly the feed crops. Hay and pasturage suffered greatly. About 30 States, including all those in the great central area extending from Virginia to Montana and from Pennsylvania to Texas, were hard hit. In many localities farmers have little to sell and will be obliged to practice strict economy in their livestock feeding. In some parts of the country, thousands of farm families will suffer privation. Unhappily, moreover, the cut in farm production coincided with a sharp decline in the demand for farm commodities, and consequently in the farm-commodity price level. This development, a result of world-wide economic depression, bore heavily upon farmers outside the drought areas as well as upon those within it. Only in the case of a few commodities was the drop in production partly compensated by a rise in prices. Farm-commodity prices as a group slumped toward the end of the season to the lowest point in 15 years. Hence, the immediate economic consequences of the drought fell predominantly on the farmers. They were not shared to any great extent by the consuming public. Perhaps the farm-commodity price level would have gone lower under the shock of the world depression had farm production in this country been normal. In the case of some crops sold on the world market, prices are not greatly affected by variations in the production of the United States. Commodities produced and sold on a domestic basis usually respond quickly to changes in domestic supply conditions. One thing is clear. The demand for farm commodities fell off more than the supply did. Hence, the drought though it may have retarded the decline of prices, did not, except in the case of a very few commodities, cause any advance. Eventually the shortage of feed for livestock may reduce the supply of meat products and bring about a rise in the prices of those commodities, but no such results are noticeable as yet. Some areas not affected, or little affected, by the drought are finding wider markets for their products than they would otherwise have had. Local benefits of that sort, however, can not be set down on the credit side of the agricultural ledger, because they are merely the reverse side of distress and difficulty elsewhere. Through an unusual combination of economic circumstances, the effects of the drought were heavily concentrated upon agriculture instead of being rather widely diffused, as usually happens when serious crop shortages occur.

DROUGHT RELIEF

On August 14, at a conference of governors of drought-stricken States called by you, it was agreed that a committee representing the various Federal agencies concerned should be organized, that State drought committees should be set up, composed of State officials and farmer, banker, and Red Cross representatives, and that county committees should be organized in each county seriously affected by the drought. These county committees were to survey their local situations and determine the extent and character of the needs. At your request I have served as chairman of the Federal Drought Relief Committee, and much of the work of the committee has been done by members of the staff of the Department of Agriculture, to which representatives of several other departments have contributed materially. The State and county committees were set up promptly in most of the States and in general have been active where definite need has existed. Surveys of needs are still in progress.

The State committees were urged to give consideration particularly to credit needs of farmers for funds to finance necessities for their families, for feed for livestock, and for financing crop production. At a meeting of banker representatives of the State committees on August 27, recommendation was made for the setting up of agricultural-credit associations where normal financial agencies are not in position to furnish credit to those who can offer tangible security as a basis for loans. Some of the States decided that they had no need for such associations, while others have taken or are taking active steps looking toward their organization.

The railroads have cooperated by granting reduced rates on the movement of hay, feed, and water into drought-stricken counties, and livestock out of such counties into sections where feed is available. These rates were put into effect during the latter half of August to continue until October 31. They were later extended to November 30.

The Department of Agriculture assumed the responsibility for (1) determining the counties in which drought damage had been sufficiently severe to justify the granting of these rate reductions to farmer-consumers, and (2) issuing certificates recommending the granting of the rate reductions on specific shipments to farmer-consumers, or dealers. Several hundred counties were certified as in need of this aid, on the basis of telegraphic advice from county extension agents regarding needs and on crop conditions shown in the August crop report. About August 15 a special questionnaire on the condition of pasture, feed crops, and corn was sent to 108,000 crop correspondents in the drought-stricken States. Additional counties were certified to receive the reduced rates on the basis of the information contained in these questionnaires. In general, certification was made only of those counties that showed a condition of pastures, corn, and feed crops of not more than 50 per cent of normal. Altogether, 1,017 counties in 21 States were certified to the railroads to receive the rate reductions. The list included all or a large part of the counties in the States of Maryland, Virginia, West Virginia, Kentucky, Tennessee, Mississippi, Missouri, Arkansas, Louisiana, and Oklahoma, with considerable numbers in Ohio, Illinois, Indiana, Alabama, Texas, and Montana, and a few in Pennsylvania, North Carolina, Georgia, New Mexico, and Wyoming.

The rate reductions were made available on direct shipments to individual farmers or groups of farmers whose feed supply and pastures had been seriously depleted by the drought and who were in need of assistance, and also to dealers who agreed to sell to such farmers and to pass on to them the advantage of the reduced rates. Certificates covering the movement of many thousand cars of hay and feed have been issued, and material relief has been given the farmers over a wide area.

To aid in providing employment in the drought-stricken States, the Federal-aid road authorizations for the fiscal year 1932 were made available for the making of contracts for construction, and, under certain limitations, arrangements were made for payments on such contracts. As yet, however, comparatively little has been done in the utilization of these funds.

The cooperation of wood-using industries, particularly the railroads and the cooperage industry, was requested in making purchases of ties, timber, and stave bolts from farmers owning wood lots in the drought area. Extension agents assisted in the location of available supplies of feed, and a special letter on feed and livestock market conditions was sent weekly to these agents by the Bureau of Agricultural Economics. That bureau also gathered and distributed information on the location of feed and hay surpluses. The planting of fall pasture crops and gardens was urged, and in certain States loans were made to farmers to assist them in planting such crops. In other States seriously affected by drought, in which the seed loan appropriation was not available, the American Red Cross cooperated by giving seed rye for pasture to farmers who were unable to obtain it, and also by distributing seed for fall gardens.

Extension agents have called the attention of farmers to the need for saving available surpluses of seed for farm crops, particularly corn, and have suggested to farmers outside the area seriously affected by drought the desirability of saving extra supplies of seed corn, with a view to having supplies available for the drought area next spring. Home-demonstration agents not only urged the planting of fall gardens and the preservation for winter use of all available surpluses of vegetable crops, but demonstrated the canning of beef and poultry, thus aiding in saving for food many animals which otherwise would have been sacrificed for lack of feed and water. These agents have also cooperated with public-health agencies and the Red Cross in assisting rural women to make the best possible use of available food supplies or of funds for their purchase, particularly with a view to prevention or control of nutritional diseases such as pellagra.

EMERGENCY LOANS TO FARMERS

Following severe damage to crops by storms and floods in the Southeastern States, Congress early in 1929 made $6,000,000 available to the department for emergency loans to farmers for seed, feed, and fertilizer. About $5,550,000 was loaned in Virginia, North Carolina, South Carolina, Alabama, Georgia, and Florida on staple crops. About $200,000 was loaned in southern Florida on vegetables. By June 30, 1930, $4,580,683 had been repaid. This is an excellent record, especially in view of the stringent financial conditions that prevailed in the area and the low prices received by the growers there for the principal crops. This year Congress appropriated an additional $6,000,000 for emergency loans to farmers in drought, storm, or flood stricken areas. The amount became available by the approval of the first deficiency act of March 26, 1930. From this fund loans were made to other farmers in the six States already mentioned, and crop financing was aided in Indiana, Illinois, Missouri, Oklahoma, New Mexico, Minnesota, North Dakota, and Montana. Except in the Southeastern States and in North Dakota and Montana, however, the amounts loaned were negligible. The total amount loaned in the spring of 1930 was $4,612,136. In August and September approximately $500,000 was loaned in Florida on winter vegetables, while loans up to October 15 to aid farmers to plant fall pasture crops in Alabama, Missouri, Oklahoma, and Virginia had amounted to $170,000.

CROP PRODUCTION IN 1930

As a result of the drought, crops were poorest this year from Virginia and Maryland westward to central Missouri, Arkansas, and Oklahoma. In much of this area, including most of Ohio, Kentucky, and West Virginia, the southern third of Indiana and Illinois, and south-central Pennsylvania, the yields were only about two-thirds of the normal. In a larger area the crops were somewhat less severely affected. This area included western Pennsylvania, Michigan, northern Indiana and Illinois, most of Iowa, the Dakotas and Montana, and the region from Kansas south to central Texas. On the other hand, crops were mostly average or better than the average in New England, New York, New Jersey, Nebraska, and Wisconsin. Fair yields were harvested in most of the Cotton Belt east of the Mississippi River. Particularly good yields were obtained in Georgia and South Carolina, and yields were above the average in Alabama. Satisfactory results were obtained also in most of the Western States, with the exception of Montana and parts of Washington and Wyoming. In Colorado, Arizona, and Oregon crop yields were 13 to 19 per cent heavier than usual. They were about 10 per cent better than usual in California.

Acreage

Spring weather favorable for farm work and an ample supply of labor brought an increase of about 1 per cent in the total acreage planted, though farm-commodity prices were rather unfavorable at planting time. Large increases in acreage were made in the case of several important cash crops. Thus the acreage in flaxseed was increased 47 per cent, that in rye 9 per cent, that in broomcorn 31 per cent, that in beans 12 per cent, that in rice 10 per cent, and that in tobacco 5 per cent.

The acreage in potatoes was increased 3 per cent, that of sweetpotatoes 4 per cent, and that of other commercial truck crops 6 per cent, though the strawberry acreage was reduced appreciably and the cabbage, carrot, onion, and spinach acreages in a lesser degree. The principal increases were in lettuce, snap beans, green peas, tomatoes, and muskmelons. Increased acreages also were planted to watermelons, cauliflower, and celery. The acreage of vegetables grown for canners and packers was one-sixth larger than in 1929 and was the largest on record. The acreages in certain crops were decreased. Some shifts from barley to oats took place, owing to the unusually early spring and to the fact that trouble had been experienced the previous year from barley diseases. In parts of the South a shift was made from cotton and peanuts to feed crops. In the Corn Belt States, which began the season with rather large supplies of hay on hand, some shift took place from hay to grains and cash crops. As already noted, however, the increase in the total acreage and in the acreages of particular crops was more than offset by low yields. In proportion to the population, the harvest showed nearly the usual production of food crops, about an average production of cotton, tobacco, flaxseed, and broomcorn, and a greatly reduced production of feed for livestock.

Cereal and Other Food Crops

The wheat crop totaled about 840,000,000 bushels, as compared with 806,000,000 bushels in 1929 and an annual average of 833,000,000 bushels for the five years 1924–1928. Winter wheat, which constituted 597,000,000 bushels, was a larger proportion than usual of the total wheat output. Its relative amount reflected continued gradual expansion of wheat acreage in the Great Plains area, relatively low production of durum wheat on a reduced acreage, and a production slightly below the average production of the other spring wheats. Rye production, with yields close to the usual average, was estimated at 46,700,000 bushels, as compared with 40,500,000 bushels harvested in 1929 and an average production of 50,900,000 bushels during the five years 1924–1928. Among the grains principally used for human food only buckwheat is in seriously short supply. This crop was caught by drought in practically all States where it is grown and yielded only about 12 bushels an acre, or less than in any previous year since 1886. The total production is estimated at 8,700,000 bushels, or 24 per cent less than in 1929 and 37 per cent less than the annual average of the 5-year period 1924–1928.

Rice production is estimated at 38,600,000 bushels, as compared with 40,200,000 bushels harvested last year and an average of 39,100,000 bushels harvested annually during the preceding five years. The yield was slightly below the average and much below that of 1929. The bean crop was very large. Sugar-beet production likewise was unusually heavy. The production of sorgo for sirup, however, was considerably reduced. Peanut production was less than usual.

Cotton

Cotton production is estimated at 14,486,000 bales, as compared with 14,828,000 bales harvested in 1929. The crop, though not large in comparison with those of some recent years, is nevertheless more than ample for the market's reduced requirements. Yields varied greatly in different States. In the eastern Cotton Belt the severe winter of 1929–30 and dry weather during the early summer kept the boll weevil in check. As a result South Carolina, Georgia, and Florida are harvesting the best yields of cotton in a number of years. Record yields are being harvested in New Mexico and Arizona. California's yield, estimated at about 400 pounds an acre, is the highest since 1916. Oklahoma and Arkansas, on the other hand, have the lowest yields since 1923 Texas has the lowest yield since 1925. Taking the cotton-producing States as a whole, however, the yield per acre is expected to be close to the usual average, or about 155 pounds.

The Feed Crops

Total production of corn, oats, barley, and grain sorghums was estimated at only 90,000,000 tons, as compared with 103,000,000 tons in 1929 and an annual average of nearly 107,000,000 tons during the 5-year period 1924–1928. All told, the output of the principal feed grains is thus about 13 per cent less than in 1929 and 16 per cent less than the 5-year average.

Corn production is estimated at 2,047,000,000 bushels, or 22 per cent less than the production in 1929 and 24 per cent less than the average annual production of the preceding five years and less than the production in any year since 1901. The yields were low in practically all the important corn States. In the seven States most seriously affected by the drought yields averaged less than half those usually obtained. The proportion of the crop available in the form of grain will probably be considerably less than in any recent year, since much more than usual of the crop will be utilized for silage and forage.

Oat production was reduced by the drought in North Dakota and Montana and in parts of the South. In other States, however, the yield per acre was equal to or better than the average. For the country as a whole, oat production is estimated at 1,410,761,000 bushels, or 15 per cent above the production in 1929 and 3 per cent above the average production of the 5-year period 1924–1928. The barley crop is estimated at 328,000,000 bushels, about 8 per cent more than the quantity harvested in 1929 and 36 per cent more than the average production of the preceding five years. The yield per acre was estimated at 25.7 bushels, as compared with 23.2 bushels in 1929 and an average of 25 bushels during the previous 10 years.

Grain sorghum, which takes the place of corn in parts of the Southwest, was much affected by the drought in Texas, Oklahoma, Kansas, and New Mexico, where about nine-tenths of the crop is usually grown. Including the grain sorghums that will be fed to livestock in the bundle, the production was estimated at 79,232,000 bushels, as compared with 100,845,000 bushels in 1929 and an annual average of 128,175,000 bushels during the 5-year period 1924–1928. The output was lower than in any year since 1919, when the records on this crop were started.

Hay production was estimated at 96,100,000 tons, or about the same as in 1926 and less than the production in any other year since 1918. It was 16 per cent below the production in 1929 and 10 per cent below the average annual production of the previous five years. Both tame and wild hay were damaged by the drought. In some States grass and clover gave but a fraction of their usual yield. Alfalfa, soybeans, and other deep-rooted hay crops, though less hurt, did not make a normal growth. Wild hay made up 12,000,000 tons of the hay crop and tame hay 84,100,000 tons. The wild-hay crop was the smallest in 20 years, with the exception of that in 1926, and the tame-hay crop was the smallest since 1921. Yields were below the average in all States except in New England, Iowa, Wisconsin, Georgia, Colorado, the far Southwest, and the Pacific Coast States. In California, Oregon, and Arizona record hay crops were obtained. The drought killed new seedlings of grass and clover in many fields and the result will be noticed in next year's hay crop.

Livestock feed supplies are augmented, of course, by such commercial feedstuffs as bran, middlings, cottonseed meal, and flaxseed meal. Output of these products is expected to be somewhat heavier than usual this year, though not in excess of the production last year. Taking the feed situation as a whole, the total tonnage of feed grain, commercial feedstuffs, and hay produced will be about 12 per cent below the usual average. In proportion to the number of livestock needing to be fed, it will be about 10 per cent less than usual. Economical use of the available supply will stretch it somewhat. More straw and corn fodder will be fed, as well as increased quantities of wheat and cottonseed. Hogs will be marketed at lighter weights. Fewer cattle will be put on grain feed, and these will be fed grain for shorter periods. The grain ration for livestock of all kinds will be reduced. These expedients will not, however, suffice to obviate serious effects from the feed shortage.

Tobacco and Flax

Tobacco production was estimated in October at 1,500,000,000 pounds, the total including about 800,000,000 pounds of flue-cured tobacco and 290,000,000 pounds of Burley tobacco. Yields in Kentucky and Virginia were extremely low and reduced the average yield for the United States to about 700 pounds an acre, or less than in any year since 1897. Though the area planted was about 100,000 acres greater, the production was about 1 per cent less than in 1929. However, the final yield is not yet accurately known, since it depends greatly on shrinkage in curing.

Flax production was estimated at 25,200,000 bushels, or 50 per cent above the production in 1929, but only approximately 6 per cent above the average annual production during the five years 1924–1928. As a result of the increased planting previously noted, the flax area was nearly 4,400,000 acres, by far the largest ever planted to flaxseed in the United States. The yield, however, averaged only 5.7 bushels an acre. This was only slightly better than the yield in 1929 and was the second lowest yield in 10 years.

Fruits and Vegetables

Fruit production was at least one-fifth greater than in 1929. Prunes, plums, and apricots were abundant, and a good crop of citrus fruits is expected. Apples and peaches were a smaller proportion of the total supply than in the previous year. Taken as a whole, the bearing acreage of fruits and nuts produced less than an average yield per tree or vine, but the reduced yield was offset by an increase in the bearing acreage, which continued the trend of recent years. The net result was a fruit crop somewhat greater than the usual average total supply. Allowing for the year's increase in population, it represented about the average quantity per capita.

For the second year in succession much of the central portion of the country had a light fruit crop. In the northeastern, southeastern, and western areas conditions, however, were more favorable. The supply from these areas was more than sufficient to offset the shortage in the central areas. New England, New York, New Jersey, Florida, Washington, Oregon, and California had an exceptionally good year. The large crop in California was in sharp contrast to that of 1929, when early spring freezes limited the output.

Apple production was about 153,400,000 bushels, or 8 per cent larger than the short crop of 1929, though 15 per cent below the average crop of the 5-year period 1924–1928. The commercial crop, or the part marketed for consumption as fresh fruit, amounted to nearly 32,000,000 barrels, slightly below the average quantity but about 10 per cent larger than the commercial crop of 1929.

The peach crop was 49,250,000 bushels, 8 per cent larger than the 1929 production, but 13 per cent below the 5-year average. Low winter temperatures and spring frosts cut the crop sharply in the Central States. It was practically a failure in Indiana, Illinois, Missouri, and Arkansas.

The pear crop was close to 25,000,000 bushels, about one-sixth larger than either the 1929 production or the previous 5-year average production, and was the largest crop on record except that of 1926. It was relatively light in most of the central and southern areas, but exceptionally large in New York and the three Pacific Coast States, where the bulk of the crop is grown.

Grape production amounted to 2,350,000 tons, about an average production, but 12 per cent larger than in 1929. The increase was in California. Production outside California was less than in the year before, though 8 per cent better than the average. The orange and grapefruit crop now being picked is estimated at almost half larger than in the previous season and lemon production at about one-fourth larger.

Potato production, on a slightly increased acreage, amounted to about 352,200,000 bushels, as compared with 359,800,000 bushels in 1929 and an average crop of 393,000,000 bushels during the five years 1924–1928. The early commercial potato crop largely escaped the drought. It was grown on an acreage one-fifth larger than that of the previous year, and the output was correspondingly larger, the yields averaging about the same. A large part of the late-potato crop was damaged. The northeastern and central regions, including many of the important late-potato-shipping States, suffered the full effect of the hot, dry spell. The sweetpotato crop also was hurt. The total production is estimated at 67,670,000 bushels, as compared with 84,660,000 bushels in 1929. Fall rains partly restored the crop in southern areas. In the four commercially important sweetpotato-producing States on the Atlantic coast north of the Carolinas drought persisted into the fall. Production in this area was much below normal.

Despite the increase in the vegetable and truck-crop acreage, yields were so much lower than in 1929 that the supply of these perishables was not greater. Snap beans and sweet corn were the vegetable crops most seriously affected by the drought. The supply of sweet corn was comparatively short. The production of other canning crops was not exceptionally light in the aggregate, though the yields were low.

THE WHEAT SITUATION

Income from this year's wheat crop is likely to be considerably below that received from the previous crop. Farm prices through the first four months of the marketing season (July through October) averaged only about 71 cents a bushel, whereas in the corresponding months of the previous season the average was about 109 cents a bushel. Despite the short corn crop and the feeding of much wheat to livestock in the United States, prices have declined to the lowest level since 1901 and 1902.

The carry-over of wheat has increased each season since 1926. The carry-over in the United States on July 1, 1930, amounted to 275,000,000 bushels, as compared with 247,000,000 on July 1, 1929, and a 5-year average of 122,000,000 bushels. The world stock as of July 1, though very large, was not quite as large as at the beginning of the previous season. World stocks outside Russia and China probably were reduced approximately 100,000,000 bushels during the 1929–30 season.

The world is harvesting about an average wheat crop. Production outside Russia and China for the 1930–31 marketing season probably will exceed the production of the past season, when several countries had short crops. Conditions reported toward the end of October indicated that the world's wheat crop will amount to about 3,650,000,000 bushels—about 160,000,000 bushels more than in 1929, but 320,000,000 bushels less than in 1928. During the 1929–30 season consumption apparently exceeded production by at least 100,000,000 bushels. Short feed-grain crops and low wheat prices should cause some increase in wheat consumption, both in the United States and in Europe. Increased consumption in the United States alone may suffice to offset the increase in world production.

Russia continues to be an uncertain factor in the situation. Apparently the Russian wheat crop is better than that of the previous season. Russia's exports through southern ports are reported as having amounted by the middle of October to about 25,000,000 bushels. Just before the World War Russia was the leading wheat-exporting country. During the war and the revolution, however, her exports practically ceased. In the 1926–27 season Russia's exports amounted to 49,000,000 bushels and then declined to small amounts until the beginning of the present season. Apparently wheat production in Russia is now equal to or greater than her pre-war production. Although Russia's exports during the present season may not greatly exceed those of the 1926–27 season, the producers in the United States should watch carefully the possibility of keen competition from Russia during the next 10 years.

THE COTTON SITUATION

Developments in the cotton market continue to emphasize the importance of adjusting as far as possible the production of each quality of cotton to market requirements. Our cotton crop in 1929 was the fifth largest in our history, and the area harvested was exceeded only in 1925 and 1926. As the carry-over from the previous year was relatively small, the world supply of American cotton in the 1929–30 season was the smallest in five years. Farmers who marketed their crop early received fairly good prices. From August to December, 1929, the prices paid to farmers for cotton ranged from about 18 cents to 16 cents a pound, or slightly less than the average for the previous season. These are the months during which a large proportion of the crop normally leaves the farmer's hands. Thereafter prices declined, and at the close of the marketing season were about 11 cents a pound, or on a level as low as that reached during the large crop year 1926–27. The downward movement of prices partly reflected reduced world consumption of American cotton. In fact, there has been a shift away from American cotton to that grown elsewhere during the last two years. Price differences during this period have been less favorable to American cotton, and quality differences between American and foreign growths have been less marked. It is evident that an adjustment between the quality of cotton produced and the consumers' preferences is very important if American cotton producers are to maintain their supremacy in the world's cotton markets.

Yields of cotton per acre in 1929 averaged 155 pounds for the United States as a whole. This was about equal to the average for the 10-year period 1919–1928. There were wide variations in the yields of the different States. In Texas, Oklahoma, and North Carolina yields were unusually low. In all the other cotton-producing States yields were above the average. Although the crop as a whole was fairly satisfactory from the standpoint of yield, the quantity of each quality produced was not in adjustment with the market's wants. In fact, it was distinctly lacking in that respect, whereas some foreign cottons, notably Indian cotton, showed improvement. In recent years the Department of Agriculture has gathered and published information on the number of bales of cotton ginned of each grade and staple. The last grade and staple reports showed that the cotton ginned during 1929–30 was lower in grade and slightly shorter in staple than the cotton ginned during 1928–29. About 20 per cent of the 1929 crop was thirteen-sixteenths of an inch or less in length of staple; 38 per cent was seven-eighths of an inch; 19 per cent was fifteen-sixteenth of an inch; 12 per cent was $1\frac{1}{32}$ inches; 11 per cent was $1\frac{1}{16}$ inches or longer. No less than 24 per cent of all the cotton ginned in the United States during 1929–30 was untenderable on futures contracts. In 1928–29 the corresponding proportion was 18 per cent.

These facts have a close bearing upon the trend of the world's consumption of American cotton. Previous to 1929–30 there were three years of record world consumption of American cotton. The total consumed in 1926–27 was about 15,777,000 bales. In 1927–28 the total consumption was 15,407,000 bales, and in 1928–29, 15,066,000 bales. Never in any previous year had the world consumption reached 15,000,000 bales. In 1929–30 the world's consumption of American cotton was 2,000,000 bales less than in 1928–29. The world's consumption of all kinds of cotton in 1929–30 declined only about 700,000 bales from that of the previous year. American cotton was thus replaced to a considerable extent by that grown in other countries. The consumption of Indian cotton increased 900,000 bales and the consumption of cotton from other countries increased 500,000 bales. Reduced consumption in our own mills accounted for half the decline in the world's consumption of American cotton. The remaining drop of 1,000,000 bales was in Europe, half of it in Great Britain. Comparative prices and qualities made it economical for many spinners to use foreign cotton exclusively or for mixing with American cotton.

More information is needed about the trend in the world's consumption of various growths, and study of the problem is under way in the department. Its results should help farmers to anticipate changes in the demand and to adjust their output thereto more promptly than they have done heretofore. Efforts to improve the quality of cotton grown in the United States meet difficulty in the system whereby cotton at primary markets is bought at flat prices without sufficient regard to the quality of individual bales. Producers have small encouragement to grow better fiber when they have no assurance that they will get more for good fiber than their neighbors will get for poor. Manufacturers gladly pay premiums for superior cotton. The effect of this action on production practice is negligible when the premiums at central markets are not reflected in the prices paid at country markets.

In 1928–29 premiums paid in the central markets for white grades above Middling were reflected in price differences at local markets in a proportion varying from less than 20 per cent for Strict Good Middling to less than 50 per cent for Strict Middling. Of the discounts established in the central markets for white grades below Middling, the proportion reflected in the local markets varied from about 40 per cent for Strict Low Middling to about 75 per cent for Good Ordinary. Only 12 per cent of the discounts made in central markets for cotton having a staple length of thirteen-sixteenths of an inch or less was reflected in local price differences. Staple premiums in the central markets were reflected to growers at local markets in proportions varying from less than 15 per cent for fifteen-sixteenths of an inch cotton to less than 40 per cent for cotton with a staple length of 1⅛ inches. In other words the central but not the local markets discriminated with some nicety between the different quality cottons produced. This situation obviously penalizes the grower of superior fiber and retards the production of better-quality cotton.

THE LIVESTOCK SITUATION

The livestock situation was favorable at the beginning of 1930, but adverse conditions developed as the year advanced. Returns to livestock producers fell far below those of 1929. In the case of cattle and hogs, a decline in the demand was the principal difficulty. Cattle numbers in January were only slightly above the low point reached in 1928, and cattle slaughter seemed not likely to exceed that of the previous year. Hog production had been reduced and a marked reduction in hog slaughter was in prospect. Only in the sheep industry were there indications of overexpansion. Yet the prices for all three classes of livestock dropped greatly, the sheep industry suffering particularly because it had to deal with an increased production as well as with a reduced demand.

Cattle prices began to weaken early in March, evidently as a result of a declining consumer demand. Weakness in the demand was particularly marked from the beginning of June to the middle of August, when unusually high temperatures prevailed over much of the country. Toward the end of July the average price of all grades of slaughter steers had fallen to the lowest level since 1926, and at the low point was 40 per cent below the average price at the corresponding period in 1929. A sharp advance took place in August and September, notably in the prices of the better grades. Early in

October, however, the price level was still about 22 per cent below that which prevailed a year previously. Feeders, who had suffered losses in the spring and early summer, bought less than their usual supply of feeder animals. As a result, more than the usual proportion of market offerings went into slaughter channels.

For cattle and calves slaughtered under Federal inspection during the first eight months of 1930, producers received about $119,000,000 less than they received for the cattle and calves slaughtered under Federal inspection in the corresponding period of the previous year. In gross value this represented a decline of 18 per cent, though the total slaughter of cattle and calves was only 1.4 per cent less. From a supply standpoint, however, the cattle industry is still in a strong position. Improvement in the demand for beef should, therefore, be quickly reflected in better prices for beef animals.

Hog producers suffered less severely. Hogs slaughtered under Federal inspection during the first eight months of 1930 numbered 29,331,018 head, or 8 per cent fewer than in the first eight months of 1929. The average price received was $9.74 a hundred pounds, or 6.8 per cent less than in the corresponding period of the previous year. The combination of reduced slaughter and reduced prices lowered the gross return to $670,000,000, a reduction of 14 per cent from the $779,000,000 received for hogs slaughtered under Federal inspection from January to August, inclusive, in 1929. From the gross return in the first eight months of 1928, however, it was a reduction of only $28,000,000.

Foreign markets for American pork and lard were relatively unfavorable. Hog numbers had increased in the important hog-producing countries of Europe, and our exports of both bacon and lard declined. Our total exports of cured pork from September 1, 1929, to August 31, 1930, were somewhat smaller than in the corresponding months of the previous marketing year. Depressed economic conditions, as well as increased hog production in Europe, reduced the demand for American hog products.

The sheep industry had to market an unusually large supply of both lambs and wool. Slaughter supplies of fed lambs from December, 1929, to April, 1930, were about a million head larger than in the corresponding period a year earlier. On a tonnage basis, the increase exceeded 21 per cent. In the first four months of 1930 the market was compelled to absorb a fourth more lambs than in the first four months of the previous year. This heavy marketing, combined with reduced consumer buying power, resulted in an average price for sheep and lambs during the fed-lamb season of only $10.56 a hundred pounds, as compared with $15.03 in the 1929 season. Returns to lamb feeders, despite the increase in marketings, were approximately $10,000,000 less than in the preceding season.

These low returns curtailed the demand for feeding lambs from the 1930 lamb crop, which was 2,000,000 head larger than that of 1929. Producers were therefore obliged to sell more lambs than usual for slaughter, and prices were forced down to the lowest level in many years. In August the average prices of Good and Choice feeder lambs fell to $6.50 a hundred pounds. The average price of Good and Choice slaughter lambs at Chicago in the first week of October dropped to $7.52 a hundred pounds. These prices were, respectively, 50 and 40 per cent lower than the prices prevailing in the corresponding weeks of 1929. Wool prices, in the foreign as well as in the domestic market, declined during the year in about the same proportion as lamb prices. After a period of steadiness, the wool market early in October indicated some further weakness.

THE DAIRY SITUATION

From about 1921 to the end of 1929 the dairy industry of the United States was more stable and on the whole more profitable than most other agricultural enterprises. Late in 1929 and in 1930 it suffered a setback. The demand for dairy products fell off, underlying tendencies to overproduction were disclosed, feed supplies and pasturage were reduced by the drought, and feed costs advanced beyond the costs that would have prevailed but for the drought. Unfavorable conditions in foreign dairy markets affected American dairy interests, though the margin between domestic and foreign butter prices did not widen sufficiently to cause any increase in our butter imports. Since October, 1929, butter prices have been lower than in the corresponding months of the previous season and also below the 5-year average. A pronounced upturn took place in July and August, when dairy production was affected by the drought. Yet butter prices are still below those of a year ago. They seem likely to remain for a time at a lower level than that of the last few years, owing to a continuing tendency toward expansion in the industry.

On two previous occasions since the World War—in 1921–22 and in 1924–25—the dairy price situation was similar to what it is now. In those seasons, however, the difficulty was remedied by a rather prompt cut in production. The reduction came from three causes: (1) A decrease in the use of concentrated feeds; (2) increased culling of herds; and (3) a tendency among farmers, especially in the Corn Belt, where many beef cows are milked, to let the calves do the milking. Only one of these causes—a reduced use of concentrated feeds—has been noted this year. Farmers seem to have had no more profitable alternatives than dairying; hence there has not been much close culling of herds or any marked shift from dairying in the Corn Belt. Rigorous culling of low-producing cows should be profitable, especially in view of the tendency toward overexpansion in the dairy industry.

Though the drought caused a heavy drop in dairy production during the pasture season, supplies of roughage and hay are fairly ample in the more important dairy sections. Accordingly dairy production this fall and winter, though it will not be as large as it was during the corresponding periods last year, will not be as much below the last season's level as the summer production was. More than the usual seasonal advance in corn prices is expected; supplies of oats, barley, and wheat, however, are so abundant that no extreme advances in feed-grain costs are probable. In the specialized dairy territory, where about 85 per cent of our total butter output is produced, feed supplies are not seriously depleted. Feed shortages could reduce production in other areas by as much as a third without causing more than a 5 per cent drop in our total butter production. Milk cows and heifers are increasing in numbers. It is therefore probable that the effects of the drought in curtailing production will be only temporary. Improved business conditions would stimulate the demand for dairy products, probably not sufficiently, however, to obviate the need for reducing production.

The immediate outlook for the dairy industry varies widely in different localities as a result of the varying degree in which they have suffered from the drought. Following the drought a critical situation existed in most of the Ohio Valley and in parts of a larger area extending from Maryland to southern Missouri and southward into the lower Mississippi Valley. In these areas water was scarce, pastures failed, crops were seriously damaged, and farmers began feeding their scanty supply of hay and grain earlier than usual. There has been some distress selling of milk cows. As already noted, however, the more specialized dairy regions are in better shape. In the northern dairy sections production during the winter months will largely depend, as usual, on the spread between the cost of grain and the price received for milk or cream. Where grain and hay supplies are ample, milk production may be as profitable as other livestock enterprises. Only local milk shortages are probable, and there is no scarcity of milk cows for replacement purposes. In short, the dairy industry faces the combined influence of lessened consumer demand, both at home and abroad, and a tendency toward expansion. Though it can make rather quick changes within certain limits in the volume of its output of milk and other products, it can change the supply of its basic stock only very slowly.

THE POULTRY SITUATION

Egg production in 1929 was less than in 1928, and the summer movement of eggs into storage was smaller than usual. As a result the poultry industry entered 1930 with prices generally high. As the year advanced, however, laying flocks were considerably expanded. The resulting heavy egg production, combined with a lighter demand, caused a marked decline in egg prices. In the first part of the flush production season, the demand for eggs to be placed in storage remained good. Eggs in storage accumulated rapidly, however, and on August 1 the supply was the largest on record. Egg prices dropped instead of showing the usual seasonal rise. At this writing the heavy supply of eggs in storage and the early lay of the 1930 pullet crop are depressing factors. Material improvement in the egg market, other than the normal seasonal rise, is not expected before the early part of 1931. Exceptionally good demand for baby chicks prevailed during the first few months of 1930. From February to June the production of salable chicks by the hatchery industry, according to reports received from commercial hatcheries, was about 22 per cent above the production of the corresponding period in 1929. Some of the increase undoubtedly represented a shift from farm to commercial hatching. Returns covering about 20,000 ordinary farm flocks indicated that on July 1, 1930, chickens and young chicks of the current year's hatch numbered about one-half of 1 per cent less than on July 1, 1929. The contrast between the showing of the commercial hatchings and the showing of the farm flocks may be partly attributable to reduced hatchings on farms, heavier mortality of baby chicks, and a tendency among poultrymen to market a larger number of pullets as broilers.

The number of laying hens in farm flocks on July 1 was about 1 per cent greater than on the same date in 1929. Since then, however, relatively low egg prices have caused a fairly heavy movement of fowls to market. It is therefore probable that farm flocks in 1931 will be smaller than they were in 1930. Moreover, the current low egg prices may cause poultrymen to feed their flocks less intensively. Indications are, in fact, that laying flocks will enter the spring of 1931 in a condition below normal. Hence the total egg lay during the flush production of 1931 is likely to be less than it was in 1930. Whether the prospective decline in production will be accompanied by a proportionate rise in prices depends, of course, on the consumer demand, which is primarily affected by the business situation.

The poultry market, as well as the egg market, was oversupplied in 1930. Heavy hatchings from the preceding year and a lessened consumption demand caused a marked accumulation of poultry in cold storage. Heavy hatchings this year aggravated the situation. The movement of both old and young stock to market was very free. From January to September, inclusive, the receipts of fresh-killed western poultry at principal western markets were 3 per cent more than the receipts in the corresponding months of 1929. These liberal receipts, added to the influence of storage stocks that were nearly at the record level, caused a slump in poultry prices. However, the lower prices stimulated poultry consumption. In the first nine months of 1930 the consumption was 15 per cent heavier than in the corresponding months of 1929. Hence the prospect for 1931 is not unfavorable. Producers should find the market more nearly normal, without burdensome storage accommodations and without excessive market receipts.

THE FRUIT AND VEGETABLE SITUATION

Many fruit and vegetable producing sections were seriously affected by the drought of 1930. Some crops in the Central and East Central States were a complete failure. Others were greatly reduced. In other localities a combination of unfavorable weather at planting time and high temperatures during the harvesting period not only reduced yields but caused certain crops to mature within an abnormally short period. The result was a temporary flooding of markets, with sharp price declines. Early watermelons all matured in a short period instead of over several weeks, and shipments became so heavy that for a short time cars of melons could not be sold at shipping points at prices sufficient to cover the harvesting and loading charges.

These disasters, while of great importance locally, had but little effect upon the total shipments of fruits and vegetables for the country as a whole. The staple fruits and vegetables are now produced commercially in so many sections that a failure in a few areas does not mean a national shortage or prohibitive prices for what is produced. Even when there is a material reduction in a crop which is grown in restricted areas, such as the citrus fruits, the price is only moderately affected. The great variety of fruits and vegetables from which the buyer has to choose during practically all months of the year serves as an equalizer of prices. A material increase in the price of one results in the substitution of some cheaper product.

The rapidity of transportation and the wide distribution of market information by the department's market news service, the daily press, the telegraph, telephone, and radio are doing much to secure equitable distribution of these highly perishable products, which often are in too heavy supply in some markets while others are bare. The motor truck is doing much to equalize distribution. Overnight hauls of 250 miles or more from oversupplied to undersupplied markets are common. There is a tendency toward heavier car-lot shipments to the larger markets, from which daily deliveries of mixed truck loads are made to the jobbing houses and retailers within an ever-increasing radius. An opposite tendency, which has had some success, is an attempt to expand the shipment of mixed car lots to the smaller cities.

The development of large terminals by the carriers and by other private capital in many of the principal markets during the last few years has done much to overcome the confusion which formerly existed because of inadequate unloading facilities and the use of the railroad car as a warehouse and a salesroom.

FARM INCOME IN 1929 AND 1930

Farm incomes from the production of 1930 are expected to be lower than for any season since 1921. The gross income from the 1929 production amounted to about $11,851,000,000, or about $110,000,000 greater than that for 1928, but the returns from this year's livestock marketings have to date been considerably lower than the comparable returns last year, and returns from the 1930 crops now in process of being marketed are also considerably below those obtained from the 1929 crops. The aggregate gross income from the 1930 production will probably be about $9,950,000,000, or 16 per cent below that of 1929.

In 1929 the major farm expenditures showed very little change. Hence the increased gross income in that year resulted in an increase in net income computed as a return for the farm operator's capital and labor. The net income available in 1929 as a return for the operator's capital and labor was $1,055,000,000, as compared with $984,000,000 in 1928 and $1,206,000,000 in 1925, which was the best year since the post-war slump. Farm expenditures in 1930 have been less than they were in 1929, but the reduction is small compared with the reduction in gross income.

The reduced farm incomes of 1930 follow a series of years—1924 to 1929, inclusive—in which, despite diverse conditions in different agricultural sections, the aggregate income was fairly stable. This year all sections suffered because of world-wide industrial depression. In addition, farmers in a wide area suffered seriously from drought. In the drought-stricken area the gross farm income will be reduced about 25 per cent below that of 1929. In other sections the gross income, though greatly reduced, may be better than it would have been had the drought not lessened the country's total farm production.

Farm Prices in Relation to Farm Income

The great change from moderate improvement in 1929 to severe depression in 1930 is largely attributable to price movements since the summer of 1929. Total farm production in the fall of 1929 was not excessive, as compared with that of recent years. In August, 1929, the index of prices received by farmers was higher than in any month in the previous season and averaged 143 per cent of pre-war prices. By November the index had declined to 135 and by March, 1930, to 126. After a slight recovery in April it resumed the downward trend. A still more severe decline in the prices of practically all farm products in July lowered the index to 111. On August 15 it stood at 108, 2 points lower than the lowest level reached in the drastic deflation of 1921 and only 8 per cent above the pre-war level. The level of prices received by farmers declined nearly 30 points in one year, from September 15, 1929, to mid-September this year. With no offsetting increases in marketings this drastic decline in prices caused a 25 per cent drop in current gross farm incomes as compared with those of August and September, 1929.

Practically all branches of American agriculture received lower returns this year. Last year in August the cotton growers received 18 cents a pound for cotton; in August, 1930, they received less than 11 cents a pound for a crop believed to be slightly smaller than last year's.

Wheat growers in August, 1929, received an average of $1.11 a bushel. This season, for a crop not much larger, the August price averaged 74 cents—37 cents less than last year's. Even the potato crop, which is expected to be the smallest since 1925, sold in August at $1.09 a bushel, compared with $1.39 a bushel for a larger crop last year.

Producers of livestock and livestock products fared no better. Wool at 19.8 cents a pound in August was nearly 30 per cent below the prices received in August last year. Lambs brought less than $7 a hundred pounds, as compared with $11.46 last year. Beef cattle at $6.26 a hundred pounds on August 15 averaged $3.36 below last year's prices. Hogs, which in August, 1929, brought $10.28 a hundred pounds, sold for about $8.50 in August this year.

The dairy and poultry industries lost much of their previously advantageous price positions. The price of butterfat on August 15. 1930, at 35.7 cents a pound, was more than 7 cents lower than in August, 1929. Eggs sold for nearly 30 per cent less and chickens for 20 per cent less. Last year, when all farm prices averaged 143 per cent of the pre-war level, poultry products averaged 151 and dairy products 137. In August, 1930, when the average of all farm prices had slumped to 108 per cent, poultry products averaged 107 and dairy products 117. As compared with the prices received for other farm products dairy prices remained relatively high. Grains at 101 and cotton and cottonseed at 94 per cent were relatively low.

Farm prices declined more than nonagricultural prices. The average level of the wholesale prices of all commodities, according to the Bureau of Labor Statistics, declined about 15 per cent from August, 1929, to August, 1930. The wholesale prices of farm products during the same period declined 21 per cent and food 16 per cent, while the prices of nonagricultural products declined only about 10 per cent.

The prices that farmers pay for the goods they usually buy declined much less than the prices of farm products. The average of the prices paid by farmers in August, 1929, was about 155 per cent of the pre-war level. By August, 1930, the prices of these articles had been reduced to an average of 149 per cent of the pre-war level, a reduction of only about 4 per cent in the year. The ratio of prices received to prices paid was reduced from 90 per cent in August, 1929, to 72 per cent of the pre-war average in August, 1930.

FACTORS IN THE CURRENT DEPRESSION

The current slump in agricultural prices and incomes reflects the combined influence of continued overproduction in some important farm products and of the world-wide business depression. Agricultural overproduction existed before the business depression began. Its effects were heightened when the depression curtailed demand. The business depression caused a tightening of credit, a world-wide decline in commodity prices—in which agricultural prices suffered most—widespread unemployment, and a general reduction in the purchasing power of consumers. Agriculture's added difficulties this year are attributable largely to conditions outside the agricultural industry.

The year began without the prospect of increased burdensome agricultural surpluses. There was a large carry-over of old wheat in the United States, but the world's production in 1929 was below normal. It seemed likely that the United States would be able to market the increased carry-over and the new crop at prices better than had prevailed in the previous season. The cotton crop was of moderate size, as compared with the crops of 1925 and 1926, and the carry-over was not large. Fruit crops were generally short, and relatively high prices were to be expected. Prospects were for relatively small marketings of cattle and hogs at relatively high prices. Large production of lambs, wool, and dairy and poultry products was in prospect, and lower prices were to be expected, but not enough lower to constitute a material depression. There was a reasonable expectation that the prices of agricultural products in general for the season would be higher than in the previous season and that agricultural income would continue to improve. All such expectations had to be abandoned with the break in the business situation and the subsequent marked decline in prices.

Many of the factors which contributed to the decline in agricultural prices and income are related, and their influences can not be measured separately. Business activity in the United States in 1928 and 1929 was greater in some lines than could be maintained. The volume of business in the United States began to decline in the summer of 1929. The stock market turned down in September and broke sharply in November, and the break appeared to precipitate similar slumps in many other countries. Increased unemployment reduced the purchasing power of consumers. The prices of agricultural products fell not because of an increase in the supply, but because consumers were either unable to buy as much as usual or were unwilling to buy for future needs, except at lower prices.

The effect of this reversal in the business situation on agriculture was most clearly seen in the prices of cotton, butter, and meat animals. In these commodities there were no great changes in supplies. The price declines clearly resulted from a decline in the demand. A reduction in the mill consumption of cotton, both at home and abroad, was a principal factor in depressing the price of cotton to low levels in March, 1930, and to a still lower level in the summer months. The 1930 crop is slightly smaller than that of last year, but the cotton farmers are faced with a larger carry-over because of the depression. Cotton prices are about 6 cents a pound below those of last year, a decline of more than 30 per cent. The change in domestic and foreign business and the general decline of commodity prices have cost the cotton growers so far this season about $30 per bale, or more than $400,000,000 on the total crop.

The turn in the business situation began to affect the dairy industry in the summer of 1929, when the consumption of butter declined. Toward the end of 1929, increased production and declining demand produced record cold-storage holdings. Prices on surplus fluid milk were lowered, and butter prices not only failed to make their usual seasonal advance, but dropped to the lowest levels since 1921. Though some recovery in butter prices took place during the summer of 1930, they are still well below last summer's prices.

The reduced purchasing power of consumers was reflected also in prices for meat animals lower than those that usually prevail for such numbers as have been marketed so far this year. The combined production of all meats has been practically constant since 1924, but prices and returns to farmers for their marketings have varied with changes in the purchasing power of consumers. In 1929 the total cash income from the sale of livestock amounted to more than $2,500,000,000. The returns in recent months have been at a rate fully 25 per cent lower. The prices received by farmers for meat animals in August, 1929, average 165 per cent of the pre-war level. By August, 1930, they had declined to 119, or a drop of 28 per cent. If business activity this year had remained on the high level of last year, the prices paid to farmers last year probably would have prevailed in general this season. Hence it appears that the business slump is probably causing the livestock producers a loss of more than $500,000,000.

World-wide Price Decline

In some countries commodity-price recessions were in progress before the summer of 1929. In most countries the downward movement was accentuated in the last few months of that year. The combined price level for the countries that take most of our farm exports (the United Kingdom, Canada, Germany, France, Italy, the Netherlands, Japan, and China) followed a downward trend after 1924. In the succeeding five years, until the summer of 1929, an average of their prices showed a decline of about 10 per cent. Commodity prices in the United States declined in the same period but to a somewhat lesser extent. High industrial activity in 1928 and 1929 was a sustaining influence. The decline in the United States during this 5-year period was about 6 per cent. Since July, 1929, and particularly since September, 1929, the average of commodity prices in these countries has declined more than 10 per cent.

The decline in general price levels in foreign countries has been brought about in the same manner as the reduction in the general price level of the United States. Business depressions have reduced the demand for raw materials for manufacture, such as cotton and wool. Unemployment has reduced the power of consumers to purchase foodstuffs and clothing. These conditions have affected the international market for agricultural products. Many countries have endeavored to strengthen the domestic markets for their own products by increased tariff duties and other restrictions upon imports. Countries that export agricultural products have been forced to sell at low prices. This necessity has naturally curtailed their power to buy industrial products.

It is perhaps significant that the general price declines this year in June and July did not continue in August and September, although certain key products, both industrial and agricultural, notably copper and wheat, reached new low levels in September. The reduced agricultural production of 1930 has already strengthened some agricultural prices. This in turn should help to stabilize the general commodity price trend, and tend to create more confidence in the business situation. The depression has already continued about as long as former depressions of this character. In the immediate future, however, any marked price advances are likely to reflect supply changes, rather than improvement in the domestic or the foreign demand.

AGRICULTURAL EXPORTS

Exports of agricultural commodities in the year ended June 30, 1930, were the lowest since the year ended June 30, 1915. The export index number for the 12-month period was 97. This index is based on the exports of 44 of the principal farm commodities, with the movement in the period 1909–10 to 1913–14 taken as the base. The decline in the exports was general. With cotton (which bulks so large in the total) excluded from the reckoning, the index number for the remaining commodities was 117. This was lower than the corresponding number for any preceding similar 12-month period since 1913–14. The index for cotton calculated separately was 82, the lowest in six years.

These figures reflect essentially the volume, not the value, of the exports, though values are considered in the weighting of the index. In value the agricultural exports of the United States were 19 per cent lower in 1929–30 than in 1928–29. Lower prices diminished the unit value of the goods exported, and increased world competition lessened the foreign demand for United States crops. Excluding forest products, our agricultural exports for the year 1929–30 were $1,495,000,000, against $1,847,000,000 in the previous year. Agricultural products constituted only 32 per cent of our total exports, as compared with an average of 40 per cent in the period 1925–1929.

The dominant factor in reducing the value of the exports was a smaller movement of cotton at a lower average price. There were also substantial decreases in the value of the exports of grains, fruits, animal oils and fats, vegetable oilcake and oilcake meal, and dairy products. Tobacco made the best showing. In quantity the tobacco exports increased notably and in value slightly. Exports of meat were higher in both volume and value. Lard exports were larger but the total value was less.

Cotton exports (excluding linters) were 7,097,000 bales, valued at $667,251,000. This was a decrease of 19 per cent in volume and of 26 per cent in value from the annual average for the period 1925–1929. Germany again displaced the United Kingdom as the principal outlet for American cotton. It took 1,770,000 bales, or 25 per cent of the total exports, whereas Great Britain took only 1,307,000 bales, or 18 per cent. Much cotton credited to Germany in the exports statistics, however, is reexported to other European countries.

Japan took 1,078,000 bales. As compared with the figures for the previous year, cotton exports to Germany declined 6 per cent, those to the United Kingdom 32 per cent, and those to Japan 21 per cent. Only France among the principal cotton-importing countries took more than in the previous year.

Exports of wheat decreased slightly and those of other grains heavily. The movement of wheat and flour was lower than in any year since 1914 except 1918 and 1926. It was 20 per cent less than the average annual movement for the period 1925–1929, though only 6 per cent under the movement in 1928–29. Japan took the equivalent of 9,863,000 bushels, or more than double the amount taken in the previous season. China, on the other hand, took less. The net gain in the shipments of wheat to the Orient was 2,023,000 bushels. Rye and rye-flour exports amounted only to the equivalent of 3,000,000 bushels, the lowest figure since 1914. This was a decrease of nearly 89 per cent from the average of the five preceding years, though the production for the season was only 14 per cent less. Rice exports were only 10,401,000 bushels, as compared with 14,137,000 bushels the previous year. The decline was particularly marked in the exports of California rice. Drastic declines were recorded in the exports of feed grains. Exports of corn and corn meal were 10,280,000 bushels, the lowest since 1925. Oats exports dropped to 7,966,000 bushels, the lowest since 1914. Exports of barley, including malt, were only 24,054,000 bushels, or 33 per cent less than the annual average for the period 1925–1929, despite the fact that barley production in the United States in 1929 was the second highest on record.

Most classes of meat exports showed an improvement both in quantity and in value. Hams, shoulders, and pickled pork were exceptions. Heavy exports to the United Kingdom chiefly accounted for the increase. About 60 per cent of all the meat exported was cured pork. More bacon was shipped than in the previous year but less hams and shoulders. As a result the total exports of cured pork were slightly under those of 1928–29 and lower than in any year since 1875. Exports of lard were about 7 per cent above the average volume for 1925–1929 but were 12 per cent lower in value. The average price for lard during the season was lower than in any year since 1922. Exports of fresh pork amounted to 18,771,000 pounds, an increase of 23 per cent over the average for the five years immediately preceding. Shipments of beef amounted to 17,227,000 pounds. This total, though greater than the amount exported in 1928–29, was 19 per cent under the 1925–1929 average and was equal to only 14 per cent of the quantity of beef imported into the United States.

Exports of leaf tobacco exceeded those of 1928–29 by 29,230,000 pounds. They were larger than those in any preceding year except 1919 and 1920. Exports of bright flue-cured tobacco amounted to 429,942,000 pounds, a gain of 15,993,000 pounds over those of 1928–29. Exports of dark-fired Kentucky and Tennessee tobacco were 96,395,000 pounds, an increase over the shipments in the preceding two years, but a decrease from the annual average for the period 1925–1929.

Exports of all classes of fresh, dried, and canned fruit declined. The movement of both boxed and barreled apples was less than half that of the 1928–29 period. Exports of oranges and grapefruit were under those of the preceding year, but with that exception were higher than those of any preceding year. Exports of prunes were 31 per cent below the average for the period 1925–1929. Exports of raisins were 19 per cent below the corresponding average.

More vegetable oils were exported than in the previous 12 months but at lower prices. The volume of the movement, however, was less than the average for the preceding five years. Cottonseed-oil exports, though greater than in 1928–29, were 38 per cent less in volume and 46 per cent less in value than the annual average for the 1925–1929 period. Exports of linseed oil were 9 per cent below the 1925–1929 average. Exports of soybean oil were 37 per cent above the 5-year average. Exports of canned vegetables were only slightly under the record figure reached in 1928–29.

AGRICULTURAL IMPORTS

Imports of agricultural products also declined. The value of agricultural imports, excluding forest products and rubber, declined from $1,943,000,000 in the fiscal year ended June 30, 1929, to $1,696,000,000 in the fiscal year ended June 30, 1930. The value of imports of all agricultural products, excluding forest products and rubber, was about the same as in 1924 and not so low as in 1922.

The principal causes of the decline in the value of imports were a decline in the prices of many products and, in some cases, a material curtailment in the demand. The reduction in the value of the imports of sugar and coffee constituted nearly half the reduction in the value of the total imports. More coffee was imported, but prices fell so much that the total value was greatly reduced. A curtailment in the manufacturing demand for such raw materials as silk, wool, and cotton subtracted about $74,000,000 from the total imports. The value of the imports of oils and oilseeds declined $21,000,000. Flaxseed imports were maintained, but the value of palm kernel, copra, and other coconut products reduced the total.

Rubber is not included in the above total valuation of imports. Though more rubber was imported, the value of the rubber imports was $39,000,000 less than in the preceding year.

Imports of hogs, cattle, and sheep were reduced. A large clip and a reduced demand for wool resulted in a reduction of about $24,000,000 in the value of the imports of carpet and combing wools. The value of the imports of dairy products was reduced by about $6,000,000. The imports of eggs and egg products, on the other hand, increased by a small amount. The Orient sent larger quantities of the dried yolks and albumen of eggs. A short fruit crop in the United States in 1929 also resulted in a slight increase in the imports of fruits, including some increase in the imports of bananas.

OVERPRODUCTION AND CROP ADJUSTMENTS

One aspect of the farm problem overshadows all others. Production in a number of important lines is out of balance with the market, and surpluses pile up continuously. Barring such temporary fall in demand as we experienced in the past year due to world-wide business depression, our difficulty is not a sudden emergency, but a cumulative overproduction. Farm production, already above normal requirements, became disastrously excessive when the depression curtailed purchasing power. Exceptional weakness on the demand side was added to the trouble on the supply side. I want to emphasize the need for equitable, intelligent, systematic, and collective action to bring supply into better relationship with demand.

Farmers, of course, must deal mainly with the supply phase of the problem in one way or another. There are two main alternatives. They can let matters drift until production is reduced by the ruin of thousands and their elimination from the farming industry, or they can consciously direct the readjustment process to lessen its difficulty and hasten its end.

The answer to overproduction is less production. Crops must be balanced as nearly as possible with market demands and offered only in such quantities as can be sold at prices covering the farmers' cost of production plus a profit. If readjustment is not brought about by intelligent action, it will be effected through blind economic forces at excessive cost. Let us not deceive ourselves by saying that real overproduction is impossible, since all the foods and fibers produced are eventually consumed at some price. There is overproduction if the price received does not exceed the cost of production by a margin sufficient to give the reasonably efficient farmer a fair net income.

Technical Progress in Production

The growing efficiency of American agriculture helps to explain but does not justify its persistence in overproduction. Technical progress has increased farm productivity tremendously in the last 15 years, but the benefit has gone largely to the consumers. Farming has been industrialized and mechanized. It has used science, decreased its production costs, and increased its output, without finding either profit or security in the process. It has made two blades of grass grow where one grew before, only to find the second blade depressing the price of both. Continuing in this path, in the hope that still greater efficiency will eventually force our competitors out of the market, seems likely to work no better in the future than it has done in the past. Farming is becoming more efficient all over the world, and crop acreage and livestock breeding are increasing. The competing groups know that a halt in production will have to be called, but no group wishes to be the first to slow down.

Other industries behave differently. In the first seven months of 1930 the production of motor vehicles in the United States declined 44 per cent. This decline was not compelled by bankruptcies, but resulted from voluntary concerted effort to adjust output to the demand. Low-cost as well as high-cost plants participated. They found that course better business than to go on glutting the market, in the hope of driving enough producers out of it to leave a good field for the rest. While the problem in farming is more difficult, this same logic should apply to agriculture. It does not follow, because some farmers can produce at a lower cost than others, that the low-cost farmer should do nothing to prevent overproduction. Narrow competitive views of that sort invite bankruptcy. Bankruptcy is contagious. Ruthless competition means, in the end, measuring living standards by the lowest in the scale.

World Wheat Expansion

Since wheat particularly is overabundant, let us consider the wheat situation. The world's wheat area is 42,000,000 acres larger than it was before the war. The United States has contributed 14,000,000 acres to the increase. These figures do not include Russia's acreage. Russia will undoubtedly increase its wheat exports. Wheat surpluses have piled up steadily in the last half decade, and world carry-overs reached huge proportions after the bumper crop of 1928. The current year's world carry-over on August 1 exceeded 500,000,000 bushels, though the 1929 world crop was less than that of the preceding year by almost the same amount.

Consuming countries have reduced their wheat imports by high tariffs, by forcing the consumption of substitute cereals and starches, and by encouraging their own wheat production. For instance, Germany has raised her tariff on wheat to $1.62 a bushel. Importing countries in the crop year 1929–30 imported 237,000,000 bushels less than in the previous year. Meantime wheat growing continues to expand in the exporting countries, particularly in parts of the United States and in Canada, Argentina, and Australia. The area sown to wheat in our southwestern winter wheat States increased approximately 4,000,000 acres from 1924 to 1929. During the same period the area in Canada, Argentina, and Australia combined, increased more than 10,000,000 acres, from 49,000,000 to 59,000,000 acres. This is in line with the trend in expansion since 1910. The entire wheat-producing world faces increased acreage, increased production, and unsatisfactory prices. It is vainly trying to beat the law of supply and demand. In the last seven years it has produced an annual average of 43,000,000 bushels of wheat more than has been consumed, and the United States' carry-over has piled up to the record total of 275,000,000 bushels. This year, moreover, our wheat crop is larger than that of last year.

It is sometimes urged in defense of continuous wheat expansion in the United States that certain extensive wheat-growing areas in this country can produce wheat more cheaply than it can be produced anywhere else in the world. Whether or not this is entirely correct we do not know. Our methods and our machinery are up-to-date, but other countries are efficient too; and some of them have much cheap and fertile land. Even if our growers are in a relatively strong competitive position, it does not follow that they should blindly offer themselves for punishment. Competition to see who can stand the heaviest losses is irrational. Live and let live is a better doctrine. Moreover, the number of relatively low-cost producers in this country is too great to justify an endurance contest among them. Their interest lies not in fighting among themselves but in combining to adjust their total output to market needs. In this task they can expect help from the Federal Government, but only if they approach it practically. By this time it is evident that supply-and-demand conditions can not be set aside by legislation, that the dumping of surpluses abroad is not feasible, that the indefinite storing of surpluses tends to prevent rather than to cause a rise of prices, that tariff duties are not effective on commodities produced largely for export, and that subsidies would increase rather than restrain production. Voluntary curtailment of production is the only logical remedy for the surplus problem.

A striking instance of world resistance to dumping has been afforded us lately by Russia's efforts to sell wheat and other products in other countries at extremely low prices. Agitation began in France some months ago against soviet dumping, particularly of wheat. As a result the Government issued a decree on October 3, which provided for the control, through licensing, of imports from Russia into France of certain merchandise, including "cereals and their derivatives," and also a number of other products, mainly foodstuffs. The license system limits the quantities that may be admitted. Similar action was taken by Belgium on October 25, under a decree requiring an import license on grains, flour, wine, and a number of other articles from Soviet Russia. Rumania has issued an ordinance understood to apply particularly to imports from Soviet Russia. It requires on imports the stamp of the country of their origin, and also a permit issued by the Rumanian trade attaché. Rumania has no such official in Soviet Russia, because of the absence of diplomatic relations between the two countries. Hence, the ordinance seems to place a complete embargo on importations into Rumania from Soviet Russia. It was recently announced that Hungary was contemplating a license system covering imports from countries with which it has no trade agreements. Soviet Russia is the only country to which this condition applies. The latest increase in Germany's tariff on wheat, though applying to imports from all countries, is acknowledged to be a move to control the dumping of Russian wheat in the German market.

Curtailment of Acreage

The curtailment of acreage, indispensable if wheat growing is again to be profitable over a period of years, can not be recommended as a blanket policy applying equally to all farmers regardless of their special circumstances. In areas specially adapted to wheat and on farms that have no other satisfactory alternative cash crop, the problem is not the same as it is where nature or circumstances offer a choice of major enterprises. Adjusting production is an intricate process with varying applications in different regions and on different farms. Not merely the available crop enterprises but the size and shape of fields, the characteristics of the soil, the climatic conditions, and the extent to which farm operations are mechanized must be considered.

These considerations justify a flexible adjustment policy. They do not justify a refusal to make adjustments. Not every acre now growing wheat should be in that crop even in the specialized wheat areas, whose opportunities for making crop shifts are often underestimated. Whole-hearted cooperation in a concerted effort to bring our wheat industry more nearly in line with its market would disclose many useful modifications of the existing 1-crop system. It would develop forage-crop and other side lines, and eliminate many high-cost acres from wheat growing. If by leaving acres fallow a better profit can be obtained, that, in itself, is good farm economy.

There is no merit in growing a crop at a loss merely because there is no crop that might be grown at a profit. Continuing to do that may, in fact, turn one's attention away from possible profitable alternatives. The intentions-to-plant reports this fall showed that continuous expansion is not unavoidable in the wheat fields. They indicated an intention to reduce the winter wheat acreage by 4½ per cent. Whether this is a response to the price situation or to the general argument in favor of readjustment makes no difference. It shows that adjustment is possible.

Eliminate High-Cost Acres

Mainly, readjustments in acreage are necessary as a corrective of low prices. It is elementary that prices can never rise in an overstocked market. That, however, is not their sole value. Wise acreage adjustments can help to decrease the unit cost, as well as the volume of production, and thus to widen the favorable margin, when any exists, between costs and prices, or to decrease that margin when it is unfavorable. This effect is produced by the elimination of the higher-cost acres, and the concentration of the remaining production on the more productive land. In the case of a widely distributed crop like wheat, acreage readjustment would affect lands varying much in productivity. On some farms, where wheat is a rotation crop, it might be retained at a cost of production that would be prohibitive in a cash-wheat area. Everywhere, however, the general principle of the readjustment process would be the same. In each region or locality it would transfer the highest-cost acres to other uses and thus tend to reduce average costs of production. This would obviously be an important advantage in world competition.

It is not correct to say that the same result would be reached by leaving the curtailment to the free play of economic forces, as is often recommended. That course lacks scientific discrimination. It forces good land as well as poor into the discard, because it acts primarily on farmers instead of on acres. When a farmer is driven out of business, his whole farm suffers. Acreage readjustments collectively engineered have more precision in relocating production to economic advantage. This procedure, instead of throwing much valuable agricultural land blindly out of use, makes crop shifts that maintain the farm business as a going concern, while at the same time modifying its tendency to create surpluses. Comparatively small changes, on a sufficient number of farms, have in the aggregate a great beneficial effect. All that is necessary to set this constructive force in motion is team play. Farmers must recognize their common as well as their competitive interests.

Not sentiment but logic is the foundation of this policy. If all the wheat land in America were owned by one man the problem of adjusting the output to the market demand would be easy. The owner would reduce his production when need arose, not by abandoning scientific methods or the use of machinery but by reducing his acres. Though our wheat acreage will never be owned by any one man, the problem, from the standpoint of the wheat industry, is the same as if it were, and the solution is the same. Our numerous farm operators have the same reason for not systematically oversupplying the market as an individual owner would have. At present they are engaged in destructive competition, each, by surplus production, beating down the price of the commodity for all. This is illogical and destructive.

Many farmers think production can not be controlled by controlling acres, since output depends also on the weather and on insect pests and plant diseases. Locally this is true. But taking the country as a whole production per acre is surprisingly uniform. In the last 25 years the average yield of wheat per acre has been 14.5 bushels. The highest yield was 17 bushels and the lowest 12.2 bushels, a maximum variation above the average of only 17 per cent and below the average of 16 per cent. In most of these years the yield was much closer to the average. Production, taking the country as a whole over a period of years, is primarily determined by acreage. Farmers who take a national as well as a local view of their business problems will recognize the practical application of this truth. In the long run man rather than nature controls the volume of farm production.

What has been said about wheat applies to many other farm commodities. It is easy to find objections to the policy of concerted action for the regulation of production. Like most things worth while, the policy involves labor and thought. It calls for a widespread cooperative spirit, alertness in recognizing opportunities for profitable crop shifts, close study of market prospects, and more careful farm accounting. Much farming is done unprofitably because the farmers do not count the costs. Not knowing what it costs them to grow a crop, they have a poor idea as to what it should bring them. Continuing to grow a crop at a loss merely because one's neighbor does, or through the force of inertia, is not rational production adjustment. But those who emphasize the obstacles to concerted action for the regulation of output fail to reflect that the alternative policy, namely, reliance on the competitive elimination of high-cost men and high-cost acres, has also its drawbacks. It means wholesale bankruptcies. It has the destructive wastefulness of other uncontrolled natural laws. Letting the surplus problem solve itself by progressive calamity is not creditable in a scientific age.

Goal Is to Increase Farm Profits

The final measure of agriculture improvement must be a rise in the average net farm income. There is no other satisfactory criterion. Productivity will not do, nor a rise in the quality or variety of the things produced. Nor is it admissible to be satisfied with figures showing increased investments in agricultural land or plant. Unless gain in these respects is translated into income, it is illusory from the standpoint of the working farmer. Net income, as every farmer knows, depends on two factors—costs of production and prices received. These factors vary in relative importance with circumstances, and circumstances determine which should be most emphasized at any given moment. At present, the price factor is predominant. Production in many lines is excessive, demand has shrunk somewhat, and farm commodity prices are at a heavy disparity with the prices of other goods. That is why I emphasize the supreme importance of production adjustments as a means of affecting profits favorably.

It goes without saying, however, that the other factor in net income, production costs, remains important, no matter how greatly it may temporarily be overshadowed by the price situation. Action taken to control the volume of production can not save the consistently high-cost producer. He must either get out or accept a low standard of living. If prices should show a downward trend in the next few years, not necessarily downward from the low point of the summer of 1930 but downward in the sense that the peak of the next price cycle is not as high as the peaks of the preceding ones, efficiency in farming, to keep costs down, will be more imperative than ever. So much progress in individual efficiency has been made by American farmers in recent years, however, that reiteration of its value seems unnecessary. Rising output per man engaged in agriculture shows clearly that American farmers understand the importance of keeping down their costs of production. There is one point about the subject of efficiency that may need to be emphasized. Increasing efficiency is not in contradiction with the need for reducing production. Sometimes it is accompanied by increased output, but that is not an inevitable relationship. Efficiency should reduce costs of production, while organization regulates the total volume. These two principles, far from being antagonistic, are the twin pillars of agricultural prosperity.

FARM TAXATION

Farm taxes last year continued to rise. In 1928 the real-estate tax per acre for the country as a whole was 5 per cent above the 1924 level. In 1929 it was 7 per cent above the 1924 average. The upward trend since 1924, however, has been less steep than that from 1913 to 1924. The most rapid increase in farm taxes since 1913 occurred in the period 1917 to 1923.

The ratio of taxes to land values has advanced rapidly. This is a result not only of the rise in taxes but also of the decline that has taken place in land values in the last decade. Tax levies in 1928 were $1.43 and in 1929 $1.46 for each $100 of the full value of farm real estate, as compared with $1.22 in 1924 and $0.68 in 1913.

With lower land values, and with the usual increase in taxes, the tax rate this year probably is about $1.50 per $100 of the full value of farm real estate. Farm real estate taxes now equal the interest which farmers would pay at 6 per cent on a mortgage indebtedness amounting to 25 per cent of the full value of the real estate, as compared with about 11 per cent in 1913.

In the last 15 years there has been a tremendous increase in State and local expenditures in the United States, which has put a heavy strain upon the prevailing system of raising revenues. The cornerstone of that system is the general property tax. In 1922, the last year for which official data are available, the general property tax accounted for 79 per cent of State and local taxes combined, and 89 per cent of local taxes alone.

The general property tax is little more than a tax on real estate. Personal property, especially intangibles, generally escapes taxation. The inducement to withhold property from the tax rolls becomes greater as taxes increase. Hence the revenue from the taxation of personal property has diminished greatly in relation to the total value of that property. The attempt to tax personal property, especially intangibles, by means of the general property tax, is generally a failure. Accordingly it has been necessary to increase the tax rate on property that can not escape taxation. Farm property is of that kind because it consists mainly of real estate, and of tangible personal property. Tangible personalty on the farm, such as livestock and equipment, can not be as easily hidden as intangibles, such as notes, stocks, and bonds.

More so than that of other groups of citizens, the farmer's income is directly dependent upon tangible property, primarily real estate, which is readily accessible to the tax assessor. The farmer's acute tax problem results from a rapidly increasing public expenditure met by a system of taxation that places most of the burden on real estate and tangible personal property. The burden has been made heavier in recent years by a diminution in the farmer's equity in his real estate, through the increase in mortgage indebtedness and the decline in real estate values.

The remedy lies in two directions: (1) More effective control of expenditures, and (2) revision of the prevailing system of taxation, so that more revenue will be derived from sources other than general property. Greater economy is imperative in State and local expenditure, not only through the careful scrutiny of expenditures but through the consolidation of local government units and the realignment of administrative functions. In recent years more progress has been made in these respects by the Federal Government than by State and local governments.

Of the total increase in State expenditures from 1915 to 1927, 41 per cent resulted from added expenditures for education and 20 per cent from added expenditures for highways. Probably about half the total increase in taxes on farm property since 1915 resulted from increased expenditures for education and about a fourth from additional expenditures for roads. Nevertheless the rural schools are not, generally speaking, up to the standard prevailing in cities; and the roads need further improvement. It would be easy to exaggerate the possibility of reducing farm taxes by cutting down school and road expenditures.

There is more prospect of farm-tax relief by changing our system of State and local taxation so that wealth other than real estate and tangible personalty will carry more of the load. The State governments, and to some extent the National Government, contribute to the support of schools; perhaps their responsibility in this respect is not fully recognized. Education is far less local in character than the present system of school financing indicates. The children in rural communities, many of whom are the future citizens of other communities and other States, should have educational opportunities comparable to those enjoyed by city children. This need should be met to a greater extent by taxes levied on sources other than general property and by the larger taxing jurisdictions.

A constructive position is taken by organized agriculture. By formal resolutions and otherwise the American Farm Bureau Federation and other organizations have emphasized the need for economy and urged careful study as a basis for revision of the State systems of taxation. No fixed program is applicable to all States, because their legal and economic problems vary.

Fuller information is necessary as a basis for public economy and tax revision, and farm organizations have taken steps to create permanent committees to study the problem. The American Farm

Bureau Federation has also formally urged that the tax-investigation work of this department be extended. Though legally a State problem, farm taxation from a broad economic standpoint concerns the whole Nation. Organized agriculture is justified in asking additional Federal research regarding farm taxes, for sound policy in taxation requires impartial research and the translation of the results into informed public opinion.

FARM-LAND VALUES

Farm real-estate values, though not regionally uniform in the direction or the extent of their movement during the last year, continued downward, considering the country as a whole. Recessions in the year ended March 1, 1930, rounded out a decade of declines. The number of farms that changed hands through forced sales and related defaults in the 12-month period up to March 1, 1930, was high in relation to the number of voluntary transfers. Recovery in values was impeded by heavy taxation and by other factors, notably falling agricultural commodity prices.

Surveys indicated that the average decline in value per acre of farm real estate for the entire country for the year ended March 1, 1930, was approximately the same as in the previous year, 1 per cent of the pre-war value as represented by a 1912–1914 average. This compares favorably with decreases of 2, 5, 3, and 3 per cent for the years ended March 1 of 1928, 1927, 1926, and 1925, respectively. The declines of the last two years have been the smallest reported since the break following the peak of land values reached in 1920. Farm valuations were then approximately 170 per cent of the 1912–1914 level. The March 1, 1930, level was 115 per cent of the 1912–1914 average.

A significant development was an apparent resumption of the decline in the East and West North Central and the Middle and South Atlantic States, which had previously shown some tendency toward stability. In a majority of the States, declines of 3, 4, and 5 per cent replaced the declines of 1 and 2 per cent reported for the previous year. An exception was Kansas, which for the fifth consecutive year reported practically no change in the average for the State as a whole. In western Kansas much new land has recently been brought into cultivation by power machinery. This may largely account for the State's favorable showing. The averages for the Pacific and the West South Central States remained essentially stationary. Those of the New England and Mountain States increased slightly. All told, 24 States reported declines, 6 reported increases, and 18 reported no change. In the previous year 28 States reported declines, 4 reported increases, and 16 reported no change. By States, the reduced number reporting declines and the larger number reporting increases were a favorable indication. Many of the declines, however, were more severe than those of the previous year.

Forced Sales and Voluntary Sales

Taking the country as a whole, forced transfers of farm realty were nearly as frequent as voluntary transfers. Tax sales, mortgage foreclosures, sales in bankruptcy, and sales made to avoid such formal actions involved approximately 20.8 farms per 1,000 for the year ended March 1, 1930, as compared with 19.5 per 1,000 reported the previous year. A downward trend was indicated during the three preceding years. The rate of voluntary sales and trades in farm real estate was 23.7 farms per 1,000—practically the same as in the previous year. In the New England, Middle Atlantic, East South Central, Mountain, and Pacific divisions voluntary transactions were more frequent than involuntary. In the West North Central and South Atlantic States, the converse was true. In the East North Central States the two types of transfer occurred with nearly equal frequency. The number of farm bankruptcies concluded in the courts in the fiscal year ended June 30, 1929, was five and a half times the pre-war figure. Later figures are not yet available.

During the last decade a large number of farms have been acquired by mortgagees. Mortgage loan companies, insurance companies and the land banks, as well as smaller operators, find themselves with land which they must either sell, operate, rent, or leave idle. Since these agencies are not organized primarily to operate or rent farms, the pressure to sell is very strong. Buyers are largely local farmers. But the extraordinarily large supply of farms for sale and the impaired buying power of prospective purchasers do not make a strong market.

FARM-CREDIT CONDITIONS

Farm-credit conditions were unfavorable this year. Lowered farm-commodity prices interfered with the liquidation of loans, and reduced the supply of new credit in country banks. In the smaller country banks of the leading agricultural States, deposits dropped to the lowest level since 1922. Many banks failed in parts of the Middle West and in some of the Southeastern States. Declining farm-land values affected the credit status of farmers and forced many to reduce their mortgages though they were ill prepared to do so. For the country as a whole, as previously indicated, farm-land values averaged 32 per cent lower than in 1920, and only 15 per cent above the average of the pre-war period. With allowance made for postwar changes in the value of the dollar, farm-land valuations were 20 per cent below the pre-war level. Bank loans based on the shrinking security of farmers' equities in their land were difficult to liquidate. In areas affected by the drought, credit facilities were strained, while the demand for credit, particularly for the purchase of feed, increased. Special measures, however, afforded substantial relief from this condition.

In short, the year saw the borrowing power of the farmers much reduced. This can not be attributed in any large measure to a lack of credit machinery or of credit institutions. Agricultural credit facilities have been vastly improved in recent years. The Federal reserve act, by giving greater flexibility to our banking system, greatly strengthened the country banks as well as the city banks. The Federal farm loan act of 1916 began a sound policy of farm-mortgage finance, through long-term amortization loans. The Federal land banks in 1930 had $1,194,000,000 in loans outstanding, and the joint-stock land banks $570,000,000. Under the agricultural credits act of 1923, 12 regional intermediate credit banks were set up to provide production credit for terms longer than those usually covered by bank credit. Though these institutions have not been as much used as was expected, they play an important part in our farm-credit system, particularly in the financing of cooperative associations. More go-between institutions are necessary to make their resources directly available to the farmers, since the law does not authorize direct borrowing by farmers from the intermediate credit banks. Some fairly large credit corporations formed to use the discount facilities of the intermediate credit system have been very successful, and there is room for more. Under the agricultural marketing act of 1929 the Federal Farm Board provides funds for loans to cooperative associations for marketing, for the acquisition of plant and equipment, and for other purposes. Credit thus supplied supplements that furnished by other agencies. Agriculture is much better served with credit facilities than it was 10 or 15 years ago.

The Risk Factor

The farm-credit problem, however, is not exclusively a problem in facilities. It is also a problem in risks. Its dual nature is evident from a study of the numerous bank failures that have taken place in recent years. More than 4,000 banking institutions in the agricultural areas have closed their doors since the postwar depression began. These failures might have been fewer had certain errors in banking methods and in banking organization been avoided. Too many country banks were chartered before 1920, and destructive competition for an insufficient total volume of business resulted. Many risks were assumed that prudent banking would have rejected. Often, too, bank managements were relatively inexperienced. In so rapid a growth of banking institutions the supply of trained men was inadequate. Obviously, however, defects of this character explain the bank casualties only in part. The underlying cause was the agricultural depression, with its reduced farm commodity prices and its reduced farm valuations. Loans that had seemed secure when made proved uncollectible. The farm-credit problem is merely a phase of the farm problem as a whole. Healthy credit conditions demand not merely sound credit institutions but sound farm management and sound farm conditions. If the supply of farm credit is to be adequate and the cost low, farmers and bankers must unite in action to lessen the hazards of the agricultural industry.

Farm credit remains costly in many parts of the United States notwithstanding the improvements brought about by the Federal reserve act, the farm loan act, and the agricultural credits act of 1923. Regional differences in the cost of credit reflect partly differences in local credit facilities and partly differences in agricultural risks. In some areas there is room for improvement both in the facilities and in the lessening of risks. Many farmers, especially in the South, depend excessively on costly merchant credit. They do so partly because an undependable farming system discourages banking enterprise and forces recourse to the merchant, and partly because of faulty credit management on the part of individual borrowers who often use the costly merchant credit even when in a position to avail themselves of the less expensive cash loans. Studies made by the department show that the high cost of merchant credit results largely from the high percentage of losses incurred.

Field for Production Credit

There is a large field for constructive activity by banking and credit institutions to correct these conditions. Credit institutions can not be expected to make loans at low rates where agricultural hazards are extreme, but they can do something to reduce these hazards. They can urge better farm management when loans are being negotiated, and can offer special inducements for the promotion of side-line or other enterprises calculated to strengthen the farm business. Production credit furnished at reasonable rates, on conditions tending to improve the business organization of agriculture, is urgently necessary.

Credit policy should not confine itself to the exercise of a legitimate influence upon the choice of farm enterprises, but should consider also the basic financial structure of agriculture. For certain purposes it is convenient to distinguish short term from intermediate credit, and both from long term or mortgage credit. But the distinction should not obscure the essential interdependence of these forms of credit. Unsoundness in one form is quickly communicated to the others. This happens conspicuously when shrinking farm equities make difficult or impossible the funding of " frozen " short-term credits.

It is particularly important that mortgage financing should be based on careful and scientific land valuations. Too often the guide is not the current earning power of the land but its estimated selling value as security for loans. As this is reckoned on hopes for the future as well as on current realities, it frequently is wrong. More emphasis on farm earning power is required, and the educational process necessary to effect this should reach lenders as well as borrowers. For the most part, the United States is in no present danger of a reinflation of farm-land valuations with consequent over-borrowing. In fact mortgage credit just now is too short rather than too plentiful. But there is always danger in too much reliance on estimated capital values and too little on actual earning power, as the basis for loans. Our newer agricultural areas in the Great Plains, where power machinery is farming lands formerly not capable of being profitably farmed, run some risk of this sort. Farmers in these areas should be careful not to build excessively on the results of too short a period. Practically every State in the Union made this mistake in the World War period and is now paying for it.

The Trend in Mortgage Debt

Recent studies by this department indicate that up to 1920 the volume of mortgage indebtedness in the United States closely reflected the upward trend in farm real-estate values. After the postwar slump, however, the two curves diverged. Mortgage debt continued to increase though land values fell. As a result the total farm-mortgage debt of the United States now represents about 22 per cent of the value of all farms, compared with only 10 per cent in 1910. For the year 1928 the estimated total of farm mortgage debt for the United States was $9,468,526,000, as compared with $7,857,700,000 in 1920, and $3,599,000,000 in 1910. The total has continued practically unchanged during the last two years. It seems that since 1928 a halt has been reached in the long upward trend. In fact, the principal lending agencies reported a definite decline in 1928 and 1929 in the amount of their farm-mortgage loans. Some of the increase in farm-mortgage debt since 1920 represents the funding of short-term bank debt. A proportion of course represents new credit. It need scarcely be remarked that the burden upon agriculture represented by the postwar rise in farm-mortgage debt is very heavy. The part played in the creation of the burden by past errors in borrowing and lending should be carefully considered.

The criterion in negotiating any type of agricultural loan should be the amount of credit the borrower can profitably use. When the lender considers only how much it seems safe to lend on the security offered, he goes against his own interests as well as against those of the borrower. Capital values, though ultimately based on earning power, are not necessarily a true measure of earning power at any given moment; and earning power is the only source from which the debt payments can be maintained. Essentially it is the earning power of a farm that determines the limit of profitable borrowing. When farmers borrow excessively in the hope that advancing land values will enable them to pay off their obligations in the future, they run heavy risks.

It is quite impossible, of course, to lay down a general rule as to the proportion that should subsist between the farmer's own capital and the capital that he borrows. That will vary with the man, with the farm, and with the general economic and market situation. Lending institutions are, just now, perhaps too conservative in making agricultural loans. They are naturally impressed with the practically continuous fall in farm-land values since the war and with the resulting heavy damage to themselves. Short-term as well as long-term credit sources respond in the same way to the postwar situation. Country-bank failures counsel conservatism powerfully. It does not follow, however, that the prevailing conservatism is wise. It may be merely a blind reaction from the preceding excessive liberality. More attention is paid to earning power in negotiations for short-term credit than in long-term credit operations, but even in the short-term field the prevailing influence is the memory of recent losses, rather than a sober study of current opportunities. When credit can be profitably used it should be furnished. In such circumstances it is wasteful to withhold it, just as it is wasteful to extend credit for which there is no profitable use.

Common Interest of Lender and Borrower

Increased farm earnings, though indispensable, are not all that is necessary to make agriculture prosperous. The producer must retain a fair share of the increase. In other words, care must be taken to see that capital charges are moderate. Farmers can not succeed when interest, rent, and other fixed charges continually absorb an increased proportion of the farm income, as has happened in recent years. It is necessary to maintain a correct relationship between capital charges and what is called labor income, or the margin left after interest, rent, operating expenses, and taxes have been paid. The first essential is to estimate farm earning power with approximate accuracy, so that land prices and mortgage debt will not discount speculative hopes excessively. Borrowers and lenders have an equal interest in bearing this truth in mind. Since current income is the only source from which debt can be paid, it profits nothing in the long run to burden agriculture with more capital charges than its current income can sustain.

LAND UTILIZATION

How to make a better use of our land resources is a pressing problem. It would demand attention even if there were no crisis of overproduction. It is not simply a question of finding new uses for farm lands whose products can not now be profitably sold, but of allocating various types of land to the most advantageous ends.

In the United States we have a domain of nearly 2,000,000,000 acres, of which about 400,000,000 acres are classed as employed for cultivation. But if needed we could use nearly a billion acres for crop production. This is about half the total area of the Nation. In a general way our crops are grown in the areas to which they are best adapted; but a much better adjustment than that brought about by trial and error is possible. Heretofore much land has been occupied in ignorance of better lands elsewhere, as well as of progress in agricultural technic, and is now unprofitable. Much land has been put into crops that should have been left in grass or forest. Large areas have been settled under conditions that invited failure. The time has come to correct some of the mistakes of the past and to take precautions against similar mistakes in the future.

A profitable agriculture, however, can not be brought about merely by correction of past errors. It is becoming necessary to reshape the very foundations of the agricultural industry. Nothing less will accommodate it to the pressure of the powerful economic forces affecting supply and demand conditions. On the demand side, for instance, the displacement of work animals by power-driven machinery is removing the need for many million tons of corn, oats, and hay. Changes in diet are lessening the demand for certain products and increasing the demand for others. The American people are eating less bread, less corn meal, and less cereal foods per capita than they did 10 years ago. They are consuming more milk, more pork, more sugar, and possibly more fresh vegetables and more fruit. Export demand is narrowed by the recovery of European farm production from the effects of the war. Pre-war levels in production have been regained in most European countries and surpassed in some. Europe seeks greater self-sufficiency also through import restrictions. This year world-wide business depression has further weakened the agricultural markets.

On the production side technical progress is bringing extensive semiarid areas into cultivation not only in the United States but also in Russia, Canada, Australia, Argentina, and elsewhere. Labor-saving machinery is promoting the cultivation of low-yield areas that formerly could not be profitably cultivated. American agriculture, always more economical of labor than of land, is pushing this principle to a new high level. Yet it has, of course, no monopoly on efficient farm technic. Production is outrunning consumption in most of the world. Argentina is now the leading corn-exporting country and has four times the corn acreage it had in 1900. Its exports of beef in 1929 were nearly a hundred times greater than ours. Exports of butter from New Zealand, Australia, and Argentina have increased sevenfold since 1900, and last year exceeded 350,000,000 pounds. Australia's wool production in 1929 was twice what it was in 1900. Russia is exporting wheat again. With a population only 20 per cent greater than that of 1900, the world's wheat and rye production is now something like 40 per cent greater and its production of corn, oats, and barley, taken together, about a third greater.

Seven Major Objectives

These conditions emphasize, though they do not create, the need for a rational land-utilization policy. Such a policy (1) calls for a scientific classification of our land resources, so that crop, pasture, and forest requirements may be more efficiently met. Knowledge of land resources is indispensable to the wise direction of production. (2) The contraction of farm acreage is necessary in some areas, and a check upon its expansion is necessary in others. (3) Steps should be taken by public agencies, local, State, or Federal, to divert tax-delinquent lands or lands obviously submarginal for farming purposes to other than farm uses. (4) Our national reclamation policy should be reconciled with the need of restricting farm production. (5) Public reforestation should be pushed. (6) Our public-domain policy should equally serve the interests of the local farming and grazing industry, the interests of agriculture as a whole, and the interests of the Nation. (7) Information should be made available to guide private enterprise in land settlement.

These points need not all be discussed in detail, though one or two may be amplified. It is particularly important to foster the contraction of farm acreages in unprofitable areas and to discourage expansion in others. Recent technical progress in American agriculture has changed our agricultural map considerably. Expansion in some areas has created distress in others. This is one of the inevitable penalties of progress. Specialized cotton growing on large farms in Texas and Oklahoma has put a heavy handicap on extensive areas in the Old South where boll-weevil infestation is heavy. Tractors and combines have caused a marked concentration in the production of wheat in the Great Plains area. In the States to the east wheat growing has declined.

Farming by the old methods, in fact, has become unprofitable in extensive areas, and much acreage has been abandoned and become tax delinquent. Often, however, the abandoned farms are resold instead of being excluded from crop production. It should be an essential aim of our agricultural policy to facilitate the withdrawal from agriculture of acreages that seem likely to remain unprofitable. Public provision should be made for the utilization of this land for purposes other than farming. This is not possible in many States under existing laws, which generally provide for the resale of tax-delinquent lands. There seems to be an opportunity here for Federal cooperation with State and local governments to promote the economic stability of distressed areas. A study should be made to determine what classes of land are ill-adapted to private cultivation, grazing, or timber growing, and to indicate what benefits might be derived from the public acquisition of such areas.

The States should take the leading part in acquiring lands unsuited to private utilization; in fact, several are progressing in that direction. In most States, however, lack of funds or other difficulties prevent such action. The Federal Government might well cooperate with the States through a system of Federal aid to acquire lands suited to forestation, and it might cooperate with State and local governments in consolidating tax-delinquent and similar lands into administrative units.

The public acquisition of idle lands, though in contrast with our historic land policy, seems justified by present conditions and by changing national objectives. Land not immediately needed for crops or pasture often suffers under private ownership or control. Private interests seldom do much to protect stream flow, to prevent erosion, or to conserve game and fish. Often, under the pressure of heavy carrying charges, they try to push idle land into agricultural uses, whether that is economically sound or not. This is easy in times of temporary agricultural prosperity, but the practice leads to distress. Public ownership of lands that can not be profitably farmed would, in many areas, mean a better economic use of the lands in question, and also do something to relieve the pressure of unneeded production upon the markets.

Our land-utilization policy should also tend to prevent unnecessary and ill-advised farm expansion. Most of our potential crop land is in private ownership, and to prevent mistakes in employing it for farming when the owners wish to promote that use is difficult. It should be possible, however, to discourage ill-advised expansion. Farmers may easily be misled about the character of lands that they do not know. An information service to tell them about the economic possibilities of different areas would be a restraining influence. It is true that no agency can make infallible judgments about agricultural possibilities. Much better information could be made available, however, than that on which intending settlers commonly rely. Heretofore little has been done by public agencies to direct agricultural expansion. The opportunity to do so in the future should not be neglected. In this field the Department of Agriculture and State agencies should work in close cooperation.

Economic Problem of the Public Domain

In the past we have neglected the opportunity for helpful guidance when new lands in the public domain were made available for settlement. The responsibility for selecting his land has been placed largely on the settler himself. Some safeguards were provided in the grazing homestead act of 1915, but these did not prevent much poorly judged settlement. Our homestead policy in the last two decades has stimulated overproduction and caused heavy losses to homesteaders. Little land remains in the public domain suitable for cultivation, but the homestead policy still has a tendency to encourage uneconomic farm expansion. The danger would be increased should land now in Indian reservations be thrown open. Research to show the economic feasibility of using different areas for agriculture and the amount of land requisite for an economic unit and wide publication of the results must be the mainstay of any program for the better control of agricultural expansion, whether in the public domain or in private hands.

Relation of Reclamation to Farming

In our Federal reclamation policy it seems highly desirable to weigh the advantages of local or regional development against the disadvantages of promoting excessive agricultural expansion. Many proposed reclamation projects involve nonagricultural considerations, such as flood control and the development of water power. Such projects obviously can not be judged exclusively from an agricultural standpoint. Moreover, the number and scope of such projects seems likely to increase. The Nation is working gradually toward comprehensive flood control in place of piecemeal local drainage and levee construction. This broad policy should be more efficient and economical than the one it replaces. There are, however, many reclamation projects under discussion that should be considered primarily, if not exclusively, from the standpoint of agricultural welfare. It is a serious question whether in view of the existing overproduction in agriculture it is advisable to promote agricultural expansion through irrigation and drainage. The Federal reclamation policy involves a direct subsidy to agricultural expansion in the form of interest-free loans. This subsidy policy seems inconsistent with the efforts now being made by the Federal Government to restrict agricultural production. Studies of our land requirements which take into consideration the available land areas, the probable growth of population, the trend in consumption, technical progress in agriculture, and foreign-trade prospects indicate that the present need is not agricultural expansion but contraction. For a decade at least our chief task will be to prevent too rapid an expansion of the arable acreage.

Reforestation

Reforestation will be more fully discussed later, but I mention it here because reforestation is a fundamental part of the land-utilization problem. Our reserve of timber, though fast shrinking, is still large enough to prevent timber prices from rising sufficiently to stimulate private reforestation. Hence, though private reforestation should be encouraged where it operates on a basis of sustained yields, the foundation of reforestation in the United States must be public action. Fortunately, it is now generally acknowledged that the public ownership of forest lands is desirable. Many countries where timber is scarce and dear, and where in consequence private enterprise might seem to be attracted to reforestation, have more of their forests publicly owned than has the United States. Japan has more than 60 per cent of its forest land in public ownership and Germany more than 45 per cent. Italy and Rumania each has more than 50 per cent of their forest land in Government hands. Some of the newer countries also have followed the policy of retaining a larger proportion of the forest area in public ownership. Thus, Canada has 90 per cent and Australia and New Zealand nearly 80 per cent each.

The United States has more than half a billion acres that could be devoted to timber growing without detriment to farm development. Much of this land may become a neglected waste of small value unless our public reforestation program is greatly enlarged. Some abandoned farm land is growing up to brush and timber of low utility, and the lack of an individual or public interest in its protection against fire makes it a menace to other more valuable areas. Public reforestation is imperative for several reasons. It is necessary to promote timber production, to protect stream sources, to check erosion, to provide recreational facilities, and to utilize land resources that would otherwise produce little or nothing.

FIELD RESEARCH IN FARM MANAGEMENT

There have been many discussions, but too few demonstrations, of sound farm-management principles. This is true in part because our experiment stations have not been able to demonstrate the best labor practices for a certain crop in a given area and year, for instance, as well as they have demonstrated the quantity of nitrogen, potash, and phosphorus needed to grow that crop on a given soil. We have talked about the size of farms, the size of fields, the location and topography of farms, the use of one farm practice rather than another, the use of machinery, and so on. Practical tests of all these economic and production principles on individual farms would be desirable. Many farmers have developed their own systems of farm management—largely by trial and error. The cost of trial and error is high. Its results are not always the best. It would undoubtedly be helpful if the State and Federal experiment stations could expand their operations to include research in farm management in the field on land specially set aside for the purpose.

The object of improvement in farming is a high standard of living. To obtain this, agriculture must be profitable. This has long been recognized as a matter of public concern. It is now to the public's interest, as well as to agriculture's interest, to encourage economic research as vigorously as we have encouraged the research in the technic of production, without diminishing our efforts in the latter field. On farms given wholly to experimentation and demonstration we could test the soundness of various farm practices and farm-management methods.

MOVEMENTS OF POPULATION

Movements of population from the farms to the cities and from the cities to the farms of the United States, though still very large, have decreased somewhat in the last few years. The movement to the towns and cities, according to surveys made by this department, comprised 1,876,000 persons in 1929, 1,923,000 persons in 1928, 1,978,000 persons in 1927, and 2,155,000 persons in 1926. In 1929 the total number of persons who went to the farms from the cities was estimated at 1,257,000; in 1928, 1,347,000; in 1927, 1,374,000; and in 1926, 1,135,000. The net cityward movement was 619,000 in 1929, 576,000 in 1928, 604,000 in 1927, and 1,020,000 in 1926.

These figures do not indicate the net loss of farm population. The latter figure is determined not only by the ebb and flow of population between the country and the town, but also by birth and death rates. As the birth rate on the farm is much higher than the death rate, the annual loss of farm population is less than the net annual migration. For 1929 the net loss of farm population is calculated at 269,000 persons, for 1928 at 208,000 persons, for 1927 at 193,000 persons, and for 1926 at 649,000 persons. The estimated farm population of the United States as of January 1, 1930, was 27,222,000, as compared with 27,491,000 on January 1, 1929, 30,200,000 on January 1, 1922, and 32,076,960 on January 1, 1910.

Our farm population has been a declining proportion of our total population for many decades. This is partly a result of increasing farm efficiency, which enables fewer men to produce a given quantity of food and fiber. Some migration to the cities is therefore inevitable and desirable. It lessens agricultural competition, while broadening the urban market. In recent years, however, the cityward movement has been excessive, as is evident from the magnitude of the return movement. A smaller migration, had it been more definitely in one direction, would have sufficed for the necessary redistribution of population between town and country.

The slight decline in the total population movement both ways in the last few years—3,133,000 in 1929 and 3,290,000 in 1926—indicated, up to the present year, a gradual stabilization of economic conditions, an increasing permanence in the adjustment of persons to their occupations. Too much scurrying backward and forward betokens social and economic maladjustment. We seem very slowly to be getting away from that evil.

Always, no doubt, there will be a considerable movement both ways. Progress in farm technic will progressively release men from agriculture. On the other hand, many city persons will be drawn to agriculture. Some will inherit and others will buy farms. Many farm people who try city life will find themselves unsuited to it and will return to the country at the first opportunity. It is well to keep the doors swinging freely. Just how much ebb and flow of population between the farms and the towns is desirable depends on economic and social factors so complex and numerous that they can not be measured. This much we can say with certainty: Population movements as large and conflicting as those of recent years betoken economic disorder. What effect the current world-wide depression will have on population movements will be indicated by the 1930 census.

THE TARIFF ACT OF 1930

The tariff act of 1930 came in answer to the growing sentiment that a protective tariff must become more and more an integral part of our national agricultural policy. Three substantial reasons for this point of view present themselves.

In the first place, tariff protection is of increasing importance to agriculture in the United States because agriculture is becoming less dependent on foreign markets and more dependent on home markets. Fifty years ago farm products comprised 80 per cent of all our exports; to-day they comprise less than 35 per cent. Similarly, our agricultural exports are becoming a smaller percentage of our total domestic farm production. At the turn of this century we exported about 24 per cent of the total value of animal products and of crops not fed; to-day we export well under 15 per cent. There is every reason to expect that this trend will continue and that the domestic market will grow in importance to the domestic producer.

Protects Domestic Market

In the second place, competition in farm products in world markets has increased enormously. Wheat, to name only one of many examples, has increased 40 per cent in world production since 1900, whereas world population has increased only 20 per cent. Products from new lands, produced by cheap labor, fill the market places of the world. And yet the world is far from its productive limit. An additional obstacle to surplus-producing countries has been the steady increase in import duties in Europe, the principal importing area for products which compete with our farm products. A report by the United States Tariff Commission on 14 major agricultural products reveals, for 1929, a widespread increase in import duties and milling restrictions throughout Europe. The height to which import duties on farm products have risen throughout the world is startling. The duty on wheat is now 74 cents a bushel in Spain, 85 cents in France, 87 cents in Italy, and $1.62 in Germany. Our duty is 42 cents a bushel. On barley our duty is 20 cents a bushel; foreign duties go as high as 66 cents. On corn our duty is 25 cents a bushel; foreign duties reach 48 cents a bushel. On bacon our duty is 3¼ cents a pound; foreign duties reach 13 cents a pound. On lard our duty is 3 cents a pound; foreign duties reach 6 cents a pound. On butter our duty is 14 cents a pound; foreign duties go as high as 27 cents a pound. Sweetened condensed milk imported into the United States pays a duty of 2¾ cents a pound; foreign duties go as high as 26 cents a pound. On unstemmed leaf tobacco our import duty is $2.27¼ a pound; foreign duties go as high as $5.49 a pound.

Under these conditions our domestic market is of the utmost importance. The tariff act of 1930 is the best means available of preserving the American market for American farmers.

Helps Balance Production

A third reason why agriculture places increased reliance upon the tariff lies in the tariff's value in helping balance production against market demand. By improving the domestic market for products which might be raised in greater quantity in this country the tariff will permit shifts from surplus to deficit crops. For instance, we import vegetables which it requires 388,000 acres to produce; dairy products and by-products which it requires 450,000 acres to produce; cattle, hogs, and sheep which it requires 818,000 acres to produce, and so on. The total shift in acreage from crops of which we now produce a surplus to crops to which increased tariff protection offers a better market could run as high as 10,000,000 acres. Farmers contemplating such shifts should of course figure relative production costs closely.

It is not surprising, then, that the American farmer is to-day taking a far greater interest in the protective tariff than he once did. His interest in the recent tariff legislation was vigorously voiced through his organizations. He looked to the tariff act of 1930 to remove some of the disparity between the protection afforded industry and the protection afforded agriculture. The tariff bill as enacted should give him considerable satisfaction.

Measured in terms of equivalent ad valorem rates, the average rate for all 15 schedules of the tariff was increased from 33 to 40 per cent, a gain of 7 points, or 20 per cent. The average rate for Schedule 7, agricultural products and provisions, was increased from 20 to 34 per cent, a gain of 14 points, or 69 per cent. This is by far the largest increase for any schedule in the tariff act. In other schedules of direct interest to agriculture there were the following increases: Sugar, molasses, and manufactures of them, 14 per cent; wool and manufactures of wool, 21 per cent; spirits, wines, and other beverages, derived principally from agricultural products, 30 per cent. Fifty-four per cent of the items in Schedule 7 bear higher import duties now than in previous tariff acts. This increase is greater, both in number and percentage, than the increase in any other schedule with one exception—wool and wool manufactures. In that schedule, also of direct concern to agriculture, increases affected 79 per cent of the items.

The tariff act of 1930 includes substantial increases in duty on cattle, meats and meat products, hides, wool, long-staple cotton, flaxseed, soybeans, butter and cheese, milk and cream, casein, eggs and egg products, sugar, and a long list of fresh fruits and vegetables. Many of these rates, such as those on wool, eggs, long-staple cotton, and dairy products, will be generally beneficial. Others will be of maximum assistance in border markets and under favorable market conditions. All will help hold the home market for the American producer and add to the economic urge to agriculture to balance its production against the market demand.

Increases Favor Agriculture

This protection would, of course, be fictitious if the rates on the things the farmer buys were increased as much as the rates on the things he sells. I have already indicated, however, that the average increase for all schedules in the tariff act was only 20 per cent, in terms of equivalent ad valorem rates, whereas items in the agricultural-products schedule were granted increases averaging 69 per cent. The point can be illustrated by this concrete example:

The average farm family's annual budget amounts to $1,159, studies by the Department of Agriculture indicate. In order to test the effect of the tariff upon this budget the new rates have been applied to it. The rate on each item was then weighted by the expenditure for that item to get a weighted tariff rate. We find that the weighted average tariff rate on commodities bought by farmers was 16 per cent by the tariff act of 1922 and is 20.2 per cent by the tariff act of 1930. The maximum possible increase in the farmer's budget appears, therefore, to be around 4 per cent, or about $48 a year.

Stated in round numbers and assuming that the rate increases on farm products are entirely effective, the average income per farm on the basis of 1928 production and prices would be increased by about $150. The average expenditures per farm—assuming, again, that the tariff rates are fully effective—would be increased about $48 by increases in duties on the things the farmer buys. The net balance resulting from the new tariff rates, therefore, would be about $102 per farm in favor of the farmer.

Neither the increases on the commodities the farmer buys nor on those he sells will be fully effective. But the foregoing analysis is sufficient to demonstrate that, so far as tariff protection can go, the farmer is in a stronger position by virtue of the 1930 act.

FOREIGN AGRICULTURAL SERVICE

A much-needed expansion of the foreign service of the Department of Agriculture is provided for by a new act of Congress, Public, No. 304, approved June 5, 1930. This measure directs the Secretary of Agriculture to (1) acquire information regarding world competition and demand in agricultural products; (2) investigate farm management and economic phases of agriculture in foreign countries; (3) demonstrate standards for cotton, wheat, and other American products; and (4) appoint representatives of the Bureau of Agricultural Economics as officers of the foreign agricultural service of the United States. These officers will be attached, through the Department of State, to the diplomatic missions of the United States, or to the consulates of the United States in the countries where they are stationed. The measure recognizes the increasing need of precise and extensive information about foreign agricultural conditions. Heretofore information about foreign crops and markets has been fragmentary and often inaccurate. Many Governments do not report upon the agricultural activities of their countries, and some that do report the subject inadequately or in terms that are not satisfactory for comparative purposes. Supplementary field work by trained observers, as contemplated under the new law, should add much to the practical value of our foreign crop and market reports.

This department spends annually more than $2,000,000 on domestic crop and livestock estimating, on price analysis, and on market news distribution. Similar work on foreign conditions is necessary to supplement the domestic information. Farm-commodity prices within the United States often depend as much on conditions abroad as on conditions at home, and an economic information service that does not broadly cover foreign conditions obviously can not fully answer its purposes. American farmers can not adjust their production intelligently to market requirements if they are in the dark about foreign demand and foreign competition.

Correlation of Foreign Work

Prior to the enactment of the new legislation this department maintained a foreign agricultural information division with resident representatives in London, Berlin, Shanghai, and Marseilles. Subsequently a resident representative was stationed in Belgrade to cover the Danube Basin. Resident agricultural representatives are to be stationed in South America, South Africa, Australia, India, and the Scandinavian countries. In addition, specialists will be assigned to study the world situation with respect to specific commodities, notably cereals, cotton, tobacco, wool, fruits, livestock and meats, and dairy products. Work done by the department's foreign information service will be correlated as closely as possible with similar work in the Consular Service of the State Department and in the offices of the Department of Commerce in foreign countries.

40442°—31——4

For this purpose a committee has been appointed, with the Department of State, the Department of Agriculture, the Department of Commerce, and the Federal Farm Board each represented by one member.

The International Institute of Agriculture, at Rome, furnishes considerable material on agriculture in foreign countries. Adequate world reporting on important commodities will require at least 10 foreign posts to cover the important producing and consuming areas. In short, the situation calls for a national organization to interpret crop and market data in terms of prospects for American agriculture. This need the new legislation should in large measure supply. A knowledge of world conditions in regard to acreage sown, crop conditions, harvest yields, stocks, numbers and kinds of livestock, and prices, together with information on present and prospective demand conditions, is the aim.

REGULATING TRADE IN PERISHABLE PRODUCTS

Regulation of the trade in fresh fruits and vegetables is provided for by an act of Congress passed this year, Public, No. 325, approved June 10, 1930. This law, designed to suppress unfair and fraudulent practices, prohibits fraudulent charges, improper rejections, failures to deliver, discarding or dumping of products without reasonable cause, false reporting about shipments, failure to account correctly for shipments, misrepresentations as to the origin of shipments, and the removing or altering of tags representing Federal inspection. It provides for the licensing of commission merchants, dealers, and brokers, and authorizes the Secretary of Agriculture to reject or revoke licenses for violation of the act. It also gives the Secretary authority to order the payment of reparations to injured parties. Civil suits may be entered in the courts to compel the fulfillment of such orders.

The act gives permanent authority for the department's fruit and vegetable inspection service. All branches of the fruit and vegetable trade, as well as organizations representing the producers, indorsed the principles of this legislation. The Food Administration during the World War period required all handlers of fruits and vegetables to take out licenses; the results of this system were generally satisfactory. It lapsed, however, with the return of peace. Shippers and others have urged its restoration through permanent legislation. Both shippers and receivers of fruits and vegetables have sought protection against unethical practices and against difficulties created by the lack of uniform methods for the settlement of disputes. These requests became so insistent that many bills designed to meet them were proposed before the present one was adopted. Though it has been in operation only a few months, it has done much good already. Notably it is causing some formerly haphazard phases of the fruit and vegetable industry to be brought under contractual relationships. Incomplete and indefinite contracts are a common cause of misunderstanding between shippers and receivers of fresh fruits and vegetables. Cooperative associations, as well as private merchants, dealers, and brokers, are required to take out licenses. Individual producers, however, are not obliged to if they sell only produce of their own raising. A person buying produce solely for sale at retail is not considered a dealer within the meaning of the act, unless his annual purchases exceed 20 carloads. These are the only exceptions to the operation of the measure in interstate and foreign commerce. Essentially all that the act requires of the licensee is square dealing and proper records. It will not interfere with the proper conduct of his business, but will make it less hazardous by reducing the frequency of disputes.

CENSUS OF AGRICULTURE

The agricultural census, taken this year in connection with the decennial census of population, will furnish much more complete information than did any of the preceding agricultural censuses. Besides giving particulars about crop acreages, classes of livestock, landlords and tenants, farm valuations, and so on, it will go into detail about certain phases of agriculture not previously covered in census material, or covered less fully, such as farm incomes, expenditures for operating, equipment, taxes, farm mechanization, soil erosion, and movements of agricultural population. It will furnish a classification of pasture lands, statistics on milk production and poultry production, and on the use of home conveniences in farm homes, and new data on the value of farm products, which will afford a basis for classifying farms by types of farming. Census information is foundation material in the department's economic services to agriculture, and the broadened scope of the present census will make it exceptionally valuable.

As yet the only information for all States available from the census is the count of farms. This indicates that the number of farms has continued to decline in most parts of the United States since 1925. For the country as a whole the decline is about 1 per cent, or much the same as the decline between 1920 and 1925. The most notable decline in the number of farms is indicated in New England, New York, New Jersey, and Pennsylvania. In these States, however, the indicated decrease may partly reflect changes in the decisions of the enumerators as to what places should be called farms. The census taken in 1925 was exclusively an agricultural one. It therefore tended to include as farmers many persons whose main occupation may not have been agriculture. The 1930 agricultural census, since it was taken in conjunction with the general census, probably registered more precise occupational discriminations. The census instructions this year, as in prior years, provided that no place producing less than $250 worth of products annually should be enumerated as a farm, unless it exceeded 3 acres in size; but the instructions with reference to farm population added, "and which is also locally regarded as a farm." In Massachusetts, for example, it has been estimated that there are only about 13,000 real farms, but, in addition, that there are about 50,000 small home places, mostly along the main highways, which produce small quantities of milk, poultry, and garden truck. Many of these small places undoubtedly were included in the census of 1925 and excluded in the 1930 census.

In other parts of the country where the number of part-time farmers is relatively small the decline recorded by the census in the number of farms is undoubtedly real. This is true of Kentucky, Ohio, Indiana, and Illinois. A decline for those States is recorded of from 5 to 15 per cent since 1920. A decline has taken place also in South

Carolina and Virginia. In the western Corn Belt, and in the wheat regions generally, the number of farms has remained about stationary. The same is true of the Rocky Mountain States and the Pacific Northwest States. The number of farms has increased in Oklahoma, Texas, Louisiana, Arkansas, Mississippi, North Carolina, Arizona, and California. There has been a partial recovery in Georgia from the great decrease that took place in that State between 1920 and 1925. Power farming, particularly in the Great Plains States, has made many large farms; in other parts of the country the automobile has brought into existence a greater number of small farms.

World Census of Agriculture

Much important basic information for world crop reporting will be obtained from the world census of agriculture which is being taken this year. Practically all governments have promised their cooperation. In the last 25 years only 37 countries have taken an agricultural census. These 37 countries represent less than half the land area of the world and only about 30 per cent of its population. Moreover, the censuses they took varied in dates and in methods used. Their lack of uniformity made them not very valuable for statistical purposes. In the world census now being taken, three uniform schedules, drawn up by an international committee, are employed. One is an extended schedule for the use of the more highly developed agricultural countries, another is less extensive, and a third, representing minimum requirements, is intended for the less developed agricultural countries. In this way it is hoped to gather data much more accurate and suitable for making comparisons than have ever before existed. Agricultural progress depends to an important degree on a knowledge of agricultural resources. The world census of agriculture will furnish an inventory of such factors as land areas, crop acreage, harvest yields, the number and kinds of livestock in different countries, the amount of mechanical power and equipment used, and the amount of human labor available for agriculture. It should help farmers everywhere in adjusting their production and marketing more accurately to the demands of the market and should also disclose strong and weak points in agricultural systems.

COOPERATION WITH THE FEDERAL FARM BOARD

As required by the agricultural marketing act of 1929, the department cooperated closely with the Federal Farm Board. The Division of Cooperative Marketing was transferred from the department's Bureau of Agricultural Economics to the Farm Board. Other units of the department assisted the board with research and service. In this way duplication of effort was avoided. The board's agricultural responsibilities do not overlap those of the department, but rather supplement them. The primary duty of the board is to help farmers organize cooperative marketing associations, for the improvement of the distribution of farm products, and to aid in preventing the production of surpluses. An important part of the department's contribution to the work of the board is to furnish accurate economic and other information upon which the board may base its policies. In its efforts to minimize speculation, to prevent inefficient and wasteful distribution, to organize the producers into effective marketing associations, and to bring about a better adjustment between farm production and market needs, the board depends vitally on facts given to it by the department. It looks to the department for basic information on land utilization, credit, insurance, crop, and price conditions, foreign agricultural conditions, and market prospects at home and abroad. The board is assisted by the department's extension forces in campaigns for organization among farmers and for a better adjustment of crop acreages. This phase of the department's cooperative relations with the Federal Farm Board will be referred to again in connection with the department's extension and information work generally.

EXTENSION WORK

Cooperative extension work took a strong economic turn during the year. As a result, marked progress was made in the effort to reorganize farming so as to place equal emphasis on effective individual practice and on wise group action tending to regulate production and the movement of commodities into consuming channels. Facts presented by extension agents bearing on production and marketing and on the economic situation met with intelligent response from farmers and had a constructive influence in changing farm practices. A vigorous effort was made to acquaint farmers with the objects, relations, and business possibilities of cooperative associations and with the requirements for membership. The assistance of extension agents in organizing over 1,000 local cooperative marketing associations in 1929 indicates the practical support the Extension Service gave the Federal Farm Board in the administration of the agricultural marketing act.

Helping Farmers Look Ahead

Extension agents helped farmers to look ahead. They combined general economic information furnished by the Bureau of Agricultural Economics with local data gathered by State agencies. Facts on the needs of particular localities, and even on the needs of particular farms, were applied in farm-management recommendations. By bringing about a substantial adoption of those recommendations, extension agents made progress in aiding farmers to establish a good balance among different crop enterprises and to adjust production to market requirements. In these efforts to meet the economic situation by adjustment of production, extension agents cooperated in the campaigns conducted by the Federal Farm Board in the Cotton Belt and in the spring and winter wheat areas.

Technical and economic facts were presented at hundreds of farmers' meetings. Recommendations made in the department's periodical outlook report were more widely and painstakingly disseminated than ever before. Market conditions were analyzed in an effort to foresee the probable effects of failure to readjust farm production. Certain crop enterprises, particularly tobacco and potato growing, were brought into a better relationship with the markets as a result of extension work done in farm management and economics. An effective organization—the Interstate Early-Potato

Committee—was sponsored by the extension divisions of Maryland, Virginia, North Carolina, South Carolina, and Florida. Its representation included growers' associations, shippers, and others interested in the early-potato market.

Credit Facilities Improved

Farm-credit facilities were improved in some regions through extension work. Agents helped farmers in taking annual inventories and in making out credit statements for their banks. This work was done in a greater number of States than ever before. It resulted in a measurable shifting of expensive short-time merchant credit into much cheaper and more efficient bank credit. More than 25,000 farmers cooperated with extension agents in keeping detailed accounts which were useful, not only for credit purposes, but as a guide in farm management. Twenty thousand farmers cooperated in keeping cost-of-production records. These records showed the strong and the weak spots in farm business and helped to raise the average standard of farm practices by focusing attention on the practice of the more successful farmers. In many counties in all parts of the country, county agricultural programs were developed on the basis of census figures and other data.

4-H Clubs

Boys' and girls' 4-H clubs made an exceptional showing during the year. The total enrollment in these clubs was 758,096. Sixty-seven per cent of this membership satisfactorily completed the work prescribed in agriculture and home-making. The showing was considerably better than that of the previous year. It was, in part, a result of the use of increased funds made available by the Capper-Ketcham Act of 1928. Credit is due, also, to a quickened interest manifested in the club movement, not only by farm people but by other groups. Many national organizations cooperated with the department and with the State agricultural colleges in drawing attention to the value of the clubs and in building up their membership. Club members reported giving 994,262 demonstrations of improved farm and home practices, or more than 51 per cent of all the demonstrations of that character that were made through extension channels during the year. Taking the country as a whole, county agricultural agents and home demonstration agents devoted about a third of their time to 4-H club work. Federal, State, and county funds supported the club work. It gives boys a practical training in plant and animal production and girls an equally practical training in gardening, poultry raising, cooking, dietetics, and home-making.

The talking picture made its advent in the field of mediums used in extension teaching, such as publications, news stories, lantern slides, charts, and exhibits. A drop in the demand for silent films used by extension agents naturally resulted. Nevertheless, the call for the department's motion pictures continued to exceed the available supply. More than 3,500,000 persons attended showings of loaned department pictures, and 3,368 film shipments were made during the year. The attendance at showings of the department's films was, however, less than in the preceding year. This seemed to be a result of "talkie" competition, and the department accordingly made experiments in sound-recording projects. It purchased a disk sound-projecting apparatus and provided a synchronized accompaniment for two existing pictures. As soon as facilities are available, production will be started by the department on sound pictures.

Growth in Personnel

Cooperative-extension forces grew during the year. County agents, who numbered 2,580 throughout the country on June 30 last, were aided by 854 full-time and 246 part-time subject-matter specialists attached to the State agricultural colleges. The extension service also included 1,225 county home-demonstration agents, 246 county club agents, and 303 negro extension agents. There were 414 supervisors and assistant supervisors and 74 administrative officers and assistants. This was an increase for the year of 184 county workers, 4 administrative and supervisory workers, and 63 subject-matter specialists. Approximately 4,800 of the extension workers were cooperative employees of the department. Increased funds became available under the Capper-Ketcham Act of May 22, 1928, which made immediately available to each State an additional $20,000 for cooperative extension work. In 1929 the increase was supplemented by a lump sum of $500,000, only the latter contribution requiring to be matched with an equal contribution from the States. Nevertheless, State and local appropriations have been increased during the last two years by approximately $1,500,000. One result was an increase of 317 in the number of home-economics extension workers. On June 30 last the personnel engaged in this work was 1,685, among whom were 1,345 county home-demonstration workers. Farm women participated as local leaders in home-demonstration work in increased numbers.

Funds for Extension Work

The total funds available for cooperative extension work from all sources during the fiscal year were $24,257,800, an increase of nearly $1,340,000 over those for the previous year. Approximately $274,000 of this increase was in Federal funds and $1,066,000 in State and county funds. Of the total funds, 38.1 per cent, or $9,251,760, was contributed by the Federal Government, exclusive of the privilege of using penalty envelopes; and 28.6 per cent, or $6,948,450, was from State appropriations to the agricultural colleges and other State agencies. The remaining 33.3 per cent, or $8,057,590, came from county appropriations for extension work and from contributions by local organizations and individuals. About 95.4 per cent of all funds used for cooperative extension work in 1930 came from public sources.

INFORMATIONAL WORK

By distributing approximately 25,000,000 popular and technical publications; by giving press associations, syndicates, newspapers, and magazines some 3,000 news and interpretive articles; by cooperating with editors, special writers, and correspondents; by furnishing speakers and manuscripts daily to over 300 radio stations in all parts of the country; by having officials give hundreds of addresses, including lectures in colleges; and by writing several million letters the department made its information available during the fiscal year 1930. The purpose of these activities was not to gain publicity for the department, but to make known facts that farmers and home makers can use to improve their practices.

Economic Information Used Extensively

Popular, as distinguished from technical, publications were in such demand that only 60 per cent of the requests received from farmers could be met. A large percentage were requests for economic information, such as data on prices, probable future demand, acreage adjustments, and farm management. This showed that farmers were becoming economic minded. The demand for information on plant production and animal breeding increased also. The economic and scientific services of the department and State agencies are so correlated that farmers can readily secure information concerning all their farming operations.

Gathering and distributing facts to help farmers make adjustments to meet changing conditions in production and marketing is a major function of the department. Facts on trends of production and demand must be used as a guide in planting and livestock breeding. The agricultural-outlook service has now been extended into every State and covers over 40 crops and classes of livestock. This year's outlook report, presenting facts on production and demand and indicating the probable market for the season's crops, was not only brought directly to more than 200,000 farmers at 4,200 group meetings, but was also used in one special and many follow-up radio programs which carried the information quickly to several million farmers; furthermore, special publications were issued on this subject, and the press helped extensively. The market-news service was extended to several States in the South and Northwest which had not previously been served with daily market reports. The crop-reporting service was expanded to cover fruit, truck, and canning crops. These are only parts of a growing economic-information service which is more widespread and detailed than any other ever established by a government.

Special Informational Campaigns

Unusual developments in the agricultural situation and in Federal help to agriculture called for special informational campaigns. For example, the weakness in cotton prices prompted a vigorous educational campaign by information and extension forces to influence southern planters to grow cotton on profitable acres, and to set aside as much of the land ordinarily devoted to cotton as would be necessary to provide food for the farm family and feed for livestock. A similar campaign was carried on to encourage a reduction of the wheat acreage and the growing of crops for which a better market was anticipated. The Federal Farm Board's efforts to encourage and strengthen cooperation among farmers, the drought situation, and the fight against the Mediterranean fruit fly in Florida also necessitated intensive informational work.

A rapid expansion took place in the department's radio work at practically no additional cost to the Government. For enlarged chain broadcasts, giving the entire country daily economic information, for weather and market news broadcasts, and for general educational programs the department now uses daily more than 50 per cent of the radio stations in the country. Radio time contributed free to the department is worth commercially about $1,500,000 annually. Plans will soon be completed for a new Pacific coast program, which likewise will cost the department nothing.

In the past it has been the policy of the department to furnish its publications and other information pamphlets free to all who can use them. Necessarily there is a growing restriction on this general principle because of the large cost that would be entailed in satisfying all requests. To offset this somewhat, the Superintendent of Documents is selling more of the department's bulletins. Additional funds appropriated for printing and binding will alleviate the present condition somewhat.

TRADING IN FUTURES

Trading in wheat futures on the grain exchanges designated as "contract" markets under the grain futures act of 1922 amounted, in the year ended June 30, to 19,606,790,000 bushels. This was the largest volume of future trading done in wheat in any of the nine years for which the Grain Futures Administration has records. Wheat futures accounted for 78.4 per cent of all the trading done in grain futures on the United States markets, as compared with a 9-year average of 64.9 per cent. The total for the previous year was 12,195,034,000 bushels. The previous record volume of trading was done in the season 1924–25, when the total was 18,875,965,000 bushels. The smallest volume of trading in wheat futures done in any year covered by the Grain Futures Administration's records was 7,316,910,000 bushels in 1923–24.

The increased activity in wheat futures was not, as is frequently the case, associated with rising but with falling prices. As a group the large speculators operated principally on the short side. Hedging against the country's large stocks of wheat partly accounted for the increased trading. In addition there was large speculative buying by small traders and the general public. Apparently these buyers had hopes of higher prices. The Grain Futures Administration, as in former years, issued daily reports of the trading done and of the total of open commitments in each future at the principal markets. No particularly violent fluctuations in prices were recorded on individual days. Evidence was disclosed, however, of certain practices that led to the filing of charges against three operators on one grain exchange. Cases arising out of these charges are now pending before a commission set up under the grain futures act.

Exchanges Are Necessary

Grain exchanges play a necessary and important part in our marketing system. They afford an easy and rapid method for the expression of the mass opinions of buyers and sellers as to supply and demand relationships. Each hour of the trading day, trading in futures establishes public prices against which producers and consumers can check any offers they receive. Markets for the purchase and sale of commodities for future delivery are necessary for the obvious reason that the total available supply of a commodity can not be delivered at once, nor can it be processed or manufactured immediately it is produced. Millers and dealers use the futures markets much as other merchants use insurance. They cover present transactions in the cash-grain markets with hedging transactions in the futures markets, thereby getting protection against violent price fluctuations. This practice, by lessening speculative hazards, enables the millers and dealers to do their business on a smaller margin of profit than would otherwise be necessary. The same observations apply to the cotton-futures markets. The facilities afforded by these institutions should be retained. At the same time, they should be improved and in some respects fortified with additional safeguards to prevent abuses. Considerable improvement has already been afforded through the administration of the grain futures act; yet more remains to be done.

Trading Practices Should Be Improved

There is the problem, for example, of the deliverable grades. Until recently in Chicago a buyer who desired the delivery of wheat purchased in the futures market might be compelled to accept 17 different grades or a combination of 17 grades at different warehouses, and at prices and bonuses fixed by the exchange. Recent amendments to its rules by the Chicago Board of Trade have reduced the deliverable grades to nine, thus strengthening the contract from the buyer's standpoint.

The rules of cotton and grain exchanges are not, at present, subject to review by any agency in the interest of the producers or the consumers. It would seem to be in the public interest to change this condition.

Contract-market rules covering the execution of futures orders should be amended to give customers and traders assurance that their purchases and sales will be handled by brokers who are not themselves interested in the market. Under present conditions, brokers have an opportunity to take customers' orders to their own accounts, at prices advantageous to themselves. This is wrong. Another practice that should be stopped is cross trading whereby operators buy and sell the same quantity of grain in the same future at the same price, with exactly offsetting results. This practice affords a means of registering fictitious quotations, and of concealing the brokers' personal interest in orders handled for customers.

Grain exchanges have cooperated in the enforcement of the act and in the elimination of abuses. As I have already said, much improvement has been made. The nature of future trading and the intricate machinery necessary to conduct it on a large scale make supervision necessary and desirable. Existing legislation does not give the Federal Government any authority to limit excessively large speculative trading, or to limit short selling calculated to demoralize prices.

PLANT QUARANTINES

Efforts to eradicate the Mediterranean fruit fly have been far more successful than was expected at the beginning of the eradication campaign. While total eradication can not yet be announced, there is strong hope of it. Up to July, 1930, no adult fly had been found in Florida since August 27, 1929; and only two larval infestations (one on November 16, 1929, and one on March 4, 1930) had been found subsequent to that date. In the November infestation, 4 larvae were found in one orange in a grove near Orlando, Fla. In the March case, 10 larvae were found in two sour oranges in a grove in Orlando. The most recent infestation discovered consisted of 2 living fruit fly larvae in a dooryard at St. Augustine, Fla., on July 25, 1930.

The minor nature of these infestations, together with the results of the intensive field inspection indicate that the eradication work performed in Florida has been so successful as to justify the removal of many of the more stringent quarantine conditions previously enforced. An order approved August 9, 1930, materially modified the restrictions governing the movement of Florida fruits and vegetables. One change made it unnecessary thereafter to sterilize Florida fruits and vegetables for shipment to the Middle Western States, except in the case of products grown on properties close to recent infestations or where growers had failed to comply with clean-up, spraying, and similar requirements. On shipments to the Southern and Western States, where the fruit fly if established would be especially injurious, the sterilization requirements except in the case of limes were continued in force. Shipments to that region, however, were permitted throughout the shipping season instead of being restricted to the mid-winter months as was done in the winter 1929–30. It was decided to allow the shipment of Florida fruit throughout the entire United States up to June 15, 1931, except in the event of the discovery of new serious outbreaks of the fly. Restrictions on vegetable shipments were modified, and the so-called infested areas, in which special safeguards are required, were reduced in size. Reshipment restrictions from the Northeastern States to the Middle West were removed. The only restrictions retained in force concerned the movement of Florida host fruit and peppers from points north of the southern line of Virginia, Kentucky, Missouri, Kansas, and Colorado to the 18 Southern and Western States. This movement, as in 1929, was prohibited.

Spread of Fruit Fly Prevented

There is no doubt that the prompt action taken by the department in 1929, in cooperation with the State authorities of Florida, prevented widespread infestations of this extremely destructive pest. The saving thus effected in eradication and control work is incalculable. From March 27 to June 13, 1930, lack of funds necessitated the suspension of field-inspection work. On the latter date, however, inspection was resumed. In January last a Federal fruit-fly board was appointed, consisting of five leading entomologists—W. C. O'Kane, State entomologist of New Hampshire and chairman of the board; George A. Dean, professor of entomology, Kansas State Agricultural College; W. P. Flint; State entomologist of Illinois; P. J. Parrott, entomologist of the New York Experiment Station; and J. J. Davis, professor of entomology at Purdue University. This board studied the problem in Florida, put eradication policies into effect, and supervised the expenditure of Federal funds. It recommended a number of the changes already reported in the fruit-fly quarantine districts.

Quarantine restrictions against the Mediterranean fruit fly mean unavoidable expense to growers, shippers, and others. It is worth noting, however, that the restrictions in 1929 permitted the marketing of Florida's fruits and vegetables in almost a normal manner, though fly infestation was then very heavy. Quarantines are generally considered as tending to throttle business. In the case of the Mediterranean fruit-fly quarantine, Federal certification made the country's markets largely open to Florida's products. The Federal quarantine legally inhibited State quarantines and thus kept open many markets that might otherwise have been closed.

Japanese-Beetle Quarantine

The quarantine enforced to check the spread of the Japanese beetle was of similar advantage. Under this quarantine plants and plant products are certified for shipment after they have been inspected and, in some cases, treated. Certificates thus issued guarantee the acceptance of the certified plant by inspection officials in the States to which the shipments are sent. In the fiscal year 1930 Federal certification authorized the movement of 97,788,480 plants out of the area quarantined on account of the Japanese beetle; also many thousands of boxes of cut flowers and thousands of carloads of sand, soil, and earth were certified for shipment. The Japanese beetle spread during the year at its normal rate and was discovered at several points some little distance from the quarantined area. These points were quickly subjected to control with respect to the movement therefrom of susceptible products.

Pink Bollworm of Cotton

An outstanding development of insect infestation in 1929 was the outbreak of the pink bollworm of cotton in a large area of the Salt River Valley in Arizona. This area specializes in the growing of Pima or long-staple cotton. The department, in cooperation with the State commission of agriculture and horticulture, began eradication measures. Two noncotton zones were established, and a field clean-up of some 47,000 acres of cotton was made, with funds specially appropriated for the emergency. The undertaking promises to be successful. Congress also appropriated funds to enable the Federal Government to compensate growers in the affected area for one-half of the actual and necessary loss resulting to them from ceasing to grow cotton. The other half of the loss will be paid by the State of Arizona.

Mexican Fruit Fly

The Mexican fruit fly reappeared in the Rio Grande Valley in the last fiscal year, but was promptly exterminated. It first appeared there in 1927. The department is cooperating with the Mexican Government in measures to reduce the infestation in near-by areas on the Mexican side of the Rio Grande. Inspection and clean-up work is also in progress in the citrus areas of the Rio Grande Valley in Texas.

CONTROL OF INSECT PESTS

New means for controlling insect pests developed from the research in the Bureau of Entomology. Particularly successful work was done in the improvement of poison bait for the Mediterranean fruit fly and in the treatment of fruit to prevent its being a means of spreading the insect. A safe and effective bait spray for the fruit fly is now in general use in the originally infested area of Florida. It substitutes a copper carbonate solution for the lead arsenate solution used at first, which was believed to diminish the acid content of the fruit and make it more or less insipid. Extensive use, besides demonstrating the safety and effectiveness of the new spray, indicated that it may be valuable also against other insects. This discovery was a striking advance in pest control. It was made in a search of the entire group of available poisons for a bait spray at once harmless to citrus plants and toxic to the fly.

In treating fruit to make it safe for handling, shipment, and sale, the bureau improved both the heat process and the cold process that it developed in 1929. These methods permitted the successful and profitable handling of Florida's citrus crop and proved valuable in the handling and storing of fruits and vegetables for other reasons than the necessity of controlling the Mediterranean fruit fly. The heat treatment was used widely for the immediate handling and sale of fruit. The cold treatment, as modified on the basis of experiments made in Hawaii, permitted the successful storing of fruit for later sale and distribution. It calls for a temperature of from 30° to 31° F. continued for 15 days. This temperature practically eliminates risk of freezing the fruit and is well within the range of the standard equipment used in cold-storage plants. It is easily maintained in ordinary storage practice. In experiments in Hawaii, the modified treatment was always fatal to both eggs and the larvae of the fly.

Aid to Peach Growers

Insect-control measures advocated by the bureau helped peach growers this year to market a crop much better in quality than the crop of 1929, when insects caused heavy damage. Two species, the plum curculio and the recently introduced oriental fruit moth, were the chief causes of the 1929 loss, which was widespread east of the Mississippi Valley, particularly in the South. Though much fruit was discarded in the orchards, a considerable amount reached the market in a wormy condition. Consumers lost confidence in the quality of peaches in general, and prices suffered. This year the bureau carried on an intensive campaign to impress upon growers the necessity for insect control. It especially emphasized the importance of fighting the plum curculio. State entomologists and extension workers cooperated. Growers paid special attention to spraying and dusting, destroying infested fruit, and other means of control. These measures with the added advantage of favorable weather brought gratifying results.

Protective Treatment for Stored Grain

Better protection of stored grain from insects is now possible by a new fumigation method developed during the year. This was the outcome of cooperative work between this department (through the Bureau of Entomology and the Bureau of Chemistry and Soils) and the Bureau of Mines. It requires the use of the fumigant, ethylene oxide-carbon dioxide mixture. So efficient and easy to use is the new method that it promises to replace all other means of protecting grains stored in bulk. In tests made with the cooperation of the New York Produce Exchange, in which several million bushels of wheat were treated, the ethylene oxide-carbon dioxide mixture proved highly toxic to grain insects and practically free from the fire hazard that attended the use of certain of the older methods. Outstanding importance attaches to this discovery of a new and safe insecticide for grain insects, which cause heavy damage to stored grain and cereal products, particularly in the South.

Insect Damage to Livestock Reduced

Losses caused by insect damage to livestock have been reduced during the year in the Southwestern States. The screw worm is a destructive pest of cattle, sheep, and goats. Screw-worm damage has been much reduced by a system of prevention and control which involves the prompt destruction of carcasses in which the fly may breed; dehorning and other measures to reduce the number of wounds that afford entrance for the pest into live cattle; the control of breeding so that calves, lambs, and kids will be born out of the screw-worm season; location of " hospital pastures " on high ground; the use of fly cages to protect valuable injured animals; the use of fly traps; and the use of benzol and pine-tar oil in treating screw-worm cases.

The department in cooperation with the Texas experiment station developed a new dip for the destruction of the lice that attack the Angora goat. This treatment, which is cheap and effective, is the dipping of goats in a suspension of very fine sulphur and water, which kills all the lice and their eggs in one operation without injuring the goats or their hair. It promises to be of great value to the Angora-goat industry.

Pine-Tip Moth Controlled by Parasite

A striking result last year in forest-insect work was the control of the pine tip moth at the extensive plantations of the Forest Service at Halsey, Nebr. For 20 years the pine tip moth has seriously retarded the growth of young pines at Halsey until, in 1925, the Bureau of Entomology introduced into the Halsey area an insect parasite of the tip moth from Virginia. This year the degree of parasitism existing near the point where the parasite was originally released amounted to about 82 per cent, and the number of pine trees infested by the pine tip moth had dropped from 90 per cent to 33 per cent. Permanent self-sustained control with little expense seems probable.

European Corn Borer

The European corn borer did not spread normally this year in Pennsylvania, Ohio, Indiana, and Michigan. Its increase was checked by heat and drought. A large percentage of the eggs, which are laid on the underside of leaves, were killed when the leaves curled and exposed the eggs to the sun. The mortality was heavy in the larvae also. As a result, there was practically no westward spread of the insect. There was a little spread to the south—in West Virginia, Ohio, and Indiana. Practically no commercial damage was done in the western area. In New England, in the so-called 2-generation area, the borer increased somewhat. More infestation in vegetables and weeds as well as in corn was observed.

Introduction of the corn borer's natural enemies into the United States promises to be an important controlling influence. This season up to July nearly 650,000 imported parasites, representing 17 different species, were released. It appeared, from the recovery of parasites from previous liberations, that at least 11 species had been successfully established. In some cases colonies of the parasitic insects had become so strong that collections could be made therefrom for shipment to other areas. Whether the corn borer will prove a serious menace to the main Corn Belt is still undetermined.

Other Serious Pests

Serious damage was done this year by the range caterpillar to the valuable blue grama grass on cattle ranches in northern New Mexico and in the Texas Panhandle. This insect has barbed spines that are extremely irritating and poisonous both to range animals and to man. It causes loss of forage in addition to the grass it actually consumes because cattle will not eat where the caterpillar has crawled or fed, since it leaves behind it webs in which are incorporated its poisonous shed skins and spines. About 15 years ago an outbreak of the range caterpillar was brought under control by the natural increase of an egg parasite of the pest. The Bureau of Entomology is attempting to speed up the increase of this parasite so that control of the caterpillar, which would tend to come about under natural conditions in six or eight years, may be brought about in three or four.

In northwestern Colorado a serious outbreak of the Mormon cricket was brought under control, through cooperative work with the State of Colorado in control campaigns. Only outlying districts distant from cultivated areas remain to be cleaned up. Final clean-up work, though extremely difficult because of the nature of the country, is essential as a safeguard against future outbreaks.

The Mexican bean beetle, which was not known in the Eastern States until 1920, now inhabits most of the United States east of the Mississippi River. It has caused heavy damage to beans. Indications are that it has now reached its northern limit of destructive abundance. General remedies such as plowing under the bean crop and planting bush rather than pole beans are valuable. Insecticides, such as magnesium arsenate and pyrethrum, give satisfactory control of the insect.

The European earwig, which was introduced many years ago simultaneously on both Pacific and Atlantic coasts, probably will spread more or less widely and prove an important addition to the list of introduced pests. It is not destructive to important crops, though it harms garden plants and the succulent ornamentals. It is chiefly obnoxious in houses in which it swarms. The Bureau of Entomology has developed a bait for the earwig which is satisfactory under dry conditions and where gardens are not artificially watered.

RESEARCH IN CHEMISTRY AND SOILS

In a definite program to diminish soil erosion, which involves annually a loss of more than 500,000,000 tons of soil in the United States, the Bureau of Chemistry and Soils last year set up six experiment stations for the study of the problem. These are in Oklahoma, Kansas, Missouri, Texas, and North Carolina. Erosion under different soil conditions will be studied at these stations. The Oklahoma station is intended to serve the red-plains region, which comprises more than 36,000,000 acres. Erosive soils, comprising about 6,000,000 acres, are the subject of study at the Kansas station. The station in Missouri will serve a region in Iowa and Missouri comprising about 6,000,000 acres. One Texas station is located in a sandy region; another serves the rich black belt of that State. The work there will cover a large area of similar neighboring lands in Arkansas and Louisiana. The station in North Carolina will study the southern piedmont soils, comprising some 30,000,000 acres. More than 60 per cent of this area has been damaged by erosion, some of it irreparably.

Important facts have been learned already. In the rich black belt of Texas, for example, the white chalky subsoil absorbs water much faster than the black topsoil. This makes the subsoil less erosive. The demonstration of this fact has an important bearing on agriculture and also on highway building. In Oklahoma experiments in the protection of eroding fields by terracing have stimulated wide interest. Farmers are applying the demonstrated methods on their own farms. Terraces of various types are being built and tested at all the soil-erosion stations. Cropping schemes are being studied to show their relationship to erosion control.

Fertilizers Increase Sugar-Beet Yields

Soil-fertility experiments have produced significant results in the last year. In 7 of the 18 States where sugar beets are widely grown, it was demonstrated that the proper use of fertilizer would increase the yields by an average of 3 tons an acre. Fertilizers high in phosphoric acid produced the largest increases. It was shown that sugar-beet lands can be fertilized at from $2 to $2.50 an acre. An increase of 3 tons an acre in the yield means a gross profit of about $18 above the cost of the fertilizer. The acreage fertilized this season was estimated at from 200,000 to 250,000 acres. Should the yield be increased by 3 tons an acre as a result of the fertilizing, the value of the crop would be increased by $5,000,000, less $500,000 spent for fertilizer.

In the Southeastern States the bureau has demonstrated that small applications of manganese sulphate and other heavy metals on nonacid soils will make these soils yield profitable truck crops. When these soils are not so treated, many crops thereon fail. Similar soil treatment has proved useful in the truck sections of North Carolina and South Carolina, particularly with strawberries. The gain to the growers from the discovery that their soils may be improved by manganese sulphate is substantial.

Soil Surveys Cover 800,000,000 Acres

More than 21,500,000 acres in counties representing every important farming region of the country were mapped by the soil survey in the last fiscal year. This work brought the total area surveyed and described to more than 800,000,000 acres. It will be necessary eventually to classify the lands of the United States according to their natural productivity and adaptation to different crops. In this task the information gathered by the soil survey will be indispensable. Heretofore the expenses of the soil survey, both Federal and State, have been only slightly more than 2 cents an acre. For this small expenditure the Nation has an inventory of its soil resources which in accuracy, scope, and practical value is acknowledged to surpass anything in existence elsewhere. The surveys show what soils are the most productive and give the exact location and the extent of the different soils in each county surveyed. They show how soils may be selected in the order of their natural productivity. Special value attaches to this work at the present time because of the readjustments that are taking place in American agriculture.

Chemistry Aids Cotton Industry

The Bureau of Chemistry and Soils developed this year an entirely new series of vat-dye intermediates from diphenyl and phthalic anhydride. These are expected to be of great value to the cotton-textile industry and therefore to the growers of cotton. In 1929 the consumption of domestic vat dyes in the United States exceeded 9,000,000 pounds, as compared with 6,500,000 pounds in 1928. The new dye intermediates produced by the department's chemists will, it is expected, be a further help in meeting the competition of foreign vat dyes. The domestic vat-dye industry is based on the department's synthesis of phthalic anhydride. The new products will lead to the production of fast dyes that should materially widen the market for cotton goods.

The bureau demonstrated during the year that cottonseed meal, commonly used as a cattle feed, may become valuable in human nutrition. It is rich in and by far the cheapest source of the antipellagra vitamin G. It is also an important carrier of the antineuritic vitamin B. Yeast is considered the richest natural source of these two vitamins, but commercial cottonseed meal is the only substance that even approximates yeast as a source of both of these vitamins. Yeast is used in treating pellagra, but it is costly. Commercial cottonseed meal is not suitable for human consumption. Experiments are under way, however, which may overcome this difficulty.

Fish Oils a Valuable Source of Vitamins

The Bureau of Chemistry and Soils, in cooperation with the Bureau of Fisheries, Department of Commerce, recently demonstrated that fish oils containing vitamin D are available in immense quantities and can be used profitably in animal feeding. These oils can be obtained at about a third to a fourth of the present cost of cod-liver oil, which is widely used in livestock feeds. In fact, vitamin D is considered essential for the raising of chicks and other young animals. California produces annually about 4,000,000 gallons of pilchard oil, which is as rich as cod-liver oil in vitamin D. Tuna oil, equally rich in this vitamin, is produced in smaller quantities. Salmon oil, which is very abundant, is about half as rich in vitamin D as cod-liver oil. It ranks with the poorer grades of cod-liver oil in vitamin A content. The price paid for vitamins A and D in salmon oil is lower than the price paid for the same vitamins in cod-liver oil. It seems possible, moreover, to improve the vitamin A content of salmon oil by better manufacturing processes. The supply of salmon oil can be increased fivefold or sixfold. At present millions of pounds of salmon offal are dumped into the waters of Alaska every year.

Pine-Gum Filter Improves Rosin

The Bureau of Chemistry and Soils has developed a new type of filter for cleaning crude yellow-pine gum. This filter cleans the gum so completely that the resultant rosin is as transparent as ordinary colored glass. It is the first practical means of cleaning crude gum without diluting it with rosin solvents. The process will probably add a dollar to the value of every barrel of rosin filtered by it. Its general use would add half a million dollars to the value of the South's annual production of rosin. Rosin made by the new process should be in keen demand by manufacturers of varnishes and paper size.

Cheaper Potash Indicated

Cheaper potash for American farmers seems possible in the near future. The department has recently demonstrated that the volatilization of potash from leucite is feasible by smelting with special reagents and that the potash can subsequently be recovered in concentrated form. This can be done to special advantage simultaneously with the volatilization of phosphoric acid. The materials thus obtained can be combined to form potassium phosphate, a highly concentrated fertilizer salt.

Enormous deposits of leucite exist in Wyoming, along with plentiful supplies of high-grade phosphate rock and cheap fuels. The utilization of these resources in the production of potash by the method newly discovered, or by improvements thereof, seems entirely practicable. In fact, our annual production of potash salts has increased rapidly in recent years and now totals more than 100,000 tons. Nevertheless this country still depends largely on foreign potash. This is unsatisfactory not only because it involves high transportation costs but because our increasing use of concentrated fertilizers demands large quantities of high-grade potassium salts. The department's recent discoveries will no doubt help in the expansion of the American potash industry.

Besides studying the properties of the leucitic rock of Wyoming, the department is studying the alunite of Utah, the potash shales of Georgia, and the greensand of New Jersey. Alunite has a promising future as a raw material for potash and alumina. Heretofore the processes employed in extracting these products have not been economical. The alumina recovered has not been pure enough nor abundant enough to give it a satisfactory market position. The department is developing improved extraction methods that are expected to permit the use of lower-grade alunite than that formerly required. This will increase the latent potash resources of the raw material. Investigations made at the request of the Bureau of Mines on the ammonium carbonate-ammonia extraction of polyhalite (a Texas saline material) indicate the commercial possibility of effecting a practically complete separation of the potash from the associated calcium and magnesium compounds. It appears practicable, also, to make an additional saving at the same time through the formation of ammonium sulphate from sulphuric acid of the polyhalite and the ammonia in the leaching solution. In these concentrated forms the fertilizer salts can be transported at a greatly reduced cost. In acid-extraction experiments with the greensands of New Jersey, iron and aluminum salts and adsorptive silica (glaucosil) have been obtained as valuable by-products.

Rotenone Tested Against Destructive Pests

Research is under way to develop a synthetic process for producing rotenone, a promising substitute for lead arsenate as an insecticide. Chemists in the department recently extracted rotenone from Derris root for the first time in the United States. This poison is highly toxic to many insects, yet it is as harmless to plants and to warm-blooded animals as any insecticide that has yet been discovered. In recent tests as a stomach poison it proved thirty times as toxic to the silkworm as lead arsenate. Rotenone is being tested against the codling moth, the European corn borer, the Mexican bean beetle, aphids, and other destructive insects. The department's chemists believe it will be harmless to man if eaten in the form of a spray residue on fruit. This quality should give rotenone, if it can be produced cheaply in commercial quantities, an advantage over lead arsenate, the poisonous residue of which is difficult to remove from apples and pears. The present cost of rotenone, from $10 to $20 a pound, prohibits its use by the average farmer or fruit grower. There is hope of producing it artificially or by developing a similar chemical product. The sole present source of rotenone is Derris root (*Derris elliptica*), which is obtained in the East Indies.

Fire Hazards From Moving Belts Preventable

Means of preventing the serious fire losses often caused by static electricity in moving belts in factories have been developed by the Bureau of Chemistry and Soils. How serious the fire hazard is may be judged from the fact that in some cases 25,000 to 50,000 volts were detected between pulleys, though the shafts and pulleys were well grounded. The bureau has demonstrated that belts can be made to conduct electrical charges to the pulleys from which the charges can be grounded harmlessly. This is done by weaving wires into the belts. Accumulating static charges are carried through these wires and grounded without the risk of ignition which would otherwise be present. It is also possible to prevent electrical discharges on moving belts by treating the belts with dressings that have conducting properties. This treatment causes the static charges to pass over the surface of the belts to the grounded pulleys.

Nitrogen Fixation

Research by the fixed-nitrogen laboratory of the Bureau of Chemistry and Soils is reflected in the progress of the fixed-nitrogen industry of the United States, whose output in 1929 was more than three times that of the preceding year. Its production this year is expected to show a substantial increase over that of 1929. The research laboratory has made a number of important discoveries that have been put into commercial practice. An ammonia catalyst was discovered. Published results of studies undertaken to ascertain the essential properties of nitrogen, hydrogen, and ammonia have profoundly influenced commercial practice. Improved catalytic materials are being developed. The bureau's contribution to air-nitrogen fixation in the United States is not measurable solely in research results, but includes also a contribution of personnel to the industry. Many scientists who began their studies of the problem in the Government laboratory are now leaders in the commercial field. The Government began the study of air-nitrogen fixation about 15 years ago. Progress is now rapid in both research and practice.

Output of inorganic nitrogen by the air-fixation process in the United States was 84,000 tons in 1929, as compared with 26,000 tons in 1928 and 5,900 tons in 1923. These figures may be usefully compared with the output of by-product nitrogen, which was 187,600 tons in 1929, 170,000 tons in 1928, and 123,500 tons in 1923. Our supply of inorganic nitrogen is obtained from three sources—imports, the by-product process, and air fixation. The foregoing figures show the rapid relative advance of air fixation. Domestic production in 1926 furnished 60.5 per cent of our supply of inorganic nitrogen, as compared with 49.5 per cent in 1923.

The first successful direct synthetic-ammonia plant in the United States began production in 1921. Seven others have since gone into operation, one of them this year. The largest has an annual capacity of 108,000 tons of ammonia and the second largest an annual capacity of 54,000 tons. These two plants will be enlarged. Another is under construction. The largest makes sodium nitrate, which competes directly with Chilean sodium nitrate for use as fertilizer. Liquid ammonia is shipped from the fixation plants to the fertilizer factories, to be added to superphosphate. This practice, which is now general, is a distinct economy. Prior to 1929 practically all the ammonia produced by the direct synthetic-ammonia plants of the United States was used for other than agricultural purposes. The output of the new facilities which will come into operation soon must be marketed as fertilizer, as well as part of the output of the existing plants. Linked with the bureau's work on nitrogen fixation are studies of potash and phosphoric acid. A fuel-fired blast furnace is used on experiments in the volatilization of both potash and phosphoric acid. Farmers in the United States spend about $250,000,000 annually for fertilizer, for which outlay the progress of air-nitrogen fixation promises a much increased return.

PLANT INDUSTRY ACHIEVEMENTS

Plant types and varieties much better adapted to their environment than those now grown will eventually be developed, experiments by the Bureau of Plant Industry definitely indicate. The development and use of crop varieties specially adapted to given conditions play an increasing part in the growing efficiency of American agriculture. The bureau, in cooperation with the State experiment stations, is now applying recent genetic discoveries to many crops on a scale not previously attempted. This plant-breeding work covers practically the entire range of food, forage, and fiber crops, including fruits and vegetables and ornamental plants.

In the northern Plains region the new wheat varieties, Reliance and Ceres, proved distinctly more satisfactory than other varieties grown there. Under favorable conditions, particularly under irrigation, Reliance wheat gave a high yield though it was not resistant to black-stem rust. Ceres wheat showed some resistance to black-stem rust and proved more widely adaptable than any other variety of hard red spring wheat. Both these varieties produce a kernel of good commercial quality. In the quality of disease resistance the best variety yet developed is called Hope. This wheat seems to be practically immune to rust, bunt, and loose smut. Its commercial production is beginning.

A new variety, Tenmarq, in the central Plains region has shown itself more winter-hardy than the Blackhull variety. Oro wheat, a variety developed by the bureau in cooperation with the Oregon experiment station, has proved high yielding and also highly resistant to smut. It has yielded well in Kansas, Nebraska, and Montana. Cooperative experiments with soft red winter wheats, at the Cornell experiment station, have produced from red-kerneled selections an average of 7.5 bushels an acre more than the yield produced by an equal number of white-kerneled selections. Forward wheat, an improved red-kerneled variety developed in these experiments, is being more widely planted. Nevertheless the red varieties are still less grown than the white wheats in New York State.

Stem Rust of Wheat

A discovery of great importance in combating stem rust of wheat has been made in studies conducted cooperatively with the Minnesota Agricultural Experiment Station. Stem rust is the most serious wheat disease in the United States. The infection enters through the open stomata, or breathing pores of the plant. In the resistant varieties it was discovered these stomata remain closed in the morning until after the dew, in which the fungus spores germinate, has dried; hence the fungus spores have no opportunity to infect the wheat. This clue to one cause of rust resistance in wheat is expected to have important practical consequences.

Resistance of Corn to Cold

Important factors in the resistance of corn to cold were developed in cooperative studies at the Illinois experiment station. Some strains while maturing are injured by temperatures considerably above freezing. Others are not seriously hurt by temperatures several degrees below freezing. Some of the strains that resist cold well in the ripening stage resist it also in the seedling stage. All strains resist cold better on the more fertile soils. Strains that are resistant to cold tend also to be resistant to stalk-rotting fungi. These strains also produce better yields and better-quality corn. In the seedling stage the cold-resistant strains are less susceptible to the seedling blights. The practical importance of these facts is obvious. Early fall freezes severe enough to injure corn are often followed by several weeks of favorable weather. The varieties of corn capable of resisting such early freezes and having also several other desirable characteristics should be more widely planted.

Sugar-Beet Seed Commercially Feasible

The commercial feasibility of sugar-beet seed production from overwintered seedlings is shown by harvest records obtained by the bureau, in the Southwestern States, where mild winters permit the safe wintering of small sugar-beet plants in the field. This method is much less expensive than the one commonly employed in which mother beets must be lifted in the fall, carried over the winter in silos or pits, and replanted the following spring. Seed yields from the overwintering method approximate the standard yields in the most favored sugar-beet seed-producing countries. Commercial development of this method of producing sugar-beet seed would help to develop disease-resistant varieties. Our beet seed now comes from Europe. European beet seed, however, has no resistance to the curly-top disease, which is indigenous to the United States and threatens the sugar-beet industry west of the Rocky Mountains. It has been demonstrated that resistance to curly top can be developed in sugar beets as a varietal characteristic. The demonstration that the home production of sugar-beet seed is possible on a commercial scale by the overwintering method marks an important forward step for the American sugar-beet industry.

Other Developments

From 50 to 75 per cent of the acreage planted to lettuce in the Imperial Valley of California in 1929 was planted to disease-resistant varieties developed in the Bureau of Plant Industry. This year's lettuce acreage in the same region, estimated at 30,000 acres, is about 75 per cent planted to the resistant sorts. These varieties are resistant to mildew and brown blight. They are also more productive than the sorts previously grown.

Notable progress was made in the growing of improved strawberry varieties. The Blakemore, a good dual-purpose variety of excellent flavor, was extensively planted. It was developed at the United States Plant Field Station at Glenndale, Md. About 85,000 strawberry seedlings of known parentage, developed from well-mated crosses, were under observation in Oregon, Montana, and northern California. These studies gave promise of establishing new combinations of color, flavor, size, vigor, and yield.

In a field test near Beaver Dam, Wis., a variety of hemp called Michigan, developed by the bureau for earliness, was harvested and spread for retting 16 days earlier than hemp from unselected commercial seed. This variety was equal in quality and yield to the product of the commercial seed. Another variety developed by the bureau was harvested and spread for retting at the same time as the commercial variety, but yielded 50 per cent more.

Better Cotton Varieties Developed

In recent years many improved varieties of cotton and improved methods of production have been developed, tested, and demonstrated. It is no longer necessary for agricultural reasons to plant varieties producing less than 1-inch staple in any part of the United States. Yet we continue to grow millions of bales of inferior fiber which enters the world market in direct competition with the very short staples of India and China. Fine fabrics are in demand. Larger quantities of strong and uniform fiber are needed in the automobile industry and also in the production of fabrics for airplanes, balloons, and dirigibles. The textile industry in general wants better cotton staples than those generally offered. Here is an opportunity which is not yet sufficiently recognized.

Recent developments in cotton breeding emphasize the fact that in this field agricultural science is far ahead of agricultural practice. A new variety of cotton of real commercial possibilities was developed by crossing Pima, a long-staple variety of Egyptian type, with Sakel, the best of the varieties grown extensively in Egypt. Pima is better than Sakel in type of plant, productivity, size of bolls, and length of lint. Sakel is thought to be better in strength of lint and in spinning value. A combination of the best features of both varieties is obviously very desirable. The Sakel-Pima cross has been grown during 11 successive years. It appears to be quite as uniform as selected strains of Pima and Sakel. Tested in Arizona, it proved in average seasons to be at least as productive as the best strains of Pima. It gave indications that it will outyield Pima in seasons when the first killing frost comes late, since the plants set a very heavy top crop. The new variety has long fruiting branches and bolls that are exceptionally large for an Egyptian type. It gives a consistently higher lint percentage than Pima; moreover it is superior to Pima in abundance of lint on the individual seeds.

Another new cotton variety seems to have distinct resistance to the boll weevil. This is an early maturing type of upland cotton known as the Kekchi. It was selected from cotton discovered in 1902 in Guatemala among the Kekchi Indians. The first plantings in Texas were very abnormal and some were sterile. After several years of acclimatization and breeding, however, normal habits of earliness and productivity reappeared. In several cases Kekchi cotton outyielded all the other varieties commonly grown, and the fiber was of better quality. More important still, the Kekchi variety continued flowering and fruiting after other varieties had ceased to do so on account of weevil attack.

Plant Introductions

The introduction of foreign plants into the United States has been important throughout our history. In fact, our agricultural and horticultural industries, as well as our animal industries, are based on plants and animals introduced from other regions and largely from other continents. This is true not only of the cereals and the grain sorghums, but of corn, potatoes, sweetpotatoes, tomatoes, peanuts, and tobacco. By this time probably most of the foreign crops which can be successfully introduced without change into American agriculture have been introduced. Plant introduction is taking on a new character. It is directed more to the discovery of important new material for the plant breeder than to the immediate establishment of foreign varieties not hitherto grown here.

Varieties of sugarcane introduced from Java some years ago restored the cane-sugar industry of Louisiana, which had been threatened with extinction by mosaic disease. But the Javanese varieties lack certain desirable qualities. Therefore in 1928 plant explorers for the department obtained as breeding stock more than a hundred primitive varieties and strains of sugarcane from the jungles of New Guinea and Papua. The object is to combine these varieties with types already established in the United States. The entire collection was planted this year in southern Florida and in August was growing satisfactorily. It is planned to make crosses which will combine the vigor of the wild varieties with the high sugar content of the best commercial varieties.

Among the varieties introduced from New Guinea is a species which grows from 25 to 30 feet high, stools prolifically, and is remarkably erect and vigorous. It seems also to be disease resistant. Most of the world's cane sugar now comes from seedlings resulting from crossing a small wild cane (*Saccharum spontaneum*) with cultivated varieties. Since the new wild cane (*S. robustum*) is much larger than *S. spontaneum*, its hybrid progenies should give larger sugar yields. The Bureau of Plant Industry has devised a method whereby a ton of seed cane can be increased sufficiently within two years to plant 1,000 acres. Under the commercial methods in general use only about 30 or 40 acres could be planted under the same conditions. Hence a commercial supply of planting stock can be grown from the new canes in a comparatively short time.

Work With Other Plants

Similar work with other plants promises important results. Alfalfa in the Middle West is threatened with a serious disease called bacterial wilt. Investigators observed that certain alfalfa seed from France and Turkestan produced plants which resisted the disease better than other varieties. Accordingly, seed for testing was obtained in Europe and Turkestan. Samples were brought from every important seed-producing district in the latter country. It is too early as yet to predict the result, but it should give some relief from the bacterial-wilt disease. In the same expedition other seeds of potential value to American agriculture were obtained, including the seeds of numerous grasses, legumes, and melons. Samples of wild and cultivated apricots, pears, and pistachio nuts also were obtained.

In an effort to replace the native American chestnut, now almost destroyed by blight accidentally introduced from Japan and discovered in this country about 25 years ago, the bureau has located blight-resistant strains of the forest type of Asiatic chestnut in Japan and Chosen. It has brought large quantities of seed to this country. This year more than 70,000 trees, representing 162 selected strains of Asiatic chestnuts, were planted in permanent locations. These trees are being tested for blight resistance and other qualities under widely varying conditions. The Asiatic chestnuts have a tannin content in the wood and in the bark equal to that of the American chestnut.

More than 200 lots of soybeans of both wild and commercial strains were recently imported from the Orient. It is believed the collection will extend the areas in which soybeans can be grown in this country and will also increase yields.

Plant-Disease Control

Though some plant diseases may be checked by treating the seed before it is planted, the most destructive diseases, especially those of the fruit and vegetable groups, are more effectively controlled by dusting and spraying. Investigations in the bureau have demonstrated that zinc-lime spray, a recently discovered fungicide, is successful in controlling peach bacterial spot. Large quantities of this material were used by growers this season. Zinc-lime spray may be of value also in controlling peach scab and apple scab.

The campaign against citrus canker is practically won. An infection was found this year in a nursery in Victoria County, Tex., and 5 grapefruit and 15,000 2-year-old *Citrus trifoliata* were destroyed as a control measure. Some scattered infections were found in dooryard plantings in Louisiana. The disease is not known to occur, however, in any region commercially producing citrus fruits. No infections were found during the past year in Florida, Alabama, or Mississippi.

White-pine blister rust is increasing and will undoubtedly reach Maryland, Virginia, and West Virginia within a short time. In the protected pine areas of New England and New York the loss from this destructive disease is less than one-tenth of the losses in unprotected areas. Protection is achieved by eradicating the gooseberry and currant bushes that are the alternate hosts of the disease organism. The bureau is cooperating with the Forest Service and the National Park Service in protecting white pines in the national forests and parks. It is cooperating also with officials and lumbermen in several Western States in a campaign for the eradication of the host plants. Vigorous and prompt action is necessary to avoid heavy loss. The rust recently extended in Oregon to within 50 miles of the Californian border. This is a menace to the forests of southern Oregon and of California. Experiments in local control, however, have indicated that these areas can be protected at a reasonable cost.

In areas where most of the common barberry bushes have been destroyed in the campaign for the control of black stem rust of wheat, local outbreaks of rust have been much reduced. The effectiveness of the barberry-eradication movement is beyond question. It needs, however, to be carried on with unflagging energy.

Eradication of Phony Peach Disease

Complete eradication of the phony disease of peach trees appears practicable, even though it is now known that the disease is not confined entirely to Georgia and Alabama. This season the Bureau of Plant Industry, in cooperation with the States of Georgia and Alabama, began an eradication campaign. It obtained the willing aid of peach growers. Diseased trees were destroyed with great rapidity. Inspectors examined nearly 12,000,000 peach trees during the season, most of them in Georgia. About 87,000 in Georgia were definitely identified as infected, about 600 trees in Alabama were identified as infected, and about 140 in Mississippi. Many trees were removed on the suspicion that they might be infected. Slight infections were discovered in Louisiana, Arkansas, and Tennessee, and recent inspections located cases of the disease in North Carolina and South Carolina. Accordingly it is planned to extend the eradication campaign to all these States.

PROGRESS IN ANIMAL INDUSTRY

The Bureau of Animal Industry made some notable contributions to the technic of livestock breeding and feeding, and to the control of animal diseases and parasites.

The bureau demonstrated that suitable Wiltshire sides for the English bacon market can be obtained from American breeds of hogs fattened on the commonly grown hog feeds. This means that by the same method farmers can produce hogs for both the foreign and the domestic market. It is simply necessary to select the hogs rigidly for type and to feed them with the market purpose in view. A shipment of hogs was fattened on barley, tankage, and alfalfa pasture at the United States Range Livestock Experiment Station at Miles City, Mont. The hogs were slaughtered and processed in the United States and sold on the Liverpool and London markets. English authorities pronounced the bacon from these hogs equal to the best brands of Canadian bacon.

Recent experiments in sheep raising show that lambs raised on good pasture will produce meat as well finished and as palatable as that from lambs raised on expensive grain feeds. In one experiment a number of lambs that had only pasture brought a slightly higher net return than other lambs that were fed grain while running with their dams on pasture. This result was in accordance with the outcome of similar experiments made in cooperation with Purdue University. Pasture as a feed for lambs is exceptionally valuable both from the standpoint of the return to the grower and from the standpoint of the quality of the meat.

About a third of all the fertile eggs incubated in the United States fail to hatch. The bureau has discovered that the principal causes are hereditary factors, improper nutrition, and faulty conditions of incubation. Experiments with White Leghorns and Barred Plymouth Rocks showed that hatchability decreases as inbreeding increases, and that full brother and sister matings are more detrimental than less intensive breedings. The character of the proteins in the diet of the breeding flocks is extremely important. Tests showed that a diet generous in animal proteins, lime, and cod-liver oil if sunshine is deficient, is necessary, and that a source of pigment, such as yellow corn or green feed, is also required. It is obviously desirable to cull out the hens that lay eggs of low hatchability.

Suppression of Animal Diseases and Parasites

Progress in veterinary science, in the administration of livestock laws and regulations, and in the adoption of control methods brought notable results in the suppression of animal diseases and parasites. Records of Federal meat inspection showed a marked decline in tuberculosis among cattle and swine. In the fiscal year 1930, though federally inspected slaughter of cattle and swine was more than 1,000,000 head greater than in the previous fiscal year, 10,000 fewer tuberculous carcasses and 40,000 fewer parts of carcasses of cattle, calves, and swine were condemned. Testing to eradicate bovine tuberculosis has been practically completed in nearly a third of the counties of the United States. The tuberculosis-eradication campaign was pushed forward in cooperation with every State in the Union and with several of the insular possessions. In May, 1930, a survey indicated that only 1.7 per cent of the country's cattle were tuberculous, as against 4 per cent in 1922. The number of cattle tested for tuberculosis during the fiscal year exceeded 12,000,000 head. Approximately 217,000 affected animals were slaughtered. Three States, North Carolina, Maine, and Michigan, are now recognized as practically free of bovine tuberculosis, and other States are approaching the same goal. The feasibility of eradicating bovine tuberculosis from large areas as well as from individual herds is thoroughly established.

Fifteen counties in five States were released during the year from the Federal quarantine against the cattle tick. The last remaining counties in Alabama were freed, and that State became the tenth of the 15 originally infested States to emerge from the quarantine. Mississippi was entirely released from the quarantine on July 1, 1930. The tick-infested area of the United States is now only about 20 per cent of its original size. In many localities where the tick quarantine has been lifted purebred cattle have been rapidly introduced. Purebred bulls are now fairly numerous in many sections of the South where only tick-infested scrub sires were previously known.

Infectious abortion continued to take heavy toll of the cattle industry and also of the swine industry. Research has not yet developed a fully satisfactory means of coping with the disease. It has recently developed the important fact, however, that the eye may be a frequent channel of infection. Experiments also indicated that the infection may gain entry to the animal through the skin, even though there may be no visible abrasion.

Complete success terminated a campaign begun two years ago in California for the control of liver flukes of cattle and sheep. This pest formerly caused heavy losses, particularly to sheep growers. There were no losses last year from liver flukes in the area covered by the campaign.

In hog-cholera control work a great increase was recorded in the production of clear antihog-cholera serum. This is a more refined product than that previously in general use. In establishments licensed by the department to produce antihog-cholera serum the principle of pasteurization was introduced. Pasteurized clear serum safeguards livestock from possible contamination with harmful bacteria. As it is now made in the licensed establishments, the serum is either sterile or of very low bacterial content when marketed.

Animal-quarantine regulations designed to exclude foreign plagues were enforced, as usual, during the year, and the country was kept free of foot-and-mouth disease, rinderpest, contagious pleuro-pneumonia of cattle, surra, and other dangerous livestock maladies. The beneficial effect of all these disease-control activities is shown by the fact that in recent years less than 2 per cent of the carcasses handled in federally inspected slaughterhouses have been condemned in part or in whole because of diseased conditions.

Omaha Rate Case Decision

In livestock marketing an important development during the year was a decision by the United States Supreme Court, handed down February 4, 1930, upholding the authority of the Secretary of Agriculture to prescribe rates for the handling of livestock on a commission basis at public stockyards. This case was commonly known as the Omaha commission men's rate case. The decision, besides sustaining the Secretary's right to prescribe reasonable rates, held that the rates he had prescribed were not confiscatory. Proceedings have been instituted to determine the reasonableness of the commission rates charged at other public stockyards. Studies of stockyard rates and property values are under way to determine what rates are necessary to give a fair return.

At a conference held in Chicago on October 22, 1929, at the invitation of the Secretary, resolutions were adopted to eliminate unfair and uneconomical practices in the packing industry. All branches of the meat-packing industry were represented. The resolutions banned secret rebates, the giving of premiums, the selling of goods below a reasonable market value to injure competitors, the issuance of misleading statements concerning the grade, quality, condition, and origin of packing-house products, and other practices held inconsistent with modern business principles.

DAIRY RESEARCH AND SERVICE

Increased utilization of dairy by-products was promoted by the Bureau of Dairy Industry by developing, standardizing, and assisting manufacturers to apply a new method of making casein. This grain-curd method was adopted at a number of plants. It enabled them to produce a superior product which immediately commanded a higher price. Casein is the principal material in cheese. Commercial casein is used extensively in another form in making paper. Casein is used also in making glues, paints, fungicides, plastic products, and insecticides.

Over half of the 51,000,000 pounds of casein consumed last year in the United States came from abroad. The new tariff act increased the duty on casein. This fact and the grain-curd method of making casein should widen the market for the domestic article. It would require about a billion pounds of skim milk to produce the casein that we have heretofore imported annually. If the United States made all the casein it needs, its farmers would get annually about $3,000,000 that now goes to other countries, and they would get it for a dairy by-product, skim milk, which is hard to sell at any price in some parts of the country.

Our imports of casein were large in the past, partly because low costs of production in some other countries made it possible to sell the imported product in the United States at a price that discouraged domestic production. Prices received by the domestic manufacturers were so low and irregular that casein manufacturing was seldom profitable and the manufacturer had not much inducement to make casein of high quality. As a result paper coaters could not depend on the quality of the domestic casein supply as a whole, though many producers turned out a good article. These difficulties ought now to disappear. At present casein is high enough in price to be a fairly satisfactory outlet for skim milk. The increased tariff on casein should maintain the price at a favorable level, provided our casein industry meets the demand of the market as to quality. It is striving to do so. When the Bureau of Dairy Industry called attention through the press to its grain-curd method for making casein, numerous casein manufacturers sought aid in putting the method into practice. There is a good inquiry from paper mills for ample and regular supplies of the grain-curd product. This is significant because paper making takes more than 75 per cent of the casein consumed in this country.

Assistance Given to Manufacturers

Technical help was also given by the Bureau of Dairy Industry to manufacturers of butter, American and Swiss cheese, and concentrated sour skim milk. The bureau carried on this work in cooperation with the State colleges of agriculture. In one instance an association of farmers' cooperative creameries was helped to improve its manufacturing methods; as a result about $300 a week was added to the sales of the member creameries. A cheese factory, by the use of manufacturing methods developed in the bureau, raised the quality of its product to an extent that increased its profits several hundred dollars a month. Many other dairy-products factories reported to the bureau that they had increased their profits by improving their operation and management methods as recommended by the bureau.

The bureau developed and improved methods for the manufacture of lactose, or milk sugar, which constitutes a third of the solid constituents of milk. Research on this problem continues on three lines—to reduce manufacturing costs and increase yields; to convert the present milk sugar of commerce into a sweeter and more soluble form, better for table use; and to develop methods of fermenting lactose into products having a market value. In the manufacturing problem distinct advances were made. Valuable food proteins are discarded before the sugar is crystallized in the usual commercial processes. The bureau improved a process whereby lactose is crystallized from concentrated whey in a manner that leaves the albumen in its natural state for further purification. This was an important step toward the economic use of milk by-products, a year's supply of which is estimated to contain nearly a billion and a half pounds of milk sugar.

New facts of potential value to the cheese industry were developed by the bureau during the year in studies of the bacteria used as starters in cheese making. Fancy Swiss cheese results from the combined action of several kinds of bacteria, which produce the desired end only when a definite balance is maintained among them. Too many or too few bacteria of a particular group may materially affect the quality of the cheese. The bureau's discoveries should give increased control of the bacteria present in cheese making.

A process for separating albumen from whey without injuring its emulsifying or whipping properties was perfected. An experiment was started to determine whether the product can be used advantageously in ice cream. Another possibility is the utilization of albumen in modified milk for infants.

Dairy Herd Improvement

In the breeding of dairy cattle, research in the bureau developed principles which, if widely applied, should greatly increase the productivity of dairy herds. Modern breeding methods, carefully and intelligently followed, can develop strains of dairy cattle that are pure in inheritance for high production. The dairy herd-improvement associations, which number more than 1,100 in the United States, are an important means of translating dairy science into dairy practice. These associations are local cooperative groups of dairy farmers. They are organized by the State colleges of agriculture in cooperation with this department. They keep precise records which serve to show how much room for improvement there is in the efficiency and economy of milk production generally. It is highly significant, for example, that the average milk production of the cows handled by the associations is close to 7,500 pounds a year. The average milk production for all the cows in the United States is about 4,600 pounds. As yet only about 2.5 per cent of the dairy cows in the country are included in the dairy herd-improvement associations. As the proportion increases, the country's milk production per cow should increase.

Records compiled by the associations show that only about a third of our milk cows earn a profit, a third return just about what it costs to keep them, and the rest are carried at a loss. Study of the association records shows the dairy farmer how to increase his dairy profits by selling unprofitable cows. But culling, though it raises the average production of a herd, is costly because the butcher's price for the culled animals does not equal what has been spent to rear them. The obvious remedy is better breeding so that fewer low-producing cows will need to be culled from the dairy herds.

Feeding and Management

Success in dairying depends not on breeding alone, of course, but also on the feeding and management of the dairy herd. The Bureau of Dairy Industry studies feeding and management problems and helps dairymen to apply the results achieved. It announced last year important results in the utilization of pastures. In experiments at Huntley, Mont., remarkably economical milk production was obtained by feeding alfalfa exclusively or as the main part of the ration.

WILD-LIFE CONSERVATION AND CONTROL

This year marked the beginning of a 10-year national program for the establishment of refuges for migratory game birds. Systems of refuges for these birds are essential to carry out our treaty obligations with Great Britain for the protection of the species that twice each year pass between the United States and Canada. With funds provided at the beginning of the fiscal year for the administration of an act authorizing these refuges, the Bureau of Biological Survey began nation-wide investigations of areas recommended as suitable. The food resources for wild fowl were studied on more than 3,700,000 acres, involving 189 units in 48 States. Eighty-nine of these units were found suited, from a biological standpoint, to the object in view. On 40 of the units, involving approximately 1,225,000 acres in 24 States, land-valuation surveys looking toward purchases were made.

Migratory-Bird Refuges Established

Two refuge areas on the public domain were set aside by Executive order, one of 12,000 acres in Montana and one of 20,000 acres in Oklahoma. The Migratory Bird Conservation Commission created under the act approved the purchase of one area of more than 32,000 acres in South Carolina, and another of more than 5,000 acres in Colorado, at an average price of $1.13 an acre. Other areas aggregating 56,000 acres were recommended for purchase and await the action of the commission. This is excellent progress toward the completion, within the 10-year period, of a program that will provide a network of Federal refuges covering the important flight lines and the wintering and breeding resorts of our migrant game birds.

Under separate acts of Congress for the creation of migratory-bird refuges, progress was made on one refuge at the mouth of Bear River, Utah, and initial steps were taken for establishing another in the Cheyenne bottoms in Kansas. The former, which covers more than 56,000 acres of land and water, will provide a large fresh-water area for wild-fowl breeding, feeding, and resting in a locality where wild ducks formerly perished in thousands from disease. Engineering work has already much lessened the menace to the birds. When completed, the refuge will help to protect the wild-fowl resources not only of Utah but of adjacent and distant States, as demonstrated by bird-banding operations of the Biological Survey. The migratory-bird refuge in the Cheyenne bottoms was authorized by Congress on June 12, 1930. Data previously gathered enabled the department to proceed in acquiring needed land and water areas that will cover about 20,000 acres.

Changes in Conservation Laws

In December, 1929, the department decided to reduce the bag and possession limits on ducks and geese with the opening of the hunting season of 1930–31. Exhaustive field investigations had shown the necessity for the reduction, which was strongly recommended by the principal game-protective associations and by State game commissioners. It was urged also by the advisory board set up under the migratory-bird treaty act. Years are required to increase the number of ducks and geese and to provide enough resting and feeding sanctuaries. An immediately beneficial effect should follow restrictions on the annual kill by hunters. With the opening of the hunting season in the fall of 1930, the limits were reduced from 25 to 15 a day on ducks and from 8 to 4 a day on geese; and a possession limit was prescribed of 30 ducks and 8 geese. Sportsmen themselves must exercise restraint if wild-fowling as a sport is to continue.

International wild-life protection entered a new phase with the passage of the tariff act of 1930, under the terms of which the principle of the Lacey Act governing illegal interstate transportation of wild animals or parts thereof is made international in scope. No wild mammals or birds or parts thereof of species specially protected in a foreign country may be imported into the United States unless accompanied by a certification of the United States consul for the consular district in which the point of export is located declaring that the animal or part thereof was not acquired or exported in violation of local laws or regulations. The new law should have a salutary effect.

Progress in Rat Control

The common house rat is the most destructive rodent in the United States. Besides menacing human life, it takes heavy toll of growing and stored crops and does much damage to other property. Recent experiments by the Bureau of Biological Survey demonstrated that red-squill powder is effective in rat control and relatively harmless to human beings and to livestock. Red squill is a wild perennial plant of southern Europe, with a large bulb from which the powder is made. The experiments showed that the powder can be produced at comparatively low cost. No other known rat poison combines the same advantages. Rat-control campaigns, in which the use of red squill was recommended, have had marked success.

FOOD AND DRUG ADMINISTRATION

Enforcement of the laws within the jurisdiction of the Food and Drug Administration, though primarily intended to protect consumers, also benefits producers. This is particularly true of the farmers. Food products that reach the market in a raw state are seldom subject to adulteration. Food products that have to be processed before reaching the consumer can be, and often are, adulterated. When this is done in the manufacturing process, the producer of the raw materials suffers along with the consumer of the manufactured commodity. The demand is lessened. This was illustrated in a type of adulteration against which action was taken under the food and drugs act in November, 1929. More than 5,000 cases of canned tomatoes were seized at various points because analyses showed that they were adulterated with water. Every pound of water illegally incorporated in the product deprived the farmer of a legitimate demand for an equal quantity of tomatoes. The sale of water at the price of canned tomatoes is a cheat to which reputable canners do not lend themselves. In checking the imposition the Food and Drug Administration improved the market both for raw tomatoes and for the honestly processed article.

Prior to the enactment of the food and drugs act, canned goods were a comparatively unimportant item in the American dietary. Such goods were often of uncertain quantity and quality and were mostly used where fresh food products could not be obtained. Cans were seldom full of the food they purported to contain. Often they contained an insignificant amount of food with an excessive amount of water. This condition was changed following the passage of the food and drugs act. Cans were required to be filled with the foods mentioned on the labels, and the use of liquid exceeding the proportion necessary for processing was prohibited. Rigid and continuous enforcement of this rule made the slack-filled can a rarity. The insistence on a full can increased the demand for the products of the farm, not merely by preventing fraudulent adulteration, but by increasing the confidence of the public in canned goods.

Spoilage by Freezing

Sometimes action is necessary which protects the ultimate interests of the farmers in a manner that seems costly and burdensome at first. In January last much citrus fruit in the Rio Grande Valley of Texas was damaged by frost. Freezing causes a physical breakdown in citrus fruit. In a week or so the inside dries and becomes unfit to eat, though the fruit may still look all right on the outside. After a severe freeze, some growers rush frost-damaged fruit to the market though it may be worthless when delivered to the consumer. Such action discredits the producing region and tends to reduce the demand for the sound fruit that may be produced subsequently. The more farsighted growers understand this and do not ship frost-damaged fruit. They can not, however, restrain others less conscientious or less interested in the long-time prosperity of the industry. Accordingly, an inspector of the Food and Drug Administration, in cooperation with the State authorities of Texas and with leaders of the citrus industry in the Rio Grande Valley, showed growers how to tell whether their fruit had been hurt enough to make it unfit for shipment. He urged the destruction of seriously damaged fruit, pointing out that if shipped it would be seized under the food and drugs act. As a result a great quantity of fruit was voluntarily taken from the trees by the growers and destroyed. Only a small amount was shipped contrary to the warnings given and had to be seized. The action taken on this question helped to maintain the reputation of the Texas citrus industry. The Food and Drug Administration has been adversely criticized for adopting an "advisory before the act" attitude in situations of this kind, but the method taken assures a much more adequate and widespread protection of the consumer and likewise of the permanent interests of the producer than could be achieved by relying on strictly punitive and confiscatory measures. Educational methods make seizure or prosecution largely unnecessary. During the year many other products were brought into conformity with the law either through legal action or in appropriate instances by the advisory method just described.

Insecticide Act

Results achieved in the administration of the insecticide act illustrate the protection given by such regulatory legislation. Calcium arsenate, which is widely used to protect cotton against the boll weevil, is produced on a large scale by 21 manufacturers whose aggregate output exceeds 25,000,000 pounds annually. In the fiscal year ended June 30 last, the plants of these manufacturers were inspected, and samples of calcium arsenate were collected. Samples were also collected from dealers and distributors. Ninety-four per cent of the samples were entirely satisfactory both in composition and in labeling. The remaining 6 per cent of the samples were of a proper composition, but were not correctly labeled. Steps were taken to remove this defect.

Import Milk Act

Substantial benefits have accrued to the American dairy industry and to the consumers of dairy products from the import milk act, which was approved February 15, 1927. This measure has reduced our imports of milk and cream materially. In the year ended March, 1930, our imports of milk from Canada totaled only 29,646,561 gallons, against 53,858,992 gallons imported in the year ended March, 1927. This reduction is largely attributable to the exclusion of milk produced under conditions below the standards of sanitation imposed by the import milk act.

Farmers have a substantial interest as consumers in the enforcement of these regulatory laws. They are large buyers of manufactured food products and thus share with city dwellers in the benefits of the food and drugs law. They are specially protected by action taken to prevent the marketing of fraudulently labeled stock remedies and of adulterated or misbranded feedstuffs. Twenty-five seizures of fraudulently labeled stock remedies were made during the last fiscal year. In many cases manufacturers changed their formulas voluntarily or altered labels after their attention had been called to the necessity for so doing. Farmers reaped a twofold benefit. They saved money that would otherwise have gone for worthless goods and avoided injuring their livestock with harmful products.

EXPERIMENT STATIONS

Research at the State experiment stations continued to expand under the stimulus of increased financial support from Federal, State, and local sources. The funds available for these institutions during the last fiscal year totaled about $17,000,000, approximately a fourth of which, or $4,335,000, was contributed by the Federal Government. As provided by the Purnell Act of 1925, Federal support to the State experiment stations has been increased $10,000 annually for each State during the last five years. The increase has now reached $60,000 annually for each State, the maximum increase provided by the Purnell Act. Previously under the Hatch Act and Adams Act the Federal Government provided $30,000 annually to each of the States; hence the total annual contribution to each State is now $90,000. The income of the stations has been increased to a still greater extent from State and local sources. As a result they are cooperating effectively with one another and with this department in a research program that covers practically every phase of agriculture and rural life. They are giving special attention to agricultural economics, home economics, and rural sociology, as authorized by the Purnell Act.

Seven Thousand Research Projects Under Way

More than 7,000 research projects are under way at the experiment stations. These studies, in which the work of one station is in large measure coordinated with that of others and with the work of the United States Department of Agriculture, deal with both the technical and the economic problems of farm production. They deal also with marketing and distribution and with rural-home and rural-community problems. In general the experiment stations emphasize local or regional needs, while this department deals with farm problems largely from a broad national viewpoint. This division of effort has justified itself in practice and promises increased benefits in the future. The Office of Experiment Stations represents the Federal Government in administering the Hatch, Adams, and Purnell Acts.

Research at Insular Stations

The Office of Experiment Stations supervises the use of the funds appropriated by Congress for the maintenance of agricultural experiment stations in Alaska, Porto Rico, Hawaii, Guam, and the Virgin Islands. The Alaska station made noteworthy progress in developing strains of beef and dairy cattle suited to the Territory. Successful experiments in dairying were made in the Matanuska Valley. Satisfactory results have followed the establishment of joint control of the Hawaii Agricultural Experiment Station by the United States Department of Agriculture and the University of Hawaii. This was provided for in an act of Congress passed May 16, 1926, to extend the benefits of the Hatch Act and supplementary acts to Hawaii. Experiment stations previously maintained seperately by the department and by the University of Hawaii were combined.

The experiment station in Porto Rico helped to restore the agriculture of the island following the destructive hurricane of 1928. It was especially active in repairing the damage to coffee plantations and citrus orchards. Research men attached to the station demonstrated that leaves of banana trees, planted extensively as temporary shade for coffee, furnish a fiber that can be used in making coffee and sugar bags. This indicated a possible saving of a million dollars or more annually to Porto Rican farmers. From coffee plantings that withstood the storm, the experiment station supplied enough seed of the Excelsa variety to replant nearly 2,000 acres. It helped to get a commercial precooling plant for citrus fruits and pineapples erected at San Juan. Fruit handled in this plant reaches New York in a much better condition than fruit not so handled.

The experiment station in the Virgin Islands developed a new variety of sweetpotatoes which yields 50 per cent more, is of better quality, and keeps better than the common varieties. Planting of the new variety is going forward rapidly. The station has also demonstrated the practicability of growing vegetables to improve the local dietary and to ship to New York. The Guam experiment station has brought about an improvement in the livestock of the island, encouraged the planting of better forage crops, demonstrated the feeding value of copra meal, and helped to bring about the commercial planting of pineapples for canning.

HOME ECONOMICS

Research in the Bureau of Home Economics touches the general farm problem at some vital points. It reveals deficiencies in farm living standards and indicates remedies. It shows that in many areas a vicious circle is formed between low income and poor diet, poor health, and lowered production. Other unsatisfactory aspects of family living on the farm result from lack of skill in the expenditure of the farm income. The food purchased may be poorly chosen; the clothing purchased may be ill adapted to farm needs; farm homes may be equipped less efficiently than the means available would permit; and lack of information on commodity values may cause much waste in household buying.

The bureau recently drew attention to the dietaries reported by 61 families in a rural district of South Carolina as showing the interdependence of income and family living standards. Pellagra, a chronic disease directly caused by badly selected food, is prevalent in this area. The average farm income available did not suffice for an adequate diet. Poor diet caused disease, and disease impaired the economic efficiency of the group. It was evident that the needs of the region required the attention of the economist as well as of the home economist. It was necessary to offer suggestions looking both to improved farm practices and to a better use of the available farm income.

Preliminary surveys in other regions indicate that similar conditions exist there. The department has recognized the complex character of the family-living problem by studying it from several angles simultaneously. Thus the Bureau of Home Economics is cooperating with the Bureau of Agricultural Economics and with the Kentucky Agricultural Experiment Station in a study of land utilization and living conditions in eastern Kentucky. In this study it is the task of the Bureau of Home Economics to show wherein the standard of living is wanting.

Rural Diet Deficiencies

The Bureau of Home Economics has found that the diet of city dwellers has made more progress toward a scientific ideal in recent years than has the diet of farm dwellers. City people are eating more vegetables and fruits. On the farms, though the use of fruit and vegetables is greater than it formerly was, these foods still do not form a sufficient part of the diet. Reports of the foods used by 2,402 farm families in nine States indicated that dietaries could be much improved in some areas by the use of more fruits and vegetables. Milk consumption on the farms in all these States was lower than it should be. In the State reporting the least use of milk, pellagra is common.

Practical Value of Nutritional Studies

Research done by the bureau on the vitamin content of certain foods has a twofold value to the farm family. In the first place it shows how diets may be improved. Second, such research indicates that certain products ought to have a wider market. It has been demonstrated, for example, that the watermelon is a good source of vitamins A and C and contains small amounts of vitamins B and G. Study of the vitamin content of spinach showed that three varieties were about equal as sources of vitamins A and B. But one of these varieties is less potent than the others in vitamin C and loses more of the vitamin C in the canning process. Such knowledge has obvious practical value in view of the importance of an adequate vitamin content in the diet. As is well known, many serious nutritional disorders result from an inadequate supply of vitamins. Besides studying the composition, the bureau experiments also with the cooking of foods. It is cooperating with specialists in animal husbandry to test the palatability of meats. Facts developed by this research will be useful to livestock producers as well as to meat consumers.

Textile Utilization

In an effort to encourage a more intelligent use of cotton and wool produced in this country the bureau studies the utilization of textiles, publishes designs for clothing and household articles, and assists textile manufacturers in learning more about the consumer's needs. In this way the interests of both the producer and the consumer are promoted. The production of desirable types of cotton and wool materials is encouraged and home makers are helped to make a better selection of fabrics. In cooperative studies with other bureaus of the department the Bureau of Home Economics inquires into the relationship between different grades and qualities of cotton and wool and the value of the fabrics woven therefrom. Fabrics produced by manufacturers under scientifically controlled conditions are given laboratory and wearing tests. The interest shown in the textile studies by manufacturers and consumers is some evidence that their potential value is appreciated.

PROGRESS IN WEATHER FORECASTING

Increased appropriations made possible marked expansion of the Weather Bureau's service along airways. This now includes continuous 24-hour service along approximately 6,000 miles of airways and a less frequent exchange of reports for some 7,000 miles. The hourly reports are transmitted mostly by means of teletype systems maintained and operated by the Department of Commerce. One circuit extends from Boston to Richmond; another from Portland, Oreg., to San Diego. These are united by the main transcontinental line from New York to San Francisco, which has two channels from Omaha to Cleveland—one by way of Chicago and the other through Kansas City, St. Louis, and Louisville.

On the transcontinental line between New York and San Francisco a network of stations is maintained, covering a strip about 150 miles either side of the airway, which report every three hours to central airport stations at Cleveland, Fort Crook (Omaha), Salt Lake City, and Oakland (San Francisco). Summaries and short-period forecasts prepared at these centers are broadcast from Department of Commerce radio stations to aircraft in flight. They are picked up also by numerous airports and by others interested. During the fiscal year 1931 the airways service will be expanded still further with the aid of additional funds. Hourly reports will be organized on about 3,000 additional miles of airways, and the 3-hour forecast service will be extended to include the Southeastern, Southern, and extreme Northwestern States, with centers at Atlanta, Dallas, Fort Worth, and Portland, Oreg.

Reports from Ships at Sea

Synoptic weather reports from ships at sea were briefly described in the report for 1929. Under the international agreement concerning these, each nation is responsible for enlisting a selected number of ships to radio regular reports at least twice a day to designated shore stations. The present program includes about 21 American, 31 British, and 5 French ships. Ten German ships are expected to report in the near future. On any one day only a fraction of the whole number of enlisted ships are in position to render reports.

These reports have great value to the forescasters of the bureau, as well as to those of all other national services receiving them. The great continental areas are dotted with numerous stations which make at least two reports a day. Without ship reports the vast ocean areas are a complete blank, and the forecaster's picture of the atmosphere is incomplete. Ship reports enable him to sketch in and tie together both land and sea conditions. The combination gives from observation to observation the picture of the ever-changing circulation of the air over the whole Northern Hemisphere. The data for the vast ocean areas are still scanty and incomplete, but new reports are being added each year, and improve the basis for better and more complete forecasts.

THE NATIONAL FORESTS

The national forests are administered with a view to obtaining from them the largest net total of public benefits. Their resources are very great. During the year their net area—that is, the area of federally owned land within their boundaries—was increased by 340,297 acres, to a total of 160,090,817 acres. Their use by the public exceeded in various particulars all previous records, with a greater cut of timber, greater total receipts for uses involving a charge, and a greater number of recreation visitors by several million than in the preceding or any earlier year. Through their wise development, their scientific management, and careful safeguarding of their productivity their public value and services can be made to increase still further and immensely.

The first need of the West that national-forest administration aims to meet is that for water. This necessitates the working out of methods and plans of use that will insure the preservation of a suitable vegetative cover on important watersheds. Certain of the national forests were created specifically to protect Federal reclamation projects and at the request of the Reclamation Service. Watershed protection is a complex matter. While it is a primary objective of national-forest administration, it can not be pursued as an independent objective. To be fully serviceable the national-forest land areas must be managed with a view to utilizing their capacity to grow timber crops and forage crops along with their capacity to regulate water flow. The most difficult problems of national-forest administration lie in combining and coordinating the water-control function with the utilization of the natural products of the soil.

The Protection Problem

Severe drought made protection of the national forests against fire in the summer and fall of 1929 exceptionally difficult. Never before in the history of national-forest administration had the western fire season had so late a close. The expenditures of the year for fire suppression alone exceeded $3,400,000. The estimated damage to the Federal properties exceeded $4,300,000, of which nearly $4,000,000 represented timber and reproduction destroyed. The fires burned over more than 978,000 acres of land within the national forests, of which more than 799,000 acres were owned by the Government. Only twice has a greater area been burned over, and only three times—in 1910, 1919, and 1926—has the estimated damage been greater. Of the area burned over, 96 per cent was in the national forests of the West. Both the expenditures for fire suppression and the fire damage fluctuate greatly from year to year. The expenditures, which have averaged for the last decade $1,280,000, were less than $320,000 in 1923, as against more than ten times that amount in 1929. The damage averaged for the decade $1,363,000, but was less than $181,000 in 1923, as against a high in 1926 of more than $4,560,000. The protection problem centers in the bad fire years. Bad years are due to precipitation shortages, high temperatures, low atmospheric humidity, excessive wind, and severe lightning storms. The climate, the character of the forest, the topography, and the inaccessibility of great areas make protection in the West extremely difficult always. The years of peak load necessitate the employment of hundreds and even thousands of men on the fire lines.

Most Damage Done by Large Fires

Most of the damage and outlay are caused by relatively few very large fires. More than half the fires are put out before they have covered one-fourth of an acre. More than half the rest are held to less than 10 acres. Only a small percentage exceed 100 acres. In California last year, where fire-control conditions were exceedingly unfavorable, out of 202,000 acres burned over by 1,416 fires of all sizes, 184,000 acres, or 91 per cent, was covered by 10 per cent of the fires, which covered 100 acres or more each. Area alone, however, is not a satisfactory index of the damage done or the efficiency of the control system. Grass fires may cover a large acreage without causing much loss, and different types of timber vary widely in their susceptibility to damage. The Forest Service is adjusting its system of fire control to the degree of difficulty of the relative values at stake, and their susceptibility to damage in each case. This is done by setting up for each forest standards of satisfactory performance in keeping down the area burned over in bad years.

The standards vary from 0.1 per cent of the total area to 2.5 per cent where there is little of value to protect—for example, where the growth is only grass or brush and the watershed values involved are inappreciable. When the standard of satisfactory performance thus established is compared with what is actually being accomplished, the problem of protection is given new definiteness.

Of the 149 national forests, 74 are rated as now receiving satisfactory protection; 37 are on the border line; 38 are definitely substandard and show a ratio between the area burned in bad years and the total area that averages about five times what the standards set up would allow. It is urgently necessary to give better protection to these substandard forests, which are the critical spots, taking the greater part of the outlay for fighting large fires and accounting for the greater part of the fire losses. This calls for strengthening the preparedness of the protective organization to function swiftly and effectively under the stress imposed by the bad years.

Preparation for Forest Protection

Preparedness calls for a specially trained and competent personnel, properly organized and located; for advance plans of action, including arrangements for obtaining, transporting, provisioning, equipping, and officering additional manpower in such quantities as may be requisite; for efficient systems of detection, communication, and transportation in the form of observatories, telephone lines, roads, trails, and the like; and for adequate supplies of such forms of equipment as trucks, power and hand pumps, specialized machinery, tools, and many other accessories of fire fighting. In the past the Forest Service has been greatly restricted, in comparison with the protection needs, in making the expenditures necessary for preparedness. The appropriations for the current year, however, afford much greater latitude for preparedness than has ever existed before. To equip the critical forests adequately with the permanent improvements necessary for economical and efficient protection will take years; but the line of attack upon the problem of fire control that has now received legislative sanction should progressively safeguard the forests and increase their usefulness.

Forest protection includes protection against the ravages of destructive insects and tree diseases as well as against fire. The three are related, for large quantities of dead timber greatly increase the fire hazard, while fires increase the susceptibility of the forest to insect and disease attack. As intensive forest management becomes possible, harvesting the timber crop can be made a means of putting the forest into much better condition for protection through reduced fire hazards, applying measures of forest sanitation to check tree diseases and insect infestations, and making all parts of the forest easy to reach. Regulated grazing also can contribute to protection. But as a rule the national forests have not reached the development that permits intensive management. They are in a transition stage between the wilderness period of their history, when even the most elementary requirements for protection were lacking, and the period when all their resources will be in full use. In consequence, the problem of protection is still largely an isolated problem rather than a matter of creating and maintaining, as a part of resource development and management, the right conditions.

Trends in Western Forest Ownership

Since 1891, the year in which the President was authorized to create reserves, the western system of national forests has been moving gradually toward its completion. At the same time the available area has been progressively diminishing through disposal of the public-domain timberlands under other laws. Nevertheless there is left a considerable acreage of unreserved and unappropriated public land having forest values for timber production or watershed protection that justify and make desirable its inclusion in national forests.

Some of the forest land that has passed into private ownership since the policy of reservation was first proposed is likely to gravitate back into public ownership after its timber has been removed. In the Lake States tax delinquency and land abandonment have reached serious proportions; they are beginning to threaten in parts of the South, and they are creating acute local problems in some Western States. There is a distinct possibility of the building up of a new public domain, but this time in the hands of the States, which become the reluctant recipients of what the private owner throws away. In some parts of the West a growing disposition exists to look to the Federal Government for relief from the accumulation of abandoned cut-over lands in State ownership.

Some small relief is taking place under the exchange laws. The purpose of these laws is to facilitate the consolidation and rounding out of national forests. In or near many are private lands which the Government should acquire to form more logical administration units. The Forest Service may negotiate exchanges with the owners of lands within the forest boundaries, and in some cases up to 6 miles distant from the boundaries. For the lands acquired, lands, timber, or both may be exchanged; but usually the Government obtains land with more or less timber and gives timber only. Lumber companies wishing to operate national-forest stumpage under the customary timber-sale regulations can thus sometimes pay in land or in land and standing timber instead of in cash. Often they turn over lands with much more timber on them than they receive, being induced thereto by the more favorable location for them of the timber obtained. It may be close to lands that they are already logging. In other cases cut-over lands are turned over. In this way some land which otherwise might eventually be forfeited to the States through nonpayment of taxes is kept productive. The exchange policy should in time afford an appreciable, if minor, relief from the consequences of temporary private ownership assumed solely for the sake of the timber.

Exchanges are also made with States. Under the school-land and other grants, the Western States received extensive rights to lands subsequently included in national forests. A number of these States have received solid blocks of land in exchange for scattered sections in the national forests. Some of the lands have been outside the national forests, but Idaho, Washington, Oregon, California, Montana, South Dakota, Michigan, and Colorado have obtained or are in process of obtaining blocks of timberland from the forests. These areas are suitable for permanent forest administration by the States themselves, and the outcome will probably be State forest enterprises essentially like that of the Federal Government. As tax-reverted cut-over lands accumulate, they will presumably necessitate State plans for their consolidation and administration.

More than four-fifths of the forest land west of the Plains, not including that in Alaska, is now in public ownership. This includes national forests and national parks, State and municipal forests and parks, Indian reservation and open public domain forest lands, and State forest lands for which no policy of administration is in sight. Private ownership accounts for the rest. Every effort should be made to encourage and facilitate private forestry on this land. Nevertheless, public ownership will eventually have to take over more of the western forest area. Steps should be taken to place under administration for forest purposes, by the appropriate agencies, both the remaining timbered areas of the public domain and other timberlands subject to Federal control whose permanent status is not yet determined. It is desirable that the States also should undertake greater responsibilities for the permanent administration of forest lands.

The Eastern National Forests

Although several of the eastern national forests were created by reserving portions of the public domain and 38 per cent of the Federal land in the eastern forests has come through such reservations (chiefly in Arkansas, Minnesota, Michigan, and Florida), the eastern system of national forests is being built up under a policy of acquisition. The law of March 1, 1911 (the so-called Weeks law), provided for the purchase of "lands located on the headwaters of navigable streams or those which are being or may be developed for navigable purposes." Although the law set no regional limitations on purchases, it was accepted as providing for the building up of a small system of eastern national forests that would be confined to the mountain ranges of the southern Appalachians and to the White Mountains of New Hampshire and southwestern Maine. It was believed that Federal administration of well-chosen strategic areas totaling 5,000,000 acres in the southern Appalachians and 1,000,000 acres in the White Mountains could lead the way to right management and use of the forests of the two regions. But as acquisition advanced, forest exploitation also advanced. The result was to enlarge in these regions the area requiring Federal administration to protect navigable streams, as well as to make clear that protection should be extended to various similar areas outside the regions.

Beyond that, Congress in 1924 broadened the Weeks law by directing the Secretary of Agriculture to recommend for purchase lands necessary for the production of timber, and also by removing the restriction which had confined acquisitions for watershed protection to lands "located on the headwaters of navigable streams." This amendment was part of the Clarke-McNary law, a comprehensive measure enacted after an inquiry by a Senate committee had shown the need for enlarged Federal activities in forestry. Since the original program was formulated, and particularly since the Clarke-McNary law was passed, additional purchase areas have been established in Arkansas, Pennsylvania, the Lake States, and the southern pine region. In these areas 886,167 acres had been acquired up to the close of the last fiscal year, together with 2,527,126 acres in the two original regions.

The present program is limited to putting into effect the intent of the two laws providing for forest-land acquisition. It is not a program based on a broad survey of the requirements of the eastern forest situation. It calls for the acquisition of a total of approximately 9,500,000 acres, of which the major part will be added to some 6,000,000 acres already owned or under contract of purchase by the Federal Government to protect the headwaters of navigable streams. The rest will be acquired primarily to aid in timber production and to demonstrate forestry practice in the southern pine and the northern Lake States regions. The Federal Government already has about 1,800,000 acres in these regions, mainly derived from the reservation of areas of public lands. If this program is to be carried out within a reasonable time, the rate of acquisition will need to be substantially accelerated. A forward step was taken by Congress, near the close of the fiscal year, in authorizing appropriations up to $3,000,000 in each of the fiscal years 1932 and 1933.

The completed program will provide an eastern system of national forests containing some 16,000,000 acres of Government-owned land, chiefly in areas selected for their value in protecting the headwaters of the principal navigable rivers, in other words, chiefly mountain lands. But the needs of the East for permanent forests to control floods and erosion will not be met by this program. It will take care of only a minor part of these needs. Still less will it meet the needs of the East for public ownership and management to insure and promote timber production. In the eastern half of the United States approximately 350,000,000 acres are classed as forest land. In addition there are many million acres of marginal and submarginal farm lands which might better be used for forest purposes than for farming, and which will sooner or later largely revert to forest. Of the present area of eastern forest land, more than 95 per cent is privately owned. The practice of forestry by private owners is relatively rare. Private forestry should be encouraged and promoted by every means consistent with sound public policy, but it can not be expected to restore to productiveness all of the cut-over and burned-over lands. Sooner or later eastern public forest land ownership on a far greater scale than has yet been thought of will become inevitable. While the responsibilities and the burdens that will be involved may in the main be regarded as appropriately falling first on the States and local governments, both the magnitude of the tasks that will be imposed and the extent to which national interests are affected will almost surely make necessary substantial Federal participation along new lines.

FEDERAL-AID ROADS

Included in the Federal-aid highway system at the present time are 193,049 miles of the country's most important interstate and intercounty highways. Initial Federal-aid improvements were completed during the past year on 7,317 miles in this system.

Since 1916, when the Federal-aid policy was adopted, the Government has cooperated with the States in the improvement of 86,978 miles. Provision for the designation of the Federal-aid system was not made until 1921. Between 1916 and 1921 a considerable mileage was improved that was not included in the Federal-aid system when it was finally designated. The roads omitted were not considered of sufficient importance to warrant their inclusion, but, as Federal funds had been applied to their improvement, the States have been required by law to maintain them.

To permit the States to return these roads to the care of the county and township authorities, by whom they should properly be maintained, a plan has been developed under which the States may substitute for these unimportant roads outside of the system other roads in the system. Federal funds previously paid for the older improvements, supplemented with new funds as required, are applied to the newly included roads. As the substituted roads require more expensive improvements than the roads they replace, the mileage that can be improved with the transferred funds is less than the originally improved mileage. By such substitutions the mileage for the maintenance of which the States are held responsible has been reduced by 696 miles. By the relocation of previously improved roads in the course of stage construction, a further reduction of 64.2 miles has been made; so that the mileage now carried as a State maintenance responsibility is 86,218 miles. Of this total, 2,205 miles were in process of further stage improvement or reconstruction at the close of the fiscal year, so that the mileage classified as improved was reduced to 84,013 miles. At the close of the preceding year the mileage similarly classified was 77,944. Hence the net addition of "improved" mileage was 6,069 miles.

Status of Appropriations

At the close of the fiscal year 1929 the balance of Federal-aid funds authorized and not expended in the earlier years of the road-building program had been exhausted. It therefore became necessary to shape the work in accordance with the amount of the authorized funds for the current year.

For several preceding years unused authorized funds made it possible to carry on a program calling for an annual Federal disbursement ranging from $80,000,000 to $95,000,000, though in 1925 and afterwards the total sum annually authorized was only $75,000,000. Out of this sum, after deduction of the administrative percentage, $73,125,000 was apportioned among the States.

In the fiscal year 1929, for the first time since 1923, the amount obligated for new projects was within the amount of the year's apportionment. Thus curtailment of the program for the ensuing year and for succeeding years was foreshadowed. Federal-aid funds paid to the States during the fiscal year 1930 were smaller in amount than in any year since 1925. The amount paid, $75,880,863, was more than $6,000,000 less than in the preceding year and more than $20,000,000 less than in 1925, when the accumulated balance of unobligated funds was greatest. As the rate of the initiation of projects had been reduced to the gauge set by the annual apportionments, the rate of payment upon projects was reduced accordingly. It was but little higher in 1930 than the $73,125,000 apportioned.

For the fiscal years 1930 and 1931 the authorizations originally provided by Congress were $75,000,000, the same as for the several years preceding. This sum established the rate of operation throughout the first half of the fiscal year. The apportionment in December of the $73,125,000 originally available for the fiscal year 1931 merely permitted a continuation of the work at the same rate.

Additional Funds for 1931

In April, 1930, however, Congress authorized an additional appropriation of $50,000,000 for the fiscal year 1931. It thus recognized the need of increased authorizations to restore the earlier rate of construction. Congress desired also to augment public work so as to provide employment. This additional sum, less the prescribed administrative percentage, was immediately apportioned among the States and was available at once for allotment to new projects. The States submitted projects at a materially increased rate. As a result the total obligation of Federal-aid funds during the fiscal year 1930 was $102,000,000, considerably more than the amount obligated in any year since 1925. The amount obligated exceeded the corresponding amount for the fiscal year 1929 by more than $32,000,000.

The effect of the increased authorizations in providing additional employment is indicated by the fact that in April, 1930, the number of men employed on Federal-aid road construction was 20,200, as compared with 16,200 in April, 1929. In May, 1930, the number employed was 31,400 and in June 35,800, as compared with 26,600 and 34,500, respectively, in May and June, 1929. In August, 1930, the number employed was 48,513. These figures represent only the men employed in the actual construction of the roads. They do not include the workers required to manufacture and prepare materials and equipment or those employed in transporting materials and equipment to the job.

Funds authorized for appropriation for the fiscal year 1932 were apportioned on September 1, 1930. Under ordinary circumstances this apportionment would not have been made until December. It was made earlier to provide increased employment for farmers and other sufferers from the effects of the drought. The newly apportioned funds are immediately available for allotment to new construction projects wherever such projects will furnish employment for drought sufferers.

Increase in Annual Mileage Indicated

The mileage initially improved during the past year was less than in any previous year since 1921. This was the natural consequence of the contraction of the program to the scale set by the $75,000,000 authorizations. That the enlargement of the authorization to $125,000,000 for the fiscal years 1931, 1932, and 1933 will be followed quickly by an increase in the mileage improved annually is indicated by the fact that the mileage of initial and stage construction already under way and approved is considerably greater than it was a year ago.

The mileage of initial and stage improvements under construction or reconstruction on June 30 was 9,915, as compared with 9,526 a year previous. The mileage of both classes of improvement approved for construction or reconstruction at the close of the year was 3,469, as compared with the corresponding figure for the previous year, which was 2,898.

The net increases in the several types of construction during the year were as follows: Graded and drained roads, 1,041 miles; untreated sand-clay roads, 117 miles; untreated gravel roads, 661 miles; treated gravel roads, 118 miles; untreated macadam roads,. 7 miles; low-cost bituminous mixed roads, 448 miles; bituminous macadam roads, 385 miles; bituminous concrete roads, 166 miles; Portland-cement concrete roads, 3,081 miles; block pavements, 38 miles; and bridges and their approaches, 43 miles. There was a net decrease in the mileage of treated macadam roads amounting to 36 miles, which made the total net increase 6,069 miles.

Total Improved Mileage

The total mileage classed as improved at the close of the year was as follows: Graded and drained roads, 12,449 miles; untreated sand-clay roads, 7,166 miles; treated sand-clay roads, 17 miles; untreated gravel roads, 28,608 miles; treated gravel roads, 482 miles; untreated macadam roads, 1,754 miles; treated macadam roads, 603 miles; low-cost bituminous mixed roads, 742 miles; bituminous macadam roads, 4,057 miles; bituminous concrete roads, 3,205 miles; Portland-cement concrete roads, 23,693 miles; block pavements, 905 miles; and bridges and their approaches, 332 miles; a total of 84,013 miles.

The total cost of the 7,317 miles of initial improvements and the 2,011 miles of secondary improvements completed during the year was $193,648,149, of which sum $82,158,757 was paid by the Federal Government. These payments extended over the period of between one and two years required to complete the improvements. In addition to the payments made during the year on the projects that were completed, payments were also made on other projects not completed. The total actual disbursements of Federal funds to the States amounted during the year to $75,880,863.

Mount Vernon Memorial Highway

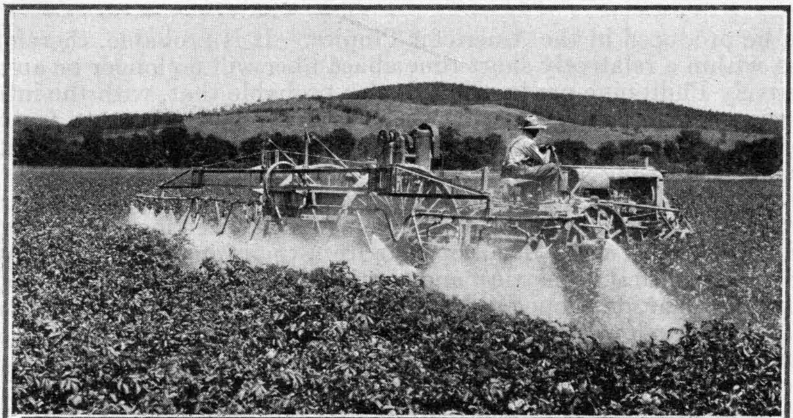
Construction of the Mount Vernon Memorial Highway from Washington to Mount Vernon, begun in September, 1929, was well advanced by the close of the fiscal year. The road should be ready for use in February, 1932, as planned.

Provision for the construction of the memorial road was made by an act of Congress approved May 23, 1928. This act authorized the Commission for the Celebration of the Two-hundredth Anniversary of the Birth of George Washington to select the route and approve the plans for the road. It directed the Secretary of Agriculture to cooperate in making the surveys, and to supervise the construction. The act authorized an appropriation of $4,500,000. The Bureau of Public Roads surveyed two feasible routes. The commission, on January 24, 1929, selected a route beginning at the Arlington Memorial Bridge on Columbia Island and following closely the Virginia shore of the Potomac, a distance of approximately 15½ miles, to Mount Vernon. The plans provide for a pavement 40 feet wide on a right of way of a minimum width of 200 feet, except through the city of Alexandria, Va. The grade and alignment are designed to permit a rapid and easy flow of traffic and a smooth blending of the highway into the natural roll of the land. This requires careful landscaping.

For the safety of traffic, all important crossroads are carried under or over the highway on grade-separating bridges. The minor roads intersecting at the grade will enter the highway from the two sides at points separated by a considerable distance, so as to avoid direct crossing of the principal traffic stream. At suitable points flared and divided roadways will facilitate the turning and parking of vehicles and permit visitors to halt for views of the river and the Capital City. A large terminal circle at Mount Vernon and tree-screened parking areas at this point will permit the expeditious loading and unloading and the orderly parking of many vehicles.

The first work was begun on the road in September, 1929, on a contract for the construction of a sea wall, the building of a cofferdam, and the supplying of stone for bridge facing. Contracts subsequently awarded provide for the construction of 2¼ miles of hydraulic fill, for 12½ miles of dry-land grading and small drainage structures and incidental construction, and for 12 major bridges. At the close of the fiscal year 1930 the sea wall had been completed, four of the five hydraulic fills were near completion, and excellent progress had been made in the dry-land grading and the construction of the bridges. Tenders for the construction of the pavement are to be invited shortly after January 1, 1931.

Arthur M. Hyde,
Secretary of Agriculture.



WHAT'S NEW IN AGRICULTURE

ABACÁ Growers in Philippines Face Outside Competition Abacá (Manila hemp), which is one of the so-called "hard" fibers, is produced by a plant that closely resembles the well-known banana plant. With the exception of small quantities produced in the Dutch East Indies, the entire world supply of abacá is obtained from the Philippine Islands. The approximate annual consumption of abacá fiber in the United States is 150,000,000 pounds.

This fiber is used principally for the manufacture of the superior grades of cordage. Its remarkable strength, elasticity, and resistance to the action of salt water make it a particularly suitable material for marine cordage. Manila rope is also used in large quantities for well drilling, heavy construction, transportation work, and for many other purposes where cordage of superior quality is required. During periods when there is a shortage of henequen fiber, or when the price of this fiber is unduly high, there is an increased use of abacá fiber for the manufacture of binder twine.

The fact that there is no entirely satisfactory substitute for abacá fiber, and the further fact that practically the entire world supply of this fiber is now produced in the Philippine Islands, indicate very clearly the need for maintaining the Philippine abacá industry in at least a reasonably healthful and prosperous condition.

During the period of American occupation of the Philippine Islands, and particularly during the last 15 years, there have been changes and developments in the abacá situation that promise to alter very materially the conditions under which this fiber is now produced. For nearly a century the Philippine Islands enjoyed a natural monopoly in the production of abacá, and there has existed a somewhat general opinion that abacá fiber of good quality could not be produced in any country other than the Philippines. In recent years, however, the production of abacá has been established on a commercial basis in the Dutch East Indies. It has also been demonstrated during the last two years that abacá fiber equal in quality to that produced in the Philippine Islands can be produced in the American Tropics. It is probable, therefore, that within a relatively short time abacá fiber will no longer be an exclusively Philippine product. It is also probable that, with the introduction of the competitive factor, it will become necessary for the Philippine planters to make some improvement in their present methods of production.

During the period from 1901 to 1907 abacá fiber was the leading export product of the Philippine Islands and constituted more than 66 per cent of the total value of all exports from the islands. Subsequently other agricultural industries, and particularly the production of coconuts and sugar, developed much more rapidly than the abacá industry. In 1928 the value of the abacá exported was only 17.1 per cent of the total value of all Philippine exports for that year.

Antiquated Methods Continued

With no direct competition from other countries, and with but relatively little competition from other industries in the islands, the Philippine abacá planters have been able to continue the use of antiquated and wasteful methods of production and still make a reasonable profit. In the older abacá provinces, in the southern part of the island of Luzon and in the Visayan Islands, abacá has been grown for generation after generation without cultivation and without the use of fertilizers. But little attention is given to the selection of the superior varieties, and the fiber is cleaned by the same old hand-stripping process that has been in general use for at least a century. In these provinces, and with these methods of production, the abacá industry is barely holding its own.

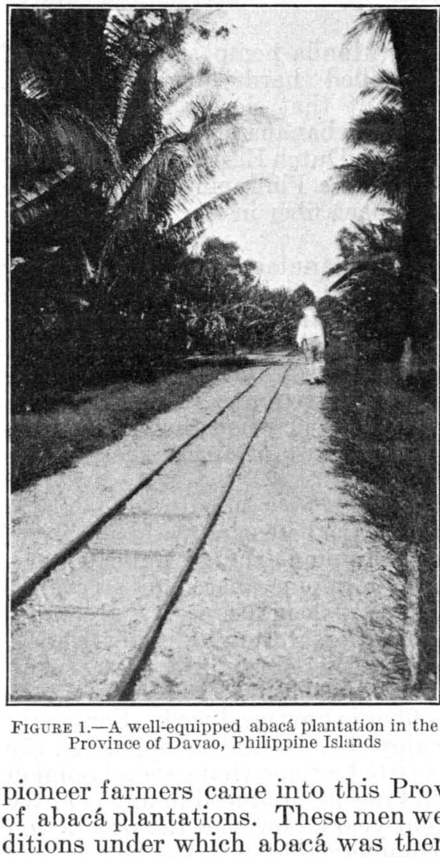


FIGURE 1.—A well-equipped abacá plantation in the Province of Davao, Philippine Islands

Fortunately for the future of Philippine abacá, the production of this crop has been established during recent years on a relatively efficient basis in the Province of Davao in the southern part of the island of Mindanao. (Figs. 1 and 2.) About 25 years ago a small group of American pioneer farmers came into this Province and started the development of abacá plantations. These men were determined to improve the conditions under which abacá was then being produced, and they immediately made improvements. The different varieties of abacá were observed and studied, and only the superior varieties were planted. A new system of planting was introduced, and an effort was made to obtain a machine that would satisfactorily clean the fiber. After experimenting for several years, a small fiber-cleaning machine was perfected, and this machine is now in general use throughout this Province.

Some years after the American plantations were established a group of Japanese planters became interested in the production of abacá, and the Japanese now control a large part of this industry in Davao. Numerous changes and improvements have been introduced by them. They have established an auction system that has greatly improved conditions for the local marketing of fiber; they are now conducting field experiments with different systems of planting, and with the use of cover crops and commercial fertilizers; and they are developing the production of machine-cleaned fiber.

The one thing that is now most urgently needed in the abacá industry is improvement in the present method of cleaning and drying the fiber. The small machine that is now used in Davao, although better than the old hand-stripping process, requires a large amount of labor and wastes about half of the product.

FIGURE 2.—Bundles of abacá fiber that have been brought from the plantations to the market in the town of Davao

Fiber-Cleaning Tests

Experimental fiber-cleaning tests made several years ago by the Bureau of Plant Industry of the United States Department of Agriculture indicated that abacá fiber could be cleaned with the large automatic machines that are used for cleaning sisal and henequen fiber. The preliminary experimental work of the Government was followed by a more elaborate series of tests, and subsequently a machine was installed on an abacá plantation in Davao. The production of machine-cleaned abacá fiber is now established on a commercial basis, with a current average monthly production of about 170,000 pounds. This machine-cleaned abacá is an excellent binder-twine fiber, and it has been used to some extent for the manufacture of the medium grades of cordage. Undoubtedly improvements will continue to be made not only in the cleaning but also in the methods of drying and handling this product. With these improvements it should be possible to produce machine-cleaned abacá fiber that will be entirely satisfactory for cordage purposes and that can be produced much more cheaply than the hand-cleaned product.

During the 15-year period from 1915 to 1929 there was an increase of 377,393 bales in the annual production of abacá fiber in this one district of southern Mindanao. The total annual increase in production for all of the other Provinces of the islands combined was only 201,011 bales of fiber.

The Province of Davao, with exceptionally favorable climatic and soil conditions, with 5,000,000 acres of agricultural land of which only 325,000 acres are now under cultivation, and with a group of abacá planters who are improving each year the conditions under which this crop is produced, should be able to furnish in the future any supply of abacá that may be required to meet a normal increase in the world demand for this fiber.

Senior Technologist, Bureau of Plant Industry.

ABORTION-DISEASE Tests Give Information on the Presence of this Malady

Infectious abortion is probably the most troublesome and costly disease with which dairymen and cattle breeders have to deal. Since it may spread rapidly throughout a herd, accurate means for its early detection are highly desirable. One would suppose that the appearance of its principal symptom, an abortion, would be sufficient for this purpose, but that does not imply definitely that the disease is present; neither does its absence insure that the herd is unaffected.

All abortions are by no means caused by what is known as infectious abortion, also called Bang's disease in recognition of the scientist, Bang, who discovered the causative organism. Some abortions are due to other infections, some possibly to deficiencies in iodine or other substances, and others to causes not yet understood. Any abortion should, however, lead to suspicion and the aborting animal should be kept in isolation and all the products of the abortion and the discharges following it destroyed. Immediate steps should then be taken to determine whether the herd is infected with the abortion microorganism. To the trained eye the appearance of the afterbirth gives some indication of whether the abortion is due to Bang's disease, but this indication is not entirely dependable. Several abortions occurring in succession strongly indicate the presence of this disease, but even such evidence is not conclusive.

The Nature of Abortion Tests

How, then, can the stock owner determine whether the disease is or is not present? Nearly all are familiar with the tuberculin test, by which the injection of a minute amount of tuberculin detects tuberculosis even in its very beginning. Efforts have been made to find a like substance, the injection of a small quantity of which would detect animals infected with abortion disease, but up to the present time substances of this kind have not proved wholly reliable for this purpose.

However, another kind of a test, known as the agglutination test, has proved to be reasonably reliable and is extensively used. In this test nothing is injected into the animal, but instead results depend on the satisfactory for cordage purposes and that can be produced much more cheaply than the hand-cleaned product.

During the 15-year period from 1915 to 1929 there was an increase of 377,393 bales in the annual production of abacá fiber in this one district of southern Mindanao. The total annual increase in production for all of the other Provinces of the islands combined was only 201,011 bales of fiber.

ABORTION-DISEASE Tests Give Information on the Presence of this Malady

Infectious abortion is probably the most troublesome and costly disease with which dairymen and cattle breeders have to deal. Since it may spread rapidly throughout a herd, accurate means for its early detection are highly desirable. One would suppose that the appearance of its principal symptom, an abortion, would be sufficient for this purpose, but that does not imply definitely that the disease is present; neither does its absence insure that the herd is unaffected.

All abortions are by no means caused by what is known as infectious abortion, also called Bang's disease in recognition of the scientist, Bang, who discovered the causative organism. Some abortions are due to other infections, some possibly to deficiencies in iodine or other substances, and others to causes not yet understood. Any abortion should, however, lead to suspicion and the aborting animal should be kept in isolation and all the products of the abortion and the discharges following it destroyed. Immediate steps should then be taken to determine whether the herd is infected with the abortion microorganism. To the trained eye the appearance of the afterbirth gives some indication of whether the abortion is due to Bang's disease, but this indication is not entirely dependable. Several abortions occurring in succession strongly indicate the presence of this disease, but even such evidence is not conclusive.

The Nature of Abortion Tests

How, then, can the stock owner determine whether the disease is or is not present? Nearly all are familiar with the tuberculin test, by which the injection of a minute amount of tuberculin detects tuberculosis even in its very beginning. Efforts have been made to find a like substance, the injection of a small quantity of which would detect animals infected with abortion disease, but up to the present time substances of this kind have not proved wholly reliable for this purpose.

However, another kind of a test, known as the agglutination test, has proved to be reasonably reliable and is extensively used. In this test nothing is injected into the animal, but instead results depend on the use of a small quantity of blood taken from the animal. There is also another blood test called the complement fixation test, but it is somewhat complicated and, since it is no more reliable than the agglutination test, is rarely used, except in experimental work.

The agglutination test for infectious abortion depends on the power of the animal body when it is invaded by the *Bact. abortus*, the germ that causes infectious abortion, to produce a substance that will cause these bacteria to be agglutinated or clumped when suspended in a saline solution. This agglutinating substance is present in the blood of animals affected with this disease and remains there as long as the animal is infected and for a considerable time afterward.

It seems that, once the body cells have been called on to make the agglutinating substances, they continue to do so in many cases to some extent for months or even years after the infection has disappeared. The amount of the agglutinating substance in the blood, to some extent, indicates the activity of the infection. Thus if one part of blood serum of the animal being tested is added to 200 parts of test fluid and agglutinates all of the bacteria in it (causing them to settle and leave the fluid clear), it is said to react in a titer of 1 to 200. The test fluid consists of a suspension of *Bact. abortus* in water containing a small amount of salt. If one part of the blood serum agglutinates all the abortion germs in 400 parts of test fluid it is said to react in a 1 to 400 titer, and so on. Reactions of 1 to 25 and 1 to 50 are usually regarded as suspicious; that is, they may be given by animals so recently infected that the agglutinating substances are just beginning to develop in their blood, or by animals that have lost their infection but have not entirely ceased to react. Later tests are necessary to determine to which class they belong. If animals have been recently infected a later test, made in two or three weeks, will in all probability show that the titer has increased, while if the animals are of the other class the titer will have remained stationary or fallen. Animals that continue to react in low titers, 1 to 50 or less, are probably safe animals, though it is not certain that all of them are. It is advisable to have the blood of such animals tested at least every six months to detect any that may possibly have developed a reaction of increased titer.

Calves' Resistance is High

New-born calves from infected cows seldom react to the agglutination test until after they have partaken of their dams' colostrum. After they have done this they react for a time in about the same titer as their dams, but the reactions gradually disappear, even though they continue to nurse infected milk from their dams. Occasionally a calf is found that fails to lose its reaction, but this is the exception and indicates that the animal is infected. As a rule, calves seem to be highly resistant to the disease.

The agglutination test has certain shortcomings which have led some persons to question its reliability. Perhaps the most serious of these is the tardiness with which some animals begin to react after becoming infected. In most animals the reactions begin to appear in a few weeks after infection but in some this does not occur until after several months, and occasionally, in pregnant animals, not until after their periods of gestation have been terminated by an abortion or parturition. A few cases of infected animals have been reported as never reacting, but it is believed that such animals are rare.

The tardiness with which the reactions sometimes appear is a rather serious failing because some infected animals may become spreaders of large amounts of infection before they can be detected. Moreover, the test does not tell whether an animal will abort or not and, as before stated, does not always sharply distinguish between present and past infection.

While it has these limitations it gives much valuable information as to whether infectious abortion is present in the herd and the extent of the infection, and points out those animals that are or may become dangerous. It has the advantage that it can be repeated as often as desired and by proper interpretation will greatly aid in combating the disease. Already it is rendering good service in aiding cattle owners to free their herds from the disease and in keeping them free. The test is not always successful in doing this but it goes a long way in the desired direction. Further experience should lead to a better understanding of the test and an increase in its efficiency.

A Promising New Method of Testing

Recently a modified method of making the agglutination test for infectious abortion has come into use and promises to become popular. This is the rapid method brought out by Huddleson and Carlson, of the Michigan Agricultural College. This test appears to compare favorably with the older and slower method and has the advantage of requiring much less apparatus and time. Most laboratories still prefer the slow method but if the rapid one stands the test of time it should prove very useful.

ALFALFA Acreage Shifts Much Annually Despite the Crop's Popularity

Constant shifts in alfalfa supplies within the various States and from State to State are revealed by even a casual glance at statistics on this most valuable forage crop. Although alfalfa is an extremely popular feed with dairymen and cattle feeders everywhere, the acreage devoted to it varies considerably from year to year. The causes of this gypsy-like wandering about are many, chief among which are plant diseases and insect enemies as well as efforts of overenthusiastic farmers who have introduced the plant, or poorly acclimated strains of it, into sections having light annual rainfall, severely low temperatures in winter, or an acid condition of the soil. Another very important cause of this shift in acreage, particularly eastward, is due to a desire to bring production nearer to the consumer and to more profitable markets.

The early history of alfalfa in this country is so well known that it is not necessary to go into detail here. Suffice it to say that the early colonists attempted to grow it in Virginia, North Carolina, Pennsylvania, and New York before the Revolutionary War. George Washington tried it at Mount Vernon with a fair degree of success, but his experiments were cut short by his death in 1799. Thomas Jefferson seems to have been even more successful than Washington, but the lack of sufficiently well-drained limestone soil greatly handicapped

ALFALFA Acreage Shifts Much Annually Despite the Crop's Popularity

Constant shifts in alfalfa supplies within the various States and from State to State are revealed by even a casual glance at statistics on this most valuable forage crop. Although alfalfa is an extremely popular feed with dairymen and cattle feeders everywhere, the acreage devoted to it varies considerably from year to year. The causes of this gypsy-like wandering about are many, chief among which are plant diseases and insect enemies as well as efforts of overenthusiastic farmers who have introduced the plant, or poorly acclimated strains of it, into sections having light annual rainfall, severely low temperatures in winter, or an acid condition of the soil. Another very important cause of this shift in acreage, particularly eastward, is due to a desire to bring production nearer to the consumer and to more profitable markets.

The early history of alfalfa in this country is so well known that it is not necessary to go into detail here. Suffice it to say that the early colonists attempted to grow it in Virginia, North Carolina, Pennsylvania, and New York before the Revolutionary War. George Washington tried it at Mount Vernon with a fair degree of success, but his experiments were cut short by his death in 1799. Thomas Jefferson seems to have been even more successful than Washington, but the lack of sufficiently well-drained limestone soil greatly handicapped farmers of that time, and alfalfa, or lucern as it was then called, was considered of little importance until about 1854, when it was introduced into California from Chile. Since that time the development of strains more or less adapted to various sections of the country and the introduction of the winter-hardy Grimm alfalfa in the extreme northern parts has led to a rather general spread of this valuable crop into practically every State.

Thrived on West Coast

Conditions being naturally more favorable for alfalfa growing on the west coast, it thrived and soon became an important crop there. By 1870 it had spread eastward as far as Kansas. Conditions in the central western States seemed to be even more favorable than on the Pacific coast. As a result, Kansas, Nebraska, Colorado, and Okla-

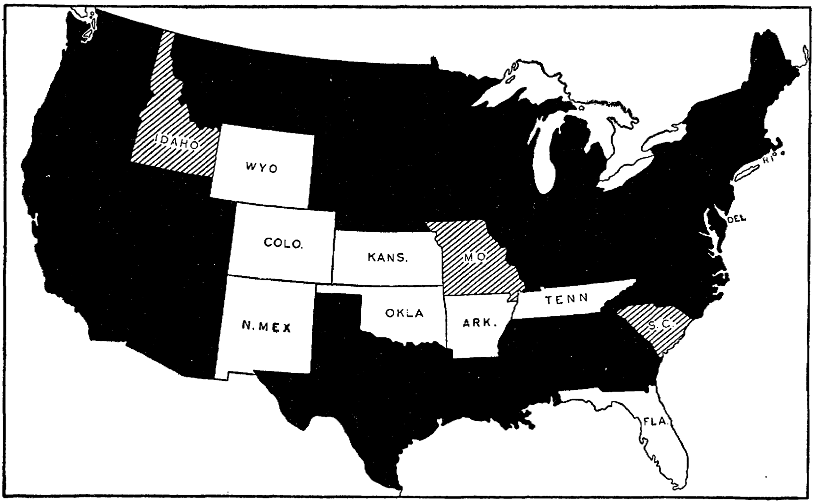

FIGURE 3.—Shifts in alfalfa production, 1920 to 1929. Heavily shaded portions indicate States having a 1929 acreage greater than that for 1920. Acreage continued about unchanged during this period in States shaded with lines. The acreage decreased rather steadily in the unshaded portions with the exception of the State of Florida where alfalfa production is negligible

homa soon became and still remain large alfalfa producing States and furnish the bulk of the market supplies. There has been considerable shifting of production within those States, however, as well as elsewhere in the United States, particularly within the past decade. Kansas had for many years the largest alfalfa acreage of any State in the Union, but about 1920 the lead was taken by Nebraska where the acreage is in turn declining at a rate that promises soon to let California take first place. Losses in these States, however, have been met by substantial increases in acreage in the Dakotas and Iowa, permitting a continuous gain in acreage for the central-western section as a whole until the present time, although this gain has been slower during the past few years. (Fig. 3.)

Alfalfa is again invading the Atlantic Seaboard States but this time with a greater degree of success, due to a better knowledge of the needs of the plant, improved methods of farming, and rather extensive educational campaigning on the part of the extension agents and others interested in more profitable farming practices. The acreage is still not great in most of these States, however, largely because of the lack of sufficient limestone soils and the difficulty of curing the hay in that area.

In the Southeastern States, with the exception of Florida where little if any alfalfa is grown, and South Carolina where the acreage has remained about constant for many years, there has been a gradual increase in acreage during the past decade. This increase has been due largely to greater interest in livestock production and better farming methods. Low cotton prices, particularly in 1920 and 1921, were also an important factor in inducing many cotton growers to increase their acreage of hay and forage crops as a matter of economy, although the acreage is still comparatively small in practically all these States. Production in Arkansas, Oklahoma, and Tennessee is now somewhat smaller than 10 years ago but it has made fair gains during the past five years.

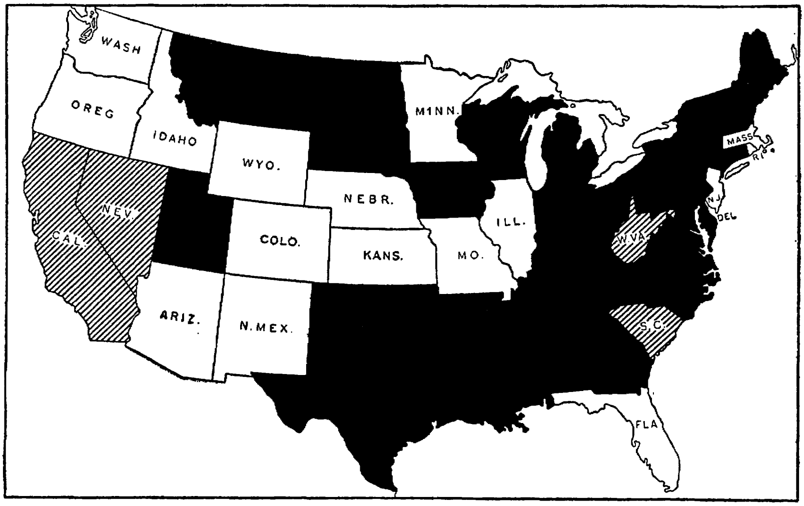

FIGURE 4.—Shifts in alfalfa production, 1925 to 1929. Heavily shaded portions indicate States having a 1929 acreage greater than that for 1925. Acreage was about unchanged during this period in States shaded with lines. Acreage decreased rather steadily in the unshaded portions with the exception of the State of Florida where alfalfa production is negligible

Adapted to Irrigation Farming

Although alfalfa is most highly adapted to irrigation farming in arid regions, Utah is the only State in the far-western section showing an increase in acreage to the present time. The acreage in California and Nevada was almost stationary during the past five years while the remainder of these States showed a decline.

Alfalfa acreage for the United States as a whole has increased constantly since the beginning of its migration eastward from California some 50 or 60 years ago but the gain in later years is not so great as formerly due to the recent more or less general falling off in production in the principal producing States. (Fig. 4.)

This constant shifting has been due quite largely to unique characteristics of the alfalfa plant itself. In the first place, the plant is a heavy and comparatively particular feeder with an unusually high water requirement. Under favorable conditions, it will send its roots down a considerable depth which often results in the using of such quantities of stored water in the drier sections that the plant can no longer survive. This alone has probably been the principal cause of the decreasing acreage in many nonirrigated sections of the West. Bacterial wilt and other diseases and insect pests have also been influential in reducing the acreage in several of the older and larger producing States. A third factor that has been important in some sections, is the introduction of seed of nonhardy strains or strains that were not capable of adjusting themselves to the soil and climate of the new location. A continuously good demand from eastern dairymen which has created and maintained comparatively high alfalfa prices at eastern markets has stimulated production in eastern sections. This, together with a desire on the part of many farmers to produce sufficient forage for their own use or to supply adequately local demand, has been responsible for a large part of the increased acreage east of the Mississippi River.

Bureau of Agricultural Economics.

APPLE Market Supply is Composed Largely of a Few Varieties Hundreds of varieties of apples are grown in the United States but relatively few are of commercial importance. A survey in 41 leading markets in a recent season of generally heavy apple production showed considerable differences in varietal composition and source of market supplies. In planning for production and marketing, apple growers may benefit by considering the special requirements of their markets.

Fifteen varieties composed 83 per cent of the market supplies, according to the survey. In order of importance these were: Winesap, Jonathan, Baldwin, Rome Beauty, Delicious, Yellow Newtown, Stayman Winesap, Rhode Island Greening, McIntosh, Esopus Spitzenburg, Ben Davis, York Imperial, Gravenstein, Yellow Transparent, and Grimes Golden. Winesap and Jonathan were of nearly equal importance and together made up slightly more than one-fourth of the supply. Five varieties—Winesap, Jonathan, Baldwin, Rome Beauty, and Delicious—represented almost one-half of the total.

When considered by geographical groups and even by individual markets, there are pronounced differences in the varietal composition of the supplies. In six eastern cities as a group the Baldwin was the leading variety, representing 13 per cent, followed by the Winesap with 12 per cent, and the McIntosh with 9 per cent. In the group of 11 mid-western cities the Jonathan was far in the lead, composing 22 per cent of the supply, and was followed by the Winesap with 12 per cent and the Baldwin and Delicious with 10 per cent each. In five far-western cities the Yellow Newtown comprised one-fourth of the apples on the markets. Jonathan, Yellow Bellflower, Rome Beauty, and Winesap were also prominent in the markets in the far West. Slightly more than one-fourth of the quantity of apples in 19 southern markets was of the Winesap variety. The Delicious and Stayman Winesap were also popular in the South. The South is generally considered a good market for Ben Davis but this variety constituted only 3 per cent of the apples in southern markets.

down a considerable depth which often results in the using of such quantities of stored water in the drier sections that the plant can no longer survive. This alone has probably been the principal cause of the decreasing acreage in many nonirrigated sections of the West. Slightly more than one-fourth of the quantity of apples in 19 southern markets was of the Winesap variety. The Delicious and Stayman Winesap were also popular in the South. The South is generally considered a good market for Ben Davis but this variety constituted only 3 per cent of the apples in southern markets.

Causes of Regional Preferences

Differences in the proportions of varieties of apples used in individual markets or in groups of markets in different areas may be due to such factors as proximity to areas where certain varieties are grown in large quantities or to customs and preferences of dealers and consumers. The relative demand for different varieties may change somewhat from year to year in response to changed conditions.

Market preferences, as indicated by the proportions of varieties in the supplies in different cities, are rather pronounced. New York City is our greatest market for the McIntosh variety in so far as actual quantity is concerned. In percentage of total supply for each city, however, Boston used about 16 per cent of McIntosh compared with 11 per cent in New York. In contrast, other important markets such as Philadelphia and Pittsburgh used so few McIntosh that they were not reported separately in the survey and probably were less than 1 per cent. This does not mean that there is no potential demand for the McIntosh variety in markets other than New York and New England cities but it indicates that introduction of the variety into other markets has not so far been necessary.

Philadelphia is the outstanding Stayman Winesap market. About 31 per cent of this city's apples were of this variety, compared with an average of 5 per cent for all cities included in the survey. The Rhode Island Greening, apparently, is not in demand on the Pittsburgh market. Only one-fifth of 1 per cent was of this variety in Pittsburgh compared with 9 per cent in New York and 6 per cent as an average for the group of six eastern cities. In Chicago and other mid-western cities the Jonathan is the market leader and in a number of cities in this region it comprised from 20 to 30 per cent of the receipts. This is in contrast with the East and South where only about 6 per cent was of the Jonathan variety.

As examples of peculiarities in individual city requirements in the South the cases of Spartanburg, S. C., and Savannah, Ga., are worthy of note. In the former city one-third of the apple receipts were Stayman Winesap with no York Imperial reported, whereas in the latter city, 22 per cent were York Imperial and only 11 per cent Stayman Winesap.

In all sections the trend seems to be toward the consumption of larger proportions of the so-called higher quality varieties. The demand for high quality as reflected in price is significant. In a recent season in New York, prices to jobbers for New York McIntosh averaged $9.14 per barrel and for Yellow Newtown $9.25 compared with $6.56 for York Imperial and $5.60 for Ben Davis. Delicious averaged $3.78 per box at auction compared with $2.87 for Winesap.

Apple Crop Widely Distributed

The wide distribution of the apple crop is illustrated by the fact that the carload supply of New York City during a recent full crop season was shipped an average distance of about 1,300 miles and more than half of this supply came from points over 2,000 miles distant. For Chicago, the average distance was more than 1,050 miles, with slightly over 50 per cent coming more than 1,500 miles. The average distance for Atlanta was more than 900 miles and 31 per cent was produced more than 2,000 miles away.

Western-grown apples are shipped to all parts of the country, whereas eastern apples are shipped as far west as cities in the Mississippi Valley. A comparison of the characteristics of northwestern apple supplies with those from the East and Middle West shows that many of the northwestern varieties, such as Winesap, Jonathan, Stayman Winesap, Rome Beauty, Yellow Newtown, and Delicious, are also grown extensively in the East and Middle West. The principal difference is that the northwestern apples are packed in boxes and are more closely graded and sized than are most apples from the East and Middle West, which are usually packed in barrels and bushel baskets.

Continued progress in the development and production of better varieties, changing consumer demands, and improvements in marketing methods, including better transportation and storage facilities, are causing gradual changes in the composition of the commercial apple supply.

APPLE-TREE Plantings Since 1920 Show Trend Toward Newer Varieties In a recent survey of apple orchards 243 varieties were reported by the commercial growers of Michigan and 241 by New York producers, whereas less than 75 varieties were reported by Washington growers. Although orchards throughout the United States contain hundreds of varieties, it is estimated that five varieties make up approximately 37 per cent of the total number of trees in commercial orchards and that the first 15 varieties include 71 per cent of the trees. Twenty-five varieties are listed in Figure 5 according to their importance in commercial orchards of the United States. They are shown by numbers of trees on January 1, 1928. The periods when they were set indicate the age of the trees and in a general way reflect changes in varieties planted from one period to the next in response to consumer preference.

Fifty-six per cent of the Delicious trees in commercial orchards were set in the period 1920–1927 while less than 7 per cent of the Ben Davis trees were planted during this period. Other varieties in which large proportions of the trees now standing were planted during this period are the Stayman Winesap, 38.5 per cent; McIntosh, 48.3 per cent; Yellow Transparent, 52.4 per cent; and the Golden Delicious, 94.4 per cent. Still other varieties of which more moderate percentages of the trees were planted from 1920–1927 are: Winesap, Jonathan, Rome Beauty, Grimes Golden, Wealthy, Rhode Island Greening, and Northern Spy. (Fig. 5.)

Only a relatively small percentage of the trees of such varieties as Baldwin, Ben Davis, York Imperial, Yellow Newtown (Albemarle Pippin), Gano, Arkansas (Mammoth Black Twig), Esopus Spitzenburg, and Stark were planted during the period 1920–1927. From 85 to 90 per cent of the trees of most of these varieties were planted before 1920, and for individual varieties the percentage of trees planted before 1910 varies from 35 to 77 per cent.

Trees of the four varieties—Delicious, Winesap, Jonathan, and Stayman Winesap—number about 25,000,000, or 31 per cent of the

Still other varieties of which more moderate percentages of the trees were planted from 1920–1927 are: Winesap, Jonathan, Rome Beauty, Grimes Golden, Wealthy, Rhode Island Greening, and Northern Spy. (Fig. 5.)

Only a relatively small percentage of the trees of such varieties as Baldwin, Ben Davis, York Imperial, Yellow Newtown (Albemarle Pippin), Gano, Arkansas (Mammoth Black Twig), Esopus Spitzenburg, and Stark were planted during the period 1920–1927. From 85 to 90 per cent of the trees of most of these varieties were planted before 1920, and for individual varieties the percentage of trees planted before 1910 varies from 35 to 77 per cent.

Trees of the four varieties—Delicious, Winesap, Jonathan, and Stayman Winesap—number about 25,000,000, or 31 per cent of the total number of apple trees in commercial orchards. These varieties are widely grown and occur in most of the important commercial apple-producing areas of the country.

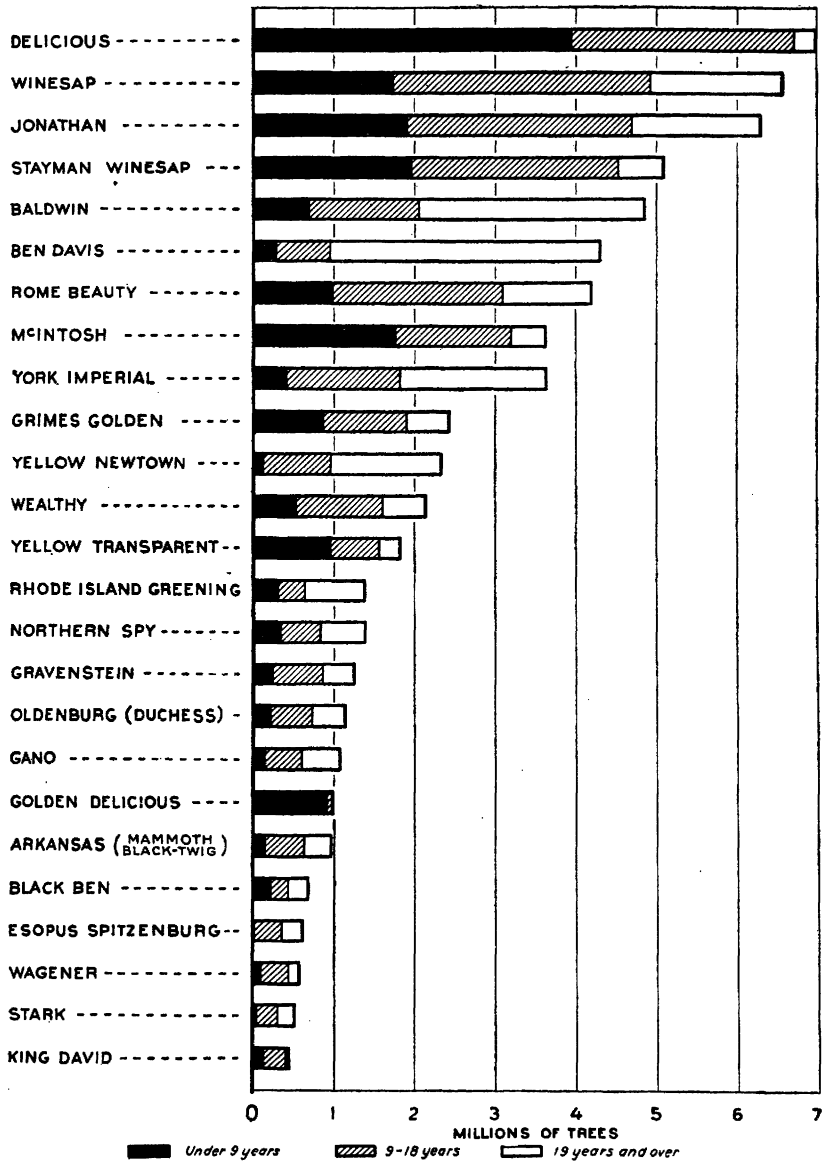

FIGURE 5.—Of 80,000,000 trees in commercial orchards, Delicious, Winesap, Jonathan, Stayman Winesap, Baldwin, and Ben Davis make up 42.6 per cent of all trees; 28.7 per cent of all trees were set during the period 1920–1927 and 38.7 per cent were set in the years 1910–1919. (Preliminary estimates. See also statistical section of this yearbook)

The Baldwin, Rhode Island Greening, and Northern Spy are confined largely to the Northeastern States. There are about 7,700,000 trees of these varieties in commercial orchards. These trees represent about 10 per cent of the total trees in the commercial orchards.

The Ben Davis, a widely distributed variety, has been only lightly planted during recent years.

The Rome Beauty has been planted commercially in certain localities throughout the country extending from coast to coast.

The McIntosh, like the Delicious, has been heavily planted during late years. The trees of this variety probably constitute 4½ per cent of all trees in commercial orchards and nearly 50 per cent of them have been planted since 1919. The McIntosh is grown extensively in New York and in the New England States and to a lesser extent in Michigan, the Cumberland-Shenandoah area, and Montana.

The Grimes Golden probably makes up 3 per cent of all apple trees in commercial orchards. Its popularity is evident in localities throughout much of the country extending from New Jersey to the Pacific coast.

Of the early varieties the Yellow Transparent and Gravenstein are most important. The Yellow Transparent has been planted rather freely during recent years in New Jersey, Maryland, Delaware, Tennessee, and Illinois. The Gravenstein is grown primarily in California and to a lesser extent in the New England States.

Varieties in Recent Plantings

Another indication of the widespread importance of some of the newer and more popular varieties is found in the fact that over 17 per cent of all trees now in commercial orchards that were planted during the period 1920–1927 were of the Delicious variety. Trees of Delicious, Jonathan, Stayman Winesap, Winesap, and McIntosh make up nearly 50 per cent of the trees now standing in commercial orchards that were planted during the years 1920–1927.

Space does not permit detail concerning the hundreds of varieties reported in the tree survey. Suffice it to say that many of the little known and none too popular varieties are giving way to the newer and more popular varieties in response to consumer demand.

Many varieties that are rather important in a given community are not listed in Figure 5 because of their unimportance from a national standpoint. For example, 95 per cent of the Cortland apple trees, a new variety as yet significant only in New York, where it ranks seventh, were planted during the years 1920–1927. Two other varieties that were planted commercially for the first time during the last 10 years and that promise to become commercially important are the Starking and the Richared (bud sports of the Delicious).

Many of the trees now in commercial orchards were planted 20 to 25 years ago. As a result of overexpansion of the industry at that time many orchards have been forced out of production and others have been neglected. In spite of this condition some of the more popular varieties have returned relatively favorable prices and during the period 1920–1925 a fairly heavy planting of these more popular varieties occurred. This accounts for the large numbers of young trees of varieties like the Delicious, McIntosh, Stayman Winesap, and Yellow Transparent. Trees of some of these varieties have been planted in new localities but are so young that it is not known to what extent they will succeed in their new environment. It is felt that if they thrive and bear well in all sections in which they have been planted, the relatively favorable price position of some of these varieties that has obtained for several years may not continue. It is probable that some of the less popular varieties will continue to give way and as production of these decrease there will be more room for any increase in production of the more popular varieties.

Corner Seems Turned

Taken all in all the apple industry has turned the corner and probably is in a better position now than for many years since the gross overplanting which occurred during the period 1905–1912. There is no indication that commercial production will decline, but rather that it will gradually work higher as the years go by but at a more moderate and uniform rate than the rate of increase that accompanied the expansion of the apple industry of 20 to 25 years ago.

AUSTRIAN Winter Pea Has Superior Value as a Green Manure

Of the many problems that perplex the farmer none is as ever present as that of maintaining soil fertility. The growing and removal of crops from the land depletes the available plant food, and this must be replaced by the breaking down of the soil particles already there or by additions of plant food from other sources. Furthermore it is not only desirable to maintain an average soil fertility, but everything possible should be done to assure the continuous production of maximum crops. Many plants, especially legumes, have been used for their benefit on succeeding crops, and the practice of using such crops in rotation as standard cash crops and also for green manure is not new. The search for new or superior crops for specific purposes, however, has attracted the attention of many experimental workers. In recent years, more particularly, efforts have been made to procure legumes that would make superior growth during the winter months, when growing conditions are unfavorable for most plants, and that would give superior benefits from their use in a crop rotation.

The Austrian winter pea has recently come into prominence in this rôle, and its favorable performance has resulted in its use being rapidly extended. As a winter green-manure crop in the Cotton Belt it has proved well adapted, and in the comparatively few years in which it has been used the area planted has increased to approximately 75,000 acres.

In experimental trials in Georgia, Florida, Alabama, and other States, greatly increased yields of cotton and corn have followed the use of this crop. Its value has been recognized by the pecan and citrus growers, although in the more southern area other winter legume crops have proved of apparent equal value. When planted in the early fall it will make a good growth for turning under, preceding the active growth of the trees in the late winter or early spring, and will supply readily available plant food to the growing trees. The maintenance of orchards in good condition is dependent largely on the supplying of organic matter to the soil, and where a green-manure crop can be grown during the more nearly dormant period of the tree and without interfering with cultural operations, it is one of the cheapest and most effective methods of supplying organic matter.

some of the less popular varieties will continue to give way and as production of these decrease there will be more room for any increase in production of the more popular varieties.

AUSTRIAN Winter Pea Has Superior Value as a Green Manure

Of the many problems that perplex the farmer none is as ever present as that of maintaining soil fertility. The growing and removal of crops from the land depletes the available plant food, and this must be replaced by the breaking down of the soil particles already there or by additions of plant food from other sources. Furthermore it is not only desirable to maintain an average soil fertility, but everything possible should be done to assure the continuous production of maximum crops. Many plants, especially legumes, have been used for their benefit on succeeding crops, and the practice of using such crops in rotation as standard cash crops and also for green manure is not new. The search for new or superior crops for specific purposes, however, has attracted the attention of many experimental workers. In recent years, more particularly, efforts have been made to procure legumes that would make superior growth during the winter months, when growing conditions are unfavorable for most plants, and that would give superior benefits from their use in a crop rotation.

The Austrian winter pea has recently come into prominence in this rôle, and its favorable performance has resulted in its use being rapidly extended. As a winter green-manure crop in the Cotton Belt it has proved well adapted, and in the comparatively few years in which it has been used the area planted has increased to approximately 75,000 acres.

In experimental trials in Georgia, Florida, Alabama, and other States, greatly increased yields of cotton and corn have followed the use of this crop. Its value has been recognized by the pecan and citrus growers, although in the more southern area other winter legume crops have proved of apparent equal value. When planted in the early fall it will make a good growth for turning under, preceding the active growth of the trees in the late winter or early spring, and will supply readily available plant food to the growing trees. The maintenance of orchards in good condition is dependent largely on the supplying of organic matter to the soil, and where a green-manure crop can be grown during the more nearly dormant period of the tree and without interfering with cultural operations, it is one of the cheapest and most effective methods of supplying organic matter.

Withstands Extreme Changes of Temperature

The superior value of the Austrian winter pea lies largely in its ability to stand the extreme cold of winter and yet in the warmer spells to make enough growth to turn down in early spring preceding the planting of cotton and corn. The minimum temperature at which it will make growth is lower than that for hairy vetch or other legumes commonly used for green manure, and this fact, together with the fact that it is especially winter hardy, makes it of special worth. That the seeds germinate quickly, and good stands are usually secured, should also be noted. Furthermore, the root system is extensive, and the plant is succulent and decays quickly, thus making a large amount of plant food readily available.

Aside from these advantages there seem to be beneficial results following the use of Austrian winter peas as green manure which can not be explained in terms of measurable plant-food fertilizer. The benefit on succeeding crops, however, can be noted for several years, and after the fertilizing elements and organic matter seem to have disappeared.

To insure success with the Austrian winter pea several points should be specially noted. Seeding should be done in the Cotton Belt during the last of September or early October. Earlier plantings are likely to be damaged more or less by nematodes, and later plantings may give poor stands and light growth.

When planting on a field for the first time Austrian winter peas should always be inoculated with bacterial cultures to induce root nodulation and should be inoculated in subsequent years until it is known that the nodulation will be secured.

One of the most important things, both with reference to inoculation and good winter growth of the Austrian winter pea crop, is the use of commercial fertilizer or barnyard manure.

Superphosphate is Most Needed Fertilizer

Superphosphate is the most essential fertilizer compound for this crop, and where the preceding corn or cotton or other crop has not been well fertilized 400 pounds of superphosphate per acre should be used. Austrian winter peas may need little or no fertilizer when the preceding cotton or corn has been heavily fertilized. In planting Austrian winter peas for the first time, however, it is well to use at least 300 pounds of superphosphate and 50 pounds of nitrate of soda per acre, even though the preceding crop may have been heavily fertilized. Barnyard manure should be used whenever available, as it is especially valuable in insuring inoculation and greatly increases yields.

The quantity of seed needed per acre varies with latitude and soil conditions, but in general 30 pounds is recommended for the southern part of the Cotton Belt and 40 pounds for the northern part. Seeding is usually done broadcast, but the use of a drill when available is advised.

If the peas are seeded with Abruzzi rye, as is sometimes practiced on sandy lands, the full amount of pea seed should be used and about half the amount of rye that is commonly used in seeding rye alone. The use of rye in this combination is a good practice in building up poor sandy lands, since the rye is especially well suited to such conditions and will contribute more organic matter than any other winter crop. (Fig. 6.)

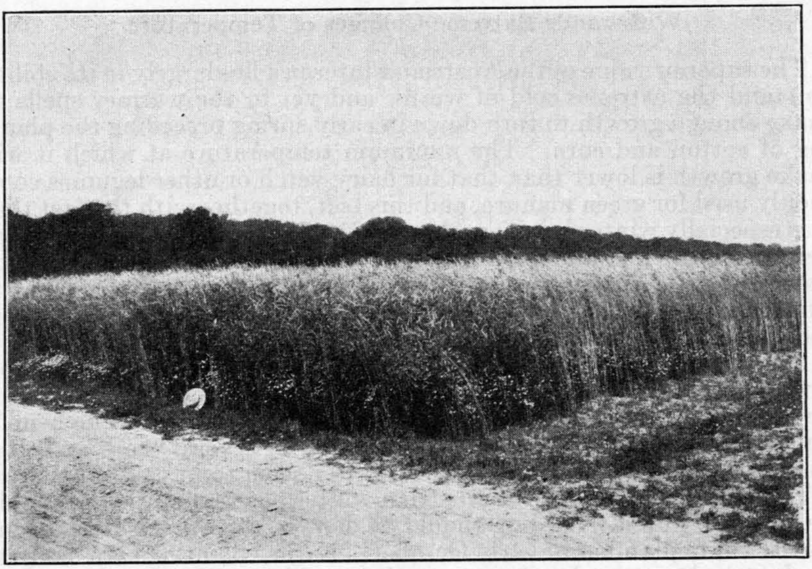

FIGURE 6.—Austrian winter peas and rye growing together. This is a good mixture for sandy lands

When Austrian winter peas as a green manure crop precede corn or cotton the peas should be plowed down two weeks before the corn and three weeks before the cotton is planted. If less time elapses the seedlings may sometimes be damaged.

Senior Agronomist, Bureau of Plant Industry.

AZALEAS Introduced From Japan are Suited to Wide Area in U. S.

At the present time there are two distinct groups of azaleas that Japan has contributed for the use of gardeners in this country, the one characterized by deciduous foliage and a general habit of growth more or less resembling that of our native species, and the other with evergreen foliage, except in the extreme northern limits of their range, and flowers more like those of the tender Indian azaleas so largely grown for the florists' trade.

The first group is the less common at the present time and is marked chiefly by the Japanese azalea (*Rhododendron japonicum* Suring.). (Fig. 7, A.) This is more vigorous and hardier than the Chinese azalea (*R. molle* G. Don), which also is found in gardens and is the species most commonly found in cultivation together with numerous hybrids derived from the two species and from the crossing of these species and American natives.

For the ordinary garden the use of the Japanese azalea can be recommended wherever there is an acid soil suitable for such plants as far north as Boston near the coast and as far north as the central portion of the Corn Belt farther inland. From these points the plants are hardy but often suffer from the winterkilling of the flower buds.

The flowers are large and range in color from fairly light yellows to deep orange reds and are produced in large terminal heads appearing before the leaves have made any conspicuous growth.

The first group is the less common at the present time and is marked chiefly by the Japanese azalea (*Rhododendron japonicum* Suring.). (Fig. 7, A.) This is more vigorous and hardier than the Chinese azalea (*R. molle* G. Don), which also is found in gardens and is the species most commonly found in cultivation together with numerous hybrids derived from the two species and from the crossing of these species and American natives.

For the ordinary garden the use of the Japanese azalea can be recommended wherever there is an acid soil suitable for such plants as far north as Boston near the coast and as far north as the central portion of the Corn Belt farther inland. From these points the plants are hardy but often suffer from the winterkilling of the flower buds.

The flowers are large and range in color from fairly light yellows to deep orange reds and are produced in large terminal heads appearing before the leaves have made any conspicuous growth.

Interest in the preceding group, however, has been much overshadowed in the last few years by the increase in cultivation of the various evergreen and semievergreen variations from the more southern portions of the Japanese islands.

Particular attention has been given to the so-called Kurume azaleas (fig. 7, C), which represent a strain rather than a species. The original wild plant of *Rhododendron obtusum* Planch., has been known for many years and was described in 1854, but apparently has not made any particular appeal to gardeners as its flowers are small and the colors are not particularly pleasing. There seems to have been considerable difference of opinion and experience as to the hardiness of the plant so that it is only within the last decade that it has been determined that this plant and its horticultural forms are hardy over a considerable area. Special attention has come to this group, once familiar only by the varieties Amœna, Hinodegiri, Benigiri, and Yayegiri, by the introduction of the Kurume azaleas mentioned before. This group represents largely the work of two Japanese amateurs who raised these plants from seed and selected the best color forms for propagation by cuttings. As a result of this raising of plants from seed and selection over a long period of years, one now may have any color from pure white (fig. 7, D), through rose pink to deep crimson to magenta, and through rather yellowish and flesh-colored pinks to scarlets. The Japanese have developed, in addition, varieties with flowers having a light ground, usually white, splashed with irregular stripes of darker colors. There are also forms in which the upper lobes of the corolla are more or less heavily blotched with varying shades of red, and others in which the calyx has been transformed into petallike tissue giving a hose-in-hose effect.

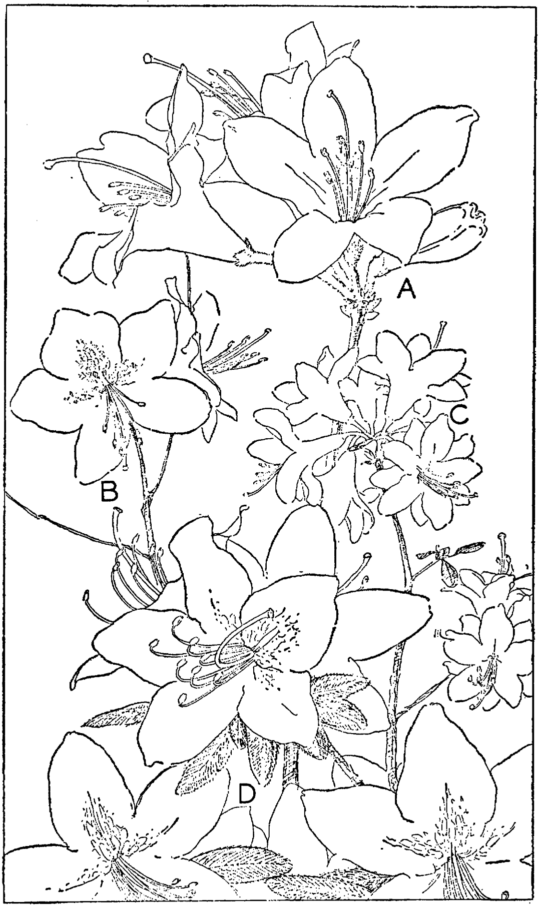

FIGURE 7.—Japanese garden azaleas: A, *Rhododendron japonicum;* B, *R. obtusum kaempferi;* C, *R. obtusum japonicum;* D, *R. mucronatum*

Whole Group Easy to Cultivate

As the exact parentage of the last is not absolutely certain, one is not surprised to find differences in habit and growth range, from a low prostrate form with small leaves to a tall, rather straggly growth suggesting Kaempfer azalea (fig. 7, B) that is believed by some botanists to be a distinct species and by others to be the northern representative of *Rhododendron obtusum*. The whole group is of the easiest culture, succeeding in soils of nominal acidity, producing great masses of rather small-sized flowers in such quantity as to hide the leaves in the spring. The one essential in their cultivation seems to be that the plants must be thoroughly matured before the beginning of cold weather and that new plantings should be made of 2-year-old plants rather than rooted cuttings. The reason for this in each case is that young growth produced late in the summer is almost never sufficiently ripened before freezing weather to survive the winter.

Kaempfer Azalea for Northern States

Kaempfer azalea, already mentioned, is the azalea that should be used in the more northern States. Its general appearance is much like that of Kurume azaleas except that the plant is very robust, making in time tall bushes up to 7 feet with as much spread. The flowers are larger than many of the Kurume varieties, but their color range is limited through various shades of rather salmon-tinted pinks and light reds.

Two other groups of evergreen and semievergreen azaleas from Japan have played a more important rôle in times past than at present. These are the large white-flowered azalea of the Orient, *Rhododendron mucronatum* G. Don, and the red-flowered *R. indicum* Sweet.

From the first of this pair we have numerous forms aside from the large-flowered white type. This albino was known many years before the discovery of the lavender-colored type of the species. Other forms have long been cultivated in Japan in which the corolla is variously tinted and blotched with rose and pale pink, in which the stamens have been transformed into petals, giving a semidouble bloom, and in which the corolla has also been split into separate linear petals, giving a curious tattered effect.

The second of this pair is not to be confused with the so-called Indian azalea of common cultivation, which is a tender plant. It is characterized by a very compact, twiggy growth, often of a widely spreading nature, with shining evergreen leaves and large flowers with salmon or light red color, produced usually in June after all the other oriental azaleas are passed.

Both these species at one time were used somewhat in the development of the hybrid strain of azalea commonly known as the Indian azalea, but as both of them give their seedlings certain characteristics, that were held to be undesirable by the florists of the time, their use was abandoned, and the present seedling of Indian azaleas represents in all probability only selections and interbreedings from *Rhododendron simsi* Planch., which is not a Japanese species in the strict sense of the word.

B. Y. Morrison,
Senior Horticulturist, Bureau of Plant Industry.

BEEF of Good Finish Is Produced by Mature Cattle on Grass Alone "Grassy" is a term which the wholesale beef trade has long used to describe a rather medium grade of beef that usually floods the market in summer and fall. The meat comes from all kinds of cattle, is usually underfinished, lacks bloom, and is often somewhat too soft and thin to store well. Since much of this beef comes from grass-fed cattle, it is natural that the trade should attribute the undesirable characteristics mentioned to the ration used.

Stockmen have long wondered, however, whether the lack of quality observed in this meat is the result of the grass itself or to its general lack of finish and the miscellaneous nature of the droves of pasture cattle that produce this meat.

In cooperation with the West Virginia Agricultural Experiment Station, the department recently completed a 3-year test to compare the composition and palatability of the beef from 3-year-old steers fed on luxuriant bluegrass pasture for 125 days with that from similar steers fed on similar pasture with a daily supplement of 7½ pounds of corn and cottonseed meal.

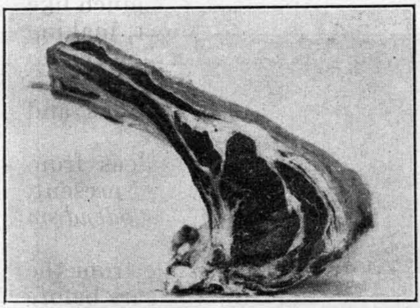

FIGURE 8.—Rib from 3½-year-old steer fattened on grass alone

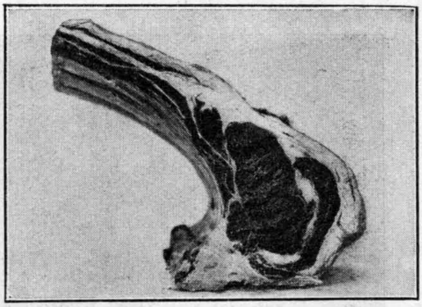

FIGURE 9.—Rib from 3½-year-old steer fattened on grass and a daily supplement of 7½ pounds of grain

Comparison of Palatability

Rib roasts from the two lots were cooked by the Bureau of Home Economics and compared for tenderness, flavor, and other characteristics by a committee representing that bureau and the Bureaus of Animal Industry and Agricultural Economics. Although the meat from the cattle that had received a supplement of grain was slightly more tender than that from cattle on pasture alone, the difference was small and the committee reported no distinct contrast in either flavor or juiciness. The ribs of cattle fed on pasture and grain supplement had an average fat content of 38.5 per cent and those from the pasture lots, 30 per cent. (Figs. 8 and 9.)

Neither grass alone nor grass with a supplemental feeding of 7½ pounds of grain daily is a highly concentrated ration, yet the carcasses of cattle fed on them had very satisfactory fat coverings. Even those fed on grass alone, which as noted had 30 per cent of fat in their rib cuts, were sufficiently fat to please the average consumer.

It should be remembered that these cattle were mature and that the pasture was good. The results were reasonably well-finished carcasses that compared favorably with carcasses from similar cattle that had received the grain supplement.

The question naturally arises whether younger cattle would be as well finished under the same conditions as were the mature steers. New trials, begun by both the West Virginia and Virginia experiment stations in cooperation with the department, have been designed to answer that question.

K. F. WARNER,
Animal Husbandman, Bureau of Animal Industry.

BEEF Cattle Tests Show Profits are Increased by Feeding Grain With Grass Feeding grains to fattening cattle on grass is a method of beef production to be recommended, particularly on farms having considerable land in pasture and a limited acreage in grain. Many farms in beef-producing areas have these conditions.

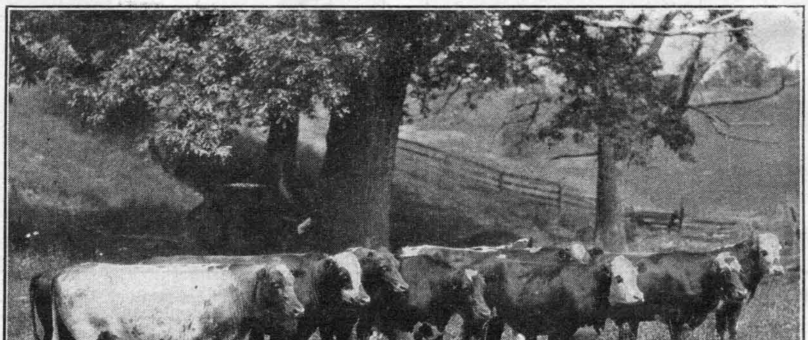

FIGURE 10.—Steers that were fed a grain supplement for 60 days, while on grass

Recent experiments conducted in the Appalachian region show rather conclusively that a 2-year-old or 3-year-old steer fed a ration of approximately 6 pounds of coarsely ground shelled corn and 1½ pounds of cottonseed meal in addition to good bluegrass pasture can be expected to gain 100 pounds more in four and a half months than a similar steer fed on grass alone.

The question naturally arises, Does this increased gain pay for the grain supplement? Under ordinary conditions it does. If market conditions are at all favorable, cattle that receive the supplemental feed (fig. 10) generally bring a greater net return than cattle fattened entirely on grass. In a 3-year experiment conducted cooperatively by the Bureau of Animal Industry and the West Virginia Agricultural Experiment Station, steers fed 13 bushels of corn and 200 pounds of cotton-

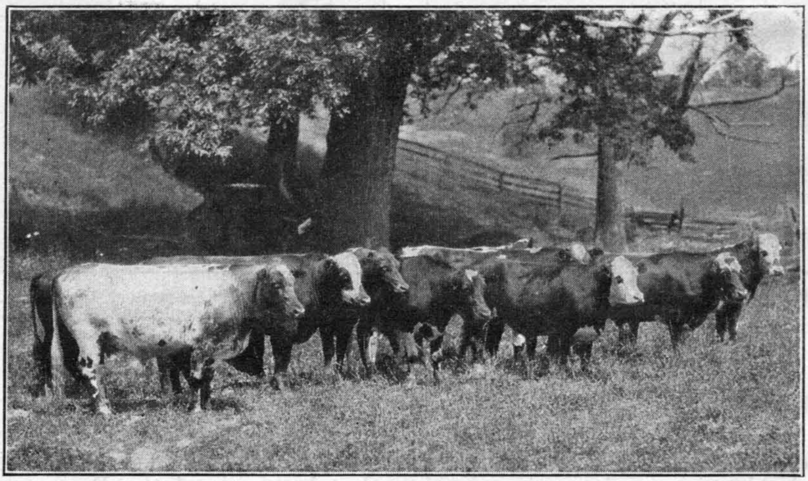

FIGURE 10.—Steers that were fed a grain supplement for 60 days, while on grass

Recent experiments conducted in the Appalachian region show rather conclusively that a 2-year-old or 3-year-old steer fed a ration of approximately 6 pounds of coarsely ground shelled corn and 1½ pounds of cottonseed meal in addition to good bluegrass pasture can be expected to gain 100 pounds more in four and a half months than a similar steer fed on grass alone.

The question naturally arises, Does this increased gain pay for the grain supplement? Under ordinary conditions it does. If market conditions are at all favorable, cattle that receive the supplemental feed (fig. 10) generally bring a greater net return than cattle fattened entirely on grass. In a 3-year experiment conducted cooperatively by the Bureau of Animal Industry and the West Virginia Agricultural Experiment Station, steers fed 13 bushels of corn and 200 pounds of cottonseed meal per head during a period of 125 days, returned $9.50 more profit per steer, after paying their feed cost of $17, than similar steers receiving grass alone. The steers fed the grain supplement made greater gains and showed more finish, both on the hoof and in the carcass. Their selling price was $1.25 per hundredweight more than that of the cattle fed grass alone, a fact which also indicated a higher degree of finish. The cattle fed grain with grass dressed 2 per cent higher than those fed grass alone. Although the carcasses of the steers fed grass alone showed considerable finish, experienced beef men could readily have selected the carcasses of the steers fed grain and grass by the deeper covering of fat over the carcass generally. Figure 11 shows a rib taken from a steer fed grass and grain; Figure 12 shows one taken from a steer fed grass alone. The two animals were very similar at the beginning of the grazing season.

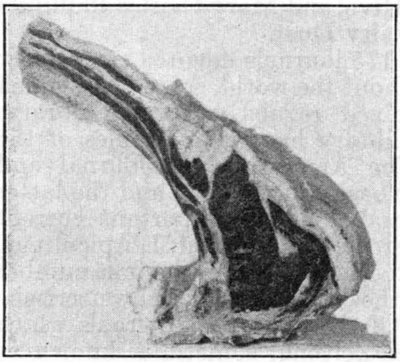

FIGURE 11.—Rib from a steer fed grass and grain

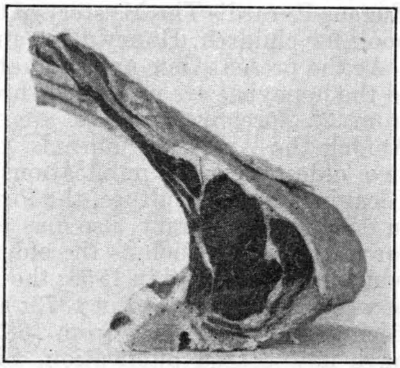

FIGURE 12.—Rib from a steer which received grass only

In more intensified farm areas, such as the Corn Belt, feeding a grain supplement to beef cattle on grass may be practical and fairly profitable, as shown by a 3-year experiment conducted cooperatively by the Bureau of Animal Industry and the University of Missouri on the Sni-a-Bar farms, Grain Valley, Mo. In this experiment beef calves on pasture with their dams were fed, previous to weaning, a grain mixture consisting of corn, oats, and linseed meal. After receiving an average daily ration, per head, of 4½ pounds of this mixture for 161 days, they gained, on the average, 373 pounds as compared with 269 pounds for calves receiving only pasture and their dams' milk. The average slaughter-appraisal value of the calves fed the grain mixture was $1.75 per hundredweight greater than that of calves not fed grain.

Feeding a grain supplement with grass pasture, whether to a fattening 2-year-old steer or to a nursing calf, tends to produce a heavier and more highly finished carcass in less time. Feeding grain to spring calves before weaning increases their weight and finish sufficiently to permit their sale as fat young beeves in the fall when they are about 8 months old. It is not possible to produce a desirable beef carcass at this age on grass and milk alone.

W. H. Black,

Senior Animal Husbandman, Bureau of Animal Industry.

BEEKEEPING Library in the Department Has About 2,000 Volumes At the headquarters of the Division of Bee Culture, Somerset, Md., is housed the beekeeping library and bibliography of the United States Department of Agriculture. The library consists of approximately 2,000 volumes, in addition to many pamphlets, devoted exclusively to the various phases of apiculture. It is unique in that it deals with but one insect—the honeybee. The library can not boast of any incunabula; however, it does possess some very old books, among which may be mentioned The Ordering of Bees (1634) by John Levett, Vande Byen (1648) by Dirck Outgertz Cluyt, A Theatre of Politicall Flying-Insects (1657) by Samuel Purchas, and A Further Discovery of Bees (1679) by Moses Rusden. Although the library contains principally works of scientific importance, it also has some of the recent classical books on bees, such as Maeterlinck's The Life of the Bee, Eugene Evrard's The Mystery of the Hive, and Mary Geisler Phillips's book for children, Honey Bees and Fairy Dust.

At the present time approximately 175 journals devoted exclusively to the honeybee are published throughout the world, some 80 of which from 22 foreign countries are received regularly by the library. Among the American journals, the library has complete files of the two oldest current publications, The American Bee Journal and Gleanings in Bee Culture, the former beginning in 1861 and the latter in 1873. The library also has a number of the important current foreign journals, such as the oldest French bee journal, L'Apiculteur, which first appeared in 1856; the British Bee Journal, the first number of which was published in 1873; and the Swiss journal, Schweizerische Bienen-Zeitung, dating from 1882. Of the important journals which have now ceased publication, Bienen-Zeitung, sometimes known as the Eichstädt Bienen-Zeitung, an outstanding German journal, might be mentioned, of which the library has an almost complete file.

An extensive bibliography consisting of approximately 75,000 references is maintained at the library of the bee culture laboratory. This is probably the largest and most complete bibliography on the subject of bees and honey. Since the standard systems of classification do not treat the subject of apiculture in sufficient detail adequately to serve a research staff, it became necessary some years ago for the staff of the laboratory to devise a system of classification of its own, which is now being used.

Catalogue of Beekeeping Literature

A catalogue of the beekeeping literature in the library of the Department of Agriculture and the Library of Congress has been issued as Bibliographical Contribution No. 21 of the Library of the United States Department of Agriculture. This catalogue lists all books, periodicals, pamphlets, etc., pertaining to apiculture. It also lists all of the beekeeping periodicals, together with the number of volumes of each now in the department library. The preparation of the catalogue was supervised by the library of the Department of Agriculture, with the assistance of the librarians of the Bureau of Entomology and the Division of Bee Culture. The catalogue will be distributed to the principal agricultural libraries and institutions engaged in apicultural research. This is the first comprehensive list of beekeeping literature published in this country, and it is hoped that it will serve as a guide for other institutions that are establishing separate beekeeping libraries, of which there are a number already in existence. Efforts are being made to procure the lacking volumes of journals and to obtain as many of the important books as possible, and it is hoped that the catalogue will be of material assistance in unearthing many volumes not now in the possession of the library.

ETHEL L. COON,
Library Assistant, Bureau of Entomology.

BEE-SHIPPING Industry Grows and New Ways of Packaging Are Devised Package bees in 2 or 3 pound combless packages are shipped into the Northern States and Canada from the Southern States for three principal reasons: (1) To replace winter losses; (2) to aid in strengthening weak colonies; and (3) to establish new apiaries at a minimum of expense.

The practice of shipping bees in small screened cages is not new, having first been successfully accomplished in the early eighties, but the real growth and extension of the industry have taken place within the last 15 years. It is estimated that between 250,000 and 300,000 pounds of bees were shipped from the South during 1929. Losses in shipment, which 15 years ago were so great as almost to prohibit shipping, have been materially reduced by careful methods of handling of the bees before and during shipment and by the use of improved cages and feeding methods. The progress which has been made in the shipping industry has been due largely to individual efforts of beekeepers and has resulted in a large variety of form and design in cage structure; it has also developed a practically uniform method of handling the bees, except as this method is varied in some details to suit certain localities.

The active shipping season for bees in the South begins about March 15 and is practically over by May 15. This is the busy season for the shipper because a large part of his success depends on his filling orders at the time specified by the northern beekeeper. At this time the colonies of bees are strong and are literally overflowing the hives with young bees. The shipper is careful to send as many young bees as possible, since they will give the best satisfaction in the honey-producing sections of the North. The bees are shaken from the comb directly into a large tin funnel and through this into the screen cage. (Fig. 13.) The queen bee in her small cage is next placed in the package suspended from a wire at the top, and the feed can, containing approximately 1 pound of feed for every pound of bees, is also placed into the package and the cover nailed on. The food used in the shipment is ordinarily composed of 1 part by weight of granulated sugar dissolved in 1 part by weight of water. In large shipments these individual cages are crated together with plaster laths or crating strips so that each cage is placed about 4 inches from its neighbor, with five or six cages in each crate.

With a large number of persons shipping packages each year, and with practically all the shippers manufacturing their own cages, it was to be expected that a large number of different types and sizes of cages would be found. The standardization of these shipping packages has been undertaken by the Southern States Bee Culture Field Station at Baton Rouge, La. Through the active cooperation of southern package shippers, as well as many beekeepers in the Northern States and Canada, standards will be submitted to the shippers for adoption.

ries, of which there are a number already in existence. Efforts are being made to procure the lacking volumes of journals and to obtain as many of the important books as possible, and it is hoped that the catalogue will be of material assistance in unearthing many volumes not now in the possession of the library.

Assistant Apiculturist, Bureau of Entomology.

BEET Leaf Hopper's Annual Migrations Studied in Desert Breeding Areas The spring of 1930 witnessed extensive migrations of the beet leaf hopper into many of the important sugar-beet growing areas of the Western States. The Sacramento Delta and other districts of California, southern Idaho, Utah, and western Colorado all received migrations of more or less severity, and all were accompanied by injury due to the curly-top disease which the beet leaf hopper transmits. A rather extensive migration also occurred in New Mexico from the insect's breeding area along the Rio Grande. These migrations are of interest to other than sugar-beet growers as the curly-top disease also affects other crops, including tomatoes, beans, tobacco, table beets, peppers, spinach, and various melons.

Inasmuch as the insects breed in tremendous numbers in desert areas and migrate under favorable conditions into the cultivated sections, a knowledge of the location of the desert regions involved and the cultivated sections infested from each area is highly important. More extensive desert surveys and studies of desert conditions have been made to obtain all the information possible which has any bearing on the habits and distribution of the insect in the desert.

At least three distinct types of cages will be recommended to the trade: (1) A 2-pound combless package; (2) a 3-pound combless package; and (3) a nucleus, or comb package. The adoption of these

BEET Leaf Hopper's Annual Migrations Studied in Desert Breeding Areas The spring of 1930 witnessed extensive migrations of the beet leaf hopper into many of the important sugar-beet growing areas of the Western States. The Sacramento Delta and other districts of California, southern Idaho, Utah, and western Colorado all received migrations of more or less severity, and all were accompanied by injury due to the curly-top disease which the beet leaf hopper transmits. A rather extensive migration also occurred in New Mexico from the insect's breeding area along the Rio Grande. These migrations are of interest to other than sugar-beet growers as the curly-top disease also affects other crops, including tomatoes, beans, tobacco, table beets, peppers, spinach, and various melons.

Inasmuch as the insects breed in tremendous numbers in desert areas and migrate under favorable conditions into the cultivated sections, a knowledge of the location of the desert regions involved and the cultivated sections infested from each area is highly important. More extensive desert surveys and studies of desert conditions have been made to obtain all the information possible which has any bearing on the habits and distribution of the insect in the desert.

Although this leaf hopper probably breeds in any place throughout the arid West where the winter climate and the host plants are favorable, there are certain regions more favorable for its abundant development than others. The host plants most favored in the desert are the mustards, filaree, Russian thistle, and annual Atriplex or saltbush. Other plants also are able to support the insect, but some combination of these favored plants appears to be important in producing the more extensive breeding areas. Such large regions favorable to abundant development are located in southern Idaho, in western Washington, in western Oregon, in southern and western Utah, in western Nevada, in California along the border ranges of some of the interior valleys, and along the Rio Grande in New Mexico and Texas.

The migratory movements are of a most concerted nature, tremendous numbers coming into a given area overnight. The insects are not discernible in the air at the time of flight, except in rare cases, the movement being detected by their discovery in cultivated areas where they were previously absent. The factors responsible for this concerted movement are under observation and are probably at least twofold. One stimulus to the movement, at least on some occasions, is the drying of the host plants so that those in the winged stage of development are impelled to move, because of the food scarcity, to more favorable host-plant locations. During the spring migrations of 1930 it appears that migrations occurred, in some instances at least, from places where the host plants were in excellent condition. The other stimulus likely to be found of importance is the mating urge, and some migrations possibly partake of the nature of a mating flight.

Height of Movement Important

There are a number of points concerning these annual spring movements which are not entirely clear and concerning which additional information is needed. The height of movement, for example, is of considerable importance in connection with ability to cross the barriers offered by high mountain ranges. Evidence obtained this year indicates that in at least one flight, probably a short one, the insects maintained a very low altitude. This was shown by traps devised for the purpose and placed at various heights on a pole support. The largest number of leaf hoppers were obtained at about 10 feet above the ground. There is good evidence, however, that in long-distance flights the insects reach high altitudes.

The distance covered by the migrating insects is also of importance in determining what areas are a potential menace to sugar-beet production. It is apparently certain that flights in the California area can be measured by 200 or 300 miles. Possibly some flights have considerably exceeded that. It appears quite likely, however, that the areas of a more local nature relative to a given beet region are of far greater significance than breeding areas at a distance.

In California there is a definite fall movement, correlated with plowing operations in the valleys and later drying of host plants, which results in repopulating the dry depopulated hills where filaree appears with the first rains. This return movement has not been recognized in other areas but its occurrence is a possibility. Its detection is more difficult where a fairly large population has been able to maintain itself in the desert all summer.

There is undoubtedly a close correlation between climatic conditions and the size of a migration and the time of its occurrence. In at least some areas this correlation can be used in predicting the probability of leaf-hopper damage with an excellent chance of accuracy. The degree of accuracy obtainable is dependent on the extent of the information available regarding both the size and location of the breeding areas involved and on observations of the effect of various weather types in previous years. The cumulative data obtained through successive years adds to the probability of accuracy in following seasons. Prediction of outbreaks is at best, however, only a palliative which gives the grower an opportunity to profit as far as possible by favorable years.

Direct Control Desirable

As far as the insect is concerned, permanent solution of the problem lies in the development of some method of direct control or in the destruction of the insect in the breeding areas through some of its parasitic enemies. Spraying of beets with various insecticides, including light emulsified oil, has again proved unsatisfactory as a method of control. The migration extended this season in Idaho from May 24 to at least as late as June 16. Control by spraying the beets would necessitate from two to four applications, even with 100 per cent kill, which has not been obtained as yet. If spraying were delayed until all leaf hoppers were in the field, many insects would have been feeding for nearly three weeks.

Breeding-area control offers possibilities in some instances where the areas are of a local nature. These possibilities, which are at present under investigation, include not only those of direct insecticidal operations, but the destruction of host plants by other means, both direct and through the association of insects occurring thereon.

A number of parasites of the leaf-hopper eggs and of the insect itself are known to exist in the territories infested. For some reason these are rarely effective in bringing about an appreciable reduction in the numbers involved in the spring migration. There is a possibility that where the factors responsible for this failure are known, selection of parasites not affected by these conditions will be possible. Investigations with this object in view are now under way. It is probably true that ultimate control where necessary will involve the utilization of both parasitic enemies and direct insecticidal operations.

BLACK Stem Rust Spores Combed from the Air by Fliers

The parasite black stem rust causes serious losses each year in some of the grain-growing regions of the United States. This rust depends for its development upon the presence of the tiny spores or reproductive bodies of the rust fungus together with warm, moist weather during the time grain crops are rapidly growing.

One of the activities of the Office of Barberry Eradication is to determine the source of the first stem-rust spores to appear in the northern spring wheat growing States. They may develop on the infected leaves of common barberry bushes growing on farms or city properties and spread from there to near-by grains or grasses. The other possible source of this first inoculum is from the Southern States, where the red or repeating stage of the rust survives the winter on green grain and grasses and is carried north by the wind during the early summer. It is the first infection in the spring wheat States of the North that causes the most damage to crops, as the rust spreads rapidly when the grain is in the milk or soft dough stages.

One method of determining the source of the first spores to appear is to expose glass microscope slides from airplanes at several points in the spring wheat area. These slides are covered with a thin film of vaseline so that the rust spores will stick to them, and one or two are exposed by hand at each of several different altitudes. By making a microscopic examination of the slides one can determine how high the rust spores rise in the air, at what altitudes they are found most abundantly, and whether they come from barberry bushes or from wheat plants farther south.

By the use of airplanes it has been found that rust spores from barberry, as well as those from rusted grain or grasses, may be carried by the winds as high as 10,000 feet above the surface of the earth. From this height it takes some time for the spores to reach the earth. Investigators working with white-pine blister rust have found that spores of that rust falling in a perfectly still atmosphere from a height of one mile require 55 hours to reach the earth. As black stem rust spores are but slightly larger than those of blister rust, the time required for them to fall the same distance would be only slightly less. A hailstone, on the other hand, released a mile high would reach the earth in less than a minute. It is obvious, therefore, how easily rust spores are carried about in the air. Once these spores are carried into the air, unless brought down by rain or some other agency, they may be blown long distances before falling. (Fig. 14.)

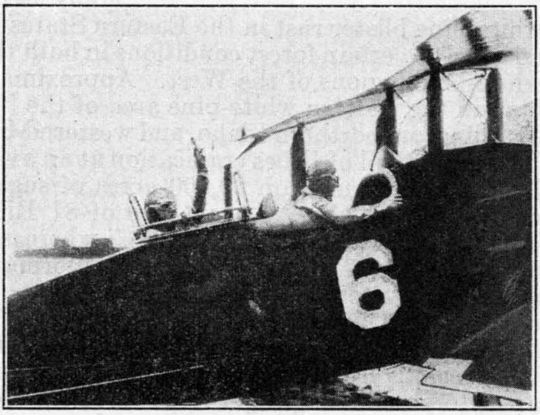

FIGURE 14.—Method of exposing microscope slides from an airplane for detecting rust spores in the air

Results of Airplane Observations

Special airplane flights in 1925 revealed the following facts: (1) No more spores were deposited on slides exposed during a rain than on those exposed on the same day when it was not raining. (2) Fewer spores were caught over Lake Michigan than over land in the same general region. (3) More spores were caught over areas in which barberry bushes were abundant than over areas in which barberries were few in number and scattered. This would indicate that rust on grains appeared first in those regions where barberry bushes were numerous. There is evidence that in spite of the slow fall of these spores they are not usually blown long distances, probably because of rains or downward air currents.

In several of the years during which observations have been made there was a close correlation between the first appearance of rust spores on slides exposed over a given area and the first appearance of rust in the grainfields of that area.

By the use of airplanes large areas can be explored and the more general movements of rust spores ascertained by the examination of slides exposed in this manner. At present this is one of the most reliable means of determining the extent of the movement of spores of disease-producing organisms from one locality to another.

Associate Pathologist, Bureau of Plant Industry.

BLISTER-RUST Control Is Aided by Power Devices for Spraying Host Plants

The eradication of Ribes (currant and gooseberry plants) by the hand-pulling and grubbing method generally used in work for the control of white-pine blister rust in the Eastern States has been found to be well adapted to certain forest conditions in both the sugar-pine and western white-pine regions of the West. Approximately 60,000 acres of pine-land in the western white-pine area of the "Inland Empire" (eastern Washington, northern Idaho, and western Montana) have been worked by this method of Ribes eradication at an average cost of $1.94. Similar work performed on 20,000 acres of sugar-pine land in California cost $1.92 per acre. An average of 81 Ribes bushes per acre were destroyed in the "Inland Empire," whereas the average number was 58 in California. The bushes in California were larger, spinier, and more firmly rooted, which largely accounts for the higher cost of 3.3 cents per bush compared with 2.4 cents in the "Inland Empire." These hand methods of eradication are satisfactory on the upland sites in both regions except where the plants are too deeply rooted in rocky areas to permit the proper removal of the crown without undue labor. In the latter case killing the plants by applying a toxic chemical may prove more effective and less costly.

In situations along stream courses, especially in the "Inland Empire," the Ribes plants occur abundantly within limited areas, commonly exceeding several hundred bushes per acre, and, as a result of prolific layering, develop such diffuse root systems that it is both difficult and costly to use hand-eradication methods. Considerable experimentation has been done in Idaho to develop an effective chemical method for eradicating Ribes in stream-type locations. The stream-type Ribes are often partly submerged in water during a greater part of the working season. This obviously limits chemical application to the aerial parts of the plants. In the stream-type areas of Idaho three Ribes species are present, *Ribes petiolare*, *R. lacustre*, and *R. inerme*. It has been found that one application of 10 per cent aqueous solution of sodium chlorate sprayed on the leaves and stems will completely kill the first species, while three applications of a stronger solution of the same chemical is required to kill all plants of the other two. It has been demonstrated that where the stream-type Ribes growth is composed chiefly of *R. petiolare* this method of treatment is from 49 to 56 per cent less costly than the hand method. In the case not usually blown long distances, probably because of rains or downward air currents.

In several of the years during which observations have been made there was a close correlation between the first appearance of rust spores on slides exposed over a given area and the first appearance of rust in the grainfields of that area.

By the use of airplanes large areas can be explored and the more general movements of rust spores ascertained by the examination of slides exposed in this manner. At present this is one of the most reliable means of determining the extent of the movement of spores of disease-producing organisms from one locality to another.

Associate Pathologist, Bureau of Plant Industry.

BLISTER-RUST Control Is Aided by Power Devices for Spraying Host Plants

The eradication of Ribes (currant and gooseberry plants) by the hand-pulling and grubbing method generally used in work for the control of white-pine blister rust in the Eastern States has been found to be well adapted to certain forest conditions in both the sugar-pine and western white-pine regions of the West. Approximately 60,000 acres of pineland in the western white-pine area of the "Inland Empire" (eastern Washington, northern Idaho, and western Montana) have been worked by this method of Ribes eradication at an average cost of $1.94. Similar work performed on 20,000 acres of sugar-pine land in California cost $1.92 per acre. An average of 81 Ribes bushes per acre were destroyed in the "Inland Empire," whereas the average number was 58 in California. The bushes in California were larger, spinier, and more firmly rooted, which largely accounts for the higher cost of 3.3 cents per bush compared with 2.4 cents in the "Inland Empire." These hand methods of eradication are satisfactory on the upland sites in both regions except where the plants are too deeply rooted in rocky areas to permit the proper removal of the crown without undue labor. In the latter case killing the plants by applying a toxic chemical may prove more effective and less costly.

In situations along stream courses, especially in the "Inland Empire," the Ribes plants occur abundantly within limited areas, commonly exceeding several hundred bushes per acre, and, as a result of prolific layering, develop such diffuse root systems that it is both difficult and costly to use hand-eradication methods. Considerable experimentation has been done in Idaho to develop an effective chemical method for eradicating Ribes in stream-type locations. The stream-type Ribes are often partly submerged in water during a greater part of the working season. This obviously limits chemical application to the aerial parts of the plants. In the stream-type areas of Idaho three Ribes species are present, *Ribes petiolare*, *R. lacustre*, and *R. inerme*. It has been found that one application of 10 per cent aqueous solution of sodium chlorate sprayed on the leaves and stems will completely kill the first species, while three applications of a stronger solution of the same chemical is required to kill all plants of the other two. It has been demonstrated that where the stream-type Ribes growth is composed chiefly of *R. petiolare* this method of treatment is from 49 to 56 per cent less costly than the hand method. In the case of the two species of Ribes that require several applications of the chlorate it has not yet been fully determined whether this chemical method is economical. (Fig. 15.)

For use in applying toxic sprays to Ribes, two types of spraying equipment were developed, namely, knapsack and power. The knapsack unit consisted of a 5-gallon tank fitted to a pack frame and held in place by adjustable straps, a double-action hand pump, and a short extension fitted with a suitable nozzle. This type of equipment is designed for general use in all stream-type sites but is most effective where Ribes occur in comparatively thin concentrations or in scattered clumps.

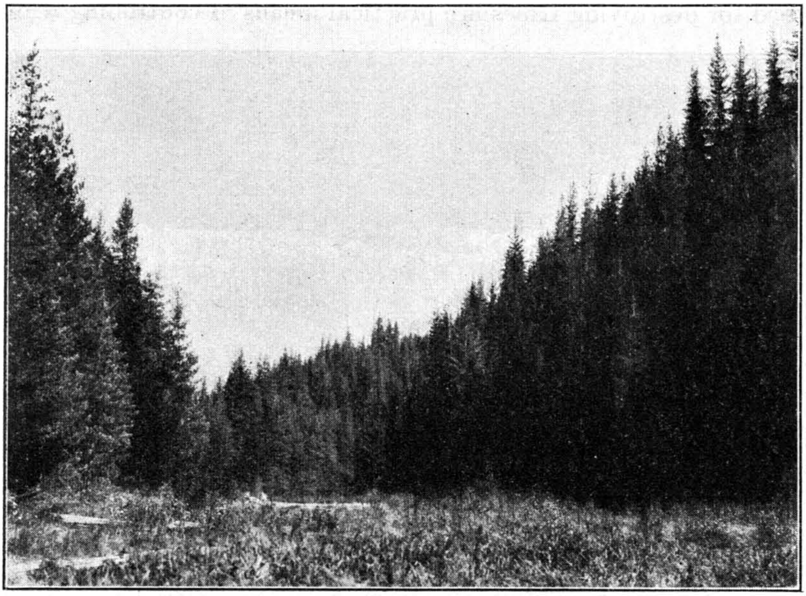

FIGURE 15.—A typical stand of young western white pine (*Pinus monticola*) with stream-type site in the foreground

Long Series of Tests Made

The adaptation of power equipment to the spraying of wild Ribes has necessitated a long series of tests with portable motors, hose, couplings, and nozzles. At the present time power-spraying units have been so organized and equipment so improved that this method of spraying Ribes gives greater promise of minimum blister-rust protection costs than does the knapsack-spraying method on extensive areas having heavy or moderately heavy concentrations of Ribes. The power plant is a specially adapted, small-capacity, forest-fire pumper with a sufficiently large by-pass to take care of surplus liquid passing through the pump and not needed at the nozzles. One of these motors will maintain sufficient pressure to produce a good film of spray when 20 nozzles are wide open and liquid is being pumped through 2,000 feet of ½-inch main line and 3,000 feet of ¼-inch lateral hose. However, it has been found not economically feasible to employ more than 10 nozzles on any one unit, and future experiments may point to a further reduction. (Fig. 16.)

Still smaller and lighter motors have been extensively used, but with unsatisfactory results. The lighter motors loaded to capacity show the effects of the load and begin to give trouble early. The heavier motors with a relatively easy load run along smoothly day after day and even week after week without giving serious trouble. The success of this type of work is dependent upon continuous operation of the motor.

Where the power unit is employed on heavy concentrations of Ribes, the average area sprayed per man per day is three-fourths of an acre. Where knapsack spraying is done on lighter concentrations the average area sprayed per man per day is 1¼ to 2 acres.

Both the hand-pulling and chemical methods that have been described for destroying Ribes are practical means of controlling white-

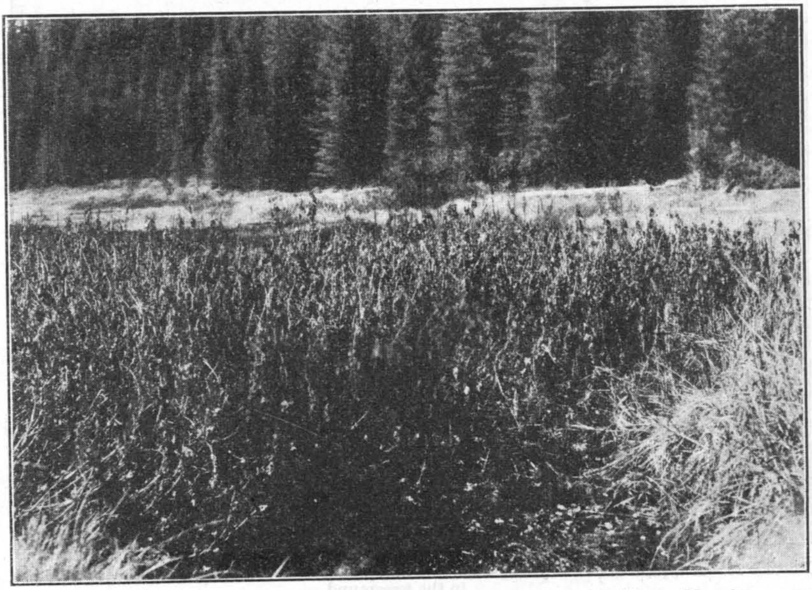

FIGURE 16.—A close-up view of a patch of *Ribes petiolare* in its natural habitat. The picture was taken shortly after the bushes had been sprayed in 1929. Note the dead leaves. In June, 1930, all the stems and roots of the sprayed bushes were dead

pine blister rust in the West. Should a chemical spray or a chemical dust be developed, however, which will be completely effective on the other species of Ribes found in the western white and sugar pine forests, hand pulling may in the future be much less extensively employed, since chemical treatment is generally a quicker and less costly method.

C. C. STRONG,
Associate Forester, Bureau of Plant Industry.

BLISTER-RUST Control Is Effective With Public's Cooperation The cooperation of the public in the campaign to control the white-pine blister rust in the Eastern States is primarily responsible for the success of this work. BLISTER-RUST Control Is Effective With Public's Cooperation The cooperation of the public in the campaign to control the white-pine blister rust in the Eastern States is primarily responsible for the success of this work. The campaign is led jointly by the States concerned and the United States Department of Agriculture. Labor is furnished by the pine owners, trained foremen by the State, and district leaders by the department. The laborers, working systematically in crew formation, do the actual control work, and the trained foremen supervise and check the work of the crews, insuring effective results. The district leaders are stationed in the white-pine districts to demonstrate the control of the disease, stimulate cooperation, and give general oversight to the practical field work. All these men work under the direction of the State regulatory agency responsible for the conduct of the work. This plan of controlling a very destructive new forest disease has produced excellent results because of prompt and generous cooperation by the public.

The blister-rust disease is caused by a parasitic fungus which lives alternately on white pines and Ribes (currant and gooseberry plants). Several kinds of wild Ribes are commonly found in forested areas along with the white pines. The rust is communicated from infected pines to Ribes and from infected Ribes to pines by means of wind-borne spores. It is not communicable between pines. The spores from diseased pines may infect Ribes many miles distant, but the spores that cause the rust on pines are very short-lived, consequently the distance of spread of the disease from Ribes to pines is usually limited to a few hundred feet. This distance varies locally, but under average eastern forest conditions adequate protection is obtained by destroying all Ribes within 900 feet of the pines.

The blister rust has spread through the white-pine regions of New England and New York and is intensifying in Pennsylvania, New Jersey, and the Lake States. The severity of damage to the pines depends upon the length of time the disease has been established in the locality and upon the abundance of Ribes. The continued production of white pine as a profitable timber crop appears to be assured as a result of coordinated State and Federal effort. The infested States all have under way comprehensive blister-rust control programs which have met with a ready and generous response from the public.

In addition to the protection of native pine areas and plantations, special measures are applied to safeguard nurseries that grow white-pine stock for forest and ornamental planting. A number of States are also systematically eliminating the European black currant (*Ribes nigrum* L.). This species is especially susceptible to the rust, causing destruction to adjacent pine stands and greatly hastening the spread and establishment of the rust. Its affinity for the rust is so great that it constitutes a plant nuisance, and the United States Department of Agriculture recommends that the growing of this currant be discontinued.

White Pine Very Valuable

The white pine is one of America's finest and most valuable forest trees. This basic fact has been responsible for the prompt and effective application of blister-rust control by pine owners, since failure to do this would mean a catastrophe to the white pine comparable to that which befell the chestnut.

Over 30,000 individual pine owners have protected their pine areas from blister rust. In some States the townships actively cooperate on a community basis by appropriating funds for the control work. These funds are used to pay for labor engaged in eradicating Ribes on white-pine areas within the township. The funds are expended under State supervision. The area to be eradicated each year is selected by the town officials and the district blister-rust leader. Local labor, working under trained foremen and supervised by the district leader, is then employed to eradicate the Ribes. In this manner a definite acreage is protected each year and the work continued annually until all of the white pine within the township has been safeguarded. Nearly 1,200 separate appropriations by townships have been made for this type of cooperation. (Fig. 17.)

In many instances cultivated Ribes plants are found within infecting distance of white pines. Over 460,000 such plants growing in such situations have been eradicated. These plants belonged to several thousand owners, who cooperated in their eradication to aid the

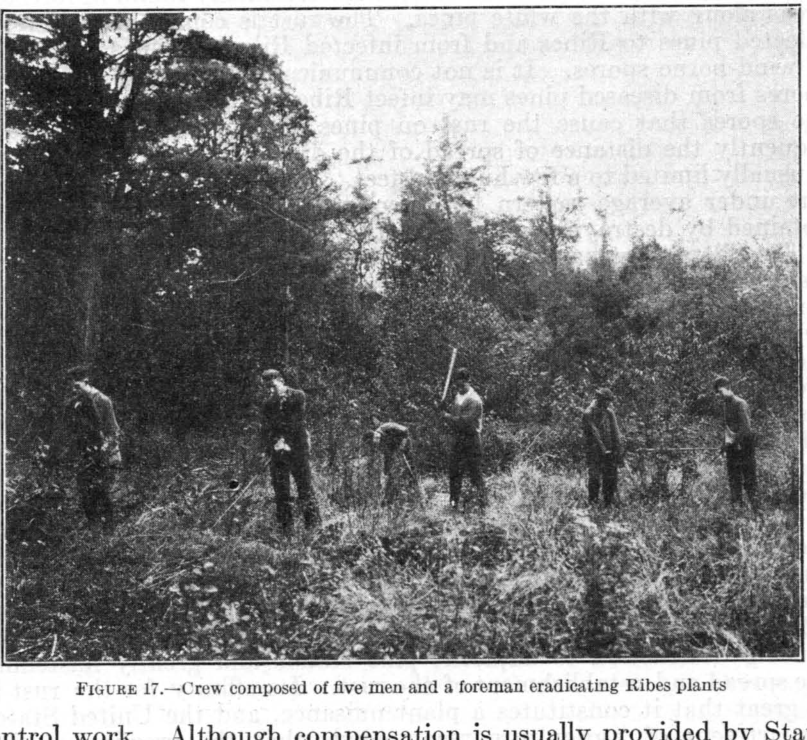

FIGURE 17.—Crew composed of five men and a foreman eradicating Ribes plants

control work. Although compensation is usually provided by State law for the loss of such plants, claims for compensation were made by the owners of only 5 per cent of these bushes. This kind of cooperation by thousands of individuals, many of whom did not own white pine, has been very helpful in establishing general control of the disease.

The cooperative application of control measures since 1918 in New England and New York has resulted in 7,757,140 acres being cleared of over 75,000,000 Ribes at an average cost of about 20 cents an acre. The cost varies considerably with local conditions, depending chiefly on the number and size of the Ribes plants, the density of the undergrowth, and the roughness of the ground. Control of the disease has been established on about 80 per cent of the major white-pine area needing protection in New England and New York. It will be necessary, however, to maintain this control by systematically reworking these lands at intervals of from 5 to 10 years, in order to destroy any regrowth of Ribes, particularly in open situations such as swamps, recent cut-over or burned areas, pastures, and along stream courses, roadways, and fence rows. In protected areas very slight or no increase can be found in the amount of disease on pine. On the other hand, it is easy to demonstrate the rapid increase of pine infection in unprotected areas and the need for prompt cooperation by the owners in the application of control measures.

Senior Pathologist, Bureau of Plant Industry.

BREEDING Studies at Experiment Stations Show Genetic Factors

Although no one questions the use of sound breeding methods in a system of successful livestock production, investigators in the field of animal breeding and animal genetics often are criticized for having contributed little of practical application to the subject. There is perhaps some justification for this criticism owing to the time and funds required in conducting breeding experiments with the domestic animals. The State experiment stations have, however, made distinct progress in explaining how different characteristics are inherited and in pointing out how certain undesirable qualities may be eliminated from the breeding stock.

The presentation of the results of all the contributions to the field is not attempted in this brief article, which is intended to give a general idea of the type and application of the work. Important contributions have been made in studies of different breeding practices, including the use and limitations of inbreeding, linebreeding, and crossbreeding. Investigations at the Connecticut, Delaware, California, Maine, Massachusetts, and Wisconsin Experiment Stations with swine and poultry show that inbreeding tends to concentrate the qualities present in the stock, whether they be good or poor. Consequently undesirable as well as desirable individuals may be produced. The purification of strains through inbreeding frequently results in the production of abnormalities and loss of vigor. The latter, however, may be restored by subsequent crossing. Close inbreeding is a dangerous practice in the hands of the uninformed, but it is a valuable tool when intelligently used for the concentration of qualities of superior individuals.

The inheritance of production characteristics in the different classes of animals has been an interesting subject of investigation at many of the stations. The Illinois, Maine, Wisconsin, and other stations have demonstrated that the mode of inheritance of milk and butterfat production is not simple. For example, as many as 10 genetic factors have been indicated for milk yield and 14 for fat percentage. The factors for high yield appear to be dominant, permitting a high-yielding animal to carry factors for lower production which may be transmitted to her progeny. The many factors responsible make the identification of individual factors very complicated. Studies of the inheritance of wool characters, carcass conformation, and the like in sheep at the New Hampshire, Ohio, Texas, and Wyoming stations indicate that these will be necessary, however, to maintain this control by systematically reworking these lands at intervals of from 5 to 10 years, in order to destroy any regrowth of Ribes, particularly in open situations such as swamps, recent cut-over or burned areas, pastures, and along stream courses, roadways, and fence rows. In protected areas very slight or no increase can be found in the amount of disease on pine. On the other hand, it is easy to demonstrate the rapid increase of pine infection in unprotected areas and the need for prompt cooperation by the owners in the application of control measures.

Senior Pathologist, Bureau of Plant Industry.

BREEDING Studies at Experiment Stations Show Genetic Factors Although no one questions the use of sound breeding methods in a system of successful livestock production, investigators in the field of animal breeding and animal genetics often are criticized for having contributed little of practical application to the subject. There is perhaps some justification for this criticism owing to the time and funds required in conducting breeding experiments with the domestic animals. The State experiment stations have, however, made distinct progress in explaining how different characteristics are inherited and in pointing out how certain undesirable qualities may be eliminated from the breeding stock.

The presentation of the results of all the contributions to the field is not attempted in this brief article, which is intended to give a general idea of the type and application of the work. Important contributions have been made in studies of different breeding practices, including the use and limitations of inbreeding, linebreeding, and crossbreeding. Investigations at the Connecticut, Delaware, California, Maine, Massachusetts, and Wisconsin Experiment Stations with swine and poultry show that inbreeding tends to concentrate the qualities present in the stock, whether they be good or poor. Consequently undesirable as well as desirable individuals may be produced. The purification of strains through inbreeding frequently results in the production of abnormalities and loss of vigor. The latter, however, may be restored by subsequent crossing. Close inbreeding is a dangerous practice in the hands of the uninformed, but it is a valuable tool when intelligently used for the concentration of qualities of superior individuals.

The inheritance of production characteristics in the different classes of animals has been an interesting subject of investigation at many of the stations. The Illinois, Maine, Wisconsin, and other stations have demonstrated that the mode of inheritance of milk and butterfat production is not simple. For example, as many as 10 genetic factors have been indicated for milk yield and 14 for fat percentage. The factors for high yield appear to be dominant, permitting a high-yielding animal to carry factors for lower production which may be transmitted to her progeny. The many factors responsible make the identification of individual factors very complicated. Studies of the inheritance of wool characters, carcass conformation, and the like in sheep at the New Hampshire, Ohio, Texas, and Wyoming stations indicate that these qualities also are controlled by a large number of factors. Specific genetic factors influencing egg production and broodiness have been discovered in investigations at a number of the stations, particularly Kansas, Maine, Massachusetts, and New Jersey. All of these experiments dealing with the inheritance of production characters have indicated that the only satisfactory measure of the ability of an individual to transmit desirable qualities to its offspring must depend on a record of the performance of the progeny.

Inheritance of Abnormalities

The mode of inheritance of many abnormalities and undesirable characteristics has been established. For example, the Ohio and Wisconsin stations found that the tendency to produce swine with inguinal hernias was hereditary. The Texas and Ohio stations also observed that the ridgling characteristic in goats was inherited. The findings showed that these tendencies could be eliminated from the herd by intelligent selection and by discarding all animals which produced defective offspring.

Investigations with plants indicate that variations in the resistance to certain diseases are hereditary, and likewise in animals different degrees of resistance to diseases appear to be hereditary. Variations in the resistance of chicks to bacillary white diarrhea were found by the Illinois station to be hereditary. The Iowa station also reported the inheritance of resistance to Danysz bacillus in the rat and to fowl typhoid in poultry. Studies at Wisconsin indicated that resistance to contagious abortion was hereditary in rabbits. The Illinois and Iowa stations also have investigated the inheritance of resistance to cholera in hogs. Although the studies made thus far have not developed any practicable means of combating, by breeding, the diseases named, they represent interesting scientific observations.

The basic factors controlling color in farm animals have been largely established or confirmed by investigations of the inheritance of coat color in horses by the experiment stations in Kansas and Kentucky; cattle in Connecticut, Illinois, Iowa, Kansas, Maine, Texas, and Wisconsin; swine in Illinois, Iowa, Kansas, and Wisconsin; and poultry by the experiment stations in Connecticut, Kansas, Maine, Massachusetts, and Wisconsin. A practical application of these findings is the recognition that in the black breeds of cattle red animals are only produced in cases where both the sire and dam carry red. Thus, if red is to be eliminated from the herd it is necessary to discard for breeding purposes the parents of red animals, at the same time appreciating that black progeny may carry red if they are the produce of a sire or dam that have produced any red offspring. Another application of the results of color studies is the determination of the sex of crossbred chicks at hatching.

Experiments in Fertility

A wide variety of experiments have been conducted which deal with fertility and fecundity and the control of sex. It is difficult to obtain clear-cut results in studies of fertility and fecundity owing to the complication of environment and the fact that the different elements of which these characters are composed may tend to offset each other. Much progress has, however, been made in carefully controlled investigations dealing with the physiological factors influencing the viability of spermatozoa under different environmental conditions and after frequent matings. In attempts to throw light on the factors influencing the occurrence of heat in sows and the determination of the proper time for breeding, the Missouri station has observed the changes in the genital organs associated with heat, to obtain information essential for improvement in breeding practices. Progress has already been made in inducing heat in sows, increasing the number of eggs produced at a heat period, and in the isolation of hormones associated with pregnancy and the initiation of lactation following calving in dairy cattle. Although the factors influencing sex determination have been studied frequently, attempts to control the sex of the offspring have given negative results.

Investigations in animal breeding at the State experiment stations have been quite widely distributed geographically, and practically all phases of the subject have been considered. In their preliminary stages the results of many of the more thorough investigations have been fundamental in character, but it is the carefully planned investigations which tend to give conclusive results and play an important rôle in guiding the practices of the modern livestock breeder.

Senior Animal Husbandman, Office of Experiment Stations.

CANNING Grades in Increased Demand as Their Utility Is Seen Since the practicability of standard grades for fresh tomatoes for canning has been conclusively demonstrated under commercial operations, there has been a considerable demand for United States grades for fruits and other vegetables intended for cannery purposes.

The principle of buying and selling on the basis of standard grades has come to be looked upon as very essential to successful merchandising. The adoption of this principle in transactions in farm produce has eliminated much of the source of misunderstanding and dissatisfaction. It seems logical, therefore, that this principle which has met with so much success in connection with the merchandising of fruits and vegetables marketed for consumption in the fresh state may also be applied to such products when grown for cannery use.

It is recognized that there are differences in quality, condition, size, color, maturity, etc., and that these differences vary in different fields under changing weather conditions. On account of these differences it is impossible to establish a flat price for such a crop as canning tomatoes that will be just to both canner and grower under all conditions. Uniform grades provide a common language with which to describe these differences. The use of standard grades offers certain very definite advantages to both grower and manufacturer. Clear-cut grades based on variations in quality provide a practical basis for contracts and purchases upon which the buyer and seller can deal with mutual confidence and understanding. Agreements can be made definite, with gradations in price corresponding with variations in the quality of the stock delivered, thereby assisting in placing transactions in raw stock upon a plane of equality and fairness. Tomatoes may be bought and sold on a grade basis at prices commensurate with their actual value for canning purposes. The incentive for the grower to strive to deliver a high-grade product in order to secure the attendant premium

CANNING Grades in Increased Demand as Their Utility Is Seen Since the practicability of standard grades for fresh tomatoes for canning has been conclusively demonstrated under commercial operations, there has been a considerable demand for United States grades for fruits and other vegetables intended for cannery purposes.

The principle of buying and selling on the basis of standard grades has come to be looked upon as very essential to successful merchandising. The adoption of this principle in transactions in farm produce has eliminated much of the source of misunderstanding and dissatisfaction. It seems logical, therefore, that this principle which has met with so much success in connection with the merchandising of fruits and vegetables marketed for consumption in the fresh state may also be applied to such products when grown for cannery use.

It is recognized that there are differences in quality, condition, size, color, maturity, etc., and that these differences vary in different fields under changing weather conditions. On account of these differences it is impossible to establish a flat price for such a crop as canning tomatoes that will be just to both canner and grower under all conditions. Uniform grades provide a common language with which to describe these differences. The use of standard grades offers certain very definite advantages to both grower and manufacturer. Clear-cut grades based on variations in quality provide a practical basis for contracts and purchases upon which the buyer and seller can deal with mutual confidence and understanding. Agreements can be made definite, with gradations in price corresponding with variations in the quality of the stock delivered, thereby assisting in placing transactions in raw stock upon a plane of equality and fairness. Tomatoes may be bought and sold on a grade basis at prices commensurate with their actual value for canning purposes. The incentive for the grower to strive to deliver a high-grade product in order to secure the attendant premium

40442°—31——9

will tend to encourage the production of larger crops of superior quality. Waste and losses will be materially reduced. The price gradations will induce the grower to discard culls and unmarketable stock in the field, thus saving handling costs.

Basis for Sampling Provided

The United States grades which have been issued simply provide a basis for sampling loads of fruits and vegetables as they are delivered to the canneries. It is not intended that these products be sorted into different grades by the grower but that all usable stock should be delivered, leaving the culls in the field.

Progressive growers, who deliver good quality stock to the canneries, justly contend that they should receive more money for their products than the indifferent grower who delivers inferior fruits and vegetables which entail considerably more waste in preparation for use.

Canners who receive high-quality fresh stock are in a better position to manufacture their products economically. Labor costs in trimming green, decayed, or otherwise defective parts of the fruit or vegetables can be reduced. Other overhead expenses can also be held to a minimum by the increased capacity of the plant when culls are prevented from slowing up the quantity of stock run through the factory. This is particularly true during the peak of the season.

Increased profits for the canner eventually should mean more money for the grower. As a matter of fact many canners are already paying growers more money for their tomatoes, since they have been using the Federal-State inspection service as a neutral agency to determine the quality of various growers' loads of produce.

During 1930 approximately 90 Federal-State inspectors were stationed at canneries and loading stations in 10 States for the purpose of reporting the quality of loads of tomatoes, apples, spinach, cherries, and green beans. Although United States grades for cannery cherries and green beans had not been recommended at that time, the inspectors reported the percentages of various defects and secured information upon which a practical set of grades for each product might be based. Intensive studies were also begun with a view to establishing Federal grades for green peas and raspberries for canning, and cabbage for sauerkraut manufacture.

Marketing Specialist, Bureau of Agricultural Economics.

CASEIN of High Quality Increases Profits of the Dairy Industry

Casein, a product of skim milk, is used in the United States to the extent of about 50,000,000 pounds annually. In the period 1920–1929 the annual imports of casein exceeded the amount produced in the United States by approximately 5,000,000 pounds. The amount manufactured in the United States fluctuates within rather wide ranges from year to year, depending largely upon prevailing market prices. For the 5-year period 1920–1924 the average domestic production was 12,367,000 pounds, and for the 5-year period 1925–1929 it was 20,867,000 pounds. In 1929, 30,535,000 pounds was produced in 214 American factories, and 27,583,000 pounds was imported, making the total supply for that will tend to encourage the production of larger crops of superior quality. Waste and losses will be materially reduced. The price gradations will induce the grower to discard culls and unmarketable stock in the field, thus saving handling costs.

CASEIN of High Quality Increases Profits of the Dairy Industry

Casein, a product of skim milk, is used in the United States to the extent of about 50,000,000 pounds annually. In the period 1920–1929 the annual imports of casein exceeded the amount produced in the United States by approximately 5,000,000 pounds. The amount manufactured in the United States fluctuates within rather wide ranges from year to year, depending largely upon prevailing market prices. For the 5-year period 1920–1924 the average domestic production was 12,367,000 pounds, and for the 5-year period 1925–1929 it was 20,867,000 pounds. In 1929, 30,535,000 pounds was produced in 214 American factories, and 27,583,000 pounds was imported, making the total supply for that year slightly more than 58,000,000 pounds. The best grades of casein have been selling recently for 3 to 4 cents more per pound than the average grades. Imported casein, which comes mostly from Argentina, is more uniform in quality than most of the domestic casein which is not sold according to grade.

Investigations made by the Bureau of Dairy Industry show that while our best grades are equal or superior to the best imported products, there are great differences in the quality and uniformity of domestic brands.

Standardization of manufacturing methods and the introduction of better methods will enable dairy-products plants to make a more uniform, higher-grade product which can be more readily marketed, at a price higher than that paid for casein of inferior quality.

Many of the leading dairy plants throughout the country have already adopted manufacturing methods recommended by the bureau, and are producing casein which brings premium prices. There are many other plants, which, by adopting better manufacturing methods, will likewise be able to improve the quality of their casein and market it to better advantage.

With improvement in quality will come a greater demand for domestic casein and the extension of casein manufacture to new sections. Within the last year several new casein plants have been started in Minnesota and Idaho, and these now have profitable casein business.

Casein is used principally as a binder in coated paper, and for making glue, as well as in numerous other commodities where its adhesive and waterproof qualities are of value.

Casein, as commonly made, is not a food product, and oftentimes is made only as a means of utilizing surplus skim milk. Many casein-plant operators become careless in their manufacturing methods and assign unskilled and inefficient labor to do the work. Under such conditions the finished casein lacks uniformity and is usually of inferior quality. With casein, as with other dairy products, the more exact and careful the manufacturing methods are, the better the product will be. When casein is made in the right way, casein manufacture can be not merely a means of utilizing surplus skim milk, at small profit to the manufacturer, but can be a profitable undertaking.

Profitably Utilizes Skim Milk

By making high-grade casein, which brings good prices, dairy-products plants can not only use up their surplus milk, but can profitably utilize more of their available skim milk in casein manufacture throughout the year. For example, when market conditions are unfavorable for converting skim milk into one or more of its usual by-products, its manufacture into high-grade casein may be profitable. The diversion of definite amounts of skim milk into casein of high quality would tend to stabilize the by-products branch of the dairy industry.

Casein properly made by the grain-curd method, which was developed in the research laboratories of the Bureau of Dairy Industry, is a casein of very high quality and uniformity, and has properties which the users of casein demand. Grain-curd casein is now being made in a number of plants in various parts of the country, with very satisfactory results.

In connection with the improvement in the quality of casein, better equipment has been developed for making casein in large quantities.

Although the grain-curd method has special advantages, casein of good quality can be made by any of the customary methods with proper manufacturing care. Regardless of the type of casein produced, exactness in manufacturing methods is essential for the production of a high-grade casein for any commercial use.

In field studies made by the Bureau of Dairy Industry in the last year, in Vermont, Pennsylvania, New York, Maine, Wisconsin, Minnesota, Massachusetts, Montana, Washington, Oregon, Idaho, and California, it was found that there has been no uniformity in manufacturing methods, even in plants making the same type of casein. The great differences in quality of caseins of the same type and of different types are largely due to variations in manufacturing methods. Any type of casein that is made right should have about the same desirable commercial properties as any other type, and the different types, as far as their practical utilization is concerned, should be interchangeable.

The general adoption of the methods of manufacture recommended by the Bureau of Dairy Industry should result in an increase in casein production, and be of great value to the dairy industry in producing high-grade casein suitable for all commercial purposes.

C. S. Trimble,
Associate Manufacturing Specialist,
Bureau of Dairy Industry.

CATTLE Often Killed by Nails, Wire, Etc., Eaten With the Feed In the dairy herd at the United States Dairy Experiment Station at Beltsville, Md., among animals more than a year old, 38 deaths have occurred in the last four years. Eighteen, or 47.36 per cent, of these were due to foreign bodies eaten by the animal with the feed. In addition to these, 22 animals were seriously affected by foreign bodies. Also, numerous minor injuries and adhesions occurred in other cows which were due to foreign bodies. In a good commercial dairy herd these losses would have included the deaths of animals ranging in value from one hundred to several thousand dollars each and the decreasing of profits in milk production and breeding.

The foreign bodies most frequently found in Beltsville animals were pieces of wire and nails. In 12 of the 18 cases resulting in death the diaphragm had been pierced. In 3 cows wires were found in the liver. One cow died as the result of wire passing from the stomach through the abdominal wall. Another died from bloat caused by an abscess due to a foreign body that pierced the diaphragm and entered the lung. In still another case the animal had swallowed a metal burr which ruptured the fourth compartment of the stomach.

Other foreign bodies, such as needles, splintered wood, and knives, are sometimes found in cows. Such objects as stones, sand, bolts, money, and watches have been found in the digestive tracts of cattle. Pieces of wire from baled hay or from fences and construction work and nails are the foreign bodies that are most commonly found. Pieces of wire and nails may easily be swallowed with the feed, for cattle chew their feed only superficially before swallowing it. The many strong papillae (pronglike projections) which are on the tongue and point backward, prevent the foreign bodies from falling out of the mouth. While the feed is being tossed about in the stomach these heavier objects fall to the bottom of the second division of the stomach, known

Although the grain-curd method has special advantages, casein of good quality can be made by any of the customary methods with proper manufacturing care. Regardless of the type of casein produced, exactness in manufacturing methods is essential for the production of a high-grade casein for any commercial use.

In field studies made by the Bureau of Dairy Industry in the last year, in Vermont, Pennsylvania, New York, Maine, Wisconsin, Minnesota, Massachusetts, Montana, Washington, Oregon, Idaho, and California, it was found that there has been no uniformity in manufacturing methods, even in plants making the same type of casein. The great differences in quality of caseins of the same type and of different types are largely due to variations in manufacturing methods. Any type of casein that is made right should have about the same desirable commercial properties as any other type, and the different types, as far as their practical utilization is concerned, should be interchangeable.

The general adoption of the methods of manufacture recommended by the Bureau of Dairy Industry should result in an increase in casein production, and be of great value to the dairy industry in producing high-grade casein suitable for all commercial purposes.

C. S. Trimble,
Associate Manufacturing Specialist,
Bureau of Dairy Industry.

CATTLE Often Killed by Nails, Wire, Etc., Eaten With the Feed

In the dairy herd at the United States Dairy Experiment Station at Beltsville, Md., among animals more than a year old, 38 deaths have occurred in the last four years. Eighteen, or 47.36 per cent, of these were due to foreign bodies eaten by the animal with the feed. In addition to these, 22 animals were seriously affected by foreign bodies. Also, numerous minor injuries and adhesions occurred in other cows which were due to foreign bodies. In a good commercial dairy herd these losses would have included the deaths of animals ranging in value from one hundred to several thousand dollars each and the decreasing of profits in milk production and breeding.

The foreign bodies most frequently found in Beltsville animals were pieces of wire and nails. In 12 of the 18 cases resulting in death the diaphragm had been pierced. In 3 cows wires were found in the liver. One cow died as the result of wire passing from the stomach through the abdominal wall. Another died from bloat caused by an abscess due to a foreign body that pierced the diaphragm and entered the lung. In still another case the animal had swallowed a metal burr which ruptured the fourth compartment of the stomach.

Other foreign bodies, such as needles, splintered wood, and knives, are sometimes found in cows. Such objects as stones, sand, bolts, money, and watches have been found in the digestive tracts of cattle. Pieces of wire from baled hay or from fences and construction work and nails are the foreign bodies that are most commonly found. Pieces of wire and nails may easily be swallowed with the feed, for cattle chew their feed only superficially before swallowing it. The many strong papillae (pronglike projections) which are on the tongue and point backward, prevent the foreign bodies from falling out of the mouth. While the feed is being tossed about in the stomach these heavier objects fall to the bottom of the second division of the stomach, known as the reticulum or honeycomb, and remain in the stomach when the feed is regurgitated for mastication.

Foreign bodies rarely lodge in the esophagus of cows, and they are seldom found in the digestive tract beyond the reticulum, but sometimes straw or small splinters of wood get into the bronchial tubes of cattle and cause irritation.

Various Injuries Caused

On account of the contraction of the powerful muscles of the stomach, diaphragm, and abdominal walls, sharp-pointed foreign bodies are forced through the wall of the stomach. Usually they travel forward but they may move in any direction. As the heart is adjacent to the reticulum it frequently is injured.

Foreign bodies have been known to pass through the abdominal wall to the outside, making a pus canal as they went. Abscesses usually form in the organs injured by the foreign bodies and sometimes severe hemorrhages occur. The liver, spleen, diaphragm, and lungs are sometimes destroyed by such abscesses.

When a foreign body passes forward through the diaphragm it comes into contact with the heart sack and sometimes even enters the heart. The type of wound made depends to some extent upon the speed with which the object travels. If passage is slow, pus is formed, even to the extent of several gallons, around the heart. Abscesses may develop in the heart muscle. If passage is more rapid, it may tear a hole through the heart muscle and death occur before there is time for pus formation.

Frequently the symptoms of the presence of foreign bodies in cows appear after some great exertion, such as giving birth to young or fighting. An illustration is that of a cow that died two days after her rumen had been vigorously massaged.

A cow with a foreign body may appear normal, then suddenly refuse to eat, stand in one position for long periods, look distressed, breathe cautiously, move stiffly, and give less milk. The stomach works slowly and the conjunctiva and body fluids may appear yellow if the liver is involved. Usually the temperature is elevated in very acute or prolonged cases, and there may be considerable pain, depending upon the location of the foreign body.

The cow may recover in a day or so only to show similar symptoms again within a few weeks. Thus the symptoms may come and go over a period of several months before death. At times the symptoms may come on suddenly and the animal die within a week. Oftentimes in the latter stages of a long siege when the foreign body has penetrated the heart sack, the splashing of fluid around the heart may be heard.

Swelling of the joints of the legs, and a change of the milk to a gray watery fluid, with enlargement of the udder, may occur in cases of long duration. When the circulation is disturbed, edematous swellings may appear along the lower parts of the body.

Many of these symptoms are present in other digestive disturbances and ailments of the internal organs. However, where baled hay is being fed, or construction work is going on near the herd, foreign bodies may be suspected.

Medicinal treatment is of little or no value. Surgical interference has been successful in some cases when resorted to early. This consists of opening the abdominal cavity and removing the foreign body.

Methods of Prevention

Prevention is decidedly more profitable than treatment. Before baled hay is fed all wire should be accounted for and should be moved to a safe distance from the cows. The same precautions should be taken with baled straw and other baled material. It is advisable to have fences around the barn lots made of material other than wire; at least badly rusted wire fences should be replaced. Likewise, all rubbish and litter should be moved from the lots, yards, stables, and barns. It is poor practice to mend broken stanchions and equipment with baling wire, because the wire may break and fall into the feed. For removing certain kinds of metal from the grain a magnet may serve.

F. W. MILLER,
Senior Veterinarian and Physiologist,
Bureau of Dairy Industry.

CATTLE Ticks Can Be Eradicated by System of Vacating Pastures Although it is generally understood by cattlemen of the South that the cattle-fever tick may be readily starved to death if deprived of the opportunity of getting on cattle, horses, mules, or asses, this method of eradicating ticks is comparatively little used. Under proper conditions this plan, which is commonly referred to as the pasture-vacating method, is rapid and sure in its results, and eradication is brought about with a minimum of work and expense. This method is particularly adaptable in much of the large range country of the Southwest remaining in the quarantined area. Here the spring movement of cattle to pastures in Northern States and to market points often reduces the number remaining on the ranches to a point where a part of the range can easily be vacated. In many such cases the method can be made to fit in with the regular ranch operations with little loss of feed, or in the number of cattle carried throughout the year.

This method of eliminating fever ticks is based on knowledge of the time that ticks survive in a pasture after the removal of all cattle, horses, mules, and asses. The length of this starvation period at various seasons of the year has been determined by experiments conducted by the Bureau of Animal Industry, and the results of these experiments have been verified in many practical applications of this knowledge in tick-eradication work in the field.

Time Required to Free Pastures

The dates when a pasture will be tick free after removal of the livestock are as follows:

Date of vacating pasture	Date when pasture will be free from ticks
July 1	March 1.
August 1	May 1.
September 1	July 1.
October 1 to November 1, inclusive	August 1.
December 1	August 15.
December 15 to March 15, inclusive	September 1.
April 1	September 15.
April 15	October 15.
May 1 to June 15, inclusive	November 1.

Methods of Prevention

Prevention is decidedly more profitable than treatment. Before baled hay is fed all wire should be accounted for and should be moved to a safe distance from the cows. CATTLE Ticks Can Be Eradicated by System of Vacating Pastures Although it is generally understood by cattlemen of the South that the cattle-fever tick may be readily starved to death if deprived of the opportunity of getting on cattle, horses, mules, or asses, this method of eradicating ticks is comparatively little used. Under proper conditions this plan, which is commonly referred to as the pasture-vacating method, is rapid and sure in its results, and eradication is brought about with a minimum of work and expense. This method is particularly adaptable in much of the large range country of the Southwest remaining in the quarantined area. Here the spring movement of cattle to pastures in Northern States and to market points often reduces the number remaining on the ranches to a point where a part of the range can easily be vacated. In many such cases the method can be made to fit in with the regular ranch operations with little loss of feed, or in the number of cattle carried throughout the year.

This method of eliminating fever ticks is based on knowledge of the time that ticks survive in a pasture after the removal of all cattle, horses, mules, and asses. The length of this starvation period at various seasons of the year has been determined by experiments conducted by the Bureau of Animal Industry, and the results of these experiments have been verified in many practical applications of this knowledge in tick-eradication work in the field.

Time Required to Free Pastures

The dates when a pasture will be tick free after removal of the livestock are as follows:

Date of vacating pasture	Date when pasture will be free from ticks
July 1	March 1.
August 1	May 1.
September 1	July 1.
October 1 to November 1, inclusive	August 1.
December 1	August 15.
December 15 to March 15, inclusive	September 1.
April 1	September 15.
April 15	October 15.
May 1 to June 15, inclusive	November 1.

From this tabulation it will be seen that the time necessary to kill ticks by starvation is shortest in summer and that the best time to vacate pastures, as a rule, is between March 15 and June 15. It will then be necessary to lose the use of the range for only about six months.

Feed Not Wasted—Rest Improves Range

The time that a pasture is left idle should not be charged up as a total loss. The range improves as a result of the rest and the chance to reseed, and it will be in a condition to carry an additional number of cattle when it is ready for restocking.

Close attention to a few simple details are important in the successful application of this plan. The most important of these are: Good fencing, the removal and exclusion of all livestock, and eventual restocking with tick-free animals.

The fences inclosing the pasture to be vacated must be good enough to keep out livestock and should be regularly patrolled and kept in good repair. In dividing or cross fencing large ranges for the purpose of tick eradication by this method, the new fences should be built, when possible, through rough, inaccessible land where feed is short and where cattle will consequently be less inclined to stray up to the fence line.

It is necessary that all cattle, horses, mules, and asses be removed from the pasture and the time that it is to remain idle should be calculated from the day the last animal is removed.

Riders patrolling the fences should also examine the watering places to make doubly sure that the pasture remains vacant. The horses used by the riders doing this work must be kept tick free and regularly dipped to avoid the possibility of carrying ticks into the vacated pasture. If the pasture is crossed by a private road, this should be closed except to automobile travel.

When the starvation period is ended, every precaution must be taken to see that the pasture is restocked with tick-free animals. A safe plan is to require that all animals to be placed in the free pasture be found apparently tick free on a careful chute inspection and then be dipped and moved to the free pasture without exposure. These operations should be supervised by an official cattle inspector.

The fear is sometimes expressed that deer that may be on the vacated pasture will serve to continue tick infestation when the livestock is removed. This has not been found to be the case. Many large pastures in which deer were numerous have been made tick free by the vacating method and have remained so, in spite of the presence of deer in them.

Method Should Be Officially Supervised

When planning to free a ranch or pasture of ticks by the method described, it is advisable to notify and secure the advice of the official having charge of tick eradication in your locality. This will insure official supervision of the work and result in the keeping of records that are used in connection with the removal of quarantine restrictions when the ticks are eradicated.

For further information concerning cattle-tick eradication ask for Farmers' Bulletin 1057, Cattle-Fever Ticks and Methods of Eradication and consult State livestock sanitary officials or the United States Department of Agriculture, Washington, D. C.

Senior Veterinarian, Bureau of Animal Industry.

CATTLE Tick's Passing in South Carolina Has Brought Early Benefits Although less than four years have elapsed since South Carolina was released from Federal quarantine imposed because of cattle ticks, the benefits derived from the eradication of this pest are already evident throughout the State.

It is true that in South Carolina, as in many other parts of the country, the number of cattle has decreased somewhat in recent years, but the increase in quality in this State more than compensates for the loss in numbers. The net benefit amounts to about $2,000,000 annually. It is noteworthy also that purebred and high-grade cattle in South Carolina are steadily increasing in number and value.

Since tick eradication was completed in 1927, nearly a thousand purebred bulls of both beef and dairy types have been brought into the State for use as herd sires. As a consequence, cattle owners are now not only improving their own herds but are also supplying animals for both breeding and utility purposes to other areas that have more recently won their freedom from cattle ticks. Records of sales held by State and county breeders' associations show that South Carolina has likewise supplied purebred cattle to Middle Western and Northern States. The increased production of milk and cream as a result of the great expansion in the dairy industry is taken care of by creameries, cheese factories, and ice-cream plants located at advantageous points throughout the State. (Fig. 18.)

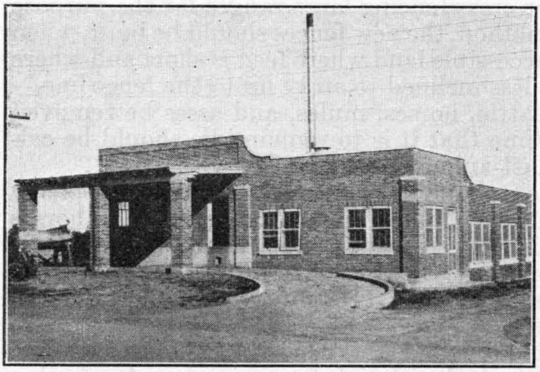

FIGURE 18.—A modern cheese factory, typical of the industrial development that has followed tick eradication

These developments illustrate the value of two factors which are commonly recognized as essential to the success of any industry. The first is good quality of products, and the second is an unrestricted market. These factors apply as much to the production of cattle as to commodities of various kinds. Because of its effect on the quality of the animals raised and on markets, the cattle-fever tick for many years was the greatest known menace to the cattle-raising industry in the South.

It is perhaps difficult for residents of other States where cattle ticks have never occurred or where they have long been prevalent to realize the change that the eradication of such a parasite can bring about. The prevalence of splenetic fever carried from animal to animal by the cattle tick and the irritation and blood loss due to the attack of great numbers of these ticks result in an inferior quality of cattle. This, together with quarantine measures imposed by the Federal Government and various States, restricted sales to designated markets, with the result that comparatively low prices were obtained. For many years these conditions prevailed and reduced returns from cattle to the extent of about $1,500,000 annually. The solution of the problem, therefore, was to remove the cause by taking advantage of early experimental work that showed the feasibility of eradicating ticks on cattle, while still allowing the use of infested pastures and premises.

Entire State Infested in 1906

The entire area of the State was tick infested when in 1906 systematic eradication was begun cooperatively between the United States Bureau of Animal Industry and the State of South Carolina through Clemson Agricultural College. Because of insufficient funds for carrying on the work and lack of cooperation on the part of the cattle owners, the results obtained at first were meager. But after ample proof of the feasibility of eradicating ticks from a given area was demonstrated, adequate funds were provided and plans were perfected for conducting the work on a larger scale.

A vigorous campaign ensued, and although numerous difficulties were encountered, public sentiment supported the work, which went steadily forward. On September 22, 1927, the last fever tick was found, and on December 1, 1927, the entire State was released from Federal quarantine. Of the States whose entire area was placed under fever-tick quarantine, South Carolina was the first to be freed from the ravages of this parasite.

Although cotton is still the chief staple crop and its price controls, in large measure, the interest taken in livestock raising, many farmers now see that their diversification plan must be put on a more permanent general program of farming. This plan includes livestock, particularly cattle. With thousands of undeveloped acres in South Carolina that can be used for stock raising, there are excellent prospects for deriving still greater benefits from tick eradication.

The steady progress of freeing the entire South from ticks and the fever which they transmit will probably cause a general readjustment in the areas of cattle production throughout the country. Accordingly, it is advisable for persons engaged or interested in that industry to make a close study of the trends and developments in States like South Carolina where noteworthy changes are now occurring.

W. K. LEWIS,
Veterinarian, Bureau of Animal Industry.

CATTLE Tuberculosis in Range Areas Is Yielding to Eradication Methods

Since 1884, when the Federal Bureau of Animal Industry was established, the United States Department of Agriculture has assisted the various States in conquering outbreaks of infectious livestock diseases. Accordingly, when in 1917 the time became ripe to wage a relentless campaign against tuberculosis in livestock, the department, in cooperation with the States, undertook to eradicate this insidious infectious disease which in some areas had gained a strong foothold.

The undertaking is commonly recognized by livestock sanitarians as the most stupendous task of its kind. The campaign was directed particularly against bovine tuberculosis, though attention has been directed likewise to the suppression of the same disease in swine and the problem, therefore, was to remove the cause by taking advantage of early experimental work that showed the feasibility of eradicating ticks on cattle, while still allowing the use of infested pastures and premises.

CATTLE Tuberculosis in Range Areas Is Yielding to Eradication Methods

Since 1884, when the Federal Bureau of Animal Industry was established, the United States Department of Agriculture has assisted the various States in conquering outbreaks of infectious livestock diseases. Accordingly, when in 1917 the time became ripe to wage a relentless campaign against tuberculosis in livestock, the department, in cooperation with the States, undertook to eradicate this insidious infectious disease which in some areas had gained a strong foothold.

The undertaking is commonly recognized by livestock sanitarians as the most stupendous task of its kind. The campaign was directed particularly against bovine tuberculosis, though attention has been directed likewise to the suppression of the same disease in swine and poultry. Through harmony and uniformity of effort, the cooperative campaign has brought about a steady decline in the prevalence of the disease. Whereas in 1920 the infection among cattle was 4.9 per cent, the corresponding figure in 1930 was 1.7 per cent. These percentages represent the average extent of the disease found in the tuberculin testing of both dairy and beef herds.

A New Undertaking in Range Livestock Areas

In the Eastern and Central States the use of the tuberculin test was already familiar to cattle owners when the cooperative campaign was launched. But in many of the Western States, especially in the extensive range areas, little had previously been done toward the control of the disease. In Idaho, for instance, the only tuberculin tests conducted had been made by private veterinarians within their own communities. This testing was performed either as a basis for interstate shipments of cattle or to comply with ordinances requiring the annual testing of dairy herds furnishing the milk supply. There had been little tuberculin testing among the herds of range cattle.

As systematic tuberculosis eradication progressed in other States there developed among livestock breeders' associations in Idaho a sentiment for the active suppression of the disease on a more extensive scale than in the past. Accordingly, the Idaho Legislature, on appeal by breeders, dairymen, and others interested, enacted suitable laws for State cooperation with the Federal Government and also made adequate provisions for operating expenses and indemnity funds.

Early in 1919 the Federal and Idaho Departments of Agriculture began a vigorous campaign which involved first the testing of individual herds under the so-called accredited-herd plan. Briefly, this plan involved Federal and State recognition of herds as being free of tuberculosis when they had successfully passed two annual or three semiannual tuberculin tests. The circulation of accredited-herd agreements among herd owners brought a remarkable response, especially from dairymen who wished to have their herds accredited. After about three years of operation, this plan was found to be inadequate to bring about the expected degree of success. Since all herds in a neighborhood were not tested, there was difficulty in preventing reinfection of the accredited herds. Moreover, the accredited-herd plan was costing an average of 43 cents a head for the test, and it seemed desirable to reduce this cost if possible.

Range Herds Sometimes Infected Seriously

In 1922 the Federal and State Government forces adopted the county-wide or area plan, which involved the testing of all cattle within a designated area or county. This plan of eradication was accepted as a forward step by all cattlemen, except a number of range cattle owners who objected on the grounds that tuberculosis was not prevalent in range herds. However, these objectors failed to alter the program of the work outlined and, in a short time after area testing began, the results fully demonstrated that bovine tuberculosis existed among range cattle to an alarming extent. In fact, some of the range herds were affected more seriously than the dairy cattle in the same locality.

In a county-wide test conducted in October, 1922, the results revealed 93 infected range herds, containing 599 tuberculous animals, as compared with 4 infected dairy herds showing but 7 tuberculous animals. One herd of 368 range cattle contained 118 reactors to the tuberculin test, or approximately 32 per cent infection. On post-mortem, 12 of the reactors were found to be generalized cases or probable spreaders of the disease. In the same county another range herd, containing 898 cattle, had 122 reactors, or about 14 per cent infection. Of these animals 41 were found to be generalized cases of tuberculosis. These herds, of course, do not represent the general condition among range herds, but they demonstrated to the range cattlemen of Idaho that it is unsafe to consider range cattle free of the disease unless proved to be so by the tuberculin test.

In county-wide area testing, clearly defined plans are mapped out by the cooperating forces. Literature is distributed, and newspapers are furnished press articles concerning the program of work. Owing

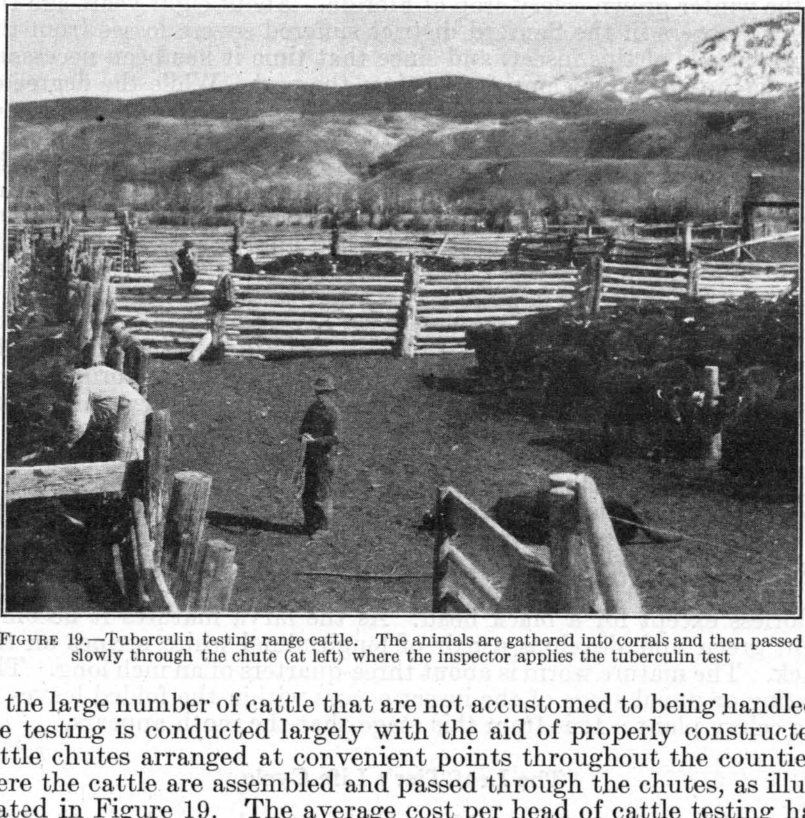

FIGURE 19.—Tuberculin testing range cattle. The animals are gathered into corrals and then passed slowly through the chute (at left) where the inspector applies the tuberculin test

to the large number of cattle that are not accustomed to being handled, the testing is conducted largely with the aid of properly constructed cattle chutes arranged at convenient points throughout the counties. Here the cattle are assembled and passed through the chutes, as illustrated in Figure 19. The average cost per head of cattle testing has been reduced from 43 cents per head, the figure under the accredited-herd plan, to 23 cents a head under the area plan.

This discussion has centered largely on developments of the work in Idaho, since that State has been one of the most successful in the systematic eradication of bovine tuberculosis in the range area. Of the 44 counties in the State, 35 have already been officially recognized as modified accredited areas, signifying the reduction of bovine tuberculosis to not over one-half of 1 per cent of all cattle.

From present indications Idaho will be practically free of bovine tuberculosis within a short time and will be the first of the Northwestern States to attain this goal. The livestock industry of the State recognizes that success in the production of animal products depends on healthy animals of high quality.

CELERY Leaf Tier Has Become Serious Pest in Parts of Florida

The celery leaf tier, *Phlyctaenia rubigalis* Hbn., a widely distributed native insect, has long been recognized as a pest of many greenhouse plants, but only in comparatively recent years has it attracted attention as a pest of the winter-grown celery crop of Florida. About eight years ago the celery growers in the Sanford district suffered severe losses from the depredations of this insect, and since that time it has been necessary to wage an intensive campaign against the pest. While the degree of infestation has varied from year to year, the presence of the insect has caused considerable concern to the celery industry.

The damage to the celery crop by the celery leaf tier is due to the feeding of the larvae or worms on the leaves and stalks of the plant. During the early development of the insect most of the feeding is done on the undersides of the leaves, but when approaching maturity the worms may devour the whole leaf. When about one-third grown they begin to knit or tie one or more leaves together. They prefer the most succulent parts of the plant and do a considerable amount of the feeding on the central leaves, thus causing ragged, unsightly stalks bearing considerable frass. Stripping to remove the worm-injured leaves is often necessary in order to obtain marketable plants, and many otherwise marketable stalks are discarded during harvest.

The adult of the celery leaf tier is a small brown moth, the female of which deposits its small, almost transparent eggs on the undersides of the leaves of the plant. The eggs may be deposited singly or in groups of 2 to 15 and slightly overlapping one another, having an arrangement and appearance in the larger groups simliar to that of a number of fish scales. When the worm first emerges from the egg it is almost colorless except for a black head. As the larva matures it becomes light green and develops a pair of longitudinal white stripes on the back. The mature worm is about three-quarters of an inch long. The resting or pupal stage of the insect occurs within the folded leaves of the celery plant. It is from this stage that the moth appears.

The Leaf Tier's Life Cycle

Under exceptionally favorable conditions for the development of the insect its life cycle may be completed in about 25 days. During the cooler months it may require a period of nearly three months from egg to adult. During the spring and late fall a generation of the worms will develop in a little over a month. The celery leaf tier usually disappears in late May or early June and does not appear again in the Sanford district until early in October, when fresh moths make their appearance in the earliest planted seed beds. Their appearance usually follows the first sudden drop in temperature after the mean tem-

From present indications Idaho will be practically free of bovine tuberculosis within a short time and will be the first of the Northwestern States to attain this goal. CELERY Leaf Tier Has Become Serious Pest in Parts of Florida

The celery leaf tier, *Phlyctaenia rubigalis* Hbn., a widely distributed native insect, has long been recognized as a pest of many greenhouse plants, but only in comparatively recent years has it attracted attention as a pest of the winter-grown celery crop of Florida. About eight years ago the celery growers in the Sanford district suffered severe losses from the depredations of this insect, and since that time it has been necessary to wage an intensive campaign against the pest. While the degree of infestation has varied from year to year, the presence of the insect has caused considerable concern to the celery industry.

The damage to the celery crop by the celery leaf tier is due to the feeding of the larvae or worms on the leaves and stalks of the plant. During the early development of the insect most of the feeding is done on the undersides of the leaves, but when approaching maturity the worms may devour the whole leaf. When about one-third grown they begin to knit or tie one or more leaves together. They prefer the most succulent parts of the plant and do a considerable amount of the feeding on the central leaves, thus causing ragged, unsightly stalks bearing considerable frass. Stripping to remove the worm-injured leaves is often necessary in order to obtain marketable plants, and many otherwise marketable stalks are discarded during harvest.

The adult of the celery leaf tier is a small brown moth, the female of which deposits its small, almost transparent eggs on the undersides of the leaves of the plant. The eggs may be deposited singly or in groups of 2 to 15 and slightly overlapping one another, having an arrangement and appearance in the larger groups simliar to that of a number of fish scales. When the worm first emerges from the egg it is almost colorless except for a black head. As the larva matures it becomes light green and develops a pair of longitudinal white stripes on the back. The mature worm is about three-quarters of an inch long. The resting or pupal stage of the insect occurs within the folded leaves of the celery plant. It is from this stage that the moth appears.

The Leaf Tier's Life Cycle

Under exceptionally favorable conditions for the development of the insect its life cycle may be completed in about 25 days. During the cooler months it may require a period of nearly three months from egg to adult. During the spring and late fall a generation of the worms will develop in a little over a month. The celery leaf tier usually disappears in late May or early June and does not appear again in the Sanford district until early in October, when fresh moths make their appearance in the earliest planted seed beds. Their appearance usually follows the first sudden drop in temperature after the mean temperature of the season has fallen to 77° F. or below. Sudden drops in temperature at this time of the year almost always follow rainstorms, so the celery leaf tier may be expected to appear when the mean temperature has fallen to 77° or below and is followed by rain. In an exceptionally hot and dry fall the moths may not appear until November and in an equally hot spring they may disappear early in May. It appears, therefore, that the most favorable conditions for the development of the insect are those which are favorable for the best growth of the celery plant.

There are normally four generations annually of the celery leaf tier in the Sanford district. When conditions are unusually favorable there may be an increase in the rapidity of development with an additional generation as the result. During the harvest of the crop, which extends from February to the middle of May, there is naturally a gradual concentration of the moths in the unharvested fields. If the development of the leaf tier is sufficiently rapid at this time to produce a generation of from one-half to full-grown worms in these fields before they in turn are harvested, economic damage results. Under average weather conditions at Sanford, the celery leaf tier is not expected to be an economic factor in the production of celery, but during periods of unusually high temperature during the winter and early spring months injury is serious.

In addition to the effect of temperature, there are other natural factors which are responsible for the limitation of the pest, such as parasites and migratory birds. The most effective parasite is an egg parasite (*Trichogramma minutum* Riley) which is active during the summer, fall, and spring. Its most valuable contribution to the control of the leaf tier is made during the first generation in the fall and again during the spring when the population of moths is at its peak. There is a succession of birds in the celery fields and they account for a large number of larvae and moths. This is especially true of the migratory birds which pass through in the spring of the year. There are cases where birds are plentiful enough to keep the celery tier entirely under control in a normal year in the isolated fields, especially those adjoining woodlands.

Control Measures Often Necessary

In addition to the natural factors which function to keep the celery leaf tier under control, it is often necessary to resort to artificial measures in order to prevent severe damage to the crop. Much can be accomplished by a systematic scheme of planting and harvesting with the object of avoiding the usual concentrations of moths in the later harvested fields. Many growers now recognize this possibility and plan their plantings so that the crop can be harvested in such a way that there will be intervening harvested fields between the celery being harvested and that to be cut later. If the season has been warm and the pest has developed in large enough numbers to cause economic loss to the late celery, it is necessary to employ some means of reducing the infestations. Arsenical poisons are not recommended because of the possibility of excessive residues on the marketable product and the difficulty of reaching the worms with these poisons. Dusting with finely ground pyrethrum dust of a good quality has given excellent results, when this dust is applied in such a way that it is distributed in the central parts of the plants. In order to obtain a satisfactory distribution of the dust it is necessary to place the nozzles of the duster so that they will pass through the plants and deposit the dust on the innermost leaves. The treatments should be directed at the immature worms, as they are more susceptible to the action of the pyrethrum than the mature ones. Treatment for the celery leaf tier should consist of two applications about 30 minutes apart, each requiring 25 pounds of the dust per acre. The dust is usually employed without dilution, but equally good results may be obtained with equal parts of pyrethrum and lime, provided the mixture is made just before the dusting is done.

CHAYOTE, Tropic Cucurbit, Finds Wider Market as It Becomes Better Known Increasing interest in the growing of chayotes for home use and for local markets has been noted during the last few years in the lower South, especially Florida. Stimulated by the efforts of home demonstration workers, housewives are finding this cucurbit native of Central America, which has adapted itself to our Gulf coast and southern California, a welcome addition to the table. Food caterers in general, too, are becoming better acquainted with this little-known vegetable that comes on the market at a season when the usual variety is somewhat reduced.

The marketing of the increasing crops of chayotes has not been unattended with difficulties for the producer. Their efforts, though, are being rewarded, for chayotes now are appearing in season in northern as well as in southern markets. A growing acquaintance among consumers has brightened the market outlook for the crop, and the chayote is now winning for itself a place that is likely to be permanent in the public esteem.

The chayote (pronounced chī-ō′tĭ—ch as in chime) is usually a late autumn crop, though sometimes a late spring crop also is produced. It is unique in form and structure, and, what is much to the point in a food product, it is attractive in appearance as well as pleasing in texture and of delicate flavor. Botanically the chayote is related to the squashes and the cucumber, but from the mature fruit alone one would not suspect the relationship. The "fruit" is more or less pear shaped and is somewhat flattened laterally. The vegetable has long been grown in a small way in a number of localities in the South and in southern California, where it has been known under different names, such as mirliton, vegetable pear, and mango squash.

Has Varied Table Uses

The adaptability of the chayote as a table vegetable is one of its outstanding characteristics. It lends itself to a wider range of methods of preparation than most of the more familiar vegetables. Chayotes usually are more easily pared after slicing, crosswise or lengthwise. The single large seed is usually cooked and eaten with the rest of the vegetable. In slices or cut into dice, the vegetable is cooked in not exceeding 15 or 20 minutes. It is best boiled in just enough salted water to cook it. A little sugar is sometimes added. Two popular that they will pass through the plants and deposit the dust on the innermost leaves. The treatments should be directed at the immature worms, as they are more susceptible to the action of the pyrethrum than the mature ones. Treatment for the celery leaf tier should consist of two applications about 30 minutes apart, each requiring 25 pounds of the dust per acre. The dust is usually employed without dilution, but equally good results may be obtained with equal parts of pyrethrum and lime, provided the mixture is made just before the dusting is done.

A growing acquaintance among consumers has brightened the market outlook for the crop, and the chayote is now winning for itself a place that is likely to be permanent in the public esteem.

The chayote (pronounced chī-ō̆′tĭ—ch as in chime) is usually a late autumn crop, though sometimes a late spring crop also is produced. It is unique in form and structure, and, what is much to the point in a food product, it is attractive in appearance as well as pleasing in texture and of delicate flavor. Botanically the chayote is related to the squashes and the cucumber, but from the mature fruit alone one would not suspect the relationship. The "fruit" is more or less pear shaped and is somewhat flattened laterally. The vegetable has long been grown in a small way in a number of localities in the South and in southern California, where it has been known under different names, such as mirliton, vegetable pear, and mango squash.

Has Varied Table Uses

The adaptability of the chayote as a table vegetable is one of its outstanding characteristics. It lends itself to a wider range of methods of preparation than most of the more familiar vegetables. Chayotes usually are more easily pared after slicing, crosswise or lengthwise. The single large seed is usually cooked and eaten with the rest of the vegetable. In slices or cut into dice, the vegetable is cooked in not exceeding 15 or 20 minutes. It is best boiled in just enough salted water to cook it. A little sugar is sometimes added. Two popular ways of serving diced chayotes are with butter melted over them and with a prepared sauce. They may also be mashed and served like squash. Mashed or in slices they are used in various types of fritters, and when sliced—either raw or previously boiled—may be plain fried.

The chayote has a remarkable texture for a vegetable of the squash family, in that it still holds its form perfectly after being cooked. The distinctive texture is, of course, lost in the mashed vegetable. The flavor of the fresh-cooked chayote is delicate and resembles that of summer squash. Some persons detect in it a flavor suggestive of stewed oysters.

Besides being prepared in the ways already mentioned, the chayote may be stuffed and baked, or, after boiling, used cold in salads. A delectable sweet pickle is made from it, and exhaustive tests have shown the young chayote fruits to be well adapted for commercial dill pickling. A much larger supply will be necessary, however, before commercial pickling is possible.

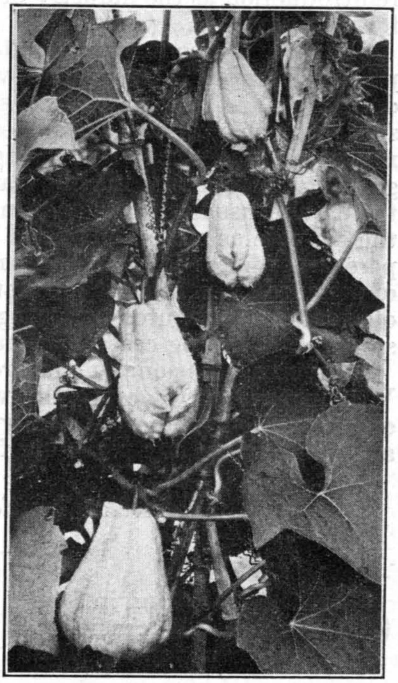

FIGURE 20.—Ivory white chayotes in different stages of growth. The largest is mature and is about 5 inches in length

The typical form of the chayote is pear shaped, but the deviation from the typical among the varieties known is quite as great as among varieties of pears. The range is from nearly spherical to slender pyriform. The surface may be more or less deeply corrugated or perfectly even and may vary from "as smooth as an apple" to "as spiny as a hedgehog." Needless to say, the spiny or deeply corrugated varieties are undesirable from the standpoint of convenience in handling and preparation for cooking, and so are not commonly cultivated. Indeed, few of the many types are as yet in regular cultivation in this country.

The diversity in shape and character of fruit is no greater than that in size. Varieties with mature fruits as small as 3 ounces each and others with individual weights up to 3 pounds are known, and some of these have been grown in Florida.

In color, chayotes are usually light green, but there are varieties that are ivory white (fig. 20) and also dark green. The flesh is always light colored but tends to follow the color of the skin.

Not a New Crop

What has been said of range in chayote fruit characters—especially when it is added that the different types originated under very primitive methods of culture—will suggest a comparative antiquity for the crop. It may fairly be assumed to be as old as the oldest civilization of the Central American region, which may be at least two or three milleniums. It is evident, then, that this "new" vegetable is new only because our acquaintance with it here is short. It is grown throughout the American Tropics and in many of the warmer parts of the Old World. Chayotes constitute a staple food for many people in Guatemala and other Central American countries. The root, which becomes tuberlike after the first season, is starchy and is boiled and eaten. It is called "ichintal" in Guatemala and "chinchayote" in Mexico.

Encouragement to the chayote industry has been given by the United States Department of Agriculture in former years by introducing and furnishing to interested farmers and gardeners many superior types of chayotes. Most of these have since been lost and will require reintroduction as the industry in the South grows and a need develops for new varieties.

Chayotes are commonly planted in the spring. The entire fruit is placed shallowly in the ground, with the broad (blossom) end slanting downward and with part of the stem end left above the surface of the soil. The chayote leaf resembles that of the cucumber or the muskmelon, but the vine is a more vigorous grower and is a climber. It is grown on a trellis and may be trained on a porch. As the plant is frost tender and usually fruits only in the fall, the successful cultivation of the chayote as a crop is limited to the far South. The fleshy root is perennial where the ground does not freeze, and it increases to a number of pounds in weight after the first year. When early vine growth from old roots is not injured by spring frost, a crop may be produced in the spring. Flowering ceases as a rule during the summer.

Chayotes occasionally mature in small numbers as far north as Washington, D. C., especially when the first autumn frost does not occur until November. Usually, however, in such localities the vines are killed before any fruits are fully grown.

CHEESE Making in Some Sections Necessitates Pasteurization of Milk

The importance of pasteurization of milk for cheese making was not generally recognized in a commercial way until the manufacture of cheese was taken up in the Southern and some of the Western States. Cheese of good quality is being made from pasteurized milk in these sections where it would not be practical to operate cheese factories if milk were not pasteurized. Practically all of the larger factories are using the flash pasteurizer and regenerative heater and cooler. During the summer months, to get the best results, milk is heated to 165° F. and occasionally to 170°. In some instances, when starting the pasteurizer the first milk which goes through is not heated to the proper temperature. Unless the pasteurizer is equipped with an automatic control oftentimes the temperature drops below pasteurizing temperature if not watched constantly. In either case the milk is not all pasteurized and the result is a gassy cheese if the raw milk happened to be contaminated with gas-producing organisms. When using a flash pasteurizer it is important to know that the milk has all been heated to the proper temperature.

CHEESE Making in Some Sections Necessitates Pasteurization of Milk

The importance of pasteurization of milk for cheese making was not generally recognized in a commercial way until the manufacture of cheese was taken up in the Southern and some of the Western States. Cheese of good quality is being made from pasteurized milk in these sections where it would not be practical to operate cheese factories if milk were not pasteurized. Practically all of the larger factories are using the flash pasteurizer and regenerative heater and cooler. During the summer months, to get the best results, milk is heated to 165° F. and occasionally to 170°. In some instances, when starting the pasteurizer the first milk which goes through is not heated to the proper temperature. Unless the pasteurizer is equipped with an automatic control oftentimes the temperature drops below pasteurizing temperature if not watched constantly. In either case the milk is not all pasteurized and the result is a gassy cheese if the raw milk happened to be contaminated with gas-producing organisms. When using a flash pasteurizer it is important to know that the milk has all been heated to the proper temperature.

The advantages of a flash pasteurizer are that as soon as the milk starts coming in the pasteurizer can be started, and the acidity does not have a chance to develop while the rest of the milk is being received. Also, more milk can be handled in less time than when the holder method is used. The surface heater regenerative type of pasteurizer is not practical in parts of the country where occasionally the acidity of the milk will exceed 0.22 or 0.23 per cent. In such cases the milk will cook on the surface of the heater and form an insulation, after which it is difficult to heat the milk to the proper temperature.

Some of the smaller factories are pasteurizing in the cheese vat. The vat system is very satisfactory and there is no additional expense for pasteurizing equipment unless the water is so warm that it is necessary to use a surface cooler. In such cases it is necessary to pump the milk from the cheese vat over the cooler, allowing it to run from the cooler back to the cheese vat and continue this process until the milk is cooled to setting temperature. When milk is pasteurized in the vat it is heated to 145° F. and held for 30 minutes. To save time heat may be turned on the vat soon enough so that when the last batch of milk is dumped the temperature of the milk in the vat is at 145°. It is then held at this temperature for 30 minutes before starting to cool. Some cheese makers waste their efforts by starting to cool as soon as the milk is all in, because the temperature has been up to 145° for 30 minutes. When this is done the milk that was dumped last is not pasteurized. This is about the only thing that can happen when pasteurizing in a vat which may cause a gassy or fast-working curd. The vat system of pasteurization makes it possible for small factories to operate in sections where it is not practical to manufacture cheese from unpasteurized milk. It is very important that all the milk be held at a temperature of 145° for the full 30 minutes.

Amount of Starter Required

The amount of starter to use depends upon the acidity of the milk and the time allowed from time of adding starter until setting. Usually 0.75 to 2 per cent is sufficient, if added from 30 to 60 minutes before setting. The acidity of the milk at setting depends upon the acidity of the milk before any starter was added. The acidity of the milk at setting should be 0.01 per cent to 0.02 per cent higher than it was before starter was added. In other words if the unripened milk has 0.18 per cent acidity it should be ripened to 0.19 or 0.20 per cent before adding rennet. If the unripened milk has 0.22 per cent acidity the rennet should not be added until the acidity has increased to 0.23 or 0.24 per cent. This, of course, depends upon the amount of starter used and the time allowed from time of adding starter to setting. Only enough starter should be used to develop from 0.24 to 0.26 per cent acidity in the whey draining from the curd at packing, which should be about 2 hours and 40 minutes from time of adding rennet. The amount of acid in whey at dipping depends upon the amount of milk in the vat and the time required to draw it off. It usually should have from 0.15 to 0.18 per cent. After the milk has been properly ripened the same method that makes a good cheese from unpasteurized milk will make a good quality of cheese from pasteurized milk.

Add enough rennet to make curd ready to cut in 20 to 30 minutes, usually from 3 to 4 ounces per 1,000 pounds of milk. Two and one-

40442°—31——10

half times the time from adding rennet until first signs of coagulation will equal the time the curd should stand from the time the rennet was added until cutting.

CHICKS May Be Fed Soon After Hatching, Thereby Aiding Yolk Absorption During its development in the egg, the chick embryo uses only a part of the yolk. Just before the chick emerges from the shell, it takes the remainder into its body and then gradually assimilates it. Although the time required to absorb the yolk varies somewhat with the individual, most healthy chicks complete this process by the eleventh day after hatching.

Before fowls were domesticated, it is possible that the baby chick was unable to obtain any other food, and the assimilation of the yolk prevented starvation for several days. This provision of nature is one of the principal factors making possible the development of mammoth hatcheries. As chicks need not be fed for two or three days after hatching, they may be shipped long distances.

It has been generally believed that chicks not only do not require food for some time after hatching, but also that early feeding interferes with the normal assimilation of the egg yolk. This belief has been fostered by the discovery of unabsorbed yolks in chicks which had been fed early, and which had subsequently died or were experiencing digestive troubles. These observations led to definite recommendations that chicks should not be fed until they were from 36 to 72 hours old.

Experimental data that substantiate or refute these recommendations, however, have been meager. Accordingly, an experiment was conducted at the United States Poultry Experiment Station, Glendale, Ariz., to determine whether the age at which chicks were first fed influenced yolk absorption. Different groups of chicks were first fed mash or grain 24, 48, and 72 hours, respectively, after hatching. The results obtained showed no significant difference among the chicks in these groups. It was noted, however, that early feeding tended slightly to stimulate yolk assimilation.

The results obtained are in general accordance with those obtained elsewhere. Roberts, an investigator at Purdue University, found that chicks may be fed as soon as they are fluffed out without influencing either the rate of growth or the mortality. At the University of California, Parker found no significant difference in the rate of yolk absorption between groups of chicks first fed when 24 and 72 hours old.

Practical experience has shown that it is not harmful to withhold feed from baby chicks for two or three days, as often happens when they are shipped. However, when conditions permit it, it is advisable to feed chicks earlier.

CHILD-WELFARE Studies Important in Work of Home Economics Bureau The work of the Bureau of Home Economics makes an important contribution to child welfare. This is a natural result of the interrelationship between the care of children and other phases of the homemaker's responsibilities. As an agency dealing with homemaking problems, the Bureau of Home Economics logically concerns itself with the needs of children. Members of its staff contributed to the deliberations of committees and subcommittees of the recent White House Conference on Child Health and Protection. An outline of their contributions to these discussions will indicate the scope of the bureau's child-welfare work.

For example, material was furnished on budgeting for the needs of children of different ages. Data on this subject were obtained from surveys made by the bureau and from standards proposed by home-demonstration leaders in conference with community women. It is well established that budgeting, besides promoting economy, enables the home maker to satisfy more adequately the family's requirements. Budgeting for the children is an important part of the budgeting task. Typical budgets for the different needs of children are being prepared by the bureau for the President's Committee on Unemployment.

Besides planning the expenditure of money for the needs of children, the home maker must consider also the time she must expend in their care. Time schedules have been drawn up in the bureau to provide for the care of children based on detailed information obtained in hundreds of homes. Planning the expenditure of time is as great an aid to economy and efficiency as planning the expenditure of money. Representatives of the bureau worked with the White House conference committee on housing to establish standards for housing which would safeguard and promote the health and development of young children. House plans and equipment were suggested for the typical home to simplify the work of the mother with young children. Also, changes were suggested for the equipment in the home already established which would make possible the larger participation of children in the home activities and make that home a more comfortable and happy place for the younger members of the family.

The studies reported by the White House conference emphasize the importance of satisfactory environmental conditions as a factor in child welfare. They show that it is important, but it is not enough, that the home should be smoothly managed. Esthetic values play a part in the personality development of the child. A home background that satisfies the demands of good taste as well as the demands of efficiency may contribute to the development of both parents and children. The bulletins on home furnishing from the bureau have been prepared to do just this.

Relation of Clothing to Health

Other material gathered in the bureau was put before the conference in discussions of the relation of clothing to the health and training of children. A monograph on this subject will shortly be published, but further research is needed, especially on the relation of clothing to health. The bureau has prepared simple designs for children's clothes. These designs combine what is known about health needs in clothing with simplicity and artistic qualities. They help children to become independent in dressing and undressing at an early age. Circulars written on this subject by members of the bureau are available.

Aided by a research assistant and a secretary made available by the conference, the bureau worked with other agencies in a broad study of home activities in relation to child development. One result of this study is a bibliography on the family, which will be published shortly. This bibliography will be issued in a series of similar publications prepared in the Bureau of Home Economics. The conference's committee on family and parent education is preparing, with the assistance of members of the bureau, a number of monographs on the family and on home activities in relation to child development. It has drawn up a plan for the study of family functions and activities. This is a field of research in which home economics must participate if these studies are to develop better homes and better family relationships.

It was repeatedly emphasized at meetings of the conference committees that better facilities are necessary for informing parents as to the results of child-welfare research. The Bureau of Home Economics has done what it could in this direction. Especially in the field of child training it is important to make available to the mother results of the findings of psychology and sociology as they apply to child training. A start has been made, as for example, in a study recently completed by the bureau on children's food habits. In child nutrition psychology as well as diet is important. In the last resort the child-welfare problem comes to embrace the larger problem of establishing satisfactory home conditions and family relationships. This might be said to be the center toward which all the work of the bureau is aiming.

LOUISE STANLEY,
Chief, Bureau of Home Economics.

CHOCOLATE Processing Regulated By U. S. Under Pure Food Law

There were imported into the United States in 1929 over one-half billion pounds of cacao beans, the raw material of the chocolate industry. This enormous volume represents some 40 per cent of the world's production and marks an increase of about one-third in American consumption since 1924.

Control of Imports

From Africa, Asia, South and Central America, and the West Indies come shiploads of cacao beans, and it is at the debarkation point that the Department of Agriculture starts its regulatory supervision. If the beans have been improperly handled during the fermentation process, which develops the characteristic flavor, they become moldy. More rarely, they may be infested with the larvae of the cocoa moth, or other vermin. Such infestation may occur either in the country of origin or in American storage warehouses. All such shipments are detained until they are made fit for food by sorting, or else they are destroyed or reexported. During the year 1929, over 138,000,000 pounds of cacao beans were examined by department inspectors at Atlantic-coast ports alone, and about 4.3 per cent of the total were denied entry because of a wormy or moldy condition.

CHOCOLATE Processing Regulated By U. S. Under Pure Food Law

There were imported into the United States in 1929 over one-half billion pounds of cacao beans, the raw material of the chocolate industry. This enormous volume represents some 40 per cent of the world's production and marks an increase of about one-third in American consumption since 1924.

Control of Imports

From Africa, Asia, South and Central America, and the West Indies come shiploads of cacao beans, and it is at the debarkation point that the Department of Agriculture starts its regulatory supervision. If the beans have been improperly handled during the fermentation process, which develops the characteristic flavor, they become moldy. More rarely, they may be infested with the larvae of the cocoa moth, or other vermin. Such infestation may occur either in the country of origin or in American storage warehouses. All such shipments are detained until they are made fit for food by sorting, or else they are destroyed or reexported. During the year 1929, over 138,000,000 pounds of cacao beans were examined by department inspectors at Atlantic-coast ports alone, and about 4.3 per cent of the total were denied entry because of a wormy or moldy condition.

Regulation of Manufacturing Process

The cacao beans are first screened to remove gross débris, such as sticks, stones, etc., and then roasted, crushed into nibs, and winnowed or fanned to remove excess shell. It is important that manufacturers see to it that the winnowing process is so conducted, especially with regard to the adjustment of the winnowing machine, that excess shell will be removed.

Cacao shell has a market value of about $5 a ton and is used chiefly as a conditioner for commercial fertilizers and in the preparation of proprietary feed mixtures. Some is used for fuel. About 51,000,000 pounds of cacao shell are estimated to be produced in the United States annually. This estimate is based on an assumed shell content in the bean of 10 per cent, with no allowance for shell contained in cocoa press cake, a by-product resulting from the pressing of the cacao bean without removal of the shell. When efficient machinery is used and proper control is exercised, the shell content of the winnowed cacao nibs will be negligible. Both chemical and microscopical methods are employed in determining, by laboratory examination, the proportion of shell in cacao products. Those found to contain excess shell, whether due to improper adjustment of the winnowing machine or to deliberate addition, are subject to action under the food and drugs act, which provides for criminal prosecution of the shipper and seizure of the adulterated food products themselves. Several shipments of cocoa containing excess shell were the subject of regulatory action in 1929.

After the cacao nibs are cleaned, they go through various grinding and milling processes which result in the production of plain chocolate, sweet chocolate, milk chocolate, and cocoa products. The chocolate products are of two general classes: Those used directly for eating and cooking purposes, and the so-called coatings, used to coat candy centers, such as cream, nougat, caramel, marshmallow, fruit jelly, and nuts. Coating is done by hand dipping or by a machine known as an enrober.

Required Fat Percentage

These chocolate products must contain not less than 50 per cent of cacao butter, or fat, in the chocolate ingredient. Breakfast cocoa must contain at least 22 per cent of cacao fat. Since cacao butter is a valuable food, it is important that manufactured cacao products contain their full complement of this ingredient. Cacao butter is sometimes replaced in part by a cheaper vegetable oil, such as hydrogenated coconut oil, especially in chocolate coatings. When the coconut oil, or other foreign fat, is pure and wholesome, there is no objection to its use, provided the manufacturer plainly discloses this fact on the label. Occasionally the manufacturer neglects to make this declaration. In 1929, ten instances of the use of undeclared foreign fat were uncovered and appropriate measures taken to correct the violations.

Dutch Process

"Dutching" has become a very popular trade practice in the chocolate industry. It consists of treating cacao beans, nibs, chocolate liquor, and cocoa with alkalies. The finished products are called "Dutch-process chocolate (cocoa)" or "alkalized chocolate (cocoa)." The alkalies used are potassium carbonate or some other similar substance. These alkalies may be added at various stages of manufacture.

The treatment darkens the chocolate and cocoa. The alkali is neutralized and does not appear as such in the treated chocolate or cocoa, which has an acid reaction. But because the alkali treatment materially changes the character of chocolate and cocoa, consumers are entitled to know when alkalies have been used. The words "Dutch" or "Dutched" are the consumers' guide. "Dutched" chocolate and cocoa contain, under the Department of Agriculture standard, no more than 3 parts, by weight, of potassium carbonate, or the neutralizing equivalent thereof in other alkaline substances, in each 100 parts, by weight, of cacao nibs. When more alkali than this is used, the label must state this fact. It was once erroneously believed that alkalies increased the solubility of cocoa or chocolate. This has not proved to be the case.

Mixtures of Cacao and Milk Products

Under the department's standards and definitions for sweet milk chocolate and sweet milk cocoa, these products should contain not less than 12 per cent of whole-milk solids. As in the case of cacao butter, milk solids are a comparatively expensive ingredient, and commercial samples of milk chocolate and sweet milk cocoa are sometimes found containing less than 12 per cent of milk solids. Skim-milk solids are also occasionally substituted for whole-milk solids. This latter form of adulteration is especially prevalent in the powdered beverage preparations used in the making of so-called hot chocolate, which is really hot cocoa in most instances. Skim-milk powder when pure is, of course, a wholesome ingredient, and its use is legitimate under proper labeling. Nor is there any objection to the use of cocoa in place of chocolate, if the label shows the product's true character. Cocoa is chocolate deprived of a portion of its fat, and pulverized. The department holds that the labeling should clearly distinguish between the two products.

Net Weight of Chocolate Candy

Chocolate candy is a relatively high-priced food commodity, and since enormous quantities of it are sold, it is important that the accuracy of the statement of quantity of net contents, which must appear on the package, be checked frequently. The food inspector can do this best in the candy factory, where dozens of individual packages can be weighed without the necessity of buying them on the open market. If the inspector finds short-weight packages, he locates interstate shipments of the misbranded products with a view to legal action.

J. W. Sale,
Senior Chemist, Food and Drug Administration.

CLOTHING Costs Among 1,425 Farm Families Reported in Survey

"Clothes for every occasion" becomes a complicated problem when there are growing children in the family and many demands on the family pocketbook. The only way of solving the clothes problem so that things seem fair to everybody is to make careful plans, taking into consideration the total amount of money the family will have to spend not only on clothing needs but on other urgent needs before the actual purchasing is done.

The treatment darkens the chocolate and cocoa. The alkali is neutralized and does not appear as such in the treated chocolate or cocoa, which has an acid reaction. But because the alkali treatment materially changes the character of chocolate and cocoa, consumers are entitled to know when alkalies have been used. The words "Dutch" or "Dutched" are the consumers' guide. "Dutched" chocolate and cocoa contain, under the Department of Agriculture standard, no more than 3 parts, by weight, of potassium carbonate, or the neutralizing equivalent thereof in other alkaline substances, in each 100 parts, by weight, of cacao nibs. When more alkali than this is used, the label must state this fact. It was once erroneously believed that alkalies increased the solubility of cocoa or chocolate. This has not proved to be the case.

Mixtures of Cacao and Milk Products

Under the department's standards and definitions for sweet milk chocolate and sweet milk cocoa, these products should contain not less than 12 per cent of whole-milk solids. As in the case of cacao butter, milk solids are a comparatively expensive ingredient, and commercial samples of milk chocolate and sweet milk cocoa are sometimes found containing less than 12 per cent of milk solids. Skim-milk solids are also occasionally substituted for whole-milk solids. This latter form of adulteration is especially prevalent in the powdered beverage preparations used in the making of so-called hot chocolate, which is really hot cocoa in most instances. Skim-milk powder when pure is, of course, a wholesome ingredient, and its use is legitimate under proper labeling. Senior Chemist, Food and Drug Administration.

Clothing Costs Among 1,425 Farm Families Reported in Survey

"Clothes for every occasion" becomes a complicated problem when there are growing children in the family and many demands on the family pocketbook. The only way of solving the clothes problem so that things seem fair to everybody is to make careful plans, taking into consideration the total amount of money the family will have to spend not only on clothing needs but on other urgent needs before the actual purchasing is done.

The Bureau of Home Economics has made a detailed analysis of the yearly clothing purchases of 1,425 farm families in different parts of the United States. The figures were collected in cooperation with the State colleges of agriculture in 11 States in 1922–1924. Though the average practice of a large number of farm families will not, perhaps, fit any particular family's problem, at least it is valuable to know how the plans of any one family differ from the practices of families in general.

The average annual clothing expenditures of all the families from whom figures were collected represented $222, or 25 per cent of the total amount of money spent by those families in the given year, not taking into account the money value of food, fuel, and rent furnished by the farm. There were, however, important variations in the proportion of the family funds going to clothes. In families of husband and wife only $127, or 19 per cent of the total expenditure, was used on the average to buy clothes. In families of husband and wife and one to three children under 21, average expenditures for clothing rose to $209, or 25 per cent of the total. Whereas in families of husband and wife and four or more children the figure is $275, or 27 per cent of the total expenditures. In families of five persons or less that included one or more adults besides the operator and home maker as part of the family group, clothing expenditures averaged only $244, but the proportion of the total money expenditure spent for clothing was also 27 per cent. The proportion rose to 33 per cent in families of this type when the number of persons in the family increased to six or more, and expenditures increased to an average of $380.

Clothing Ratio Less as Income Increases

As the income increases, it is natural to find the number of dollars spent for clothing increasing also. But there are so many other claims upon the added income that clothing expenditures do not increase so rapidly as other items in the family budget.

For instance, there are reports from 611 families of father, mother, and one to three children. Among families of this size, the group reporting the lowest incomes spent on the average 26 per cent of the total amount of money used by the family for clothes, while the group with the highest incomes spent only 22 per cent for clothes. The amount of money spent had increased, but the proportion had somewhat declined.

The highest proportion shown for any one group occurs in the case of 40 families with an average size of seven persons, each family including at least one adult beside the farm operator and home maker. For these families total money expenditures averaged $779, and 37 per cent of this amount ($292) went for clothing.

Homemade Clothing

In 5 of the 11 States included in the study (Alabama, Massachusetts, Nebraska, New Hampshire, and Vermont), the reports show for the year the number of new garments purchased ready to wear and the number made at home. The prices paid for the ready-to-wear garments and the cost of the materials for the garments made at home are also given.

Very few garments are being made at home for the men and older boys of these families and not many for boys from 6 to 14 years old.

A considerable number are reported as homemade for small boys, however, and for women and girls. The garments made most frequently for the larger boys are school, work, and play blouses. The proportion of new blouses which were homemade for boys between 12 to 14 declines from 80 per cent in the lowest income group to 10 per cent for boys the same age in the highest income group. For boys 3 to 5 years of age the report shows that more than half of the blouses, rompers, suits, and underwaists were being made at home, but 82 per cent of their overcoats and 91 per cent of their overalls were purchased ready to wear.

A majority of the garments for babies and for children of both sexes under 3 years of age were reported as made at home. At least half of their caps, suits, cotton dresses, silk dresses, panties, and underwaists were made at home for the babies and very small children, and almost half of their coats and capes and rompers.

The output of factory-made clothing for women has increased tremendously since 1900. Nevertheless home makers still find making a large proportion of their clothes one of the best ways of utilizing home skills to increase the number of things the family can have on a given amount of money income. The kinds of new garments for women and girls made at home in half or more of the cases reported, are as follows: Aprons, cotton and wool dresses, slips and petticoats, chemises and combinations, drawers and bloomers, nightgowns, pajamas, and kimonos. Almost half (49 per cent) of all new silk dresses were also reported as homemade.

Money Cost of Garments Made at Home

The reports from which these figures are taken give no indication of the relative quality of material, or of the cut and fit of the homemade as compared with the ready-to-wear garments, or of the time consumed by the women who made clothes for themselves and their children. It is possible, however, from the figures available to compare the average money cost to the family of homemade and factory-made clothes of different types. In general, as might be expected, the money cost of the homemade garments was much less than of those purchased ready to wear. In some few cases, however, the average cost of materials for garments made at home was greater than the average cost of purchased garments of the same kind for women and for girls of a given age. In these instances it seemed clear that the persons who had made the garments at home had secured clothes of quite different material from that utilized in the garments of the same type purchased ready to wear. Silk dresses made at home averaged in money cost a little more than half the average price paid for silk dresses factory made. Garments for which the average cost of materials was 45 to 75 per cent of the average price paid for the same kind of articles purchased ready to wear are as follows: Aprons, cotton, wool, and silk dresses, blouses, outer bloomers and knickers, brassières and underwaists, chemises and combinations, and kimonos. The average cost of materials for cotton and wool skirts, nightgowns and pajamas, and underbloomers was from 75 to 90 per cent of the average prices for ready-made articles of the same kind.

In planning the family clothing budget, it seems obvious from these comparisons that it is worth while considering the sewing abilities of the women and girls of the family, and the amount of their time available for sewing, before deciding whether to purchase ready to wear or whether to make at home a certain proportion of the new garments needed.

COMMUNITY Development in Lake States Aided by National Forests Any community-development program must take into account the relation of the community to the natural resources of the surrounding region. The community develops as the region develops. Regional progress and the proper development of natural resources are interdependent.

Idle acres with the attendant tax delinquency and consequent slowing up of industrial development is one of the growing problems of the Lake States. This is a direct result of handling the natural resources of the region with no regard for the future. The 1930 census figures and tax levies reflect this influence very materially.

The forests of the Lake States with their varied resources will figure largely in any regional-development program. They furnish playgrounds for thousands of vacationists and nature lovers and are the storehouse of waters that feed our lakes and streams. If properly handled they will be the home of our fish and game forever. They furnish lumber, pulp for paper, and many other necessities of life. These resources must be perpetuated if Lake States communities are to prosper and develop.

The national forests of the Lake States are part and parcel of the community. They assert their influence directly or indirectly upon every individual and industry and upon the communities in general.

Stability is Promoted

Stability is essential for any community. The national forests, while they cover but a very small portion of the Lake States, demonstrate what can be done when idle lands are placed upon a productive basis. The timber is cut no more rapidly than it is grown, thus producing an annual crop, giving permanent industry requiring labor in the woods and at the mills, and creating additional markets for the products of agricultural lands. In addition, the timber is so harvested that the esthetic qualities and social values of the forest are not impaired, as these values are considered in the development plan of the forest. Planting is resorted to where fires have done irreparable damage.

Permanence is the byword of the forest officer in charge of the handling of this public property—a permanent supply of timber, permanent industry, permanent markets for agricultural products, permanent recreational values for the development of resorts, permanent areas where man may camp out in the open, and, last but not least, a permanent home for wild life.

The national forests of the Lake States permit of regional plans of development on a permanent basis and are a very important factor in the conservation program of the Lake States region which is now going ahead in a plan-wise manner.

CONCRETE Impaired in Quality if Sand Used Is Not Clean

In making concrete, consideration must be given a number of factors if the finished product is to give satisfactory service. Cleanness of the sand is one very important item that too often is overlooked, particularly in making concrete on the farm where the sand is used as it comes from a shallow local pit in which may be roots and more or less top soil.

A sand in which is evident much dirt, shale, or foreign material of any kind is undesirable for concrete although small quantities of finely divided silt and clay may or may not seriously affect its concrete-making qualities, depending upon the presence of other and more objectionable impurities.

Impurities in a sand that are sure to cause trouble are those of organic origin, either vegetable or animal matter. Unfortunately these may be present in sand that looks clean. Impurities of this nature prevent the proper setting of cement with the result that the concrete hardens very slowly or, in extreme cases, does not harden at all. Even though it hardens reasonably well, such concrete may never attain full strength and the surface will scale and wear away if it is used for a floor or walk. The blame for such difficulties is often wrongfully placed on the cement, the workmen, or the weather, when it may have been due entirely to impurities in the sand. Trouble of this type is readily preventable by properly testing the sand before mixing the concrete.

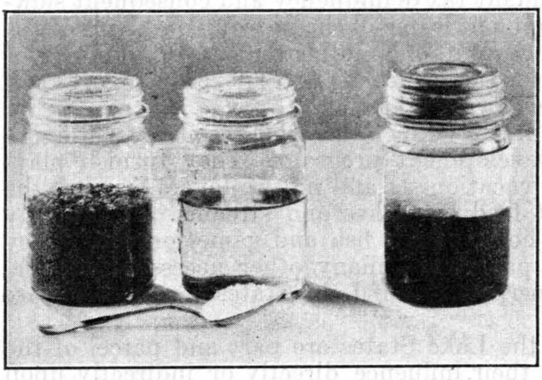

FIGURE 21.—Equipment and materials for testing concrete sand for impurities. Pint jar at left contains one-half pint of dry sand to be tested. Pint jar at center contains one-half pint of clear water. Teaspoon is heaping full of lye. Pint jar at right contains the three materials combined

Simple Test for Impurities in Sand

The following very simple test for organic impurities in sand may be made by anyone at practically no cost. It is believed the test is sufficiently reliable for ordinary practical purposes on the farm.

The necessary equipment consists of two 1-pint fruit jars with cover and rubber for one, and one teaspoon. (Fig. 21.) It is better to select jars of clear glass rather than that of a greenish or bluish cast.

The materials needed are as follows: (1) One can of household lye consisting, according to the label, of at least 94 per cent sodium hydroxide. It is desirable that the lye used be from a freshly opened can, although this is not absolutely necessary; (2) one-half pint of clean water, preferably some of the same water as will be used in mixing the concrete; (3) one-half pint of the dry sand to be tested. A half pint of water or sand will fill an ordinary pint Mason fruit jar to a depth of 2 inches.

Measure out 1 heaping teaspoon of lye and stir it into the half pint of water. The lye will thoroughly dissolve after stirring for a minute or two. Then pour the half pint of sand into the jar containing the half pint of water with the dissolved lye, put on the fruit jar rubber and cap and shake the sand and water vigorously for a minute or so and set aside to settle. Twenty-four hours later, examine in a good light the color of the water standing over the sand. If the water is clear, as will be the case if the sand is entirely free of organic impurities, or if discolored no darker than apple-cider vinegar, the sand is suitable for concrete while if the color is as dark as, or darker than, coffee as ordinarily made, the sand is unsuitable for concrete unless washed until the color is satisfactorily improved as indicated by testing again.

In judging the color, it is well to keep in mind that any such liquid as vinegar or coffee, viewed in a pint fruit jar of clear glass, will appear several shades lighter than as ordinarily viewed. If any doubt exists as to the color of the water standing over the sand as tested, fill one fruit jar of clear glass with vinegar and another with coffee and use for color comparisons. Use reasonable care in measuring all quantities as too great a variation from those given might appreciably change the results of the color test.

Washing Sand

If the local sand requires washing, and any considerable quantity is to be used, it will be cheaper and much more satisfactory in practically all settled communities to buy well-graded washed sand from a near-by commercial concern, than to attempt to wash the local supply, particularly if not well graded for concrete as is often the case.

If, however, it is desired to use the sand at hand, and a power-driven concrete mixer is to be used on the job, the mixer may be used to first wash the sand. To do so, a quantity of sand should be placed in the mixer, plenty of clean water added, and the mixer run for a few revolutions. The dirty water should then be run off. Ordinarily one washing will suffice but the operations may be repeated as often as necessary. Sand so washed may be dumped on to a stock pile to be used as required.

Washing sand for small quantities of hand-mixed concrete may be accomplished by liberally applying water at the upper end of an inclined platform of rough lumber on which the sand is spread in a thin layer. Such a platform may be 8 or 10 feet long with side and bottom boards 6 or 8 inches high and the upper end elevated 2 or 3 feet. This method is laborious and, except under special conditions, is suitable only for very small jobs.

Sand can not be washed satisfactorily by pouring water on it as it lies in the pile unless it be a very small pile on a platform from which the water can drain freely, as otherwise objectionable matter will only be transferred from one part of the pile to another. Washing sand in this manner rarely accomplishes the desired results.

Regardless of the method used, washing must continue until the sand passes the color test, for durable concrete can not be made unless the sand is clean.

Senior Drainage Engineer, Bureau of Public Roads.

COOKING Time Varies With Style in Which Beef Roasts Are Cut The style of cutting rib roasts of beef affects their shape and the amount of bone. Standing roasts contain more or less bone and are either rangy or chunky in shape, depending on the way the meat dealer saws off the rib ends. There are, moreover, many rolled roasts prepared from which the bones are completely removed. Whether the ribs are cut short or left long or are taken out altogether, it is the "eye," or the heavy meat portion, that has to be roasted to just the desired turn. Time and temperature are at the command of the cook, but how much time, even with a well-regulated oven, is not so easy for her to say.

The Bureau of Home Economics, working in cooperation with the Bureaus of Animal Industry and Agricultural Economics together with 25 State agricultural experiment stations, has detailed records on the cooking of 850 standing rib roasts of beef. Data are on hand covering the weight of each, a description of its appearance, the oven temperature used, the stage of cooking as shown by a thermometer in the meat itself, and the time each roast stayed in the oven. These records show considerable variation in the number of minutes per pound necessary to roast standing beef ribs to the stage of rare (140° F.), medium (160° F.), or well done (180° F.) at any given oven temperature.

To find how much cooking time varies with the style of the cut six pairs of 2-rib roasts were chosen and cooked. Three pairs were used in a comparison of length of rib bones, and the other three in a comparison of standing versus boned and rolled roasts. Before cooking, all the cuts were graded by representatives of the Bureau of Agricultural Economics. Two pairs of 2-rib roasts from one carcass were graded low medium, two pairs from another high medium, on the basis of the ribs only, and two pairs were cut from a carcass, stamped "U. S. Choice Steer."

All 12 roasts were cooked fat side up in open pans without added water. After 20 minutes searing in a hot oven (500° F.) the oven temperature was rapidly reduced to 300° F. and each roast cooked until it was rare, then medium, and finally well done. Time records were kept for each roast.

Standing Roasts With Short and With Long Ribs

Three pairs of the roasts were standing 12–13 ribs. The lefts were cooked as received from the market, with the ribs about average in length. From the corresponding right roasts several inches of bone were sawed off making them short and chunky. The comparative length of the ribs and the differences in weight of corresponding roasts are illustrated in Figure 22.

When the figures were averaged, the short cut roasts weighing 6 pounds were found to require 105 minutes to be rare, 143 medium, and 192 well done, while the corresponding long-ribbed roasts which weighed 7 pounds, cooked to the same stages in 103, 139, and 184 minutes, respectively. The small variations of 2 minutes at rare, 4 at medium, and 8 at the well-done stage are believed to be due to slightly different locations of meat thermometers in paired roasts. Apparently then, the length of the ribs had nothing to do with the total time required to cook these three pairs of standing roasts. When however, the cooking time was calculated as so many minutes to the pound, there was a difference.

The roasts which had been sawed off short required on the average 17 minutes to be rare, 24 medium, and 32 well done, against 15, 20, and 27 minutes per pound, respectively, for the corresponding roasts with long rib bones. These figures indicate that the time required to cook the heavy meat part of a standing roast is independent of the length of the ribs. The weight of the roast, however, is influenced by the way the ribs are cut, and so, other things being equal, short and chunky standing roasts require several more minutes to the pound than the long and rangy kind.

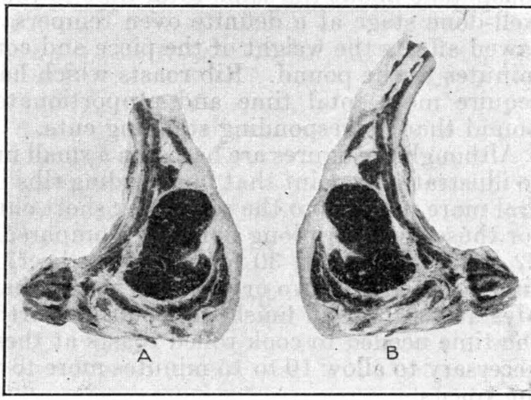

FIGURE 22.—A pair of corresponding right and left 2-rib standing beef roasts, A and B, respectively, which required practically the same total cooking time: A, with the short-cut rib bones, weighed almost 1 pound less than B. The number of minutes per pound cooking time was consequently greater for A than for B

Standing Roasts and Rolled Roasts

Of three pairs of 10–11 rib roasts from the same three carcasses as the 12–13 ribs above, the lefts were cut as standing roasts, and the rights were boned and rolled. (Fig. 23.)

The weights of the standing 10–11 rib roasts averaged 7.2 pounds. For the corresponding rolled roasts the average weight was 5.8 pounds. The standing cuts required 116 minutes to cook rare, 160 medium, and 228 well done, against 157, 206, and 289 minutes, respectively, for the corresponding rolled cuts. When the time is calculated as minutes to the pound, the standing roasts reached the rare stage in 16 minutes, medium in 23, and well-done in 33, in striking contrast to the rolled roasts, which required respectively 27, 37, and 51 minutes to the pound. These figures show a significant increase in the time required to cook rolled roasts, as compared with standing roasts, both as total time and as minutes to the pound.

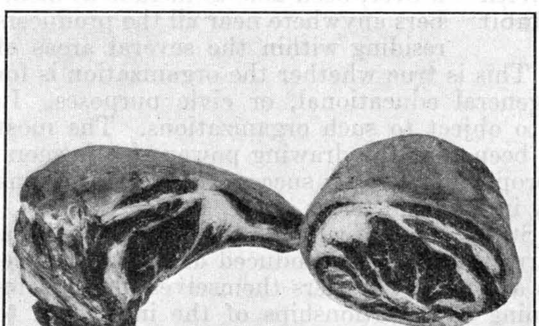

FIGURE 23.—The left rib roast standing, A, and the corresponding right ribs boned and rolled, B. Much shorter time was required to cook A than B, both in the total number of minutes and in the number of minutes per pound

Just why rolled roasts should cook so much more slowly than their corresponding standing roasts needs further study. It may be due in part to the greater thickness of meat in rolled roasts than in standing roasts.

Anyway the results of this study show that cooking time is influenced by the style of cutting rib roasts. While corresponding standing roasts take about the same total time to cook to the rare, medium, or well-done stage at a definite oven temperature, the way the ribs are sawed affects the weight of the piece and consequently the number of minutes to the pound. Rib roasts which have been boned and rolled require more total time and proportionately much more time per pound than corresponding standing cuts.

Although the figures are based on a small number of roasts they serve to illustrate the point that for standing ribs it is advisable to allow several more minutes to the pound for short chunky cuts and several less for those with very long bones, as compared with 16 minutes for rare, 22 for medium, and 30 for well-done beef, recommended as average time for standing two or three rib roasts that are seared 20 to 30 minutes at 500° F. and finished at 300°. Furthermore, when estimating the time needed to cook rolled roasts at these oven temperatures it is necessary to allow 10 to 15 minutes more to the pound than for standing roasts.

This simple illustration of a common source of variation in the time required to cook beef ribs furnishes a strong argument for a roast-meat thermometer. Whereas so many minutes per pound or so many minutes total time is not a sure guide to the stage of doneness of a roast, a thermometer properly placed in the meat itself and kept there during the cooking shows exactly when the meat is rare, medium, or well done.

COOPERATIVE Spirit of Farmers Varies With Schooling and Habit

Farmers' organizations have seldom, if ever, been able to include as members anywhere near all the producers residing within the several areas of activity of these bodies. This is true whether the organization is for marketing, purchasing, general educational, or civic purposes. In fact some farmers seem to object to such organizations. The most frequent explanation has been that the drawing power of a farmers' organization is roughly proportional to its success, the success being interpreted almost wholly in financial terms.

Recent surveys in five States, some of which were made in cooperation with the Federal Farm Board, have produced definite evidence, however, that differences among the farmers themselves play an important part in determining the relationships of the individual to farmers' organizations. These surveys include two farmers' associations that market potatoes and small quantities of other vegetables, two cooperative cotton-marketing associations, and one State farm bureau federation. The following summary gives some of the more significant findings concerning the human factor as related to these organizations. Unless otherwise stated, the situation is substantially the same for each of these organizations.

The greatest single difference among the farmers who were studied, when classified by their membership relations (members, ex-members, and nonmembers) to these organizations, is found in the amount of formal schooling that these groups of farmers have had. Thus, farmers who did not finish country school are much more likely to be nonmembers of local organizations. Those farmers who have obtained a high-school education or better are, on the whole, decidedly more likely to be members. Among the ex-members, or those who once joined these organizations but later ceased to be members, are but few who have received as much as high-school training. The majority of ex-members are men of very limited education. This situation is most marked in areas where differences in the schooling received by farmers are the greatest. Where but few farmers have even completed country school (as is true in some localities surveyed) the differences are not so striking, but they are present just the same.

Renters Less Cooperative-Minded

Renters, as a rule, are not as likely to be found on the membership rosters of the organizations surveyed as are owners. This is more characteristic of the farmers' marketing associations studied than it is of the general farmers' organization included in one of the surveys. Renters who are related by kinship ties to their landlords are, as a group, about as likely to join these organizations as are landowners. It is clearly at the lower rung of the so-called agricultural ladder that tenancy is the greatest handicap to organization membership.

Operators of larger farms are more likely to be members of these organizations than are those who farm smaller units. This trend holds true for both owners and tenants.

In two States, those farmers who are most aggressive in adopting modern farm practices and those who make most use of their county agricultural agents are lined up with the farmers' organizations to a considerably larger extent than are those individuals in the same localities who do not evidence such flexibility in farm-management operations and who rarely consult the county agents. In a third State, of all farmers studied those rated by local citizens as being the most progressive in their farm-production activities are organization members to a much larger extent than the group classified as least progressive.

Memberships in lodges, social clubs, civic organizations, and church societies are most frequent among the members of the farmers' organizations selected for study. In view of the fact that a large proportion of these other organization memberships began some time prior to memberships in the farmers' organizations, it is to be suspected at least that memberships in the first-mentioned organizations afforded experiences and contacts in working together that made joining and cooperating in the work of the latter organizations easier and more satisfactory to these farmers.

Among the ex-members was found a more-than-average proportion of men of longest farm experience. Most of these farmers joined the farmers' organizations for the minimum periods possible under the membership contracts then in force, and they ceased to be members at the first opportunity that came their way. In the case of the farmers' marketing associations, some basis may be found in this fact for believing that individualistic habits formed by long experience with traditional marketing methods proved so strong that these older farmers were not able to readjust themselves to the new methods demanded by cooperative effort. In the general farmers' organization, this trend among farmers of long experience was found to exist although differences in membership relations are not so pronounced as is true of the farmers' marketing associations.

Significance of the Findings

What is the significance of these findings for farmers' organizations, particularly cooperative business enterprises? In the first place, the leadership in such organizations will come to a fuller realization of the importance of past experiences, habits, viewpoints, and desires as forces that influence each farmer's response to the appeals of any and all organizations. Solicitation methods, means of disseminating information, membership contracts, relationships between members and management, and methods of promoting esprit de corps among the members will be developed so as to recognize these influences which so greatly affect the human factor.

In the second place, farmers' organizations will make increasing demands that the public-school opportunities of farm boys and girls be made more nearly equivalent to those afforded urban children by means of State equalization of existing inequalities and handicaps, and in other ways. This educational emphasis appears to be the greatest source of hope for the organizations from a long-time point of view.

Finally, it seems evident that a good many of the older farmers especially those whose methods of operation class them as unprogressive and unlearned, can never be depended upon to make successful cooperators. Nor should organization leaders and members feel defeated when time and energy does not cause these impossibles to join. The transition to the cooperative way of doing things is simply beyond them. Their gradual replacement by a younger, better trained, and more easily approachable generation, is the only satisfactory solution of this problem. Organizational pressure brought to bear in favor of adequate rural schools is usually better spent than is an equal amount of effort used in trying to get people who are unable to cooperate successfully to join these organizations.

Granting the importance of efficiency in business management, the study of the human factor as it relates to all forms of cooperation, and the development of organizational policy to correspond with its limitations and capacities, are of equal importance with business activities in determining the degree of success that can be secured in the future through cooperative activity.

THEO. B. MANNY,
Senior Agricultural Economist,
Bureau of Agricultural Economics.

CORN-BORER Control by Machinery Facilitated Through Seasonal Plan

In the area where only one brood of European corn borers occurs each year (western area), controlling this pest by mechanical means may be greatly facilitated if the recognized control practices be worked into the farm operating schedule, the requirements for control having been developed by the Bureau of Entomology. By carefully planning and executing, little extra work will be required and yet the ravages of the insect will be held in check and better farming result. To make the program effective each farmer should carry it through to the best among farmers of long experience was found to exist although differences in membership relations are not so pronounced as is true of the farmers' marketing associations.

Significance of the Findings

What is the significance of these findings for farmers' organizations, particularly cooperative business enterprises? In the first place, the leadership in such organizations will come to a fuller realization of the importance of past experiences, habits, viewpoints, and desires as forces that influence each farmer's response to the appeals of any and all organizations. Solicitation methods, means of disseminating information, membership contracts, relationships between members and management, and methods of promoting esprit de corps among the members will be developed so as to recognize these influences which so greatly affect the human factor.

In the second place, farmers' organizations will make increasing demands that the public-school opportunities of farm boys and girls be made more nearly equivalent to those afforded urban children by means of State equalization of existing inequalities and handicaps, and in other ways. This educational emphasis appears to be the greatest source of hope for the organizations from a long-time point of view.

Finally, it seems evident that a good many of the older farmers especially those whose methods of operation class them as unprogressive and unlearned, can never be depended upon to make successful cooperators. Nor should organization leaders and members feel defeated when time and energy does not cause these impossibles to join. The transition to the cooperative way of doing things is simply beyond them. Their gradual replacement by a younger, better trained, and more easily approachable generation, is the only satisfactory solution of this problem. Organizational pressure brought to bear in favor of adequate rural schools is usually better spent than is an equal amount of effort used in trying to get people who are unable to cooperate successfully to join these organizations.

Granting the importance of efficiency in business management, the study of the human factor as it relates to all forms of cooperation, and the development of organizational policy to correspond with its limitations and capacities, are of equal importance with business activities in determining the degree of success that can be secured in the future through cooperative activity.

CORN-BORER Control by Machinery Facilitated Through Seasonal Plan

In the area where only one brood of European corn borers occurs each year (western area), controlling this pest by mechanical means may be greatly facilitated if the recognized control practices be worked into the farm operating schedule, the requirements for control having been developed by the Bureau of Entomology. By carefully planning and executing, little extra work will be required and yet the ravages of the insect will be held in check and better farming result. To make the program effective each farmer should carry it through to the best of his ability; otherwise, neglected cornfields will nullify the control measures practiced on near-by fields.

Beginning in the spring, in fields where the corn has been hogged down or the stalks grazed, the practice of carefully plowing under the stalks should be followed. The ground should be clean and no pieces of stalk should be left exposed on the surface as a refuge for a borer which might crawl to the surface after being plowed under. (Fig. 24.) This means, when possible, the plowing of stalks under to a depth of 6 inches—8 inches would be better. With no shelter available the borer can not then continue its life cycle, as it will either die of exposure or be attacked and destroyed by birds and other natural enemies.

If standing stalks are left after the corn has been picked, and if soil conditions permit, the stalks may be plowed under in the spring by using a wide-furrow plow equipped with colters, jointers, and trash

FIGURE 24.—A clean job of plowing for corn-borer control

wires. If care is used almost a perfect job of coverage can be obtained with 16-inch plows and larger, and a good job can be done with 14-inch plows if in good adjustment and properly equipped. Late plowing in the fall, after the corn has been harvested, is about equally effective but often is impossible because of unfavorable field conditions.

Where the field is not to be plowed but is to be sown to small grain a careful job of stalk shaving, raking, and burning will dispose of the majority of the borers. The shaving is accomplished by either a sled-type or a wheel-type stalk shaver. The former consists of a sled to each runner of which a diagonal knife is attached, as described in Miscellaneous Publication No. 69. This will cut two rows of stalks flush with the ground. A wheel-type shaver which consists of an attachment for a single-row cultivator works equally satisfactorily and will cut three rows at one time. (Fig. 25.) The sled-type shavers may be hitched two abreast and cut four rows of stalks at one time. (Fig. 26.)

After the stalks are carefully severed, raking and cross raking into piles or windrows by special cornstalk rakes collect the stalks for burning. A specially adapted side-delivery rake, which is also capable of

FIGURE 25.—A wheel-type stalk shaver cutting three rows at a time

raking hay equally well, will accomplish the result in one operation. (Fig. 27.)

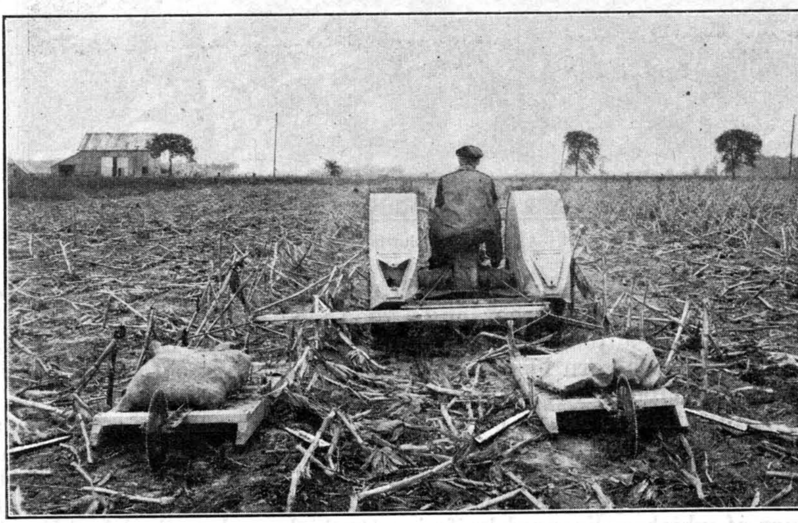

FIGURE 26.—Two sled-type shavers hitched abreast and cutting four rows

The burning operation then follows and should be carefully watched so that all outlying stalks may be raked into the flames to destroy any straggling borers. This done, small grain can be safely sown.

Preparing the Seed Bed

In preparing the seed bed after plowing care must be used in the selection and use of tillage tools so as not to bring any plowed-under stalks to the surface, as this would nullify the good job of plowing already done.

When planting corn, if conditions are favorable for the practice, the work of subsequent control machinery will be greatly facilitated if the corn is drilled rather than checked. The individual stalks are easier to cut or shave than stalks grouped in hills. Likewise, in cultivating, the operation of control machinery will be eased if the corn is laid by with the ground ridged as little as possible. This reduces the strain and racking on corn binders, rakes, and other machinery, which all function better on smooth ground.

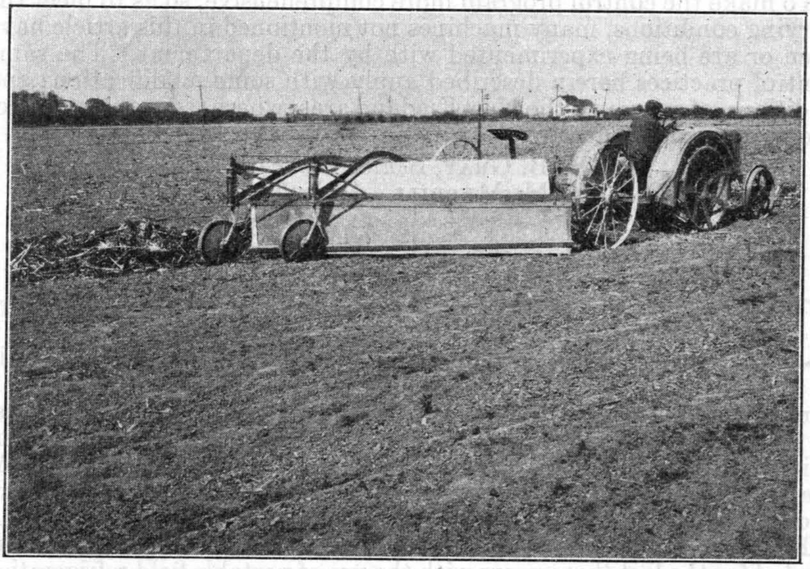

FIGURE 27.—A side-delivery rake in operation. Note absence of débris on the ground raked

If the corn is to be harvested by removing the whole crop from the field, the stalks should be cut flush with the ground surface, thereby permitting the removal of the majority of the borers from the field in the stalks. For accomplishing this, any make of binder now being manufactured may be equipped with the stationary low-cutting knife attachment. This attachment may be made up by the farmer himself according to instructions in Miscellaneous Publication No. 56, or it may be purchased at a nominal cost from the manufacturer of the particular binder in use.

Where the corn is to be cut by hand a special low-cutting hoe should be used. One type is described in the publication mentioned.

If the corn thus cut is to be ensiled, careful operation of the silage cutter with special attention to cleaning up trash around the machine after each operation will make for good control. What borers may not be destroyed in the silage cutter will be killed during the fermentation process in the silo. The silage harvester, when equipped with a low-cutting knife attachment, accomplishes practically the same result as the silage cutter.

In case the corn is to be handled by a husker-shredder, careful feeding, proper adjustment of the snapping roll pressure to a safe maximum, and the practice of cleaning up around the machine after each operation will destroy a large percentage of borers. If the shredded fodder is put into the mow or fed to the stock, the remaining live borers will perish from dessication, be eaten by the stock, or be tramped into the manurial juices. Therefore, fodder passing through a properly adjusted shredder may be spread on the fields with little danger of being a source of infestation.

When fodder is to be fed whole to the stock, or where hand husking from the shock is done, care must be exercised in cleaning up feed lots and destroying the stalks before the pupation time of the borers.

To make the control program more comprehensive, so as to meet the varying conditions, many machines not mentioned in this article have been or are being experimented with by the department. The same control practices herein described apply with some modifications and additions, of course, to the New England area, where two generations of the borer occur annually.

CORN More Resistant to Cold When Grown on Soil Rich in Plant Food

The problem of reducing the hazard of untimely frosts to the corn crop is seriously complicated by reduction in soil fertility. One of the most important factors influencing the extent of injury following frosts and freezes in the late spring and early fall is the quantity and balance of soil fertility available for use by the growing corn plants. The encouraging feature is that this factor is more or less under the control of the corn grower.

Field studies on cold injury in both spring and fall have been conducted for the last three years with the use of portable field refrigeration chambers to produce chilling temperatures and frosts. The planting arrangement and a general view of the experimental field in 1930 are shown in Figure 28. Part of the plantings were made on soil cropped since 1921, prior to which time the soil was virgin prairie sod. Comparable plantings were made on closely adjacent soil that was plowed from virgin sod in the fall of 1929.

A comparison of the reaction to freezing temperatures, 28° to 29° F., for two hours, of five strains of corn growing on the soil cropped since 1921, and of the same strains growing on the newly plowed virgin soil, is shown in Figure 29. The greater resistance to injury from cold of the plants growing on the virgin soil is very marked.

On part of the soil cropped since 1921, plant nutrients were applied, singly and in combination, and at different rates of application. The applications were made in such a way that one of the field refrigeration chambers would cover at the same time corn growing on unfertilized soil and corn on soil that had received each of three different fertilizer treatments. Both cold-resistant and cold-susceptible strains of corn were grown on each soil treatment. (Fig. 30.)

cutting knife attachment, accomplishes practically the same result as the silage cutter.

In case the corn is to be handled by a husker-shredder, careful feeding, proper adjustment of the snapping roll pressure to a safe maximum, and the practice of cleaning up around the machine after each operation will destroy a large percentage of borers. If the shredded fodder is put into the mow or fed to the stock, the remaining live borers will perish from dessication, be eaten by the stock, or be tramped into the manurial juices. Therefore, fodder passing through a properly adjusted shredder may be spread on the fields with little danger of being a source of infestation.

CORN More Resistant to Cold When Grown on Soil Rich in Plant Food

The problem of reducing the hazard of untimely frosts to the corn crop is seriously complicated by reduction in soil fertility. One of the most important factors influencing the extent of injury following frosts and freezes in the late spring and early fall is the quantity and balance of soil fertility available for use by the growing corn plants. The encouraging feature is that this factor is more or less under the control of the corn grower.

Field studies on cold injury in both spring and fall have been conducted for the last three years with the use of portable field refrigeration chambers to produce chilling temperatures and frosts. The planting arrangement and a general view of the experimental field in 1930 are shown in Figure 28. Part of the plantings were made on soil cropped since 1921, prior to which time the soil was virgin prairie sod. Comparable plantings were made on closely adjacent soil that was plowed from virgin sod in the fall of 1929.

A comparison of the reaction to freezing temperatures, 28° to 29° F., for two hours, of five strains of corn growing on the soil cropped since 1921, and of the same strains growing on the newly plowed virgin soil, is shown in Figure 29. The greater resistance to injury from cold of the plants growing on the virgin soil is very marked.

On part of the soil cropped since 1921, plant nutrients were applied, singly and in combination, and at different rates of application. The applications were made in such a way that one of the field refrigeration chambers would cover at the same time corn growing on unfertilized soil and corn on soil that had received each of three different fertilizer treatments. Both cold-resistant and cold-susceptible strains of corn were grown on each soil treatment. (Fig. 30.)

Plants growing in the soil to which fertilizers had been applied were more resistant to cold than the plants of the same strain growing in the untreated soil. Some cold-susceptible strains when grown in the unfertilized soil were killed in the young plant stage by exposure for a few minutes to a temperature of 33° to 34° F. These same strains were resistant to any visible injury from an exposure of four hours to a

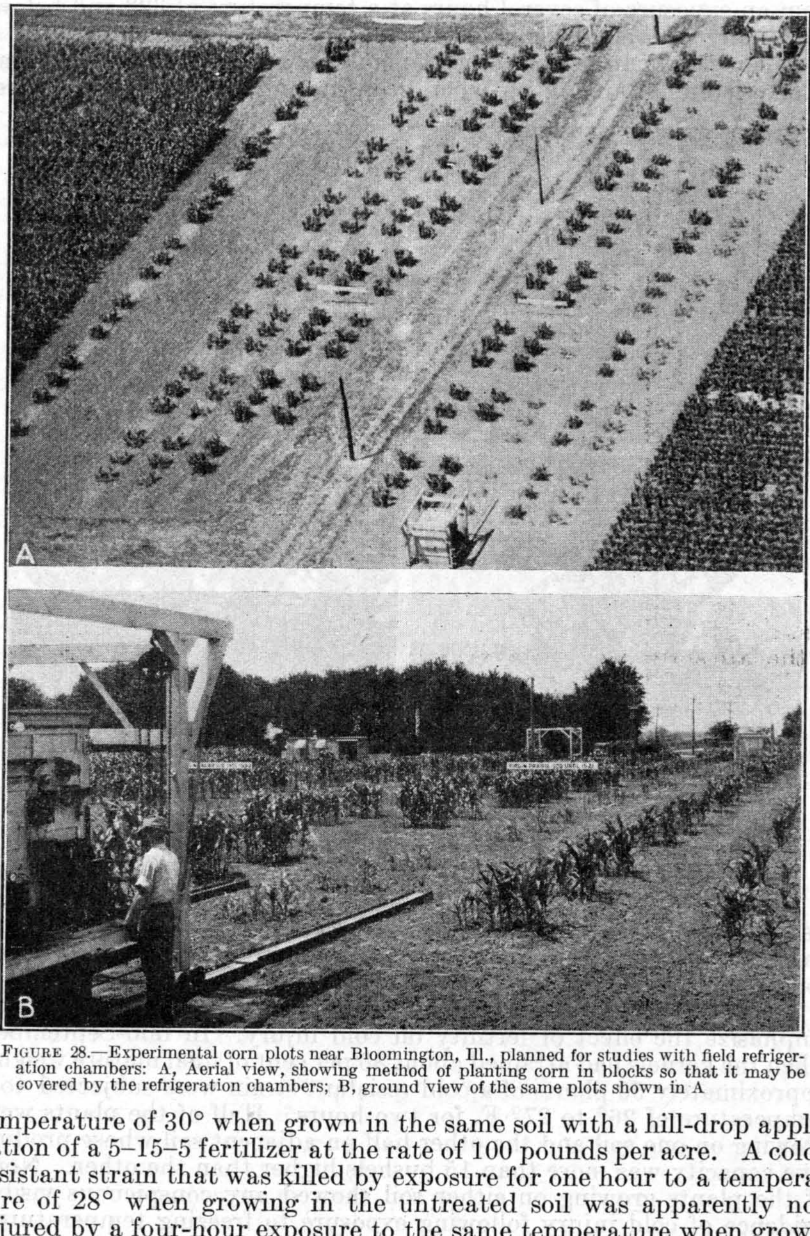

FIGURE 28.—Experimental corn plots near Bloomington, Ill., planned for studies with field refrigeration chambers: A, Aerial view, showing method of planting corn in blocks so that it may be covered by the refrigeration chambers; B, ground view of the same plots shown in A

temperature of 30° when grown in the same soil with a hill-drop application of a 5–15–5 fertilizer at the rate of 100 pounds per acre. A cold-resistant strain that was killed by exposure for one hour to a temperature of 28° when growing in the untreated soil was apparently not injured by a four-hour exposure to the same temperature when grown in the same soil with a 5–15–5 fertilizer added at the rate of 200 pounds per acre.

Cold Resistance in the Fall

Differences in the cold resistance and cold susceptibility of different strains of corn grown with and without fertilizers also have been very marked in the fall. Some cold-susceptible strains whose leaves and stalks were killed by exposure to temperatures of 40° to 42° F., when growing on untreated soil, three weeks later were resistant to injury from an exposure of several hours at a temperature of 32° and below, the difference being due to the resistant plants having received a broadcast application of 400 to 600 pounds of a 5–15–5 fertilizer. Some cold-resistant strains, even when growing on the untreated soil, re-

FIGURE 29.—Corn grown on new soil has been found to be more resistant to injury from cold, both in spring and fall, than corn grown on comparable soil of a lower level of productivity. The same five strains of corn, *a, b, c, d, e,* were planted in each of the four blocks May 12, 1930. Soil moisture in the four blocks was comparable, being approximately 45 per cent of the moisture-holding capacity of the soil. The plants were photographed July 5, 1930, 24 days after exposure in the field refrigeration chambers for two hours to a temperature of 28° to 29° F., following a prehardening period of eight hours

sisted injury from exposure to temperatures of 32° and below, but these same strains were more resistant when growing on the fertilized soil.

The results from an experiment conducted in the fall of 1929 will emphasize the effect of fertility on cold injury. In mid-September, when the kernels had attained about 80 per cent of final mature weight, approximately 50 plants of a cold-resistant strain were subjected to a temperature of 26° to 27° F. for two hours. Half of the plants were growing on one soil and the other half on adjacent soil whose productive capacity was more than 15 bushels higher than the other. None of the plants growing on either soil showed any conspicuous visible evidence of cold injury following exposure to freezing temperatures. When the corn was harvested, however, it was found that the ears from the plants on the less productive soil had not increased in weight after

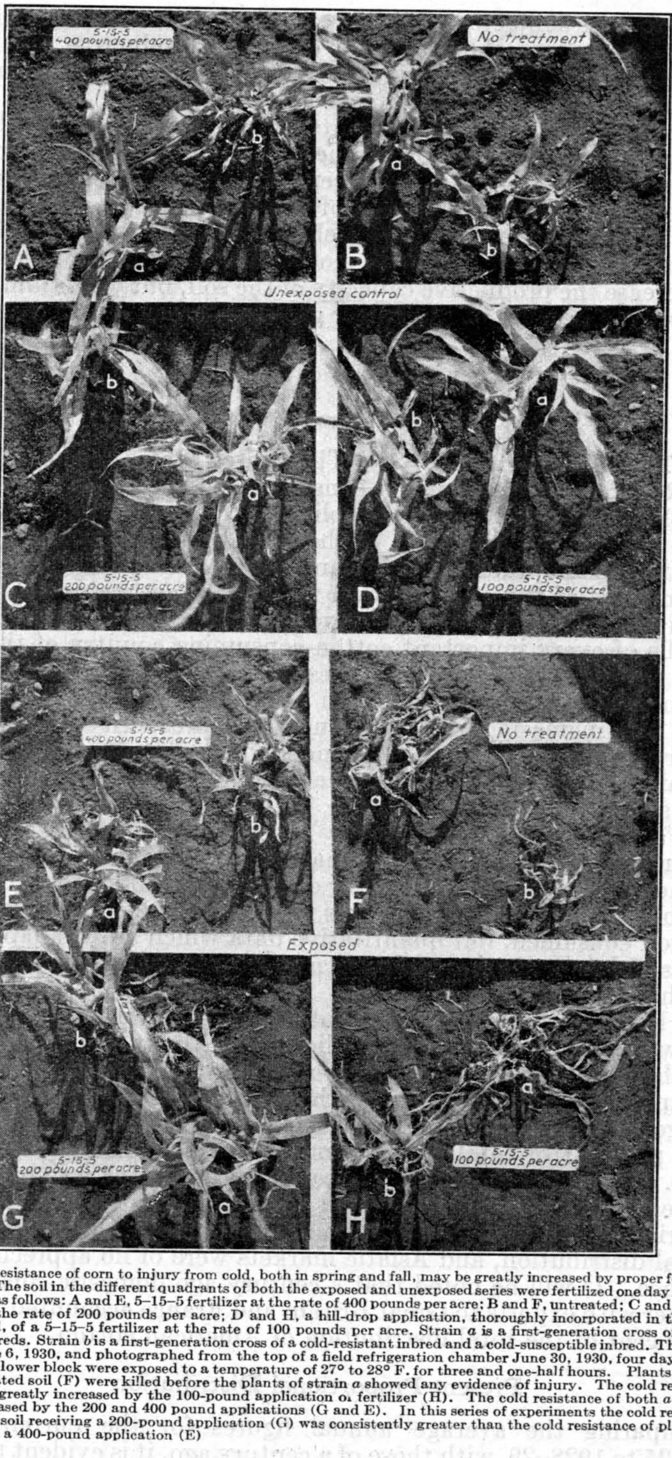

FIGURE 30.—Resistance of corn to injury from cold, both in spring and fall, may be greatly increased by proper fertilization of the soil. The soil in the different quadrants of both the exposed and unexposed series were fertilized one day in advance of planting, as follows: A and E, 5–15–5 fertilizer at the rate of 400 pounds per acre; B and F, untreated; C and G, 5–15–5 fertilizer at the rate of 200 pounds per acre; D and H, a hill-drop application, thoroughly incorporated in the upper 4 inches of soil, of a 5–15–5 fertilizer at the rate of 100 pounds per acre. Strain *a* is a first-generation cross of two cold-resistant inbreds. Strain *b* is a first-generation cross of a cold-resistant inbred and a cold-susceptible inbred. The corn was planted June 6, 1930, and photographed from the top of a field refrigeration chamber June 30, 1930, four days after the plants in the lower block were exposed to a temperature of 27° to 28° F. for three and one-half hours. Plants of strain *b* in the untreated soil (F) were killed before the plants of strain *a* showed any evidence of injury. The cold resistance of strain *b* was greatly increased by the 100-pound application of fertilizer (H). The cold resistance of both *a* and *b* was greatly increased by the 200 and 400 pound applications (G and E). In this series of experiments the cold resistance of the plants in soil receiving a 200-pound application (G) was consistently greater than the cold resistance of plants in the soil receiving a 400-pound application (E)

the plants were subjected to the freezing temperatures. On the other hand, the ears from the plants on the more productive soil had increased in weight and were almost as heavy as the ears from comparable plants not exposed to the freezing temperatures.

There is no doubt that corn plants are more resistant to cold, both in the young plant stage and in the maturing stage, when grown on more productive soil. An intelligent soil-improvement program to increase the productive capacity of the soil helps to reduce the loss hazard to the corn crop from untimely frosts. The growing of legumes and, where needed, the application of fertilizers in proper amounts not only increase the productive capacity of the soil, but yields and quality are improved because of the longer growing season for the corn.

Senior Agronomist, Bureau of Plant Industry.

COTTON Exports of U. S. Reflect Continuously Shifting World Market The United States has been the leading source of the world's cotton supplies for the last century. Although there has been a rapid increase in the domestic consumption of American cotton during this period, more than one-half of the cotton grown in the United States continues to find an outlet through foreign markets. American cotton is used in the mills of every important cotton-consuming country of the world, and in a majority of these countries more than one-half of all cotton consumed is American. Although domestic markets for American cotton are increasing in importance, the prosperity of the cotton industry in this country is dependent, among other things, upon maintaining extensive foreign markets for the sale of this raw material.

The several market outlets for American cotton are continually changing in importance. These changes usually affect both the quantity and quality of cotton taken or consumed. Sufficient data are not available to determine the changes which have taken place in quality of cotton consumed, but quantitative data which are available on the exports and consumption of American cotton reveal some rather significant shifts.

One hundred years ago, when total domestic consumption plus exports were only about one-half million bales, Great Britain and France were the only markets of any consequence to which American cotton was exported. (Fig. 31.) During the 5-year period 1824–25 to 1828–29 average annual exports of American cotton to Great Britain made up 60 per cent of total distribution (domestic consumption plus exports). During this same period about 20 per cent was exported to France, 1 per cent to Germany, and about 3 per cent to other European countries. Domestic consumption at that time was about 16 per cent of total distribution, and Asiatic markets were of no appreciable consequence. It will be noted that a century ago domestic consumption together with exports to Great Britain and France accounted for about 95 per cent of the total distribution of American cotton.

Present Proportional Distribution

Comparing the average annual figures for the current period, 1924–25 to 1928–29, with those of a century ago, it is evident that some the plants were subjected to the freezing temperatures. On the other hand, the ears from the plants on the more productive soil had increased in weight and were almost as heavy as the ears from comparable plants not exposed to the freezing temperatures.

There is no doubt that corn plants are more resistant to cold, both in the young plant stage and in the maturing stage, when grown on more productive soil. An intelligent soil-improvement program to increase the productive capacity of the soil helps to reduce the loss hazard to the corn crop from untimely frosts. The growing of legumes and, where needed, the application of fertilizers in proper amounts not only increase the productive capacity of the soil, but yields and quality are improved because of the longer growing season for the corn.

J. R. Holbert,
Senior Agronomist, Bureau of Plant Industry.

COTTON Exports of U. S. Reflect Continuously Shifting World Market

The United States has been the leading source of the world's cotton supplies for the last century. Although there has been a rapid increase in the domestic consumption of American cotton during this period, more than one-half of the cotton grown in the United States continues to find an outlet through foreign markets. American cotton is used in the mills of every important cotton-consuming country of the world, and in a majority of these countries more than one-half of all cotton consumed is American. Although domestic markets for American cotton are increasing in importance, the prosperity of the cotton industry in this country is dependent, among other things, upon maintaining extensive foreign markets for the sale of this raw material.

The several market outlets for American cotton are continually changing in importance. These changes usually affect both the quantity and quality of cotton taken or consumed. Sufficient data are not available to determine the changes which have taken place in quality of cotton consumed, but quantitative data which are available on the exports and consumption of American cotton reveal some rather significant shifts.

One hundred years ago, when total domestic consumption plus exports were only about one-half million bales, Great Britain and France were the only markets of any consequence to which American cotton was exported. (Fig. 31.) During the 5-year period 1824–25 to 1828–29 average annual exports of American cotton to Great Britain made up 60 per cent of total distribution (domestic consumption plus exports). During this same period about 20 per cent was exported to France, 1 per cent to Germany, and about 3 per cent to other European countries. Domestic consumption at that time was about 16 per cent of total distribution, and Asiatic markets were of no appreciable consequence. It will be noted that a century ago domestic consumption together with exports to Great Britain and France accounted for about 95 per cent of the total distribution of American cotton.

Present Proportional Distribution

Comparing the average annual figures for the current period, 1924–25 to 1928–29, with those of a century ago, it is evident that some marked changes have taken place in the quantities of American cotton exported to various markets. Great Britain and France no longer hold the predominant positions which they once enjoyed as export markets. The proportional distribution to Great Britain during the last century has declined from about 60 per cent to 14 per cent; to France, from 21 per cent to 6 per cent. These decreases have been absorbed largely by domestic mills, Germany, Italy, other European countries, and Japan. During the century the average annual consumption in domestic mills increased from 16 per cent to 43 per cent; Germany, from 1 per cent to 13 per cent; Italy, from practically nothing to 5 per cent; other European countries, from 3 per cent to 8 per cent. Japan was taking no American cotton a century ago, as compared to takings amounting to 8 per cent of total distribution at the present time.

Marked changes have also occurred in the importance of the different countries with respect to mill consumption of American cotton since

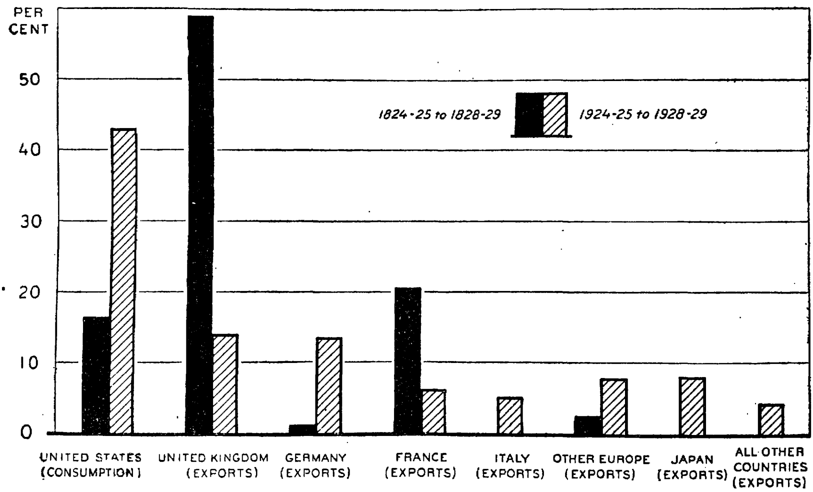

FIGURE 31.—Percentage distribution of American cotton, specified countries, average annual 1824–25 to 1828–29 and 1924–25 to 1928–29

the period immediately preceding the World War. (Fig. 32.) Average annual world consumption of American cotton between the periods 1909–10 to 1912–13 and 1925–26 to 1928–29 increased about 1,800,000 bales, reaching the highest level on record. Comparing recent years with pre-war years, the losses and gains in consumption of American cotton outside the United States practically balance each other, leaving the increases in domestic consumption as a net gain.

Comparing recent years with pre-war years, consumption of American cotton in Great Britain has declined about 1,400,000 bales, or from 26 to 13 per cent of total world consumption. Other marked changes in consumption of American cotton have occurred in the United States and Japan. Consumption in the United States has increased about 1,800,000 bales, or from 36 to 44 per cent of total world consumption. Consumption in Japan has increased almost 800,000 bales, or from 2 per cent to 7 per cent of the total. Smaller changes in the consumption of American cotton have occurred in other countries during the period under review.

The last two or three years have witnessed significant shifts in the consumption of American cotton, some of which may prove to be permanent. Following the high level reached in 1926–27 there was a general decline in world consumption of American cotton. This decline has been especially marked during 1929–30. While nearly all important cotton-consuming countries have shared in this decline, it has been much more severe in some countries than in others.

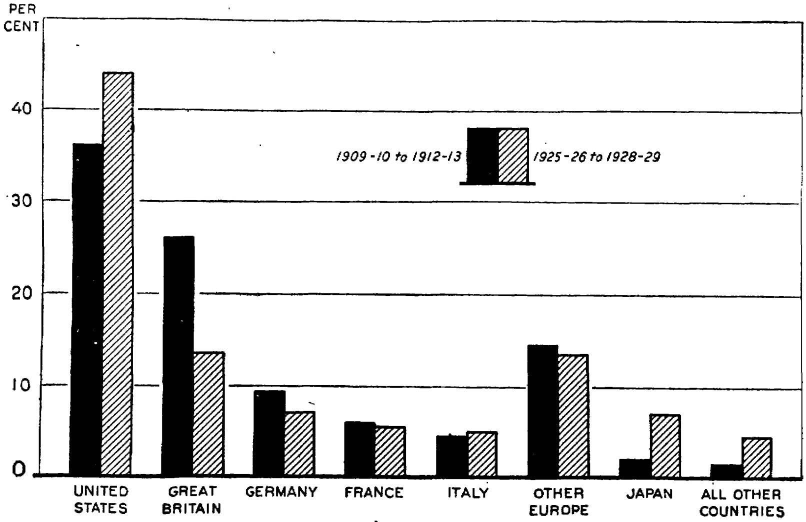

FIGURE 32.—Percentage of world consumption of American cotton in specified countries, average annual 1909–10 to 1912–13 and 1925–26 to 1928–29

Decreased Consumption in United States

Consumption of American cotton in the United States decreased about 350,000 bales in 1927–28, regained most of this loss in 1928–29, and decreased considerably in 1929–30. In Great Britain each of the last four years has shown a decrease from the preceding year in American cotton consumption. There was a slight increase in the amount of American cotton consumed in Germany during 1927–28, but decreases have occurred during the last two years. Japan, like the United States, shows a decline in 1927–28, a slight increase in 1928–29, and a decrease during 1929–30.

Very little fluctuation has occurred in the amount of American cotton consumed in France during the last four years, and consumption of this growth in Italy has been maintained at a relatively high level during recent years. The textile industries of France and Italy experienced somewhat less depression during 1929–30 than did most of the other important consumers of American cotton. Russia, Czechoslovakia, Spain, and Poland are among the countries which have shown decreased consumption of American cotton during the last two or three years; while Belgium, the Netherlands, and Canada are among those in which, until 1929–30 at least, American cotton consumption has been maintained or increased.

W. W. FETROW,
Senior Agricultural Economist,
Bureau of Agricultural Economics.

COTTON More Productive When Thick Spaced for Small Upright Plants "Thick spacing" is the farmer's expression of the contrast between the present practice in thinning cotton and that of the early years of the weevil invasion, when wide spacing or checkrowing was considered desirable, with the plants 2 or 3 feet apart. Much closer spacing is now advised, with the plant separated only a few inches, or with two to four plants left in hills at 12 or 14 inches. Several times as many plants are left in the fields as formerly, 30,000 to 60,000 plants per acre instead of 5,000 or 6,000. Closer spacing than a "hoe width" between the hills encounters difficulties of thinning by hand or of special methods of seeding. Moderate "natural stands," with the plants averaging 2 to 4 inches apart in the rows, often do not need to be thinned, so that in some districts the labor and expense of "chopping" are avoided. The method is of general application where cotton is grown as an annual, but adjustments to local conditions require further investigation. Thus in dry districts a wider separation of the rows is indicated, but with the plants close in the rows.

An agricultural invention was made by learning how the form and size of the plants could be controlled, and how small upright plants could be used to better advantage than large spreading plants, under the short-season conditions imposed by the boll weevil. The early indications of larger yields from thick-spaced cotton have been confirmed by many tests at State experiment stations, which have served

COTTON More Productive When Thick Spaced for Small Upright Plants

"Thick spacing" is the farmer's expression of the contrast between the present practice in thinning cotton and that of the early years of the weevil invasion, when wide spacing or checkrowing was considered desirable, with the plants 2 or 3 feet apart. Much closer spacing is now advised, with the plant separated only a few inches, or with two to four plants left in hills at 12 or 14 inches. Several times as many plants are left in the fields as formerly, 30,000 to 60,000 plants per acre instead of 5,000 or 6,000. Closer spacing than a "hoe width" between the hills encounters difficulties of thinning by hand or of special methods of seeding. Moderate "natural stands," with the plants averaging 2 to 4 inches apart in the rows, often do not need to be thinned, so that in some districts the labor and expense of "chopping" are avoided. The method is of general application where cotton is grown as an annual, but adjustments to local conditions require further investigation. Thus in dry districts a wider separation of the rows is indicated, but with the plants close in the rows.

An agricultural invention was made by learning how the form and size of the plants could be controlled, and how small upright plants could be used to better advantage than large spreading plants, under the short-season conditions imposed by the boll weevil. The early indications of larger yields from thick-spaced cotton have been confirmed by many tests at State experiment stations, which have served as the basis of advice to the farmers, but giving more attention to the peculiarities of the cotton plant is also to be urged, for effective application of the new method. Scientific improvements of agriculture can be used to some extent by farmers who are not aware of the underlying facts, but the best use of any practical discovery is to be expected from those who understand it. Not only are the returns from the crops increased, but the interest and satisfactions of farming are enriched by every additional insight into the habits and peculiarities of the plants that receive the farmer's care.

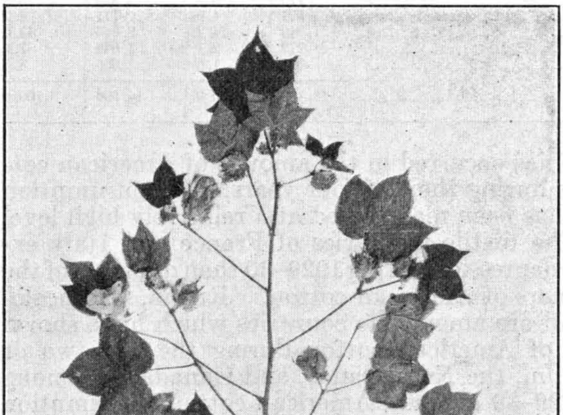

FIGURE 33.—Narrow, upright, single-stalk Acala cotton plant, grown in a thick-spaced row, showing only one small dwarfed vegetative branch at base

Nature of the Spacing Problem

The spacing problem is not so simple as appeared at first, when it was thought that the proper distances could be determined merely by trying experiments with different spacings, to see which gave the largest yields. Practical conclusions were not reached, as the agronomic results were too varied and conflicting, until it was discovered that the cotton plant has two kinds of branches which are different and distinct in their structure and functions. The recognition of the two kinds of branches brought to light a new principle which determines the space requirements of the cotton plants and is an indispensable key to an adequate understanding and use of better spacing methods.[1]

The conflicting results of the earlier experiments are explained when the branching habits are considered. The spacing problem has its joker in the different forms of the plants and their different space requirements, as determined by the formation of the branches. Plants a foot apart may be too close in one season or in one field, but too wide in another. With long seasons and equable conditions, close spacing may show no advantage. Spacing experiments may miscarry in several

[1] COOK, O. F. DIMORPHIC BRANCHES IN TROPICAL CROP PLANTS: COTTON, COFFEE, CACAO, THE CENTRAL AMERICAN RUBBER TREE, AND THE BANANA. U. S. Dept. Agriculture, Bur. Plant Indus. Bul. 198. 1911.

ways, notably where heavy stands are thinned too late, and especially where thinning is followed by dry weather, so that the plants remain stunted.

No simple agronomic solution could have been reached, because essentially different conditions were confused, until the principle of branch control was recognized. A bimodal curve of space effects might have been worked out if the full range of spacings had been tested, but spacings less than a foot were not included in the older agronomic experiments. For plants with vegetative branches the limit is above a foot, while for narrow single-stalk plants only a few inches of row-space are required. The closer spacings are safer and more practicable, because the vegetative branches are suppressed. Growing the plants closer together keeps them from being injuriously crowded.

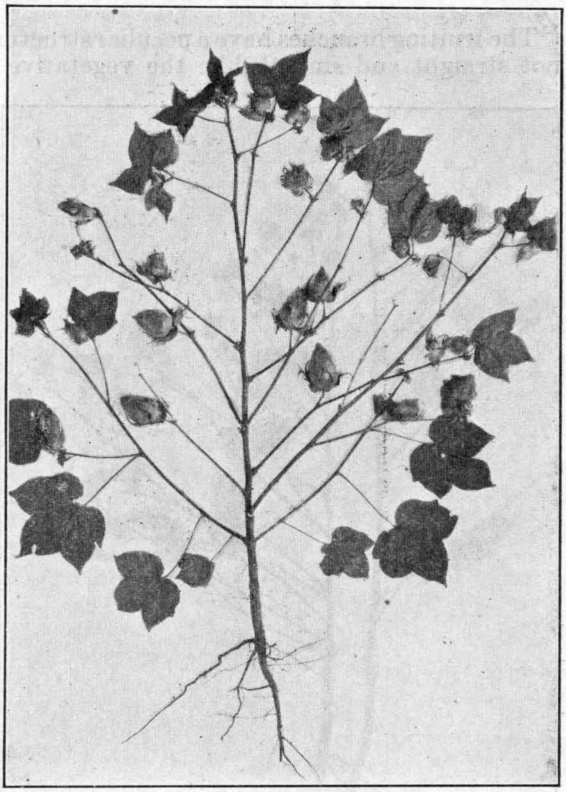

FIGURE 34.—Spreading Acala cotton plant grown in wide-spaced row showing three vegetative branches or side stalks at base. Compare with Figure 33

Two Forms of Plants

The cotton plant can grow in two different forms, depending upon whether one kind of branches or two kinds are produced. Plants that have only fruiting branches are of the simple single-stalk form, narrow and erect. (Fig. 33.) The lower joints of single-stalk plants are without branches, though vegetative sprouts may appear late in the season or after the plants have been checked by dry weather.

The other form of plant is broad and spreading, if room is allowed, and is characterized by large vegetative branches or "side stalks," produced from the lower joints of the main stalk, below the fruiting branches. (Fig. 34.) Thick spacing restricts the formation of vegetative branches and effects a substitution of several small single-stalk plants for one of the large plants with spreading side stalks. The smaller individual plants growing on their own roots have advantages over the side stalks of the large plants in maturing larger crops of bolls early in the season, as required under weevil conditions. The plants yield less individually, but usually produce more cotton per row, often 20, 30, or 50 per cent more, or even twice as much, when the period of setting the crop is very short. Many comparisons in alternating 4-row blocks have shown notable advantages for close spacings.

The control of branching becomes effective on plants less than 6 inches apart in the rows. It is possible to grow single-stalk plants a foot or more apart by later thinning, but if cotton is thinned late it should be left closer together. The seedlings give mutual protection against wind and cold, and usually grow better when not thinned too early, that is, before they are 5 or 6 inches high. The former practice of "chopping" cotton as soon "as the rows can be followed" is seldom maintained.

Two Kinds of Branches

The fruiting branches have a peculiar structure and manner of growth, not straight and smooth like the vegetative branches, but with the joints angled and zigzag. Also, the basal joint of a fruiting branch is very long, in contrast with much shorter basal joints on vegetative branches. Every joint of a fruiting branch has its floral bud or square, while vegetative branches have no flower buds. Even if all the buds are shed, the fruiting branches are permanently marked by the bud scars, though "doubtful branches" have been reported by some of the agronomic writers. (Fig. 35.)

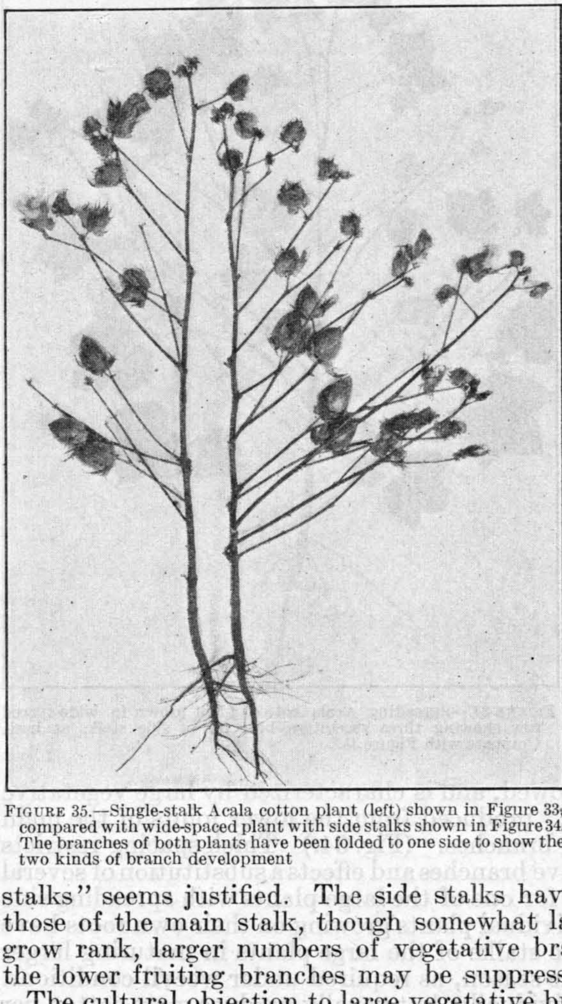

FIGURE 35.—Single-stalk Acala cotton plant (left) shown in Figure 33, compared with wide-spaced plant with side stalks shown in Figure 34. The branches of both plants have been folded to one side to show the two kinds of branch development

The vegetative branches usually are confined to the lower joints of the main stalk, below the fruiting branches. The structure and functions of the vegetative branches are the same as those of the main stalk of the plant, so that the name "side stalks" seems justified. The side stalks have fruiting branches like those of the main stalk, though somewhat later. Where the plants grow rank, larger numbers of vegetative branches are formed, and the lower fruiting branches may be suppressed or aborted.

The cultural objection to large vegetative branches is that the lanes between the rows of cotton are filled with the extra growth. A continuous canopy of foliage is formed, the ground is completely shaded, and a moist atmosphere is retained, so that the field conditions invite weevil injury and boll rot. Even where there are no boll weevils, as in the irrigated valleys of the Southwestern States, the lanes between the rows need to be kept open. Otherwise few bolls are produced on the lower parts of the plants, and the "top crop" often is too late to open before frost.

O. F. Cook,
Principal Botanist, Bureau of Plant Industry.

COTTON Prices to Growers Do Not Reflect Accurately Variations in Quality Large quantities of cotton with a staple shorter than seven-eighths of an inch are produced annually in the United States, and occasionally a considerable proportion of the crop is of very low grade. The proportion of the crop which was untenderable on futures contracts because of short staple amounted to 2,051,100 bales, or 14.3 per cent, in 1928 and to 2,920,200 bales, or 20.1 per cent, in 1929; and because of low grade amounted to 756,800 bales, or 5.3 per cent, in 1928 and to 880,100 bales, or 6.1 per cent, in 1929.

This very short-staple cotton competes directly with cotton grown in India and China where, it is asserted the cost of production is much less than in the United States. Competition with cotton grown in India and China, along with the large quantities of short-staple cotton produced, is causing public attention to be directed to the advisability of improving the staple length of the cotton grown in the United States.

Farmers are inclined to produce the kind of cotton which, at prices received in local markets, brings them the greatest net returns. The prices paid in these markets indicate to growers the qualities of cotton which are more profitable for them to produce. Where an averaged price is paid for all grades and staple lengths grown in a community, farmers tend to grow the kind of cotton which can be produced at the least cost per pound regardless of the grade and staple length. On the other hand, where growers receive prices which vary appreciably with the grade and staple length, they tend to produce cotton of superior quality.

As a means of determining to what extent the prices paid to growers in local markets in the United States reflect the differences in spinning utility of the various grades and staple lengths of cotton, data on prices paid and on the classification of 107,247 bales sold during the season of 1928–29 in 143 local markets, representing as nearly as possible a cross section of the types of local markets in the United States, were collected and analyzed.

These data show that prices paid for cotton of the same grade and staple length varied widely; and that prices paid for cotton of different grades and staple lengths varied so irregularly that it was not unusual to find that some growers received less for cotton of higher grade and longer staple than others received for cotton of lower grade and shorter staple in the same market on the same day. These wide and irregular variations indicate that differences in the bargaining power of farmers or other factors were, at times, of more importance in determining the prices received by growers than were differences in grade and staple length.

These wide and irregular variations indicate that differences in the bargaining power of farmers or other factors were, at times, of more importance in determining the prices received by growers than were differences in grade and staple length.

Premiums and Discounts

A weighted average of the prices paid shows that growers actually received for White grades above Middling an average premium per bale of 60 cents for Strict Middling, 95 cents for Good Middling, and 50 cents for Strict Good Middling. The discounts per bale paid for White grades below Middling averaged $1.55 for Strict Low Middling, $4.35 for Low Middling, $7.95 for Strict Good Ordinary, and $12.30 for Good Ordinary. Using Middling White cotton as a basis, a weighted average of the prices paid for Spotted cotton showed an average premium of 60 cents per bale for Good Middling, and average discounts per bale of $1.50 for Middling, $5.35 for Strict Low Middling, and $7.40 for Low Middling. (Fig. 36.)

Similar comparisons for different staple lengths show that the average discount in the prices paid to growers for cotton with a staple of 13/16 inch and shorter was only 30 cents per bale less than that paid for 7/8-inch cotton of the same grade. The average premiums per bale

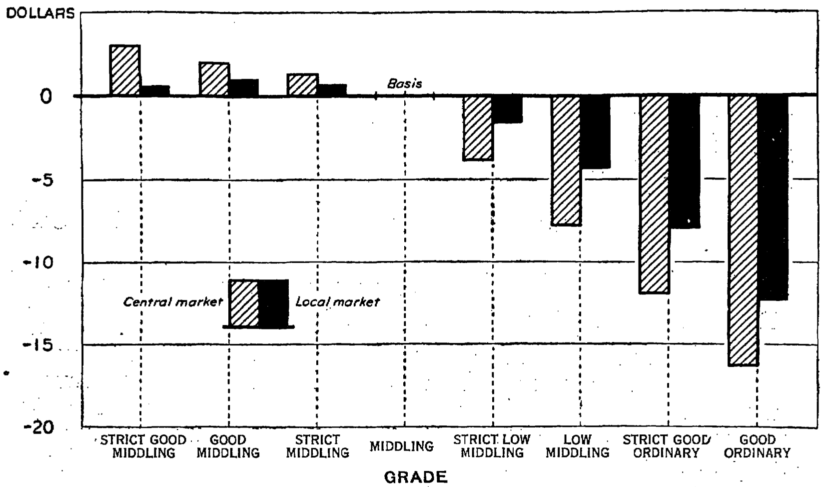

FIGURE 36.—Average grade differences in dollars per bale of 500 pounds paid for White cotton in local markets and in central markets in the United States, season 1928–29

paid for the longer staple lengths amounted to only 20 cents for 15/16 inch, 60 cents for 1 to 1 1/32 inches, $2.05 for 1 1/16 to 1 3/32 inches, $3.85 for 1 1/8 to 1 5/32 inches, $5.15 for 1 3/16 to 1 7/32 inches, and $4.50 for 1 1/4 inches and longer. (Fig. 37.)

Comparisons of the staple premiums and discounts paid in local markets with those paid in central markets show that the average discounts paid to growers for cotton with a staple of thirteen-sixteenths of an inch and shorter amounted to only 12 per cent of those paid in the central markets; and the average premiums paid for the longer staple lengths varied from 14 to 37 per cent of those paid in the central markets. The average grade differences were relatively greater than the staple premiums and discounts, as already indicated, but were considerably less than those paid in the central markets. (Figs. 36 and 37.) The relatively small variations in the prices of the different qualities of cotton in the same market at the same time, mean that, on the average, producers of high grades and long staples were penalized and that producers of low grades and short staples were paid comparatively more than their cotton was worth.

Benefits of Better Adjustment

The failure of the prices paid to individual growers to reflect accurately the grade differences and staple premiums and discounts quoted in central markets, coupled with the belief on the part of many farmers that the shorter staples can be produced at a lower cost per pound than can the longer staples, tend to stimulate production out of line with consumer demand in the direction of too much short-staple cotton. So long as the consumer demand is not reflected in the local markets in the form of differences in prices paid to individual growers, we may reasonably expect that the quality of cotton produced will

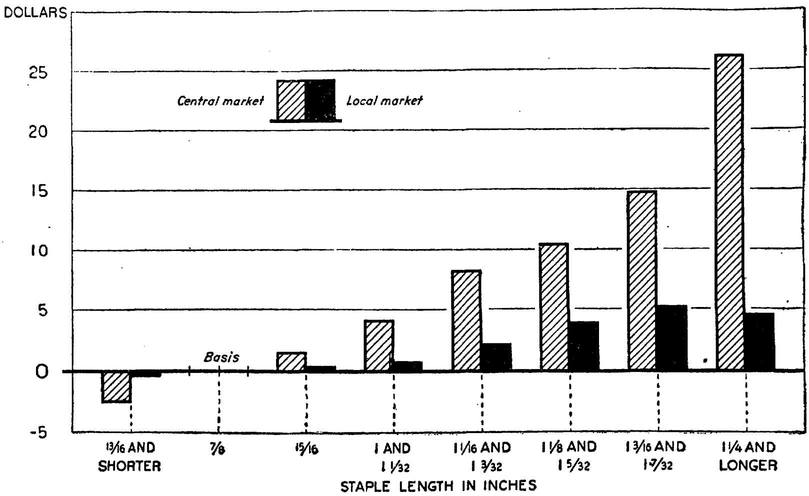

FIGURE 37.—Average staple premiums and discounts in dollars per bale of 500 pounds paid for White and Spotted cotton in local markets and in central markets in the United States, season 1928–29

continue to be out of line with consumer demand. A better adjustment of the quality of cotton produced to the demands of consumers would tend both to increase the returns to growers and to decrease the cost to consumers.

COTTONSEED Flour Rich in Vitamin G, Experiments Show

Cottonseed meal has had an important place in livestock feeding for more than a quarter of a century. When properly treated and refined it is a useful feed. Recent research in the department has demonstrated that cottonseed is a valuable source of the pellagra-preventing vitamin. Accordingly, the Bureau of Home Economic is studying the possibilities of cottonseed as a food for human beings.

Cottonseed, in the form of meal, is not a desirable human food. Cottonseed flour is better adapted to human requirements. It is more finely ground and more highly purified than the meal. Cottonseed flours were first manufactured and put on the market about 1910.

Their use increased during the war and has been continued in certain sections of the country. Cottonseed flour has high food value and palatable products can be made therewith. As it does not contain the gluten-forming constituents that give bread-making value to wheat flour, it is generally used in combinations with bolted wheat flour. Cottonseed flour can be substituted for about one-fifth of the wheat flour in various kinds of bread and baked products. This combination makes a darker bread than does white flour. The bread has a nutty flavor.

Composition of Cottonseed Flour

The composition of these flours varies with the source and method of preparation. They have been shown to contain from 50 to 58 per cent of protein and about 12 per cent of fat. About 6 per cent is ash, consisting chiefly of phosphorus and potassium. About 22 per cent of the flour is a mixture of sugar, gums, and resins. Cottonseed flour manufacturing processes eliminate lint and hulls and a large proportion of the resins. Feeding tests with small experimental animals were undertaken to ascertain the vitamin content of this cottonseed flour. The results showed that the flour is a good source of vitamins B and G. It contains from one-half to one-third as much vitamin G as yeast. At its present price of less than 10 cents a pound, cottonseed flour is a relatively cheap source of these vitamins and also contains other valuable nutrients.

Louise Stanley,
Chief, Bureau of Home Economics.

CRANBERRY Industry in Critical State Through False-Blossom Disease

As late as 1919 the disease of cranberries known as false blossom was so rare as to be a curiosity in the important cranberry-producing States of Massachusetts and New Jersey. Ten years later (in 1929) it was generally recognized as the most serious disease ever known on cranberries in those States, and its practical control constituted the outstanding problem of commercial cranberry culture.

Enough information is available regarding the introduction and spread of the disease in the eastern United States to give an unusually detailed picture of the spread of a disease on a cultivated crop and to furnish an important chapter in the history of the cranberry industry.

False Blossom a Virus Disease

False blossom is now known to be a disease of the virus type and to be transmitted by a leaf hopper, *Euscelis striatulus*.

The most easily recognized symptom of the disease is the one from which its common name is derived, that is, the development of abnormal flowers. The blossoms of diseased plants may be nearly normal in appearance but produce only small misshapen berries, or they may be so modified that all the flower parts have become merely green scalelike bracts. Another conspicuous symptom is the development of clusters of upright sterile branches in the place of the long trailing runners characteristic of the healthy cranberry. (Fig. 38.)

The disease causes a marked reduction of the crop, but usually does not cause the death of the plants unless accompanied by insect injury.

Their use increased during the war and has been continued in certain sections of the country. Cottonseed flour has high food value and palatable products can be made therewith. As it does not contain the gluten-forming constituents that give bread-making value to wheat flour, it is generally used in combinations with bolted wheat flour. False Blossom a Virus Disease

False blossom is now known to be a disease of the virus type and to be transmitted by a leaf hopper, *Euscelis striatulus.*

The most easily recognized symptom of the disease is the one from which its common name is derived, that is, the development of abnormal flowers. The blossoms of diseased plants may be nearly normal in appearance but produce only small misshapen berries, or they may be so modified that all the flower parts have become merely green scalelike bracts. Another conspicuous symptom is the development of clusters of upright sterile branches in the place of the long trailing runners characteristic of the healthy cranberry. (Fig. 38.)

The disease causes a marked reduction of the crop, but usually does not cause the death of the plants unless accompanied by insect injury.

The cranberry of commerce is native to North America, and the commercial cranberry-producing areas, with the exception of those in Washington and Oregon, are within the natural range of the wild cranberry.

Massachusetts and New Jersey together produce approximately 90 per cent of the cranberry crop of the United States. The most important varieties in both States are of Massachusetts origin. These are the Early Black, which makes up about 50 per cent of the crop of Massachusetts and 20 per cent in New Jersey, and the Howes, which constitutes about one-third of the crop in each State. The Howes has been for many years the standard late variety of cranberry which is

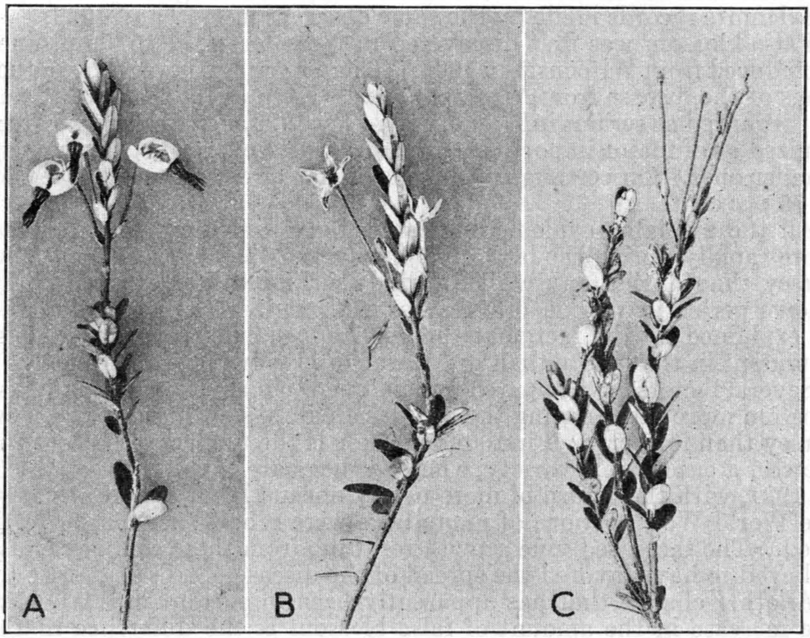

FIGURE 38.—A, Healthy cranberry "upright," showing normal flowers and growth; B and C, uprights affected with false blossom, showing distorted flowers and a small witches'-broom

held for the Christmas and later market. The extreme susceptibility of this important variety to false blossom makes the present situation a critical one for the cranberry industry.

The Spread of False Blossom

The available evidence indicates that false blossom first appeared on cranberries in Wisconsin and from there spread to other cranberry-growing States in shipments of diseased vines. Published reference to the disease in Wisconsin was first made in 1918, but it was certainly present in the State in 1895 and is believed to have been there at least 10 years earlier. Indeed, false blossom has been present so long in Wisconsin that the industry has become in a large degree adjusted to it. In those parts of Wisconsin where the disease has been severe the most susceptible varieties have been taken out because no longer profitable and the areas largely replanted to resistant varieties, notably the McFarlin.

Quite the opposite condition exists in Massachusetts and New Jersey, where the introduction of the disease is recent and where the adjustments are proving both difficult and expensive. Vines affected with false blossom are known to have been introduced into Massachusetts from Wisconsin in 1895, 1902, 1904, and 1910. The first survey for the disease was made in 1914, and it was found to some extent on five bogs. Another survey in 1919 showed that the disease was present on several other bogs, but in most of them it appeared to be of little commercial importance. In 1924 false blossom was known on 52 bogs in Massachusetts, and in 1929 it was the outstanding cranberry disease in that State. The increase was not only in the number of bogs known to be infected but in the amount of false blossom on bogs of which there are definite records made by the same observer in 1919 and 1929.

False blossom was first discovered in New Jersey in 1915 on vines introduced from Wisconsin in 1909. There were also several introductions of the disease from Massachusetts. Even as late as 1923 it was not regarded as serious in New Jersey. By 1929, however, it was recognized as of major importance on almost all the large bogs and many smaller ones. On certain areas the crop has already been reduced 50 to 75 per cent.

All the available evidence indicates that false blossom has spread more rapidly during the last 5 to 10 years in Massachusetts and New Jersey than during any earlier period in these States or during any known period in Wisconsin. Its slower spread in Wisconsin seems to be explained by the fact that the leaf hopper which carries it is less abundant in that State than in Massachusetts or New Jersey.

Several factors have apparently combined to make the spread of false blossom more rapid during the last decade in Massachusetts and New Jersey than formerly. First among these is the tendency to plant the Howes, a susceptible variety, wherever bogs are rebuilt. About 1920 or 1921, with the return of more nearly normal labor conditions after the World War, portions of many bogs were rebuilt, sanded, or fertilized. The increased vine growth resulting from these changes is also believed to have favored the spread of the disease.

Another change that has apparently been important in relation to the increase in the amount of false blossom is the difference in the method of handling the water. The most favorable time for flooding to control leaf hoppers is the latter part of June, too late, perhaps, for most effective fireworm control. During the spring of 1912 there was in Massachusetts marked and disastrous injury from flooding operations designed to control the black-headed fireworm. Following this there was much interest in problems relating to water injury. The result was a natural tendency to earlier flooding, which was safer for the plants but no doubt less effective for hopper control.

CREAMERY Industry in South is Solving Its Development Problems

Creameries are now established in all of the Southern States. Practically all the farmers in the South can now market their cream, either by direct delivery or by shipping to one or more of these creameries. The people of the South have progressed far beyond the point of establishing the fact that butter manufacturing is practical in the South, yet the progress thus far made is only a step in the direction of the possibilities that lie open for development.

Tick eradication made possible the creamery industry in the South. It was practically impossible to make any progress in creamery development while the tick scourge raged. There are yet other problems to contend with in the South that are peculiar to the region, but the greatest difficulties are those that are part of the establishment of the industry wherever it is started, difficulties which older, well-established dairy sections have met and overcome. These difficulties must be met, and some have been, and others will be met and mastered by the South.

One of the difficulties to be encountered when the creamery industry is first established is to find enough dairying in the territory covered to

FIGURE 39.—In many cases in the South, when new creameries were started in new dairy territory, the farmers wanted to be sure that the new creamery industry would succeed before they invested their money in standard creamery equipment. This picture shows a collection of miscellaneous containers at a new creamery, used by patrons during that period when they were trying to find out whether it would pay them to buy the more expensive standard cream cans

keep down to a reasonable figure the overhead costs of operating a creamery. In possibly every well-established creamery territory premature starts have been made. The South has had its share of premature starts and consequent failures; other undertakings have won out against heavy odds by intelligent efforts, persistence, and strict economy. Figure 39 illustrates the conservatism and caution that have preceded success in many communities in the South when the dairy industry was new to the people.

It is not now necessary, however, to go through the hardships of a premature start; farmers can patronize creameries already established until dairying has developed sufficiently to warrant the establishment of a creamery in their territory. Furthermore, the creameries already established can be used as a source of information and an example for anyone who wants to start a creamery in a new territory.

In spite of the fact that information may be obtained from the older creameries, and that free information and assistance, too, may be obtained from State and Federal extension services, still there are some who make starts which are bound to fail. This has proved to be the case in older dairy sections, and it has happened and will very likely continue to happen in the South.

Some Initial Difficulties

Undercapitalization is a difficulty closely allied with the premature starts. In fact, it may be possible with abundant capital to override a short period after a premature start, during which time dairying may develop and place the creamery on a paying basis.

Poorly planned, poorly constructed, and poorly equipped buildings add to the hardships of the new creamery industry. In such plants losses are incurred from unduly high costs, insanitary conditions, and wasteful machinery or machinery with which it is impossible for an operator, no matter how well trained, to apply his skill and scientific training.

Then also, creamery operators must be trained. Attempts are made to bring them from some well-established creamery section. However, the man who is skilled and capable usually has a good position at home; and many times men brought in do not have the necessary qualifications. Many, however, not only know their business and give the creamery the benefit of it, but also take a live interest in the development of the new creamery industry. They render valuable service in the establishment of creameries in the South.

Progress in the old-established creamery sections has been greatly influenced by men who have been educated in creamerymen's short courses and trained in actual creamery work. The Southern States are gradually providing short courses. Oklahoma, Mississippi, Arkansas, and Tennessee have done so. Alabama is to have a course.

Men trained and educated in their own State not only are equipped with technical knowledge, plant experience, and knowledge of the local conditions, but have an interest in their own community and State. This is an important qualification which can not always be expected from an outsider.

The conditions mentioned above are only a few of those directly affecting the creamery development and the trend of the butter manufacturing industry in the South. There are also influences of much importance which affect this industry as soon as the butter leaves the creamery and is on its way to the consumer. In the well-developed creamery sections refrigerated freight service is provided at the door of the creamery, and the butter goes under refrigeration all the way to far-off markets, a condition which did not exist in any creamery district in the early pioneering days.

Many southern creameries are shipping butter in large quantities to near and far markets without refrigeration, a large proportion of it by express at a much higher transportation rate than by freight. Only those creameries which manufacture sufficient butter to ship carload lots can avoid this difficulty of shipment without refrigeration and they are handicapped by inadequate facilities for distribution in local or near-by markets.

There are already indications of a solution to this problem in that several lots of butter from different creameries have been shipped to a point in central Tennessee and consolidated into carload lots. The

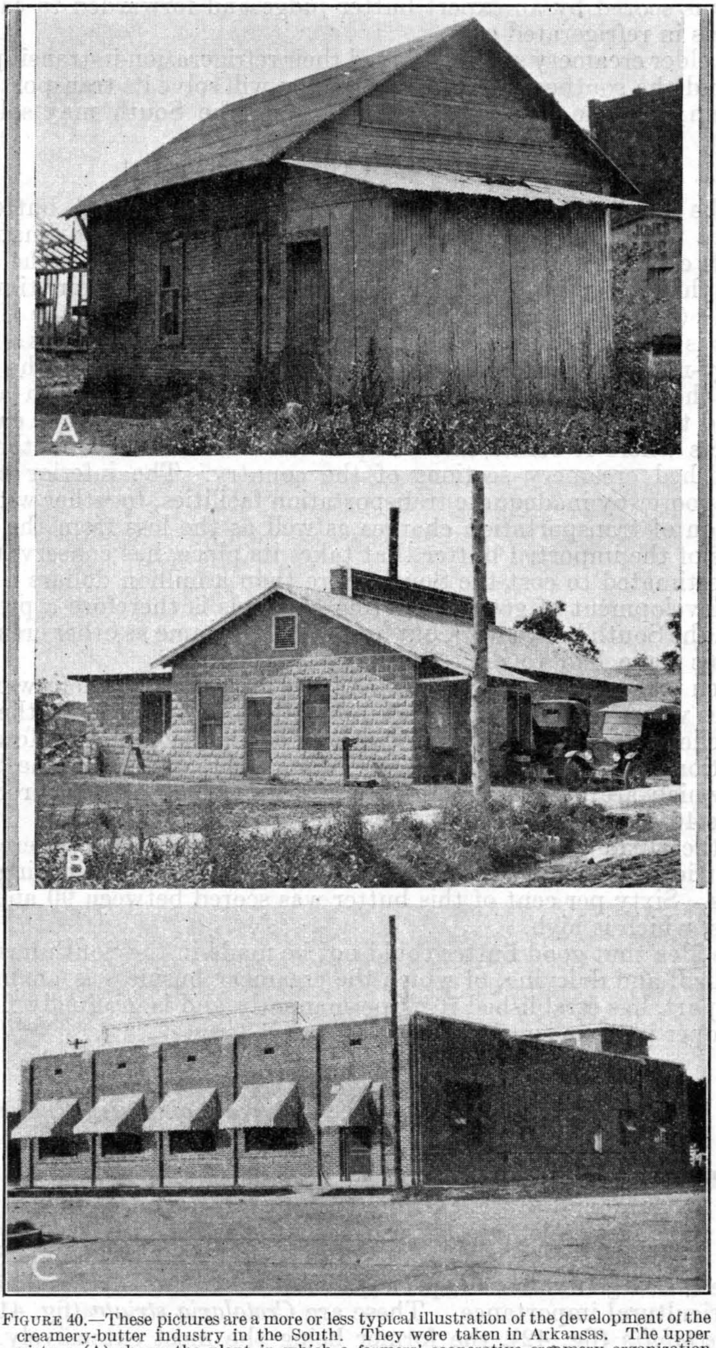

FIGURE 40.—These pictures are a more or less typical illustration of the development of the creamery-butter industry in the South. They were taken in Arkansas. butter is scored by an expert butter judge and forwarded to eastern markets in refrigerated cars.

The older creamery sections solved their refrigeration-in-transit problem, and the southern creamery industry will solve its transportation problem; with the aid of modern inventions the South may solve it better.

Marketing Channels Need Development

In the South the channels for the marketing of the South's butter are not yet very well developed. The South produces approximately 3 pounds of butter per capita of its population per year. On the other hand, the consumption of butter in the South is about four times as much. (The average consumption of butter per capita in the United States is approximately 17 pounds per year.) The South has a large hungry-mouthed market at home, yet, in certain seasons of the year, when the flush is on, the channels of the marketing stream are so flooded that the southern butter runs over and into the large eastern markets where it comes into competition with butter from the old-established creamery sections of the country. The inferior butter made poorer by inadequate transportation facilities, together with the addition of transportation charges as well as the loss from the same causes of the imported butter that takes its place, has conservatively been estimated to cost the South more than a million dollars a year. The development of good marketing channels is therefore a problem which the South has to work out for itself—the same as other creamery sections have had to do.

When creameries first began operation in the South there were instances where merchants refused to handle the butter made; they did not believe that good butter could be made in the South. However, conditions have changed. There are many creameries in the South now which are doing substantial business in high-quality products. Figure 40 shows an example.

At the Dixie butter-scoring contest in September, 1930, there were 53 entries of creamery butter from 53 creameries representing nine States. Sixty per cent of this butter was scored between 90 and 93.5 points, which is high.

The idea that good butter could not be made in the South has been dispelled, and dairying, of which the creamery business is an inseparable part, has established itself permanently and is gradually finding its proper place in southern agriculture.

Associate Manufacturing Specialist,
Bureau of Dairy Industry.

CROTALARIA, a New Green Manure and Forage Crop, Promises Well in South

Crotalaria, a new summer cover and green-manure crop, is proving to be especially well suited to the sandy lands of the South. There is a large number of species, two of which already have become of agricultural importance. These are *Crotalaria striata* (fig. 41) and *C. spectabilis* (fig. 42), the former being the most extensively used. So far their use has been confined almost exclusively to soil improvement, but they also give promise of being of value for forage. Both species are moderately branched, upright growing annuals, attaining a height of from 3 to 6 feet. The leaves of the two species mentioned, while comparatively large, are numerous, and the plants can well be described as leafy

Other species have been used in experimental work, and some of these give potential promise, but further work will be necessary to determine their real value.

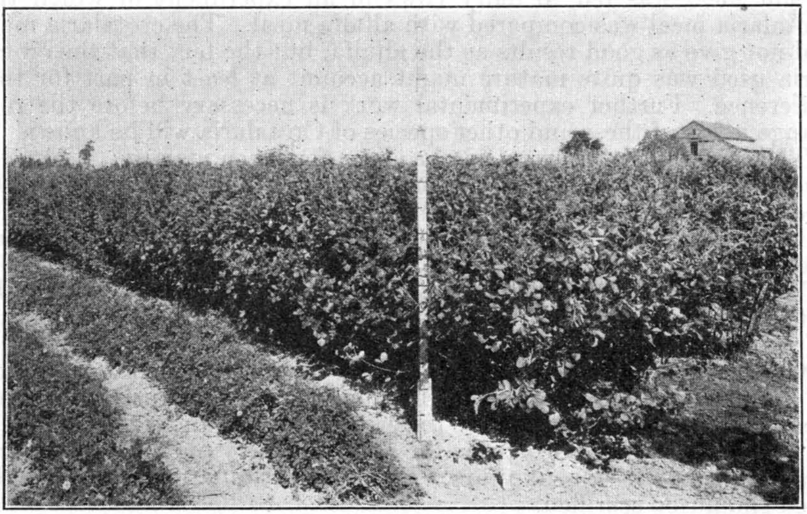

FIGURE 41.—*Crotalaria striata* planted in rows at McNeill, Miss. Plants with pods well developed

Most of the species of Crotalaria require warm climatic conditions. *C. striata* has matured seed as far north as North Carolina, while *C. spectabilis* has matured but little seed at Columbia, S. C. In 1930 the latter matured no seed at Columbia, while the former matured a heavy crop. *C. striata* matures seed farther north than *C. spectabilis*, but the latter species grows much larger in northern latitudes than the former.

FIGURE 42.—*Crotalaria spectabilis* in row plantings at McNeill, Miss. Plants in full bloom

While many Crotalaria species are native to tropical regions with heavy rainfall, none so far as tested in experimental plantings give promise of being adapted to wet or heavy soils. They make their best growth in rich sandy loam, but also do well on soils that are made up largely of sand. In the poor sandy lands of the coastal plains area of the southeastern United States, both *C. striata* and *C. spectabilis* have proved to be better adapted than the commonly cultivated crops, and it is for this region that they seem to hold the greatest promise.

Many species of Crotalaria have a bitter taste in the green state and seem to be avoided by livestock. *C. spectabilis* seems to be more palatable than *C. striata* and is eaten to some extent by stock after they have acquired a taste for it.

At the Florida Agricultural Experiment Station at Gainesville, *C. striata* meal was fed to dairy cows in an experiment in which the crotalaria meal was compared with alfalfa meal. The crotalaria meal did not give as good results as the alfalfa, but the fact that the crotalaria used was quite mature might account at least in part for this difference. Further experimental work is necessary before the real forage value of these and other species of Crotalaria will be known.

The greatest use of crotalaria has been for green manure. *C. striata* has been used most extensively in the citrus groves of Florida and *C. spectabilis* in the pecan groves.

In experimental plantings at Gainesville, Fla., greatly increased yields of corn and sweetpotatoes have followed the use of crotalaria.

While but few chemical analyses of Crotalaria have been reported, the information available indicates that it is high in protein and is similar to many other legumes in this respect.

Crotalaria seed stored under favorable conditions has a long period of viability. The percentage of hard seed is high, ordinarily ranging from 60 to 90 per cent. Where the crop is to be volunteered from year to year this is an advantage, as the seed will carry over in the soil and germinate in subsequent years. If a high germination is desired the seed should be scarified.

The organism that inoculates crotalaria seems to be present in all our soils, so that artificial inoculation is not necessary.

Commercial fertilizer has been used in experimental work to increase the yield of crotalaria, but the growth without fertilizer is sufficiently large so that probably it seldom can be used profitably.

All species of Crotalaria should be sown in the late spring. Warm weather is essential for their rapid development. For green manure or forage, seedings should be broadcast or sown in close drills, using about 15 pounds of scarified seed per acre. For seed production plantings should be in wide rows and given cultivation. Yields of seed obtained from experimental plantings have ranged from 300 to 900 pounds per acre, while forage yields have ranged from 2 to 6 tons.

Crotalaria seems to have but few enemies. All species have been immune to the root-knot nematode, and no fungous disease has done serious damage. The bella moth attacks the seed and does some damage and may be serious with further development of the crop. No method of control is known. Another insect, the pumpkin bug, feeds upon the green pods of crotalaria, but does little damage to the crop. Trouble may be encountered, however, when crotalaria is used in citrus orchards. The pumpkin bug, which is harbored by crotalaria when in the green-pod stage, may attack the citrus fruit if for any reason the crotalaria is destroyed after the pumpkin bugs have become numerous. To cut the crotalaria in the citrus groves before it comes into pod is therefore essential.

Aside from their use as field crops, several species of Crotalaria have ornamental value and can be used for both cut flowers or to beautify the out of doors. *C. spectabilis*, *C. retusa*, and *C. usaramoensis* are especially well suited for this purpose.

Roland McKee,
Senior Agronomist, Bureau of Plant Industry.

DAIRY-BULL Associations Increasing and Building Up Herds' Production Cooperative dairy-bull associations are organized by farmers for the purpose of jointly owning, using, and exchanging meritorious purebred dairy bulls. The typical association consists of at least five divisions, called blocks. Each block has one or more members, and one bull is assigned to each block.

To prevent inbreeding, each bull is moved to the next block every two years. If there are five blocks and all the bulls live until they have made one complete circuit, new bulls need not be purchased for 10 years. This systematic exchange of bulls makes it possible for a dairyman with a small or medium-sized herd to have the use of several good purebred bulls for a number of years, at a cost amounting to only a small part of the cost of one good bull. As the purchase price of the bulls and the cost of maintaining them are prorated according to the

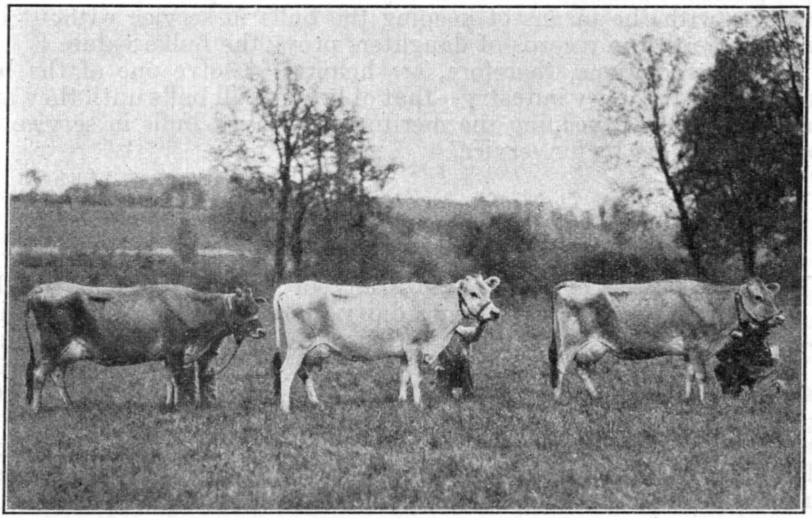

FIGURE 43.—Daughters of three bull-association bulls. Each of these daughters has produced more than 500 pounds of butterfat in one year

number of cows owned by the member, it oftentimes costs a member less to own a share in a number of good purebred bulls than to own one scrub or grade bull with himself as the sole owner. Bull associations are finding favor among not only the owners of small and medium sized herds but also the owners of the larger herds.

Growth of Associations

The first cooperative bull association in the United States was organized in Michigan in 1908. Since then the number of associations has grown steadily, until on January 1, 1930, there were 296 active associations in 26 States, with a membership of 6,930 dairymen owning 44,578 cows, and jointly owning 1,280 purebred dairy bulls.

The only way to determine whether bull associations are accomplishing the purpose for which they were organized, namely, the building of better dairy herds, is by comparing the yearly records of the daughters of the bulls with the yearly records of the dams of the daughters. On

June 30, 1930, the Bureau of Dairy Industry had compared the yearly records of 583 daughters of 72 bull-association bulls, with the records of their dams. Before doing this the records of all immature cows were figured to maturity. The dams produced, on an average, 9,602 pounds of milk and 383 pounds of butterfat. The daughters produced, on an average, 10,047 pounds of milk and 413 pounds of butterfat. The daughters produced 445 pounds of milk and 30 pounds of butterfat more than their dams, which were themselves high producers. This higher production of daughters over such high-producing dams is convincing evidence that the bull associations are helping to build better dairy herds. Figure 43 shows daughters of three bull-association bulls. Each of these daughters has produced more than 500 pounds of butterfat in a year, which was more than their respective dams ever produced.

Bull associations provide farmers not only with the service of high-class purebred bulls for a number of years at a comparatively low cost, but also with the means of keeping the bulls in service without inbreeding until the records of daughters prove the bull's value.

These associations, therefore, are helping to solve one of the big problems of the dairy industry—that of keeping all bulls until they are proved, and then keeping the meritorious proved bulls in service as long as they are fit for service.

W. E. Wintermeyer,
Associate Dairy Husbandman, Bureau of Dairy Industry.

DAIRY Bulls Proved by Herd Associations Often Fall Below Requirements Many of the proved bulls in the dairy herd-improvement associations are not increasing the production of the herds in which they are used. Up to June 30, 1930 the Bureau of Dairy Industry had proved 1,100 bulls, by comparing the yearly milk and butterfat records of five or more unselected daughters of each bull with the records of the dams of the daughters. Table 3 shows the influence which 1,000 of these proved bulls have had on the herds in which they were used.

Table 3.—*Bulls grouped according to gain or loss in butterfat of daughters as compared with dams of daughters*

Number	*Pounds*
366	−248 to −1
7	0 to 0
313	+1 to +53
314	+54 to +324

According to Table 3, about one-third of the bulls sired daughters whose butterfat production was less than that of their dams, about one-third sired daughters with a butterfat production very little more than that of their dams, and the other third sired daughters producing considerably more butterfat than their dams.

Table 4 gives the records of two of the bulls proved. These bulls were purebreds of the same breed. Each bull had 10 daughters whose yearly production records were compared with the records of their

[1] Average.

The study of the bulls that are being proved in dairy herd-improvement associations indicates that if the average production of the cows in these associations is to be increased or even maintained, only those bulls can be depended upon to do this which have already sired a number of daughters that excel or equal high-producing dairy cows.

W. E. WINTERMEYER,
Associate Dairy Husbandman, Bureau of Dairy Industry.

DAIRY-COW Culling Often Profitable in Herds of High-Average Production Success in dairy farming depends primarily upon four things: Culling, feeding, breeding, and marketing. The dairyman who culls out all unprofitable cows, and feeds the rest according to their known capacity for production, who uses only bulls of proved merit, and who can market the products of his herd at reasonable prices, is usually successful or well on the way toward success.

Investigations conducted by the Bureau of Dairy Industry show that in most commercial dairy herds, close culling should greatly increase the net profits. The beneficial effects of proper culling are brought out in a recent comprehensive study of the individual cow records in herds of average production on test in dairy herd-improvement associations. The results obtained in this work may be taken as being representative of the average herds throughout the country. They show that culling out the one lowest producer per 100 dairy cows, or 1 per cent, would reduce by only 0.4 of 1 per cent the total production of milk and butterfat from the dairy cows in this country; culling

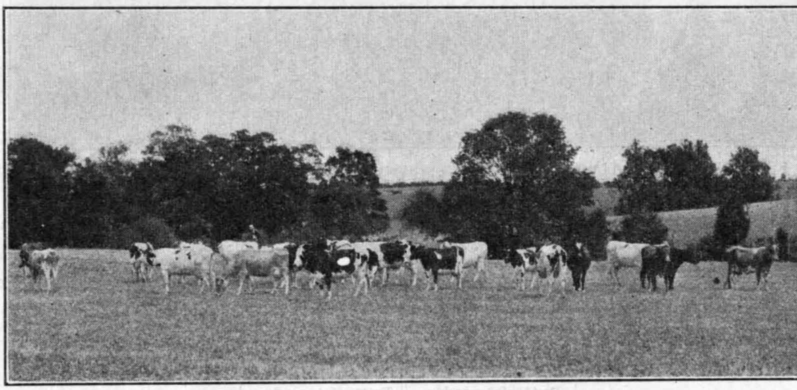

FIGURE 45.—Dairy herd in the Fairfax Dairy Herd-Improvement Association, Fairfax, Va. This herd has been so improved by close culling that the lowest producer in 1929 yielded as much as 5,958 pounds of milk containing 309.1 pounds of butterfat

out the lowest-producing 3 per cent of the cows would eliminate approximately 1 per cent of the total production; and culling out 10 per cent would eliminate only about 5 per cent of the total production.

The 10 per cent that were culled out in the herd-improvement tests averaged only 96 pounds of butterfat per cow, which is too low a production for profit. The owner of a commercial dairy herd of average production can well afford to cull out the lowest-producing 10 per cent of his cows. There are a few very high-producing herds in which the lowest producers exceed 300 to 400 pounds of butterfat annually. (Fig. 45.) Such herds are usually profitable and require little or no culling. On the other hand there are many low-producing herds which have no cows that produce more than 200 pounds of butterfat a year. With a herd made up of such low producers it might be well to sell the whole herd, buy some good cows, and start a new herd.

Closer culling might pay even in purebred dairy herds. The lowest-producing 10 per cent of the mature registered Guernseys, Jerseys, and Holsteins on test in 1928 averaged 170 pounds of butterfat per cow. The average income over cost of feed for the lowest-producing 10 per cent of the registered cows of these three breeds was only $50 per cow.

Certainly that is too low an income above cost of feed for a mature registered dairy cow.

In 10 typical herds of 20 cows each, the lowest-producing cows in each herd were compared with the highest producers in the same herd. On an average, the two lowest producers both gave less milk and butterfat than the one highest producer in the same herd. The two lowest producers together ate approximately 50 per cent more feed than the one highest producer, yet she excelled them by 62 per cent in production. In fact, it required the three lowest producers to bring in as much income above the cost of feed as was brought in by the one highest producer. If it be assumed that there is no net profit from a cow until she returns $2 for each dollar spent for feed, the highest-producing cow in the 20-cow herd brought in more net profit than the seven lowest producers in the same herd.

In herds smaller than 20 cows there would normally be less difference between the lowest and the highest producing cows, but even in herds as small as 10 cows there is a wide spread between the production and income from the lowest producer in the herd as compared with the production and income from the highest producer.

These figures indicate that even in most dairy herd-improvement associations, closer culling would generally increase the net profits. If the best cow in the herd produces more milk and butterfat than the two poorest cows, and brings in more income over cost of feed than the three poorest cows, it seems clear that it would pay the dairyman to replace the three poorest cows with one high producer, thereby culling the herd at the bottom and building it up at the top.

Culling, therefore, should be accompanied by buying better cows, and also by better breeding, in order that improvement may be progressive and permanent. Although culling will raise the quality of nearly any dairy herd and increase its production per cow, for continuous improvement good sires must be used.

Good feeding, too, is very important. After the lowest producers are culled out, the improved herd should usually have more feed per cow than the original herd. Large producers are always large eaters, but they require less feed per pound of milk or butterfat produced. A very good slogan for the dairy farm may be expressed in these words: "Breed the best, feed the best, keep the best, and cull the rest."

J. C. McDowell,
Senior Dairy Husbandman, Bureau of Dairy Industry.

DAIRY Earnings Larger if Cream Is Marketed While Fresh and Sweet The aggregate loss of income to creamery patrons through deterioration in the quality of cream before it reaches the creamery amounts to an enormous amount of money. The earnings of many dairy herds can be increased by using the best methods of producing and caring for cream and marketing it fresh and sweet. A farmer who owns 10 cows may receive more money for his cream, if it is of good quality, than a neighbor who owns 11 cows and delivers cream of poor quality, if the average production of the cows in both herds is the same. High-quality cream from 10 cows will return more profit than low-quality cream from 11 cows, when both products are sold to a creamery that pays for cream on a basis of the grade of butter that can be made from it, if the

Certainly that is too low an income above cost of feed for a mature registered dairy cow.

In 10 typical herds of 20 cows each, the lowest-producing cows in each herd were compared with the highest producers in the same herd. On an average, the two lowest producers both gave less milk and butterfat than the one highest producer in the same herd. J. C. McDowell,
Senior Dairy Husbandman, Bureau of Dairy Industry.

DAIRY Earnings Larger if Cream Is Marketed While Fresh and Sweet

The aggregate loss of income to creamery patrons through deterioration in the quality of cream before it reaches the creamery amounts to an enormous amount of money. The earnings of many dairy herds can be increased by using the best methods of producing and caring for cream and marketing it fresh and sweet. A farmer who owns 10 cows may receive more money for his cream, if it is of good quality, than a neighbor who owns 11 cows and delivers cream of poor quality, if the average production of the cows in both herds is the same. High-quality cream from 10 cows will return more profit than low-quality cream from 11 cows, when both products are sold to a creamery that pays for cream on a basis of the grade of butter that can be made from it, if the per-cow production of the two herds is the same. If this fact were more generally realized by creamery patrons, many of them would be making more money from their cows and more creameries would be paying for cream on a quality basis.

The average wholesale price of high-quality butter (93 score) on the New York market for the three years 1927, 1928, and 1929, was 47.5 cents a pound. The average price of low-quality butter (88 score) was 43 cents, a difference of 4.5 cents a pound.

Ten cows producing an average of 200 pounds of butterfat a year, selling at the high-quality price of 47.5 cents a pound, would return $950. Eleven cows averaging 200 pounds of butterfat, selling at the low-quality price of 43 cents a pound would return $946.

For cream to bring the higher price, it must be delivered at the creamery fresh, sweet, and fine in flavor. This requires cleanliness of cows and utensils; cooling the cream promptly and keeping it cold; and frequent delivery of the cream, that is, four times a week if the cream is kept cold on the farm, or daily if necessary. These items involve a certain amount of labor and labor is an item of expense.

But if selling cream at the low-quality price necessitates keeping an extra cow in order to get the same income, this requires an investment of money to buy one more cow. It also requires additional barn space, additional labor to clean and feed one more cow, additional labor for milking, additional time and labor to separate the milk, and, above all, additional feed.

The expense incurred in keeping that eleventh cow is greater than the expense involved in the delivery of fresh, sweet cream from 10 cows.

Many cream producers may find that this does not apply to them because they live too far from a creamery, or do not produce much cream, or do not have cold water for keeping the cream sweet—conditions which make it impracticable for them to deliver cream in sweet condition. However, many small cream producers can make more effective use of the cooling water available. They can cooperate with their neighbors in hauling cream to the creamery or can organize a cream-gathering route. Such a route can usually be operated profitably when a truck load of cream can be picked up at the rate of not less than 8 pounds of butterfat per mile traveled.

In many communities the delivery of cream in sweet and fresh condition can be effected by the exercise of initiative, energy, and cooperation.

WILLIAM WHITE,
Senior Manufacturing Specialist,
Bureau of Dairy Industry.

DAIRY Records Indicate Needed Margin Between Costs and Production Culling out unprofitable cows from the dairy herd is a problem that confronts every progressive dairy farmer. In order to cull intelligently, the dairyman must, of course, take into consideration the production of the cow, the cost of feed, labor, and overhead and the selling price of the product.

Feed cost, for the average dairy cow, is about 50 per cent of the total cost of milk production. The ratio of cost of feed to total cost varies considerably, however, in different sections of the country. A cow whose production might be too low to make her profitable in one per-cow production of the two herds is the same. If this fact were more generally realized by creamery patrons, many of them would be making more money from their cows and more creameries would be paying for cream on a quality basis.

The average wholesale price of high-quality butter (93 score) on the New York market for the three years 1927, 1928, and 1929, was 47.5 cents a pound. The average price of low-quality butter (88 score) was 43 cents, a difference of 4.5 cents a pound.

Ten cows producing an average of 200 pounds of butterfat a year, selling at the high-quality price of 47.5 cents a pound, would return $950. Eleven cows averaging 200 pounds of butterfat, selling at the low-quality price of 43 cents a pound would return $946.

For cream to bring the higher price, it must be delivered at the creamery fresh, sweet, and fine in flavor. This requires cleanliness of cows and utensils; cooling the cream promptly and keeping it cold; and frequent delivery of the cream, that is, four times a week if the cream is kept cold on the farm, or daily if necessary. These items involve a certain amount of labor and labor is an item of expense.

But if selling cream at the low-quality price necessitates keeping an extra cow in order to get the same income, this requires an investment of money to buy one more cow. It also requires additional barn space, additional labor to clean and feed one more cow, additional labor for milking, additional time and labor to separate the milk, and, above all, additional feed.

The expense incurred in keeping that eleventh cow is greater than the expense involved in the delivery of fresh, sweet cream from 10 cows.

Many cream producers may find that this does not apply to them because they live too far from a creamery, or do not produce much cream, or do not have cold water for keeping the cream sweet—conditions which make it impracticable for them to deliver cream in sweet condition. However, many small cream producers can make more effective use of the cooling water available. They can cooperate with their neighbors in hauling cream to the creamery or can organize a cream-gathering route. Such a route can usually be operated profitably when a truck load of cream can be picked up at the rate of not less than 8 pounds of butterfat per mile traveled.

In many communities the delivery of cream in sweet and fresh condition can be effected by the exercise of initiative, energy, and cooperation.

William White,
Senior Manufacturing Specialist,
Bureau of Dairy Industry.

Dairy Records Indicate Needed Margin Between Costs and Production

Culling out unprofitable cows from the dairy herd is a problem that confronts every progressive dairy farmer. In order to cull intelligently, the dairyman must, of course, take into consideration the production of the cow, the cost of feed, labor, and overhead and the selling price of the product.

Feed cost, for the average dairy cow, is about 50 per cent of the total cost of milk production. The ratio of cost of feed to total cost varies considerably, however, in different sections of the country. A cow whose production might be too low to make her profitable in one section might furnish an excellent market outlet for feed in another section where good roughage is grown and where other market outlets are not available.

Although, on an average, the expense for labor and overhead about equals the cost of feed, these items may be considerably below the average for farms where family labor is utilized and for farms located in a section of low-priced land.

When the price of butterfat goes down, the production per cow must go up, if a satisfactory profit is to be made. Assuming that it costs $90 a year to feed a dairy cow, the cow that is producing only 180 pounds of butterfat a year is just paying for her feed if the butterfat is bringing 50 cents a pound. If the butterfat sells for 45 cents a pound a cow must produce 200 pounds of butterfat to pay for her feed. And if butterfat is selling at 36 cents she must produce 250 pounds; and if at 30 cents, she must produce 300 pounds.

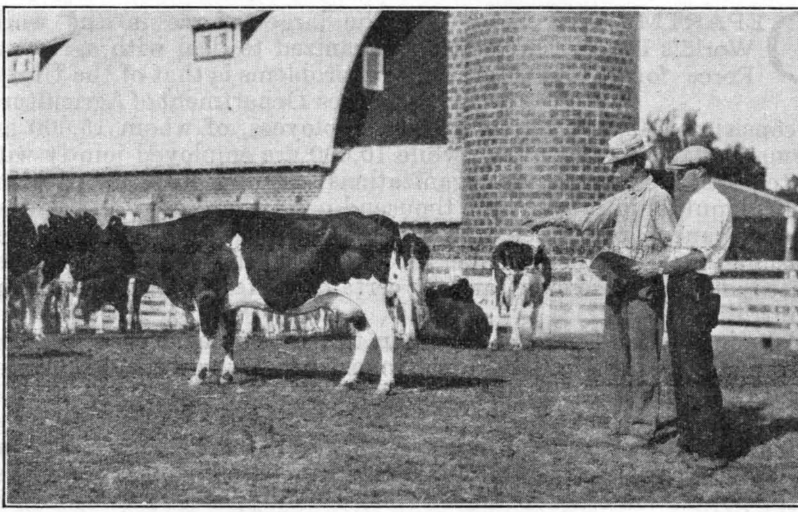

FIGURE 46.—Tester and dairyman looking over herd in barnyard

The records of more than 200,000 cows tabulated by the Bureau of Dairy Industry in 1928 show that, on the average, the dairy herd-improvement association cows returned a good profit over all items of expense. Table 5 shows the 1928 records of the average dairy herd-improvement association cow and the records of three lower-producing cows taken at random from a report.

TABLE 5.—*Average dairy herd-improvement association cow compared with three lower-producing cows*

Cow	Milk	Butterfat	Value of product	Feed cost	Income returned over cost of feed
	Pounds	*Pounds*			
A[1]	7,464	295	$193.00	$77.00	$116.00
B	5,400	216	140.40	70.20	70.20
C	4,000	160	104.00	64.00	40.00
D	3,000	100	65.00	65.00	

[1] Average of 200,000 cows.

The average dairy herd-improvement association cow paid her feed bill of $77, which may be estimated as half of the total cost of production, with a balance of $116 over the cost of feed. The cow B paid for her feed, $70.20, with an equal amount above that for labor and overhead. The cow C, although she returned $40 over her feed costs, which were $64, was not profitable unless the labor and overhead expenses were considerably below the average. There is no question about the cow D being a good example of a cull cow.

Almost every dairy herd in the country would be benefited by culling out the lowest producers. Intelligent culling, however, requires good judgment and a thorough knowledge of the production records and of the feed requirements of the individual cow.

J. E. Dorman,
Senior Dairy Husbandman, Bureau of Dairy Industry.

DEPARTMENT'S Staff Is World's Largest Organized Force for Aiding Farmer

The largest force in the world organized to deal with agricultural problems is that of the United States Department of Agriculture. It consists of approximately 25,000 employees, of whom 15,000 are permanent full-time workers, while 10,000 are employed jointly with State governments or civic organizations to study problems in which there is mutual interest. Five thousand persons or about one-third of the permanent personnel of the department have headquarters in Washington; the other members are stationed throughout the United States and its possessions and at certain strategic points in foreign countries.

Appointments of persons to aid in the development of agriculture were made by the United States Government as early as 1839 when Congress appropriated $1,000 for the purpose. From a nucleus of a few persons working under the jurisdiction of the Commissioner of Patents, the agricultural staff of the Federal Government has grown until at the present time its 25,000 members equal what is recognized as the population of a substantial American city, such as Concord, the capital of New Hampshire. The staff exceeds the population of approximately 16,000 cities in this country. In Washington alone, it occupies the whole or a part of more than 57 buildings in various sections of the city. Its annual pay roll is approximately $36,000,000.

The personnel of the department is selected through established civil service procedure. Carefully standardized assembled examinations conducted by the Civil Service Commission are the rule, but applicants for scientific positions are not usually required to assemble at a given place but are rated on education, training and experience, and on an original thesis. In line with the movement for improving the technic of employment, the commission in special cases—that of bureau chief, for instance—gives an oral examination or personal interview. From the list of eligibles thus obtained the department selects those it considers best qualified to fill the vacancies.

Education and Training of Staff

The education and training of the members of the department staff show wide variations. Some individuals have as many as six degrees from accredited colleges, whereas others have training acquired through practical experience and perhaps only a grade-school educa-

In line with the movement for improving the technic of employment, the commission in special cases—that of bureau chief, for instance—gives an oral examination or personal interview. From the list of eligibles thus obtained the department selects those it considers best qualified to fill the vacancies.

Education and Training of Staff

The education and training of the members of the department staff show wide variations. Some individuals have as many as six degrees from accredited colleges, whereas others have training acquired through practical experience and perhaps only a grade-school education. Some combine both the higher education and the practical experience. Of the permanent full-time personnel of 15,000, over two-thirds had scientific or technical training before they came to the department. Among this number are included many outstanding scientists and economists.

The highly trained workers furnish the leadership that is essential to the conduct of the department's program. Under their direction less adequately trained workers carry on investigations and experiments, thus acquiring experience which leads toward advancement. It is from the ranks of well-trained assistants that the future leaders of agriculture are recruited.

Advancement within the department comes through the assumption and discharge of increased responsibilities. Continued education and increasing familiarity with technical details of the work point the way for those in the lower grades, to an improved status. The department has a number of outstanding illustrations of gradual advancement of its members from some of the lowest positions to positions of responsibility and leadership.

To stimulate its workers to increased effort to obtain advanced training, the department in 1921 organized what is known as the Graduate School of Agriculture. Undergraduate as well as graduate courses are given by department scientists and economists, most of whom have had teaching experience in at least one of our leading agricultural colleges. Classes meet in department buildings for regular periods immediately after office hours, but individual work on definite problems is frequently done by adequately prepared students under supervision in the research laboratories. That department workers avail themselves of the opportunity for advanced training at nominal expense is shown by the fact that in the nine years the school has been functioning 1,633 have registered for the courses offered. The result has been not only a higher morale among these workers but a marked increase in their efficiency.

All positions in the department are classified in accordance with the salary classification act of 1923 and amendments. The duties of each position are carefully evaluated and the position is allocated to an appropriate grade. The distinction between grades is based upon differences in the importance, difficulty, responsibility, and value of the work. As in other Government departments, the rates of compensation, hours of work, leave of absence for sickness or for play, and retirement annuities are determined by law.

The staff of the department may be grouped roughly into five classes: (1) Research, (2) service and regulatory, (3) educational and informational, (4) administrative and clerical, and (5) mechanical.

Workers engaged in fundamental research are responsible for the increase of scientific knowledge. These are the chemists, biologists, physicists, entomologists, and other scientists, and economists who pave the way for much of the practical work carried on by the department.

The second group puts the scientific knowledge into practice. These workers develop and carry on the many and varied economic services, such as crop, market, and weather reporting, and they administer approximately 50 regulatory laws among which the meat inspection act, the plant and animal quarantine laws, the food and drugs act, and the commodity standards acts are perhaps best known.

The third group assists in making available the results of all the department's activities. Through the press, bulletins, periodicals, motion pictures, exhibits, and radio, timely information is disseminated to the public, and by personal contacts in the States the information is carried direct to the individual farm and home.

The fourth group is made up of business executives, clerks, technicians, and accountants who perform work commonly associated with the conduct of any business.

In the fifth group are the artisans trained in some mechanical art or trade. They are the workers such as are found in the department's shops, where exhibits are prepared for display at fairs and where scientific or mechanical equipment is made or repaired. They also are the gardeners and other skilled workers at the experimental greenhouses and at the six experimental farms near Washington.

Much is frequently written about the head of a department or a bureau, or of a famous scientist or economist, but often too little credit is given to the painstaking, efficient endeavor of the well-trained laboratory or office assistant. These workers compile and correlate much of the data upon which conclusions are drawn, and upon the individual's efficiency, therefore, depend in large measure the accuracy and timeliness of many reports.

Opportunity for Public Service

Opportunity for public service is responsible for holding many workers in the department against flattering offers from other institutions and commercial businesses. Many of the men and women of the department are interested primarily in their work. Because of this spirit, their capacity for serving the Nation appears to be unlimited.

For the servants of agriculture, no piece of work is too large to tackle nor too small to be overlooked. The inauguration of the several national services now conducted by the department, such as aid in Federal road construction, conservation of timber resources, and conservation and control of bird and wild animal life, are examples of tremendous undertakings which the vision, planning, and industry of the workers have brought to the present successful basis of operation. On the other hand, the invention of a small implement, perhaps a simple piece of work in itself, often improves a farm practice that has stood for years.

Whether in research, or service, or in the application of both, each worker contributes his part to the building of a permanent agriculture. Workers come together in the department for the performance of a task difficult of accomplishment by other than a thoroughly unified, well-managed, efficient organization. These hired servants are sowing for a harvest to be reaped by the Nation in the form of a better agriculture.

DISINFECTANT'S Action Depends on Conditions in Which It Is Used

Most persons seem to think that a disinfectant acts in some magic way, and that all that is necessary to do is to apply it and all will be well. Practically everyone knows that disinfectants have something to do with controlling or killing germ life. But how many people know anything about the scientific facts behind the use of disinfectants; and how many know that an understanding of these facts would make it possible to buy and use disinfectants more economically and more effectively?

It is not, for example, common knowledge that the concentration at which a disinfectant application is made is extremely important—in fact, this may be the deciding factor in the power of the disinfectant to kill germs. Disinfectants also vary in character, and should be selected for use according to their fitness for the purpose in view. All disinfectants are not alike. All are not designed for the same kind of bacteria or the same method of usage.

A disinfectant is an agent which will kill the vegetative forms of disease germs but which will not necessarily kill spores. Spores are resistant forms in the life cycle of certain bacteria and other microorganisms. Fortunately, only a few species of germs produce spores. The term "disinfection" should not be confused with "sterilization," which means the killing of all forms of life, including spores.

The Process of Killing Germs

Scientists have found that all germicidal substances do not kill germs in the same way. The process of killing germs is not a simple one, and many factors are involved.

Contact is of primary importance. In order for a chemical disinfectant to kill germs the chemical must come into close contact with them. If a germ is protected by a film of grease or albuminous matter, or if it is deeply embedded in the material to be disinfected, the disinfectant will probably not come into contact with it and, hence, will have no germicidal action in that particular case. This means, in most cases, that surfaces to be disinfected must be mechanically or physically clean before effective action can be expected.

The concentration of a disinfectant is also to be considered. Carbolic acid in weak solutions will retard the growth of bacteria, and in strong solutions will kill them, but such weak concentrations of carbolic acid can be made that the disinfectant has no effect whatever. Certain disinfectants in very weak solutions are actually stimulating to bacterial life. As a matter of fact, alleged disinfectants containing living germs have been found upon the market.

The Time Element

Another deciding factor in the effective use of disinfectants is the time element. We find that at a certain concentration a disinfectant fails to kill certain bacteria in 5 minutes but does kill in 10 minutes. A disinfectant in another concentration may kill in 5 minutes but fail in its effect in 4 minutes, or in 1 minute.

Very often the temperature at which the disinfection takes place has a marked influence upon the mortality rate of the bacteria treated.

Probably few people know that disinfection is more effective in the presence of water than in the dry state. This is true whether the process is accomplished by the application of heat or of chemicals. Some manufacturers do not realize this, and they may recommend kerosene solutions of chemicals for disinfecting purposes, whereas the product happens to contain a chemical which is a disinfectant when properly dissolved or emulsified in water, but which has no such power when dissolved in kerosene.

Some disinfectants are markedly affected by the presence of organic matter. Hypochlorites and soluble salts of mercury, for example, are effective disinfectants in very weak solution when there is a practical absence of organic matter, but they possess little disinfectant value in the presence of such matter.

The selection of a suitable disinfectant is no easy matter. Sometimes the selection is complicated by purely outside considerations. A disinfectant may have a vile odor, and therefore be of questionable use in connection with foods or utensils used for food production. Many disinfectants corrode metal and can not be used on metals. Many are caustic and burn the skin or tissues of the body. Practically all of them are poisonous when used carelessly.

Need for Proper Labeling

Some manufacturers who do not maintain research laboratories do not thoroughly understand the limitations of their own products. Because of this, and because of the complicated factors to be considered by the one who uses the disinfectant, it has become necessary to have some disinterested agency see that disinfectants are properly labeled. This work is done by the Food and Drug Administration and by different State and city health officials. The administration has no jurisdiction over articles manufactured and sold wholly within a single State or over disinfectant advertising matter in newspapers, magazines, or broadcast by radio.

The Federal law says that the labeling of disinfectants shall contain no statement, design, or device which is false, fraudulent, or misleading in any particular. Chemists, bacteriologists, and medical officers who test disinfectants know what substances are present and the amount of each, and they also have before them the results of bactericidal tests. With all this information before them, they are able to form a very good idea of the value of the product tested. When testing a particular disinfectant, Federal drugs officials consider every statement on the label very carefully in order to pick out false or misleading statements. The opinion of one expert is substantiated by the opinions of others, in order that a fair conclusion may be reached. When adulterated or misbranded disinfectants are encountered, proper corrective action is instituted under the Federal food and drugs law. Since the present Federal insecticide law went into effect, in 1910, thousands of samples of commercial disinfectants have been collected and tested.

DROUGHT in 1930 Worst on Record in Duration, Extent, and Damage Done

A comparison of the details of the 1930 drought—its long duration, the large area involved, the economic loss sustained, particularly to agriculture, the general failure and consequent inconvenience and suffering due to the failure of the local water supply in many places in the drought-stricken region—all tend to place the 1930 drought in the first place in the drought history of the country.

The beginning of the drought is not easy to fix; it may have been a carry-over from the severe drought that was experienced in the far

Northwest in 1929; it may be remembered that the Pacific Coast States, including Idaho and western Montana, experienced very dry weather and a very large fire loss of timber during the summer and autumn of that year. January, 1930, was dry in Washington, and the succeeding February was the warmest February in the United States probably in a century; it was also dry, as is generally the case.

February, 1930, was dry in Arizona, New Mexico, and Kansas in the West and in the Carolinas, Virginia, Georgia, and Alabama in the East. No drought can at any time be considered as an entity that preserves its characteristics and definitely moves from one place to another. On the contrary, a drought, which from the information at hand is now seemingly fortuitous, may eventually be found to be the orderly expression of natural laws.

In March the drought embraced a solid block of States that included North Dakota, Minnesota, South Dakota, Iowa, Nebraska, Kansas, Missouri, Oklahoma, Arkansas, Illinois, Indiana, and Kentucky.

In April the droughty States were Arkansas, Louisiana, Alabama, Mississippi, Kentucky, and Tennessee. In May the droughty States were Illinois, Indiana, and Ohio. In June two of the Plains States again became dry—viz, Kansas and Colorado—and the southeastern block of States that were dry in April again passed into the droughty class. The greatest geographic extension of the drought occurred in July, 1930, when severe drought prevailed in Maryland, Virginia, West Virginia, Kentucky, Ohio, Illinois, Missouri, Arkansas, Oklahoma, Nebraska, Iowa, and the Dakotas. In August moderate rains had relieved the situation in many of the western and southwestern group of States, but dry weather still prevailed in Minnesota, Wisconsin, and Michigan, and also in Pennsylvania, Delaware, Maryland, Virginia, the Carolinas, and Georgia. In September dry weather continued in the East and spread into New England, a district that had hitherto escaped.

Renewed Dry Weather In the Fall

Following a brief period of rains in September in the Ohio Valley, lack of rain in the late fall months brought a renewal of inconvenience and suffering for lack of water.

Maryland and Virginia, in the East, continued to suffer from drought throughout the autumn, and it was not until December 26 and 27 that a substantial rainfall (1.05 inches) was received. The rains of those dates were quite general throughout the Atlantic Coast States from the Carolinas northward.

The essential features of the rainfall distribution, January to October, 1930, with respect to the actual amounts and the departures from normal are graphically presented in Figure 47.

Other Outstanding Droughts

Owing to the very great natural variations in rainfall both in time and space, scarcely a year passes in an area so large as continental United States without more or less severe drought in some locality for a period of three weeks to a month or longer.

Fortunately, however, the rainfall over the vastly greater remaining area generally averages close to normal except in very abnormal years. A record of the local droughts experienced in Washington, D. C., and the immediately surrounding country for the 60 years 1871–1930 reveals the fact that during those years 93 more-or-less-severe droughts prevailed. Further investigation shows that in a large number of the recorded droughts substantial rains had fallen in the period immediately preceding the beginning of the rainless period. In these cases the severity of the drought was greatly minimized. The 1930 drought was different from previous droughts in that the end of the dry period did not come in one heavy downpour, but in the form of light drizzles, until finally, as previously stated, a rainfall of slightly more than an inch occurred on part of two days.

At Washington, D. C., during the 115 days between July 8 and October 31, rain fell on 39 days; the amount of the daily rains on 14 of the 39 days ranged from 0.02 to half an inch; on the remaining 25 days

% OF NORMAL MONTHLY PRECIPITATION, 1930

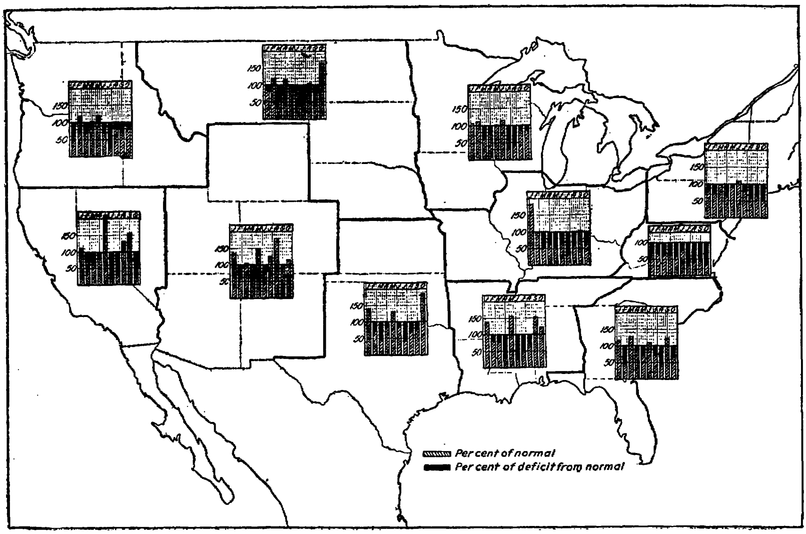

FIGURE 47.—This map shows the percentage of normal monthly precipitation from January to October, inclusive, by areas, the light shading of the respective bars indicating the percentage of normal for the successive months and the dark portions the monthly deficiencies for the several areas. In the Middle Atlantic area precipitation was deficient for all of the months, while in the Ohio Valley the shortage began somewhat later. In the Southern States, especially the lower Mississippi Valley, there was an abrupt change from wetness to dryness beginning with June, while in some Northern, Northeastern, and Southeastern States marked deficiencies did not begin until later in the season. In several of the more Western States the summer season was abnormally wet, as shown by the regional graphs for those sections

the daily rainfall was too small to measure and was therefore recorded as a "trace." Had the rainfall on these days been up to the normal expectancy, the average rainfall divided by the average number of rainy days, the total rainfall for the period would have been 76 per cent of the normal instead of 18 per cent, as was actually the case.

The drought record of the nineteenth century in the United States is far from complete. Severe droughts occurred in 1854; 1856–57; 1860; 1863–64; 1870; 1881; 1893–1895; 1901; 1911; 1916; and 1924.

The 1854 drought: The 1854 drought was most severe in Iowa, Kansas, Missouri, Arkansas, and the present State of Oklahoma; although it extended eastward, it was not especially severe east of the Mississippi. This was a midsummer and autumn drought.

The drought of 1856–57: This was not a widespread drought.

The drought of 1860: This was the most severe drought yet recorded; it was characterized by a very dry spring extending well into May and covered Kansas, Missouri, Minnesota, Wisconsin, and Indiana. In Missouri, April and May were very dry, but enough rain fell in June to save the crops.

The drought of 1863–64: This drought was confined to eastern Iowa, southern Minnesota, southern Wisconsin, and portions of Missouri and Kansas; while they were more or less summer droughts, yet they caused the lowest water hitherto recorded in the Mississippi between Dubuque and Burlington, Iowa. In Wisconsin practically no rain fell in June and August, 1864.

The drought of 1870: This was a more or less local drought in Illinois, Iowa, and Missouri.

The drought of 1881: This drought affected practically the whole country east of the Mississippi River and lasted from July to September. Its most striking characteristics was its duration and the attendant high temperature. Vegetation and the staple crops were seriously damaged, and in the later stages of the drought there was a scarcity of water for domestic purposes and for manufacturing purposes. Scores of shops and factories were obliged to shut down for lack of water.

The drought of 1893–1895: This was one of the outstanding droughts of the nineteenth century as measured by its duration, the extent of the area involved, and the shortage in rainfall. It was not particularly intense for any consecutive period but may be characterized as being a 3-year period of generally deficient rainfall throughout the country; its manifestations began in 1893 (summer months); there was some relief from the shortage of rainfall in the autumn months, but as a whole the year was one of deficient rains except in New England, the Lake region, and North Dakota. The summer months of 1894 were very dry, especially July and August; September, however, yielded substantial rains, and soil moisture was held up by fairly ample precipitation in the winter months of 1894–95. The months, July and August, 1894, were especially dry in the Ohio Valley, the South Atlantic States and Florida, the Gulf States, the Missouri Valley, and the middle and upper portions of the Mississippi Valley. In 1895, the regions of greatest deficiency apparently were shifted to the East, the Middle and South Atlantic States, thus giving an apparent drift of the droughty conditions from west to east. Notwithstanding the great and widespread shortage in precipitation during the years 1894–95 the staple crops of those years did not fall much below the yield of a normal year.

The drought of 1901: This drought was most severe in the central valleys and the western part of the Corn Belt; it was associated with exceptionally high temperature.

The drought of 1911: This drought was largely a carry-over from the very dry year of 1910. In South Carolina it lasted from November, 1910, to May, 1911, and in Kansas from November, 1910, through to September, 1911. June, 1917, was very dry in the Savannah River Basin above Augusta, Ga. The droughts of 1916 and 1924 covered comparatively small areas.

Geographic Extent of the 1930 Drought

Information now at hand shows that the drought of 1930 extended to the West Indies and the Panama Canal Zone on the south. Gatun

Lake watershed, which supplies water for the efficient operation of the canal, yielded less than the average amount of water in 7 out of the 10 months, January to September, 1930, with a maximum shortage of 48 per cent in February and a secondary maximum of 39 per cent in August.

Canada received, on the whole, somewhat more rain, and the distribution was a little more favorable than in the United States. Flood-producing rains fell in July, the month in which the peak of the drought was experienced in this country, in the northern portions of Ontario and Quebec, and also in parts of the Atlantic Provinces.

European countries did not share in the drought that was experienced in North America.

Principal Meteorologist, Weather Bureau.

DROUGHT in 1930 Showed Some Strains of Corn to be Drought Resistant The unusual drought of 1930 brought losses to the corn breeder as well as to the corn grower. The corn-breeding program of the Bureau of Plant Industry of the United States Department of Agriculture is carried on in cooperation with the State agricultural experiment stations in about 12 States. In several of these the losses due to drought were so severe as to delay progress by from one to three years. The corn breeder, however, is more fortunate than the corn grower. While losing the results of several years' carefully planned work, he obtained information on the ability of his different breeding stocks to withstand such conditions. This information is worth a great deal as a basis for developing strains that will be of value under the widely different weather conditions which occur from year to year.

The present-day corn-breeding programs, moreover, are particularly suited to taking advantage of such information. They are centered on the production of strains isolated by selection and self-fertilization. Such strains breed true, not only for various physical characters such as plant height, leafiness, color, ear characters, and the like, but also for function. Thus, some strains are better adapted to more productive soil conditions, others to less; some can withstand more cold than others, and some can stand more heat and drought. It is not too much to say that whenever many selfed strains have been exposed to an extreme condition, some have been more or less resistant. As strains resistant to any condition are found they become a valued part of the breeding stocks. They can be used to furnish this characteristic for immediate practical corn improvement. Equally important, they serve as material for finding out just why they are resistant, thereby giving a basis for further improvement.

How the 1930 Drought Affected Corn

The experience with the heat and drought in 1930 was no exception. One or more strains of corn at each station were able to stand the lack of moisture and the temperatures of 106° F. and upward better than other strains. In some cases resistance was insufficient to be of much value or was associated with the particular stage of development in which the plants happened to be at the critical time. Other strains, however, silked and tasseled with little or no apparent damage while the weather conditions were most severe.

DROUGHT in 1930 Showed Some Strains of Corn to be Drought Resistant

The unusual drought of 1930 brought losses to the corn breeder as well as to the corn grower. The corn-breeding program of the Bureau of Plant Industry of the United States Department of Agriculture is carried on in cooperation with the State agricultural experiment stations in about 12 States. In several of these the losses due to drought were so severe as to delay progress by from one to three years. The corn breeder, however, is more fortunate than the corn grower. While losing the results of several years' carefully planned work, he obtained information on the ability of his different breeding stocks to withstand such conditions. This information is worth a great deal as a basis for developing strains that will be of value under the widely different weather conditions which occur from year to year.

The present-day corn-breeding programs, moreover, are particularly suited to taking advantage of such information. They are centered on the production of strains isolated by selection and self-fertilization. Such strains breed true, not only for various physical characters such as plant height, leafiness, color, ear characters, and the like, but also for function. Thus, some strains are better adapted to more productive soil conditions, others to less; some can withstand more cold than others, and some can stand more heat and drought. It is not too much to say that whenever many selfed strains have been exposed to an extreme condition, some have been more or less resistant. As strains resistant to any condition are found they become a valued part of the breeding stocks. They can be used to furnish this characteristic for immediate practical corn improvement. Equally important, they serve as material for finding out just why they are resistant, thereby giving a basis for further improvement.

How the 1930 Drought Affected Corn

The experience with the heat and drought in 1930 was no exception. One or more strains of corn at each station were able to stand the lack of moisture and the temperatures of 106° F. and upward better than other strains. In some cases resistance was insufficient to be of much value or was associated with the particular stage of development in which the plants happened to be at the critical time. Other strains, however, silked and tasseled with little or no apparent damage while the weather conditions were most severe.

As a concrete example, there may be mentioned a strain of the Lancaster Surecrop variety developed at Ames, Iowa, in the corn-breeding program cooperative with the Iowa State Agricultural Experiment Station. This strain has been isolated through eight generations of selection within self-fertilized lines. It is familiarly known as the Dark Green Lancaster strain, because of the exceedingly dark green color of its leaves. The ears are borne somewhat high on relatively tall stalks. This strain was grown in 1930 in experiments at Ames, Iowa; at Bloomington, Ill.; and at the Arlington Experiment Farm, Rosslyn, Va.

The accumulated deficiency in rainfall at Ames on July 1, was 3.5 inches. The rainfall during July was 0.5 inch, and during August was 0.9 inch, with a total deficiency September 1 of 9.1 inches. The rainfall at Arlington Farm and that at Bloomington was somewhat more favorable. At all three places, however, the temperatures during July and August were well above 100 day after day.

It was these high temperatures, in fact, that did more damage to the corn than the lack of moisture in the soil. The moisture was taken out of the tassels and upper leaves of most plants by the hot, dry winds faster than it could be replaced. The whitened tassels and leaves seen across the field bore eloquent testimony of this condition. In marked contrast were the upper leaves and tassels of Dark Green Lancaster (and of a few other strains) where rows of this strain occurred in the experiments. The dark green leaves continued dark green and the tassels continued to shed viable pollen.

The selfed strains isolated in modern corn breeding are not themselves high yielding, but must be used in crosses or hybrids. It therefore is important to know whether desirable characteristics possessed by a strain are transmitted to its crosses. Crosses of Dark Green Lancaster with each of 10 other selfed strains were included in the experiments at Ames in 1930. Each cross was grown in 6 plots of about 50 plants each. There were thus about 3,000 plants of crosses having Dark Green Lancaster as one parent. None of these plants had any of the top leaves burned and only 12.6 per cent had burned tassels. In contrast, 37 per cent of the plants of the Krug variety had burned tassels and 13.4 per cent had burned top leaves. Inasmuch as some of the 10 other strains with which Dark Green Lancaster was crossed were heat susceptible, this is conclusive evidence of its ability to transmit much at least of its resistance to heat and drought to its crosses.

It is pleasant to see corn plants remain dark green in spite of the heat and drought. The corn grower, however, is more interested in the final yield. The 10 crosses of Dark Green Lancaster with other lines produced an average acre yield of 53.5 bushels in comparison with 37.5 bushels for Krug. The excess yield of 16 bushels, or 43 per cent, for the crosses above Krug, the best of the 12 commercial varieties in the experiment, shows clearly that heat and drought resistance as shown by lack of leaf and tassel burning was reflected also in ability to produce corn.

Most years in the Corn Belt are not drought years. To what extent may strains adapted to unfavorable conditions be expected to yield well in favorable seasons? Strains will, of course, differ in their breadth of adaptation. It is significant, however, that Dark Green Lancaster was isolated during seasons that were more or less favorable to corn production. Moreover, about 10 crosses having this strain as one parent have been in the experiments in 1927, in 1928, and in 1929, in addition to the 10 crosses in the 1930 experiments. In 1927 and 1928 the Dark Green Lancaster crosses were first and second in their groups, in 1929 they were fifth, and in 1930 they were first. In each year they were significantly more productive than the best commercial varieties.

The facts presented here are concerned with the possibilities of breeding corn for resistance to heat and drought, as emphasized by the extreme conditions in 1930. Similar methods are applicable and are being used by the corn breeders of to-day in meeting other conditions. Progress is slow at best and is retarded further by losses due to one condition or another. When this occurs all that the corn breeder can do is to forget the losses and see whether they can not be offset in part by advances in unexpected directions.

DROUGHT May Result in Lasting Damage to Stricken Forest Trees

Excessive droughts like that of 1930, which brought havoc to food crops and livestock in many eastern States, also cause serious loss to forest and shade trees. Some trees are killed outright while many others are robbed of their vigor so that within a few years they fall an easy prey to insects, disease, or some other indirect agent of death. Thus a continuing loss occurs which can not easily be forecast but which may in the aggregate equal the value of many years' growth of the forest.

Although the forest losses to be expected from the 1930 drought can not be directly foretold, a good deal can be learned indirectly from the effects of the 1925 drought in the southern Appalachian region, during which many trees turned brown and some were killed. The history of individual trees has been observed on sample areas established during the 1925 drought by the Appalachian Forest Experiment Station in the forest near Asheville, N. C. It is likely that much the same results will follow the drought of 1930.

The similarity of the two drought periods is shown by the following Asheville Weather Bureau records. These include the fall months preceding the year of drought, since the amount of rain prior to the drought affects the supply of ground water that will later be available to the trees. Apparently the water deficiency of 1925 in western North Carolina was a little more severe and protracted than that of 1930, and more closely resembles the 1930 drought in other more seriously affected States.

The Asheville observations[2] showed that browning or fall of leaves during a drought does not necessarily mean that the trees are dead. Although a great many trees on ridges and upper slopes in western North Carolina turned brown in the summer of 1925, and some species shed their leaves in August, the majority of the trees put out new foliage the next spring. On many of the trees the browning was confined to the topmost branches, and there was a difference between the species as to the extent of browning. Dogwood, sourwood, and chestnut, for example, appeared to suffer more severe browning than white ash, black locust, and pignut hickory. Leaves of chestnut oak were only moderately or slightly injured by the drought, and by the following spring the chestnut oak trees appeared to be quite normal. Black oak, scarlet oak, and red oak, on the other hand, showed severe leaf injury during the drought period, and with few exceptions trees of these species that were heavily browned were dead by 1929. Hickory leaves were not seriously browned, the principal response to the drought being an early shedding of the leaves. In most cases the recovery of the hickories was complete. Regardless of species, trees with large scars caused by fire or logging showed more severe browning of the leaves than trees with sound boles.

After Effects of Drought

Of the individual trees that were observed, not one that maintained its normal green foliage during the drought showed any evidence of injury in the four succeeding years that could be attributed to the drought. About half the trees that showed injury during the drought completely recovered. The remainder showed permanent injury in the form of dead branches, or were killed by the drought or by some cause resulting indirectly from it.

During the years that followed the 1925 drought numerous reports were received of shade trees sick or dying from some unknown cause. A large number of apparently healthy scarlet oak trees were thrown by wind in the forest near Asheville. In other parts of the Appalachian region oak trees of various species were reported to have been killed. Upon examination, various causes were assigned for the death of these trees, chief among them being insects (particularly root-boring insects), root-destroying fungi, and the freezing of young leaves in the spring. While there is no evidence to prove that the underlying cause of death was the 1925 drought, the occurrence of this heavy mortality so closely after the drought furnishes a strong reason for the belief that the drought, by destroying roots and sapping the resistance of the trees, was the factor primarily responsible for their death.

The greatest direct injury observed during the 1925 drought occurred in the case of trees with restricted root systems growing on shallow soil. In some places where rock outcrops were abundant the shallow soil contained only 5 per cent moisture during the drought. During the succeeding summer the soil was found to have from 40 to 45 per cent of moisture. It is probable that when the moisture content is reduced as low as 5 per cent clay soils such as those of the sample areas have practically no water available for plant roots. Under such conditions serious injury to trees seems inevitable, and if any survive it is undoubtedly due to the density and extent of the

---

root network that penetrates crevices and soil pockets where a little more moisture can be obtained than is available in the dried upper layers of soil. When moisture is lacking much of the root system undoubtedly ceases to function, some of it permanently. The death of roots invites attack by root-boring insects and by fungi, and weakens the hold of the tree upon the soil, rendering it subject to wind throw.

Relation Between Leaves and Roots

There is an intimate relation between the leaves and the root ends of trees. The two are opposite ends of the same water-conducting system, and changed conditions, such as a pronounced decrease in the amount of soil moisture available to the roots, will have an immediate and perhaps also a deferred effect upon the foliage. Thus a severe drought is marked by the browning of the leaves of some species of trees and the premature fall of the leaves of others. If many of the roots are killed, not only leaves but entire branches and even entire trees will die. Complete killing is most common when trees have already been weakened by some damaging agency like fire, insects, disease, or ice breakage, or when their root systems are confined by rock or hard-pan to shallow layers or pockets of soil.

Forest trees that are crippled by drought so that they show large dead branches or tops (stag-headed trees) are no longer desirable members of the stand. Their growth is slowed down, they occupy space that might better be filled by healthy young trees, and it is wise to remove them at the first good opportunity. The health and productive vigor of a forest, as well as its sightliness, can thus be improved by weeding out the poorer individuals and permitting their replacement with strong, sound trees.

E. H. FROTHINGHAM,
Appalachian Forest Experiment Station, Forest Service.

DROUGHTS' Causes Partly Known; Comings and Goings Unpredictable

To understand what causes prolonged spells of dry weather over wide areas it is necessary first to know how nature induces precipitation. Her first step is to get an adequate quantity of water vapor into the atmosphere, and her second to get it out again in the form of drops. It is got into the air by evaporation from ocean and other water surfaces, from damp soil, and from growing vegetation; but there is a limit to the amount that can be got into, or can exist in, a given space, and this limit or maximum amount decreases rapidly with decrease in the temperature of the vapor. Furthermore, this amount is the same whether other gases, such as those of the dry air, are present or not. Whenever the temperature of the air as a whole is changed, so also is that of any water vapor that may be present. Water vapor also goes into the air, or evaporation occurs, at all temperatures—the more rapidly the higher the temperature—so long as the adjacent space is not saturated; that is, does not contain all the water vapor it can contain at the current temperature. It does not condense out of the air in any form—cloud, rain or snow—until its temperature falls below the saturation point. On the average, water vapor is taken into the air by evaporation at higher temperatures and ejected by condensation at lower temperatures.

DROUGHTS' Causes Partly Known; Comings and Goings Unpredictable

To understand what causes prolonged spells of dry weather over wide areas it is necessary first to know how nature induces precipitation. Her first step is to get an adequate quantity of water vapor into the atmosphere, and her second to get it out again in the form of drops. It is got into the air by evaporation from ocean and other water surfaces, from damp soil, and from growing vegetation; but there is a limit to the amount that can be got into, or can exist in, a given space, and this limit or maximum amount decreases rapidly with decrease in the temperature of the vapor. Furthermore, this amount is the same whether other gases, such as those of the dry air, are present or not. Whenever the temperature of the air as a whole is changed, so also is that of any water vapor that may be present. Water vapor also goes into the air, or evaporation occurs, at all temperatures—the more rapidly the higher the temperature—so long as the adjacent space is not saturated; that is, does not contain all the water vapor it can contain at the current temperature. It does not condense out of the air in any form—cloud, rain or snow—until its temperature falls below the saturation point. On the average, water vapor is taken into the air by evaporation at higher temperatures and ejected by condensation at lower temperatures.

Cooling of Humid Air Makes Rain

Evidently, therefore, rain is produced only by the considerable cooling of a great volume of humid air—humid, for otherwise there would not be enough moisture present to produce rain; and cooled, for that is the one effective way of so reducing the vapor capacity of the space occupied as to force condensation of the humidity from the gaseous to the liquid form. We have just seen how the air is rendered humid, namely, by evaporation, but how is it so greatly cooled as to get any considerable portion of that vapor out again in the form of water?

The surface air over land is cooled during still, clear nights by contact with the vegetation and other objects that themselves had lost much heat through radiation, but this never involves enough air to induce rain; only at most, dew or fog. Air is cooled also when it blows or drifts over objects colder than itself, or into a relatively cool region, but this, too, only causes fog and a dew-like condensation onto the cold objects.

Still another way by which air often is cooled is the admixture with it of relatively cold air. But even under the most favorable conditions, even when both the warm air and the cold air are saturated before being mixed, this method of cooling can not induce much condensation—only some cloud and perhaps a little drizzle. There remains just one other method by which the atmosphere, and thereby the water vapor in it, is here and there, and from time to time, sharply cooled. This is by increase in its height, not necessarily above the surface of the land but above sea level. As the air rises, no matter how it is made to do so, it obviously comes under less and less pressure by the weight of the air left below. It therefore continuously expands, under decrease of load, as long as it gains in height. This expansion, however, always is against a pressure—the weight of the air still above the rising mass, and expansion against pressure means work, in this case work by the rising air, and that entails a loss of temperature, for gases can work only at the expense of their heat. Rising air, therefore, is cooling air, and as the air cools so also, and to the same extent, does the water vapor in it or of it. This in turn reduces the amount of water that can exist per cubic foot in the form of vapor. Hence, when the lower air contains a large amount of water vapor its considerable ascent, say half a mile to 3 miles, is certain to produce cloud and likely to produce rain also.

Rain, then, is induced by the ascent to decidedly higher levels of air in which there is a relatively large amount of water vapor. Conversely, dry weather obtains whenever and wherever there is but little to no ascent of the atmosphere; and also when the humidity present is insufficient to produce saturation, or much more than saturation, at the temperature reached through such ascent, great or small, as may occur. Hence the direct cause of a drought is the excessive dryness of the air, or absence of its considerable ascent, or both, during many consecutive days or several weeks over the region in question.

Forces That Cause Air to Ascend

But what makes that air ascend? There are several things that cause the air to ascend. One of them is the same thing that makes air go up a chimney when there is a fire in the fireplace; namely, difference between its densities (owing to difference in temperature) over adjacent regions. This is the cause of the so-called heat thunderstorm, the storm that brings most of the rain of tropical regions, and a large portion of the summer rains nearly everywhere. The air is made to ascend also by a mountain across the course of the wind, and where this wind is directly from a warm ocean, as in the case of the Hawaiian Islands, the rainfall thus induced is certain to be very abundant.

Another important cause of atmospheric ascent is a mass of relatively cool air in the path of a warmer current. Here the warmer, and often humid, air rises up over the colder air just as it would over a mountain, and with the same result in respect to precipitation. This is the chief source of the rainfall in the general or cyclonic storms of the middle latitudes, in which comparatively warm humid air from tropical and semitropical regions always encounters in its course the relatively cool air of the higher latitudes. In another portion of this storm area, equatorward from its center, the warm air often is actively underrun by the colder, thus lifted up and frequently made to yield brief but vigorous showers, the kind popularly known as clearing-up showers. The convergence of air currents also and obviously causes ascent of the atmosphere. This is a phenomenon of the front or rainy section of the general cyclonic storm, and likewise of the tornado, and even the dust whirl—in a small way.

How from the above can we account for the great drought of 1930 of the central and most of the eastern United States? It was owing partly to the fact that the cyclonic or rain-bearing storms that passed over this region were fewer and feebler than they normally are during the months in question, and partly to the fact that the local or heat thunderstorms also were fewer and feebler than usual. The cyclonic storms, being swirls between great interchanging currents of tropical and polar air, were few and feeble because this interchange was much less vigorous last year over the central and eastern United States than usually is the case. And this interchange was feeble here because a larger amount than normal of such interchange was occurring elsewhere—over western and northern Europe, especially, where the summer was exceptionally rainy.

Balance of Interchanges

The increased interchange at one or more places caused a decrease at others because, owing to the limited amount of heating in the lower latitudes and cooling in the higher, there also is only a correspondingly limited amount of total interzonal circulation. It can not be unusually strong everywhere at the same time, for the supply of air is limited; nor everywhere feeble, for there are large quantities of warm and cold air that somehow, somewhere, must be exchanged. It only can be excessive at some places if at the same it is unusually feeble elsewhere. Again this interchange, which is by fits and starts rather than by steady streams, tends to follow any paths that just previously had been followed. The cold air, for instance, flows best and farthest along routes already cooled by a previous flow, and similarly for the warm air. That is, the routes of interchange tend to remain fixed, and an abandoned region to remain abandoned longer than usual. That is one of the reasons why weather so often comes in spells. Again this stagnation of the air over the central and eastern United States led to its being all but equally warm from the Gulf to the Lakes, and even into Canada, and, therefore, to the removal of such interchange as was occurring in North America between cold and warm air, and the rains that accompany such interchange, to unusually high latitudes.

Also, and presumably owing to this same alteration of the general routes of warm and cold air, moderately high atmospheric pressure often extended from the Atlantic Ocean far out onto the continent in the latitude of the Carolinas, thus effectually shutting off from the areas covered, and also those to their immediate north, all access of humidity from the Gulf of Mexico, its chief source for the regions in question.

Finally, after the soil had become dry over this great territory, and vegetation withered, local showers, which depend for their moisture mainly upon inland evaporation, necessarily were relatively infrequent and feeble. Thus any drought when well established, as the one of 1930 certainly was, tends to perpetuate itself partly by maintenance of the same paths of warm and cold air interchange and partly by deficiency of surface evaporation.

Of course all this quasi-stable condition of drought, or of excessive rain, may be completely upset at any time by some unusual storm, such as a suitably timed and located hurricane, by the onset of cold weather or otherwise.

We know something of what causes droughts and how they tend to perpetuate themselves, but we can not yet predict their coming nor their going nor how severe they will be.

W. J. HUMPHREYS,
Principal Meteorologist, Weather Bureau.

EGG Hatchability Is Influenced by the Nutrition of Embryo Only about two-thirds of the fertile eggs incubated in the United States each year hatch. The developing chicks in the remaining third die at various stages before they are ready to leave the shell. Inherited weaknesses, improper conditions of incubation, and faulty diet of the breeding flocks are the principal causes of death.

Much of this loss could be prevented if poultry breeders would use only eggs from vigorous stock and incubate these eggs at a proper temperature with the correct degree of ventilation and moisture. Many fertile eggs would still fail to hatch, however, unless the breeding flocks received rations containing enough of the right quality of nutrients for the chick embryo from the time it begins to develop until it leaves the shell.

Except for the oxygen, which is obtained through the shell from the air, the food supply of the chick embryo is contained in the egg. The proteins, water, and minerals, assisted by the pigments and vitamins, form most of the structure; the carbohydrates, some protein, and fat supply energy.

Some proteins lack or contain too little of certain components needed by the developing embryo. Many hens, when fed only vegetable proteins, for instance, produce eggs which, although fertile, fail to hatch as well as when an animal protein is added to the ration.

EGG Hatchability Is Influenced by the Nutrition of Embryo

Only about two-thirds of the fertile eggs incubated in the United States each year hatch. The developing chicks in the remaining third die at various stages before they are ready to leave the shell. Inherited weaknesses, improper conditions of incubation, and faulty diet of the breeding flocks are the principal causes of death.

Much of this loss could be prevented if poultry breeders would use only eggs from vigorous stock and incubate these eggs at a proper temperature with the correct degree of ventilation and moisture. Many fertile eggs would still fail to hatch, however, unless the breeding flocks received rations containing enough of the right quality of nutrients for the chick embryo from the time it begins to develop until it leaves the shell.

Except for the oxygen, which is obtained through the shell from the air, the food supply of the chick embryo is contained in the egg. The proteins, water, and minerals, assisted by the pigments and vitamins, form most of the structure; the carbohydrates, some protein, and fat supply energy.

Some proteins lack or contain too little of certain components needed by the developing embryo. Many hens, when fed only vegetable proteins, for instance, produce eggs which, although fertile, fail to hatch as well as when an animal protein is added to the ration.

Animal Protein in Feed Results in Best Hatches

At the United States Animal Husbandry Experiment Farm, Beltsville, Md., 120 Rhode Island Red pullets, equally divided in three pens, received an all-vegetable basal ration, a mineral mixture, cod-liver oil, and some form of protein. As sources of protein, cottonseed meal was fed to the pullets in one pen, soybean-oil meal to those in another, and mixed animal protein to those in the third pen. The eggs from the three pens were incubated and 58, 64.5, and 77 per cent, respectively, hatched. The results showed the superiority of the animal-protein supplement in producing eggs of high hatchability.

During the second week of incubation, when the embryo absorbs most of the egg white, a much higher percentage of the embryo deaths occurred in the eggs of the pullets receiving cottonseed and soybean-oil meals than from those receiving animal protein. Many of the dead embryos in the eggs from the pullets receiving vegetable protein were swollen because of liquid accumulating beneath the skin. This condition is known as edema, and may result from affected kidneys. The dead embryos in which edema was very noticeable also had extremely short and backwardly curved legs and parrotlike beaks, as shown in Figure 48. This condition is known as chondrodystrophy, signifying lack of normal formation of cartilage because of poor nourishment. Most embryos so affected die before the fifteenth day of incubation, though a few live until hatching time but rarely, if ever, hatch.

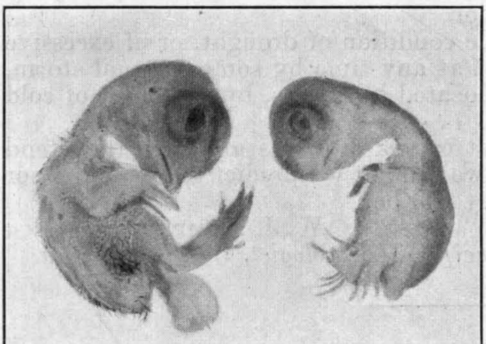

FIGURE 48.—On the left is a normal embryo after 11 days' incubation; on the right is one showing parrot beak and backwardly curved legs, caused in part by improper nutrition

Any ration lacking animal protein may result in this trouble. Less than 0.1 per cent of the fertile eggs (12 out of 15,000) from the department's breeding flock, which received a mixed ration and was allowed on range, showed this trouble. Many of these hens were of the same breeding as the hens used in the experiment mentioned.

Further poultry-nutrition studies showed that a supplement of yeast, though not so good as animal protein, gave fairly satisfactory hatchability results, when fed to pullets receiving an all-vegetable basal ration. A 20 per cent supplement of a dry-yeast preparation when fed to 40 pullets on such a ration resulted in the hatching of 74.5 per cent of the fertile eggs. When an all-vegetable basal ration and a supplement of mixed animal proteins were fed to another lot of 40 pullets, 77 per cent of the eggs hatched; and when an all-vegetable basal ration alone was fed to 40 pullets, 69.2 per cent hatched. These differences in hatchability are no greater than may be expected from the inherent variability of the hens used. The yeast supplement, however, is far too expensive to be practical.

Nutrition Effects Vary

Although in general hatchability of the eggs is lowered by the feeding of cottonseed and soybean-oil meals, all hens are not affected to the same extent and many apparently not at all; and since these feeds are cheaper than animal proteins, high in food value, and easy to obtain, there is a tendency for poultrymen to feed more of them. When they are to be used as protein supplements, it is advisable to carry on pedigree hatching, examine dead embryos in the eggs for the condition shown in the illustration, and cull the hens that have produced such eggs. However, until a vegetable-protein ration is found which results in as high a per cent of hatchability as does the use of animal proteins, it is best to include some of the latter in the ration of breeding hens.

Lime and vitamin D in the ration are also necessary for satisfactory hatchability as well as for bone formation. Cod-liver oil is the best-known source of this vitamin. However, if the hens receive an abundance of direct sunshine, no other source of vitamin D is necessary. Still another requirement for large hatches is a reasonable quantity of pigment in the ration. This term signifies the natural coloring matter in various feeds.

Although successive generations of chickens have been reared on rations containing little or no pigment, eggs from hens receiving these rations hatch poorly. Only 25 per cent of the eggs from experimental hens fed on such rations hatched, as compared with 77 per cent from hens on normal rations. The yellow pigment which colors the normal egg yolk is obtained by the hen directly from the feeds, especially green feed and yellow corn.

Briefly, it is recommended that poultry breeders feed a ration containing adequate quantities of protein, both vegetable and animal; lime; cod-liver oil unless an abundance of direct sunlight is received; and a source of pigment, such as yellow corn or green feed.

Physiologist, Bureau of Animal Industry.

ELECTRICAL Machines Aid Department's Scientists in Compiling Statistics From Maine to California there is probably no State that does not utilize electricity in some way to lighten the burden of the farmer or the farmer's wife. Help is rendered in the form of power to work a pump jack, to run a corn sheller, to milk, or to turn a cream separator, or perhaps to operate a cordwood saw. Few farmers, however, realize the extent to which electricity is utilized in the daily tasks of agricultural workers in Washington. They might even regard tasks such as compiling statistics as easy enough without electrical help, but in this modern age, a task does not necessarily require muscular effort to become laborious.

A great deal of the clerical work incidental to the research studies undertaken by scientific workers of the Department of Agriculture is done with the aid of electrical machines. Some of this work is simple enough in itself but the large volume makes the use of machines a necessity. Other phases of the work are so complex that it is hardly conceivable that they could be undertaken at all without the aid of machinery. In this latter class of work comes the minute analytical studies which involve the use of elaborate questionnaires to get the many facts concerning a given subject. A very remarkable method has been developed for work of this kind, its great advantage being in the successive reclassifying of the same material.

Few farmers, however, realize the extent to which electricity is utilized in the daily tasks of agricultural workers in Washington. They might even regard tasks such as compiling statistics as easy enough without electrical help, but in this modern age, a task does not necessarily require muscular effort to become laborious.

A great deal of the clerical work incidental to the research studies undertaken by scientific workers of the Department of Agriculture is done with the aid of electrical machines. Some of this work is simple enough in itself but the large volume makes the use of machines a necessity. Other phases of the work are so complex that it is hardly conceivable that they could be undertaken at all without the aid of machinery. In this latter class of work comes the minute analytical studies which involve the use of elaborate questionnaires to get the many facts concerning a given subject. A very remarkable method has been developed for work of this kind, its great advantage being in the successive reclassifying of the same material.

The principles of this method were first evolved in the eighties by an employee of the Bureau of the Census, who not only developed the method but invented a group of machines which greatly simplified the preparation of the census report. Since that time the machines have been improved to a remarkable extent and are now used not only for Government work in the Bureau of the Census but in many other Federal offices and in State offices, as well as by railroads, insurance companies, and almost every kind of big business throughout the United States. The chief feature of the method is the use of a record card 3¼ by 7⅜ inches in size made of lightweight cardboard similar to the standard Government post card, in which holes are punched to record the data. These cards are used in conjunction with machines of various types.

The punching is done by electricity; that is, an electrical contact passes the current through an electromagnet to actuate a simple punch mechanism. The contact is made by the operator, who depresses in proper sequence the typewriterlike keys of a small machine to record the desired information on the cards inserted in the machine. Thus, the operator is relieved of the necessity of supplying the power to perforate the holes. A skilled operator can punch from 1,000 to 2,000 cards a day, depending upon the nature of the work. After the cards are punched they are assembled in the groups desired for tabulation by means of an electrical sorting machine. In this machine the cards are passed rapidly over a brass roller against which a small steel wire is constantly pressed. The card passes between the roller and the wire and as contact is made through a punched hole the cards are caused to drop in one of 10 receptacles depending on the position of the hole in the card. This is accomplished by a system of timing very similar to the timing of the spark in an automobile engine, except that instead of an explosion the result is merely the opening of a gate through which opening the card must pass. This machine will accurately sort about 20,000 cards per hour. As the operation is continuous, the cards can be placed in and removed from the machine without stopping it.

The Listing Tabulator

After the cards have been completely sorted (it sometimes requires several sortings to arrange them in the groups desired, since the machine sorts only one column at a time) the next step is to count the number in each of the groups and add the various quantities, from which averages may be determined. This is done by sending the cards through another machine, called a listing tabulator, which counts the cards in each of the groups, accumulates the total of several items if desired, prints the group designation, the count of cards, and the totals on a sheet of paper held in a carriage similar to that of a typewriter. One of the most remarkable features of the tabulator is called the control. This mechanism, which is governed entirely by electricity, causes the machine to function in such a way that it will automatically stop the accumulation of totals upon completion of a designated group, print the totals on the paper, set the adding mechanism back to zero, ready for the next group, and then start the accumulation of totals of the next group. All this is done without the attention of the operator. The tabulator will handle from 4,000 to 8,000 cards an hour, depending upon the frequency of the totaling and resetting operation.

The great utility of this method of tabulation lies in the facility with which material may be reclassified or subdivided. An example of this kind is a study recently made of the consumption of dairy products by farm families. The basic information was secured by obtaining about 10,000 questionnaires from as many farm families. Each questionnaire showed the number of adults, number of children, milk consumed per week, number of cows, and other related questions. From the answers to these questions the investigators sought to determine: (1) Average consumption of milk per farm family; (2) average consumption of milk by farm families having no cows to compare with average consumption of milk by farm families having cows; and (3) average consumption per capita among adults to compare with average consumption per capita for families with children.

The answers to the questionnaires were recorded on punch cards, each card representing a farm family. It was then possible by successive sorting and tabulating operations to obtain the total milk consumption for all farm families in a certain State, for families having no cows, for families having cows, for families without children, and for families with children. With each of these tabulations the number of families or cards were counted, and the number of persons classified as adults or children, and total milk consumed, were all automatically printed on a strip of paper. The whole tabulating process, involving 10,000 reports, required but a few days' work on the two machines.

The use of machines is not confined to any one bureau of the Department of Agriculture or to any particular type of work. The folling bureaus make use of the machines in connection with their research work, and in some cases prepare reports of appropriations and expenditures: Agricultural Economics, Animal Industry, Biological Survey, Dairy Industry, Forest Service, and Public Roads.

The Bureau of Dairy Industry utilizes the punched cards and machines in connection with the work of the cow-testing associations while the Bureau of Biological Survey has a very interesting application in its study of bird migration through the banding method.

In spite of the labor-saving features of the machines the work handled on them is now so extensive that from 50 to 75 persons are employed in the various machine units, and the total card requirements are approximately 6,000,000 a year.

Elk in Jackson Hole Studied to Facilitate Wild-Life Management

The growing complexity of human interests and of economic developments adds to the difficulty of the task of adequately caring for the valuable forms of wild life of the country. This has been brought to attention most strikingly in the past few years through studies made by the Bureau of Biological Survey of the southern Yellowstone Park elk at the elk refuge maintained in Jackson Hole, Wyo.

The public has become familiar with the plight of the elk herds, the crowding of the animals into restricted areas by the encroachment of civilization, and the starvation of the animals in hard winters, with the splendid response of public-spirited individuals and organizations, and with the action of the Federal Government and State agencies to meet the situation. What is not so well known perhaps is that serious difficulties are encountered in adopting permanent plans for the care of the elk, and that some of the very necessary relief measures designed to remedy the situation have often been harmful in certain respects to the elk.

In the course of investigations by the Biological Survey, it has been discovered that each winter a certain percentage of the elk that come to the refuge die of disease. During the season of 1927–28 necrotic stomatitis, known to cattlemen as "calf diphtheria," or "sore mouth," was responsible for the loss of approximately 18 per cent of the calves, and it was not a particularly bad winter for game. The cause of this disease among these elk is chiefly the same as among some herds of domestic stock, namely, eating hay containing squirreltail grass (*Hordeum jubatum*). Thus, in efforts to assist the elk, man may be responsible for other dangers to the herds.

Steps are now being taken to avoid the purchase of hay containing harmful grasses and to eliminate these dangerous plants from the hay fields of the elk refuge. Even if this can be accomplished, however, the problem will not be solved. The task is larger. It does not greatly differ from some of our own social problems. How shall we aid our paupers, our unemployed, to their lasting benefit? How shall we assist the elk, in their winter forage problem, without pauperizing them? For these canny creatures, recognizing the helping hand, quickly become dependent, and eventually might lose much of their ability to rustle for themselves.

Investigations in Progress

The investigations now in progress are designed to solve some of the difficulties of management of these big-game animals. As a basis, it is necessary to have complete information on the life history of the elk, their food preferences, their breeding habits, their migrations, and other habits, in fact, a knowledge of all the factors that bear upon their welfare. Much information has already been obtained on the food habits of the animals. Elk are known to be chiefly grazing animals; it is known that under natural conditions cured grasses, which they obtain by scraping away the snow, constitute their chief winter forage, but that browse is also utilized to a great extent in winter. Inclosures now constructed in Jackson Hole will be used for various feeding experiments and in studying the effects of parasites, particularly ticks.

There is much to be learned before all the details can be worked out. The problems of diseases and parasites must be studied carefully. The food question requires further work. But enough has already been learned to outline some of the first requisites of a satisfactory management plan.

Heretofore the elk have been cared for chiefly by emergency feeding measures. These have been very necessary, but plans must be modified for permanent use. The present elk refuge administered by the Biological Survey is 4,560 acres in extent. Hay is harvested here each year and is fed to the elk in winter whenever conditions make it necessary. In theory, such artificial feeding is required only when snows on the neighboring foothills make the natural forage unavailable. But this is not the case in actual practice. The elk have learned to rely on the hay provided at the elk refuge, and each winter promptly repair to the feeding grounds. If feeding is delayed for some time the animals soon begin to worry the neighboring ranchers by breaking into their haystacks and interfering with the feeding of domestic stock. Thus feeding must very often begin early enough on the elk refuge to relieve the ranchers.

Sometimes as many as 8,000 elk congregate on feeding grounds maintained by the Federal Government and the State of Wyoming, and as many as 4,000 may assemble in a single area. There they remain throughout the winter, awaiting their daily hay ration. Such congestion of game animals is most undesirable and dangerous from a sanitary viewpoint. Under present conditions disease takes toll every winter, and there is always the dreaded possibility of an epizootic of a more deadly nature and of disastrous proportions.

Larger Winter Range Needed

The remedy for such conditions is to be found in a larger winter range, where the animals can not molest nor be molested by adjacent ranchers. It has been proposed that these neighboring ranches be purchased and added to the present refuge, thus furnishing natural pasturage on their former wintering areas for the elk of the Yellowstone Park and adjacent national forests, and obviating the necessity of feeding except in emergencies. It is certain that with enlarged grazing areas available, the elk would pass many winters in comfort without being fed artificially. Hay would be kept in reserve for a real emergency, however, as when alternate thawing and freezing produce a heavy snow crust through which the elk are unable to reach the natural forage.

The studies now being made by the Biological Survey should help not only to solve the elk problem of Jackson Hole but also to furnish facts bearing on big-game administration in other districts, whenever similar problems arise. The present programs of scientific study of wild life, undertaken by those having to do with its administration, are encouraging to conservationists. Only with more accurate knowledge of the food habits, diseases, and various biological factors, affecting our wild life, shall we be able to care for the various species efficiently.

Biologist, Bureau of Biological Survey.

ENTOMOGENOUS Fungi Attack and Destroy Many Harmful Insects

While the injurious effects of fungi are recognized as the cause of many serious plant diseases, the fact that these organisms may be an asset as well as a liability to the farmer should not be overlooked. This is especially true of the so-called entomogenous fungi, which attack insects and thus assist man in his fight against these pests. These fungi, however, should not be depended upon as an unfailing means of insect control. Their usefulness is limited by the fact that they require a high degree of heat and humidity for their best development. Under such conditions they have been very useful in Florida, Cuba, and Porto Rico, and in other semitropical regions in the natural control of scales, white flies, aphids, and other serious insect pests.

Biologist, Bureau of Biological Survey.

ENTOMOGENOUS Fungi Attack and Destroy Many Harmful Insects While the injurious effects of fungi are recognized as the cause of many serious plant diseases, the fact that these organisms may be an asset as well as a liability to the farmer should not be overlooked. This is especially true of the so-called entomogenous fungi, which attack insects and thus assist man in his fight against these pests. These fungi, however, should not be depended upon as an unfailing means of insect control. Their usefulness is limited by the fact that they require a high degree of heat and humidity for their best development. Under such conditions they have been very useful in Florida, Cuba, and Porto Rico, and in other semitropical regions in the natural control of scales, white flies, aphids, and other serious insect pests.

Fungi that flourish in these regions would be of little value in countries having less favorable climatic conditions. It should be noted that many of these fungi are now widely distributed in the regions where their host insects occur, so that when the proper climatic conditions obtain they multiply practically as rapidly without as they do with artificial distribution.

Efforts to spread infection among insects have been carried on in several ways. In some instances diseased insects are placed where they will come in contact with healthy individuals or the fungous spores mixed with flour and blown on insect-infested plants. A simple method practiced against scale insects is to select a leaf covered with scales that are heavily infected with the fungi and pin it in the center of a tree, where healthy insects will come in contact with it. When naturally infected insects are not available an infection may be produced from specially prepared cultures of the proper fungus.

In order to produce an entomogenous fungus in large quantities it may be grown on a suitable culture medium such as cornmeal, potato cylinders, or extract of beef or of some vegetable, or even on a decoction prepared from the bodies of the insect hosts. Certain fungi that have been difficult to grow artificially will thrive on bits of sterilized fish or egg and potato.

Kinds of Fungi that Attack Insects

Several hundred fungi parasitic on many different kinds of insects have been reported, but in the present article only brief descriptions of a few conspicuous examples will be given.

Among the most familiar and conspicuous entomogenous fungi are species of the genus Cordyceps. (Fig. 49, A, B, D, E.) They are of wide geographic distribution but exceedingly abundant in the Tropics and attack a large variety of insects. They appear as erect, mostly club-shaped growths, varying from one-fourth of an inch to 3 inches in height, and range in color from dark slate or subdued gray to brilliant orange or red. Fungi of this group have two distinct stages in their development. Often in a tramp through the woods one will notice on or about rotting logs a white or delicately tinged feathery growth which on closer examination will be found to issue from the body of a partially concealed or buried insect. If this growth is shaken a fine white powder will be noticed. This powder consists of numerous minute spores that are capable of starting a new infection. Later a club-shaped, generally orange body develops, which produces another kind of spores.

Species of Entomophthoreae (fig. 49, H) are among the most common of the entomogenous fungi and attack many different insects including flies, grasshoppers, aphids, scales, South African locusts, thrips, cutworms, clover-leaf weevils, and others. These fungi may appear as fine white cobwebs covering the insects and in the case of the common house fly attaching them to windowpanes like a white halo, or in other instances fastening them to wood, leaves, sticks, or whatever plant host the insects may have attacked. Sometimes species of Entomophthoreae produce a definite growth as a band or mat or spongy layer on or around the body of the insect, or they may develop entirely within the body of the victim and show no external growth. These fungi not only act as a check in the multiplication of insects but also cause a high mortality among the adults. One species is very common on aphids,

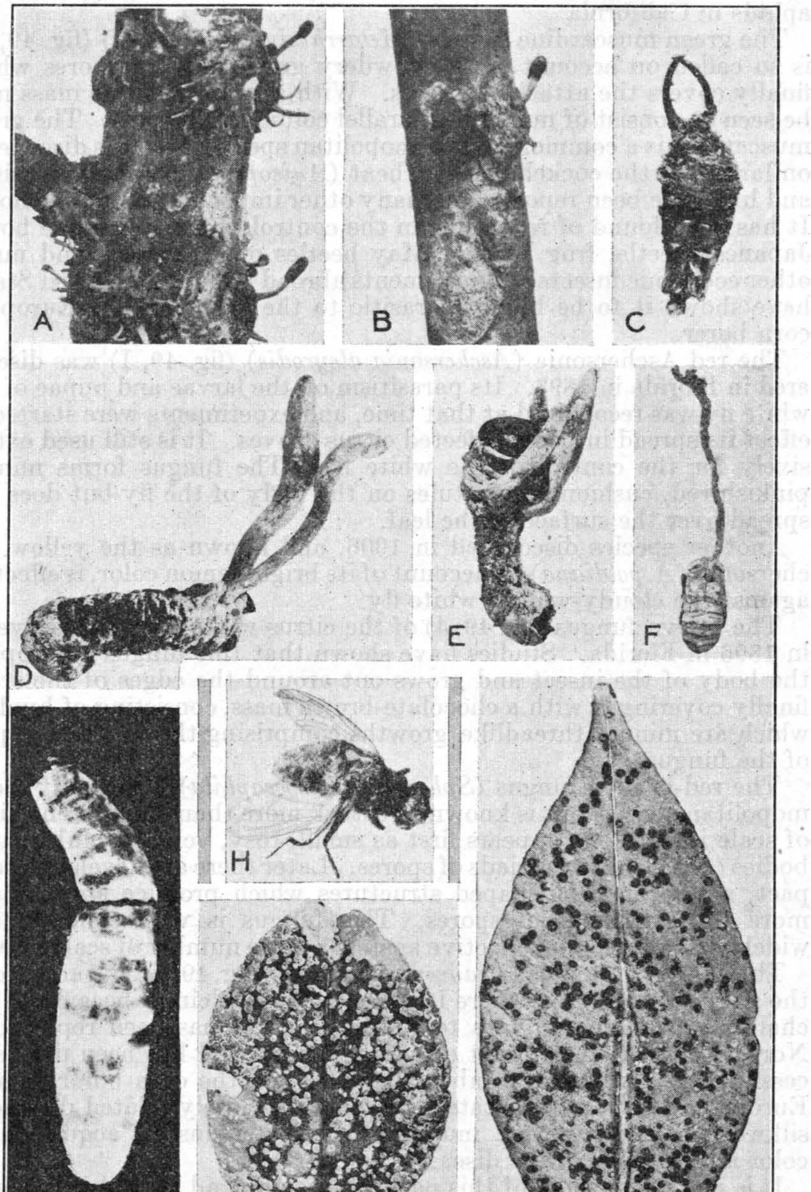

FIGURE 49.—Fungi that attack insects: A and B, *Cordyceps clavulata* on *Lecanium* sp.; C, *Metarrhizium anisopliae* on *Forficula auricularia;* D and E, *Cordyceps ricksii;* F, *Cordyceps sobolifera;* G, *Beauveria bassiana* on Japanese corn borer; H, *Entomophthora muscae* on dead house flies; I, *Aschersonia aleyrodes* on Aleyrodes; J, *Aegerita webberi* on *Aleyrodes citri*

and a recent report cites a case of 100 per cent mortality on alfalfa aphids in California.

The green muscardine fungus (*Metarrhizium anisopliae*) (fig. 49, C) is so called on account of the powdery green mass of spores which finally covers the attacked insects. With a hand lens this mass may be seen to consist of numerous parallel columns of spores. The green muscardine is a common and cosmopolitan species, but was discovered on larvae of the cockchafer of wheat (*Anisoplia austriaca*) in Russia and has since been reported on many other important economic hosts. It has been found of real value in the control of the sugarcane borer, Japanese beetle, frog hopper, May beetles of sugarcane, and many other economic insects. Experiments abroad and in the United States have shown it to be highly parasitic to the larvae of the European corn borer.

The red Aschersonia (*Aschersonia aleyrodis*) (fig. 49, I) was discovered in Florida in 1893. Its parasitism on the larvae and pupae of the white fly was recognized at that time, and experiments were started to effect its spread in badly infected citrus groves. It is still used extensively for the control of the white fly. The fungus forms minute pinkish red, cushionlike pustules on the body of the fly but does not spread over the surface of the leaf.

Another species discovered in 1906, and known as the yellow Aschersonia (*A. goldiana*) on account of its bright lemon color, is effective against the cloudy-winged white fly.

The brown fungus (fig. 49, J) of the citrus white fly was discovered in 1896 in Florida. Studies have shown that this fungus develops in the body of the insect and grows out around the edges of the scale, finally covering it with a chocolate-brown mass, consisting of hyphae, which are minute threadlike growths comprising the vegetative part of the fungus.

The red-headed fungus (*Sphaerostilbe coccophila*) is not only a cosmopolitan species but is known to attack more than 15 different kinds of scale insects. It appears first as small, rosy, velvety, club-shaped bodies consisting of myriads of spores. Later there are developed compact, spherical, flask-shaped structures which produce another and more resistant type of spores. This fungus is very common and widely distributed and effective against a large number of scale insects.

The silkworm fungus (*Beauveria bassiana*) (fig. 49, G) is parasitic on the silkworm in Italy, where it is known as "calcino" because of the chalky appearance it gives to the insects. It has been reported in North America on different economic insects and has been used successfully in experimental laboratory work on the corn borer in both Europe and the United States. In another closely related disease of silkworms, known as red muscardine, affected insects acquire a red color at one stage of the disease.

It is not the purpose of this paper to recommend the substitution of entomogenous fungi for effective insecticides, but rather to call attention to a comparatively little-known subject and explain how these fungi may and do aid the farmer in his struggle against insects. Although the results of studies have appeared from time to time, the subject as a whole has not been thoroughly investigated. That it offers much of purely scientific interest is unquestioned; what it still holds of potential economic value is yet to be discovered.

VERA K. CHARLES,
Associate Pathologist, Bureau of Plant Industry.

ETHYLENE-RIPENED Tomatoes Not Equal in Vitamins to Naturally Ripened Fruit The use of ethylene gas in the treatment of unripe fruits and vegetables resulted from a practice that had developed before our present knowledge of the fundamentals of human nutrition had been attained. Citrus fruits, such as oranges and lemons, when picked green will acquire the appearance of ripe fruit rapidly if they are placed in a closed chamber which is heated by an oil burner. This rapid change in the appearance of the fruit was generally attributed to the high temperature and humidity to which the fruit was subjected, but an investigation about 20 years ago demonstrated that the gas produced by the burner was the active agent, and that the exhaust gases of a gasoline engine were equally effective. Ten years later it was shown that ethylene was the product of combustion which had a specific effect on the fruit.

Ethylene gas is now produced in large quantities and compressed in steel cylinders so that it can be readily transported. It is, therefore, a rather simple matter to liberate the desired quantity of gas in an airtight compartment to treat fruit either in storage or in transit. The fruit can be picked at such a stage of maturity that it can be shipped with little danger of injury and loss, and then prepared for market at a rate approximating more nearly the rate of consumption. However, if forced coloration of fruit does not produce a product that is equal in nutritive value to naturally ripened fruit, the fact should be known so that the artificial product may be put in its proper category.

Experiments With Tomatoes

Investigations conducted in the Protein and Nutrition Division of the Bureau of Chemistry and Soils have shown that naturally ripened tomatoes are better sources of vitamins A, B, and C than tomatoes from the same vines that were picked green and then treated with ethylene gas. The tomatoes for these studies were grown and prepared by the food research division of the bureau. Tomatoes were selected at three stages of maturity—fully ripened, full size green, and about the size of an English walnut. Each of the two samples of immature fruit was divided into two equal portions, and one portion was treated with ethylene gas according to common commercial practice. The tomatoes were then canned with a heat treatment just sufficient to prevent spoilage. The vitamin content of the juice of these five lots of tomatoes was determined by feeding experiments. Ethylene treatment did not change the vitamin content of the tomatoes. With respect to each of the vitamins the naturally ripened tomatoes were superior to the ethylene-treated. The most marked difference was apparent in the vitamin C experiments. The full-sized green tomatoes, untreated or ethylene-treated, were markedly inferior to the naturally ripened, and the small green tomatoes contained but very small amounts of this vitamin. The vitamin A or B content of the juice of the ethylene-treated tomatoes did not differ from that of the green tomatoes, irrespective of size when picked or whether or not they were treated with ethylene. The naturally ripened tomatoes contained more of these vitamins than the green tomatoes.

Whether these observations are applicable to all ethylene-treated fruits and vegetables is not known. The fact that fully grown tomatoes treated with ethylene to produce the color of fully ripened fruit are decidedly inferior as a source of vitamin C to the vine-ripened tomatoes from the same plant indicates that vitamin C is formed largely during the final stage of ripening and that forced coloration with ethylene is not ripening in every sense of that word. The softening of tissues that occurs with ripening was apparent in the ethylene-treated tomatoes, and the juice could be expressed more readily when the treatment had been applied than in comparable untreated tomatoes. It seems very desirable to have a great deal of additional information in regard to the changes induced in fruits by ethylene treatment so that, if advisable, the process and resulting products can be used with discretion.

These studies offer additional evidence to the effect that in the handling of perishable food products new methods or processes which solve spoilage problems satisfactorily should not be accepted without first investigating the effect the process may have on the nutritive value of the product.

E. M. NELSON,
Senior Chemist, Bureau of Chemistry and Soils.

EXHIBITS Prepared by the Department Are in Growing Demand Exhibits have long been instrumental in disseminating information. They have had much to do with the advancement of industry and agriculture the world over. People in general grasp readily the significance of what they see.

In practically all the State, interstate, regional, county, and community fairs, agriculture and the industries dependent upon it have occupied the prominent place. Exhibits have afforded the observer opportunity to comprehend quickly progress in agricultural science and practice, and have enabled him to apply new knowledge to the solution of his own problems.

For a long time the United States Department of Agriculture has recognized the value of exhibits as a teaching method and has participated in fairs regularly. Some years ago it was necessary to seek opportunities for the display of department exhibits. That time has passed. Now, although the Office of Exhibits operates under an appropriation making provision for exhibitions at State, interstate, and international fairs, the demand for exhibits is much greater than the supply. During the exhibition season about 20 carload groups of exhibits are displayed at 50 or more State or interstate fairs. Approximately 2,000,000 persons view them.

Formerly the department's exhibits consisted largely of specimens of products, models, or panels presenting photographs and statements. The purpose of some was to show what the Department of Agriculture was doing, of others to stimulate emulation by portraying individual achievement. A marked evolution of purpose and type of exhibit has occurred. To-day the department exhibit must answer affirmatively the question: Will it give the visitor information likely to make his farming more profitable or his home more comfortable? The department, for instance, does not emphasize the largest ear of corn as the goal to be achieved, but the growing of corn that will bring to the grower the greatest return. What is true of corn applies to all phases of agriculture.

The exhibit must tell its story quickly, strikingly, and convincingly, so as to arrest, hold, and impress the attention of the observer. The decidedly inferior as a source of vitamin C to the vine-ripened tomatoes from the same plant indicates that vitamin C is formed largely during the final stage of ripening and that forced coloration with ethylene is not ripening in every sense of that word. The softening of tissues that occurs with ripening was apparent in the ethylene-treated tomatoes, and the juice could be expressed more readily when the treatment had been applied than in comparable untreated tomatoes. It seems very desirable to have a great deal of additional information in regard to the changes induced in fruits by ethylene treatment so that, if advisable, the process and resulting products can be used with discretion.

These studies offer additional evidence to the effect that in the handling of perishable food products new methods or processes which solve spoilage problems satisfactorily should not be accepted without first investigating the effect the process may have on the nutritive value of the product.

E. M. Nelson,
Senior Chemist, Bureau of Chemistry and Soils.

EXHIBITS Prepared by the Department Are in Growing Demand Exhibits have long been instrumental in disseminating information. They have had much to do with the advancement of industry and agriculture the world over. People in general grasp readily the significance of what they see.

In practically all the State, interstate, regional, county, and community fairs, agriculture and the industries dependent upon it have occupied the prominent place. Exhibits have afforded the observer opportunity to comprehend quickly progress in agricultural science and practice, and have enabled him to apply new knowledge to the solution of his own problems.

For a long time the United States Department of Agriculture has recognized the value of exhibits as a teaching method and has participated in fairs regularly. Some years ago it was necessary to seek opportunities for the display of department exhibits. That time has passed. Now, although the Office of Exhibits operates under an appropriation making provision for exhibitions at State, interstate, and international fairs, the demand for exhibits is much greater than the supply. During the exhibition season about 20 carload groups of exhibits are displayed at 50 or more State or interstate fairs. Approximately 2,000,000 persons view them.

Formerly the department's exhibits consisted largely of specimens of products, models, or panels presenting photographs and statements. The purpose of some was to show what the Department of Agriculture was doing, of others to stimulate emulation by portraying individual achievement. A marked evolution of purpose and type of exhibit has occurred. To-day the department exhibit must answer affirmatively the question: Will it give the visitor information likely to make his farming more profitable or his home more comfortable? The department, for instance, does not emphasize the largest ear of corn as the goal to be achieved, but the growing of corn that will bring to the grower the greatest return. What is true of corn applies to all phases of agriculture.

The exhibit must tell its story quickly, strikingly, and convincingly, so as to arrest, hold, and impress the attention of the observer. The department's Office of Exhibits is ever on the alert to find newer and better methods of presenting agricultural information. All principles of exhibit design and construction are utilized. The requirements make it necessary for the staff that prepares exhibits to become skilled in many different branches of work. Color artists have developed other specialties, such as the making of models in wax, plastic wood, plaster, sheet metal, and rubber, and the fabrication of things by tools and machinery.

Sound and Action Synchronized

During the past two or three years sound synchronized with action and light has been used effectively. One of the most popular types of exhibits the department now has is a talking-animal series consisting of dairy cows, a sow with pigs, a hen, and a ewe and lamb. Exhibits of this type appeal to both eye and ear and tell a story vividly and impressively. (Fig. 50.)

FIGURE 50.—An exhibit in which sound is synchronized with action

Department exhibits usually are not designed to give complete details of a principle, but rather to arouse interest, so that the observer will seek the further information required to put the illustrated principle into practice. The exhibits are supplemented by department publications, of which from 5,000 to 25,000 copies are distributed at each fair at which department exhibits are shown, or nearly half a million during the exhibition season. At one eastern exposition 2,168 visitors, representing 66 occupations and coming from 21 States, requested department publications.

In Arizona some years ago a wool exhibit, designed to demonstrate how to tie fleeces, was shown. A woolgrower, after studying the display, remarked that although wool buyers had told him for years he could get more for wool prepared in this way, he had never before been able to visualize the process. His enthusiasm led, while he was still at the exhibition, to an informal arrangement among neighboring woolgrowers, by which fleeces thereafter were prepared, assembled in quantities, graded, and sold in lots that gave the advantage of carload freight rates and grade prices.

Dairy Exhibits Bring Results

A visitor to the National Dairy Exposition at St. Paul a few years ago, seeing the department's exhibit, was impressed with the facts it presented with respect to the need for better cows. He persuaded his partner to substitute 9 good cows for the 15 low-producing cows they owned. The 9 good cows proved to be twice as profitable as the 15 had been, and required less work and care.

The secretary of a mid-western State fair featured dairy exhibits. Later he wrote:

> The effort that we started, with the assistance of the United States Department of Agriculture in 1923 to give special attention to dairying, is undoubtedly showing results. Increased interest in dairying is evident in almost every section of the State adapted to the industry. We can not claim, of course, all the credit for this, but we know that the sessions of the dairy congress at the fair, supplemented by the valuable dairy exhibits and demonstrations, have been important factors in increasing the interest in dairying.

JOSEPH W. HISCOX,
Chief, Office of Exhibits.

EXPERIMENT Station Record Keeps Track of Research Results

How to keep track of the new facts and findings in agriculture which the various bureaus of the department, the State experiment stations, and other research institutions are daily bringing to light is a problem that constantly confronts investigators, teachers, students, editors, writers, and many other people. So voluminous and scattered is this vast literature that its mere collection is too complicated, too expensive, and too time consuming to be attempted in any comprehensive way by individuals or even by most institutions. It is a specialized task, which becomes more difficult but also more indispensable each year.

Fortunately the need of such a service was recognized by the department at a relatively early stage in the history of agricultural investigation in this country. Soon after the passage of the Hatch Act in 1887, extending Federal aid to the States for the maintenance of agricultural experiment stations, provision was made for the establishment by the Office of Experiment Stations of an abstract journal which would summarize the results reported from time to time by these stations and the department. This record of the station work was named Experiment Station Record and was first issued in 1889. It has been keeping on with this task ever since, and consequently there are now assembled within its pages a complete epitome of the station and department publications for over 40 years.

Soon after the Record was started, however, its scope was broadened to include abstracts of all new findings of interest to agricultural science, regardless of their origin or channel of publication. This change was desirable because science knows no national boundaries, and the discovery of a new principle in animal nutrition or of a means of controlling a plant disease may be as vital whether made in Arkansas or in Bulgaria, or whether revealed in a station bulletin or an obscure foreign periodical. Accordingly the Record has been for many years, to the extent that its space limits have permitted, a digest of the world's agricultural research. Each year there are compressed into its available space of 1,800 printed pages the essential findings from perhaps 7,000 articles, representing in the original half-million pages more than a dozen languages and most of the civilized nations of the globe. During its entire history approximately 200,000 articles have thus been made available through its columns.

Library Receipts Examined Daily

What may be thought of as the raw material for this extensive grist comes chiefly through the department library. The heavy daily library receipts are examined carefully by a trained library assistant, The secretary of a mid-western State fair featured dairy exhibits. Later he wrote:

The effort that we started, with the assistance of the United States Department of Agriculture in 1923 to give special attention to dairying, is undoubtedly showing results. Increased interest in dairying is evident in almost every section of the State adapted to the industry. We can not claim, of course, all the credit for this, but we know that the sessions of the dairy congress at the fair, supplemented by the valuable dairy exhibits and demonstrations, have been important factors in increasing the interest in dairying.

JOSEPH W. HISCOX,
Chief, Office of Exhibits.

EXPERIMENT Station Record Keeps Track of Research Results How to keep track of the new facts and findings in agriculture which the various bureaus of the department, the State experiment stations, and other research institutions are daily bringing to light is a problem that constantly confronts investigators, teachers, students, editors, writers, and many other people. So voluminous and scattered is this vast literature that its mere collection is too complicated, too expensive, and too time consuming to be attempted in any comprehensive way by individuals or even by most institutions. It is a specialized task, which becomes more difficult but also more indispensable each year.

Fortunately the need of such a service was recognized by the department at a relatively early stage in the history of agricultural investigation in this country. Soon after the passage of the Hatch Act in 1887, extending Federal aid to the States for the maintenance of agricultural experiment stations, provision was made for the establishment by the Office of Experiment Stations of an abstract journal which would summarize the results reported from time to time by these stations and the department. This record of the station work was named Experiment Station Record and was first issued in 1889. It has been keeping on with this task ever since, and consequently there are now assembled within its pages a complete epitome of the station and department publications for over 40 years.

Soon after the Record was started, however, its scope was broadened to include abstracts of all new findings of interest to agricultural science, regardless of their origin or channel of publication. This change was desirable because science knows no national boundaries, and the discovery of a new principle in animal nutrition or of a means of controlling a plant disease may be as vital whether made in Arkansas or in Bulgaria, or whether revealed in a station bulletin or an obscure foreign periodical. Accordingly the Record has been for many years, to the extent that its space limits have permitted, a digest of the world's agricultural research. Each year there are compressed into its available space of 1,800 printed pages the essential findings from perhaps 7,000 articles, representing in the original half-million pages more than a dozen languages and most of the civilized nations of the globe. During its entire history approximately 200,000 articles have thus been made available through its columns.

Library Receipts Examined Daily

What may be thought of as the raw material for this extensive grist comes chiefly through the department library. The heavy daily library receipts are examined carefully by a trained library assistant, reservations are made of those publications reporting the results of experimental work, and soon the articles are in the hands of the Record's corps of 12 specialists by whom the abstracts are prepared. In the case of the station and department publications, a special and somewhat more elaborate procedure is followed, to insure that they are received and abstracted as systematically and completely as possible and that the abstracts are printed promptly and in chronological order. This service, not attempted by any other abstracting agency, assembles the results of the work of these institutions into compact and convenient form and disseminates the information all over the world. Advance carbon copies of the station and department abstracts are also made available under a cooperative agreement to Biological Abstracts and Social Science Abstracts, so that those abstracts which are of interest to their readers reach in this way an even wider circle without duplication of work.

Each issue of the Record contains about 400 abstracts, and for the greater convenience of users these are classified under 20 subject headings. The headings at present in use include the following: Agricultural and Biological Chemistry; Meteorology; Soils—Fertilizers; Agricultural Botany; Genetics; Field Crops; Horticulture; Forestry; Diseases of Plants; Economic Zoology—Entomology; Animal Production; Dairy Farming—Dairying; Veterinary Medicine; Agricultural Engineering; Rural Economics and Sociology; Agricultural and Home Economics Education; Foods—Human Nutrition; Textiles and Clothing; Home Management and Equipment; and Miscellaneous.

The various sections necessarily overlap to some extent, so that several may need to be followed to obviate the danger of an oversight. For example, the dairyman often finds articles of interest in the sections on Agricultural and Biological Chemistry, Veterinary Medicine, and Rural Economics and Sociology, while the horticulturist may also be concerned with material appearing under the headings of Agricultural Botany, Diseases of Plants, and Economic Zoology—Entomology. Ultimately, however, there are available for each volume author and subject indexes in which sectional lines are disregarded.

The indexes are unusually detailed and comprehensive. In addition to the volume indexes three general subject indexes have been issued covering, respectively, volumes 1 to 12, 13 to 25, and 26 to 40. It is expected that a similar index for volumes 41 to 50 will shortly be available, and corresponding issues on a 10-volume basis are projected for the subsequent volumes.

Guide to Past Accomplishments

The Record is used not only as a means of keeping track of what is current in agricultural science but as a guide to the accomplishments of the past. The second of these functions is of exceptional value in experimentation. Research represents an advance in knowledge over what has already been discovered, and one of the first tasks of the investigator, whether of an insect pest, plant disease, or a problem of genetics or nutrition, is to ascertain what has already been done by others. Without the services of an abstract journal or some similar aid, the proverbial "looking for a needle in a haystack" would be a comparatively easy occupation.

The data are also of much value to the many people, such as teachers, extension specialists, and students, who may need either a current or a permanent record. Writers of textbooks, treatises, and magazine and newspaper articles find in its pages a veritable mine of information. Within recent years an important group of subscribers has consisted of manufacturers of foods and fertilizers and other commercial interests who look to the Record as a means of keeping them in touch with some of the significant developments in their respective fields.

The Record was for many years issued monthly, but as the amount of literature to be abstracted increased additional numbers were added. The last enlargement of space took place in 1911. Since that time two volumes a year have appeared, each comprising six monthly and three supplementary, or "abstract," numbers of 100 pages each and an index number. The "abstract numbers" are so called because they consist almost wholly of abstracts, whereas from 10 to 15 per cent of the space in the issues bearing the names of the months is given over to editorials and notes.

Like most other technical publications of the department the free distribution of the Record is closely restricted. It is generally available to libraries, particularly those of scientific and educational institutions. The research and teaching staffs of such institutions in this country and Canada are also eligible, within the limits of the edition, as are representatives of the press in the agricultural field.

The Record is available by purchase through the Superintendent of Documents, Government Printing Office, at the rate of 75 cents per volume, or $1.50 per year, and the list of paid subscribers is constantly increasing. Many of these are the commercial interests previously referred to. The demand from all classes of readers is steadily growing.

HOWARD LAWTON KNIGHT,
Editor, Experiment Station Record.

EXTENSION Service Review Keeps Extension Workers Advised of Developments

In May, 1930, the Extension Service of the Department of Agriculture began a monthly publication entitled "Extension Service Review." The purpose of this periodical is to keep extension workers in every part of the United States acquainted with the latest results and methods in the extension field.

The need for a printed publication to help in the dissemination of extension information had been felt for many years, but owing to a lack of funds nothing had been accomplished. Recently the need for such a publication had become both frequent and insistent, and the Office of Information secured the approval of the Bureau of the Budget to the publication of a monthly periodical. The Review supersedes such informal mimeographed periodicals as the Extension Horticulturist, Boys' and Girls' 4-H Club Leader, Timely Extension Information, and Home Demonstration Review, and is the only official periodical that covers the entire field of extension activity.

The Extension Service Review contains 16 pages of printed matter and illustrations, together with a colored cover. It is set in 3-column census form, 8-point type, with attractive column headings. The issue is limited to 10,000 copies, and the publication is sent free to all extension employees, teachers in agricultural colleges, experiment station workers, college libraries, and to a few foreign correspondents.

EXTENSION Service Review Keeps Extension Workers Advised of Developments

In May, 1930, the Extension Service of the Department of Agriculture began a monthly publication entitled "Extension Service Review." The purpose of this periodical is to keep extension workers in every part of the United States acquainted with the latest results and methods in the extension field.

The need for a printed publication to help in the dissemination of extension information had been felt for many years, but owing to a lack of funds nothing had been accomplished. Recently the need for such a publication had become both frequent and insistent, and the Office of Information secured the approval of the Bureau of the Budget to the publication of a monthly periodical. The Review supersedes such informal mimeographed periodicals as the Extension Horticulturist, Boys' and Girls' 4-H Club Leader, Timely Extension Information, and Home Demonstration Review, and is the only official periodical that covers the entire field of extension activity.

The Extension Service Review contains 16 pages of printed matter and illustrations, together with a colored cover. It is set in 3-column census form, 8-point type, with attractive column headings. The issue is limited to 10,000 copies, and the publication is sent free to all extension employees, teachers in agricultural colleges, experiment station workers, college libraries, and to a few foreign correspondents.

The Review is on sale by the Superintendent of Public Documents in Washington, D. C., at a price of 50 cents a year to all others who may wish to obtain it.

The Review features from month to month statements or stories of outstanding extension accomplishments and methods. The field work is represented as far as space permits by news items contributed by the several State extension services. Many of these items and stories are illustrated by photographs sent in by correspondents in the field. Every attempt is made to select and use attractive and artistic illustrations.

Promoting Farm Board's Policies

In view of the fact that the extension forces have been cooperating closely with the work of the Federal Farm Board in its educational program, the Review has devoted much space to this type of extension work. Articles by members of the board, statements issued by the board, and facts and data obtainable from it have been printed from time to time.

The Review contains an editorial page in which are reflected the policies and opinions of the Extension Service. The editorials are planned to help extension workers and to strengthen extension field activities. Administrative announcements of importance are made from time to time, and changes in organization and personnel appear as occasion warrants. The Review frequently mentions new publications of interest to extension agents that they may be familiar with what is being written concerning their activities.

The Review is frequently used to bring to the attention of the field what the department and its bureaus have to offer for the extension of agricultural information. One page of the cover is devoted monthly to the presentation in advertising form of charts, photographs, movie films, bulletins, and other material that has recently been issued. In its columns there appear from time to time reviews and notices of recent publications that are of value to field agents.

All phases of extension are covered as fully as possible; 4-H club work, home demonstration work, and county agricultural agent work receive attention month by month. In each issue there are several signed articles written by members of the extension force. It is the intention of the editors to make the Extension Service Review in the fullest sense serve the entire field force of the cooperative extension service.

F. A. Merrill,
Senior Agriculturist, Office of Cooperative Extension Work.

FABRICS for Children's Play Suits Tested for Resistance to Weather

The lightweight durable clothing materials now on the market make it easy for children to enjoy the outdoors in rainy or cold weather. With just a little attention to appropriate clothing for open-air exercise, the average child can keep warm and dry without the burden of heavy wraps. The Bureau of Home Economics has recently made a study of both cotton and woolen materials to determine their suitability for playtime use. The woolens varied from closely woven coverts to the more open blanket materials. The cottons were for the most part closely woven

The Bureau of Home Economics has recently made a study of both cotton and woolen materials to determine their suitability for playtime use. The woolens varied from closely woven coverts to the more open blanket materials. The cottons were for the most part closely woven and included, beside a new experimental cloth, such materials as sailcloth, drill, jean, duck, mechanical cloth, cotton suède, and a special British twill cloth manufactured in England for the Grenfell mission in Labrador. Among the fabrics submitted by the manufacturers was discovered a new American cloth particularly well adapted for use in play suits.

The shower-proofed fabrics shown in Figure 51 were found to be of special interest. The British twill cotton material (fig. 51, B) is being successfully used for outer garments to resist wind and moisture in the far North. Both the British twill and the new American cloth (fig. 51, A) were made from long-fibered, 2-ply cotton yarns, but the yarns of the twill are finer and of lower twist. Since experiments with these two fabrics show that the new American cotton wears better and tears less easily, it is naturally the better adapted to play-suit requirements. The duck (fig. 51, C) is another fabric made from 2-ply cotton yarns especially noteworthy for its strength. The covert (fig. 51, D) seems to be outstanding among the woolen materials for its wearing qualities.

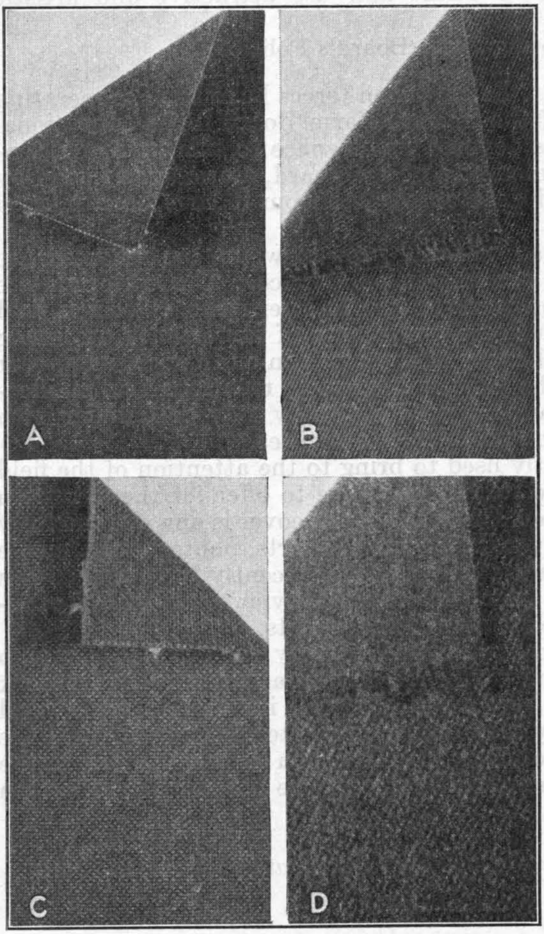

FIGURE 51.—A, New American cloth; B, British twill cloth; C, duck; D, covert

Examined Under Standard Conditions

A representative list and description of the various fabrics studied is given in Table 7. All the fabrics were examined under the required standard conditions for the following: Thread count (threads per inch in both the warp and the filling direction), yarn size, weight per square yard, thickness, tensile strength, stretch, bursting strength, resistance to tear and to wear, washability, air permeability (ease with which air passes through the fabric), and heat-retaining value. Inasmuch as different materials are not affected in the same way by varying amounts of moisture in the air, it was necessary, previous to any observations, to expose the test samples in a laboratory having known constant humidity conditions.

TABLE 7.—*A comparison of the construction, weight, and tensile strength of a representative group of the fabrics considered for children's play suits*

Fabric	Weave	Thread count per inch		Weight per square yard	Tensile strength per inch [1]	
		Warp	Filling		Warp	Filling
Cotton:		*Number*	*Number*	*Ounces*	*Pounds*	*Pounds*
Duck	Plain	63	56	9.3	118	107
British twill cloth	Twill	192	92	5.0	113	43
New American cloth	Plain	100	87	6.1	81	100

Flat knit (napped)	Plain	[2] 19	[3] 23	13.2		

[1] Strip samples 1 inch in width were used for the tensile-strength tests. [2] Wales. [3] Courses.

Power-Operated Tester Used

The strength and the tear tests were made with a power-operated tester. For a tensile-strength determination, strip samples cut both warp and filling wise were used. While the machine jaws separated at a uniform rate, an automatic recorder gave the stretch of the sample with increasing load, as well as the pull in pounds required to break the strip. The tear-test samples, which were cut longer on one side than the other, were always clamped with the shorter side stretched taut so that additional separation of the jaws would tear the cloth. For the bursting-strength tests the fabric jaws were replaced by a special ball-burst attachment. With this device a cloth sample fixed in position between two flat rings was ruptured by being drawn down over a steel ball.

In order to compare the effect of hard wear upon the fabrics, they were rubbed under tension by an abrasive sea-sand surface in an oscillating-type abrasion machine. Under these conditions the duck was more than twice as resistant to wear as any other fabric. The new American cotton cloth was next in order, and the woolen covert compared favorably with this. All the other fabrics were much lower.

When the results of the strength and durability tests are considered as a whole, the duck and the new American cotton cloth rank the highest of the cotton goods, and the covert the highest of the woolens. While the duck stands the highest of all the fabrics in these mechanical tests, it seems somewhat bulky and stiff for young children, but it would be especially useful for the boys of school age who wear overalls over their regular clothing on cool days. Although the cotton suèdes gave high tests for tear and for bursting strength, they did not resist abrasion well and were also found to require special care in laundering. The sailcloth in the gray was comparatively high in tear resistance and bursting strength, but the dyed sails and the British twill cloth gave relatively low values.

The woolen covert and the first six cotton fabrics listed in Table 7 had received shower-proof treatment. According to the several types of waterproof tests applied to these fabrics, the British twill, the duck, and the new American cotton cloth were the most impervious to water even after several washings. The covert was satisfactorily shower-proof provided it was not stretched appreciably. Results obtained in the washing tests suggest that all fabrics still need to be tested for shrinkage before they are made into service garments. The highest warp shrinkage for any cotton material was 2 inches per yard. The British twill, which did not shrink at all warpwise, gave a filling shrinkage from 2½ to 3½ inches per yard. (Fig. 52.)

To give an estimate of their relative resistance to wind, the air permeability of the various fabrics was measured. Obviously the fabric having the greatest air permeability will give the least wind resistance. The air flow per minute through the blanket material, which was the most permeable fabric, was about eighty times the value for the new American cotton cloth under the same pressure-difference. When the permeability of the latter is expressed as 1, some of the other fabrics have the following order: Duck, 1.4; British

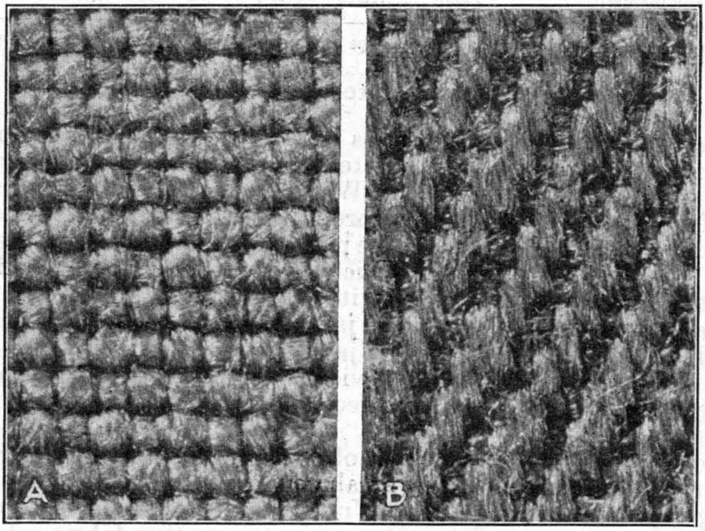

FIGURE 52.—Samples magnified 20 times. The plain weave of the new American cloth (A) and the twill weave of the British cloth (B) are shown clearly

twill cloth and sailcloths, about 2.5; covert, 6.8; drill and cotton suède, approximately 9.0; flat knit woolen, 57.0; kasha, 67.0; blanket material, 80.0.

Heat-Retaining Values

In a comparison of these materials for their heat-retaining value, the blanket material has the highest rating. The flat knit woolen is nearly four-fifths as high. The drill, the British twill, the sailcloth, and the new American cloth are all of the same order, which is a little less than half that of the blanket material when measured under the experimental conditions. Results from 11 to 15 per cent higher than those of this group were obtained for the duck, cotton suède, and covert. These values were computed from observations made on the Sale-Hedrick apparatus, in which the test sample is placed over an electrically heated plate and the current required to keep this plate at a certain definite temperature is determined. An unusually high heat retention was obtained when blanket material was placed under the sailcloth. Even the thin, open, lightweight woolen kasha, which gave a very low heat-retaining value when measured alone, was practically as warm under the sailcloth as the heavier cotton suéde with the same covering. (Fig. 53.)

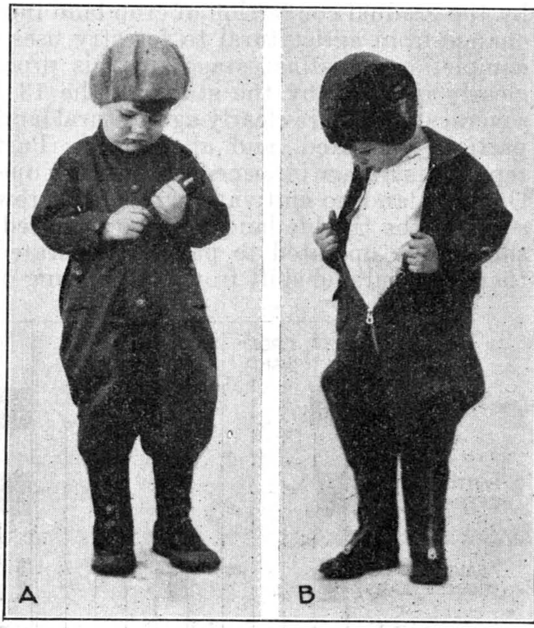

FIGURE 53.—Appropriate suits for play: A, New American cloth; B, woolen covert

The results obtained in these different tests seem to indicate that the needed protection from wind and moisture will be given by one of the tightly woven, low permeability materials such as the new American cotton or a proofed sailcloth. Worn loosely over the regular clothing, it ought to be warm enough for the healthy child engaged in active play under normal conditions. In extremely cold weather, however, it may be necessary to wear under this wind-resistant fabric a warm, lightweight, fluffy material containing many small air spaces. Protected in this way, the average child will have no difficulty in resisting snow, wind, and cold in the severe climates.

hill towns in large numbers to places of greater economic opportunities. One consequence of this exodus of population, in the following decades, was extensive farm abandonment in the hill towns.

Farm abandonment is not a single act, but a process characterized by the gradual conversion of crop land into woodland. The ultimate change from agricultural to forestry uses often requires decades for completion. Distinct stages in this process of abandonment were clearly revealed by the study of the 13 hill towns. To define the several stages more clearly agricultural land was classified as operated, partially operated, and abandoned. Partially operated farm land represents a stage intermediate between operated and abandoned land. On such land no cultivated crops are grown, but some hay is cut or some of the tillable land may be pastured. As the status of a farm shifts from operated to partially operated and then to abandoned, there is a parallel shift from the growing of cultivated crops and hay

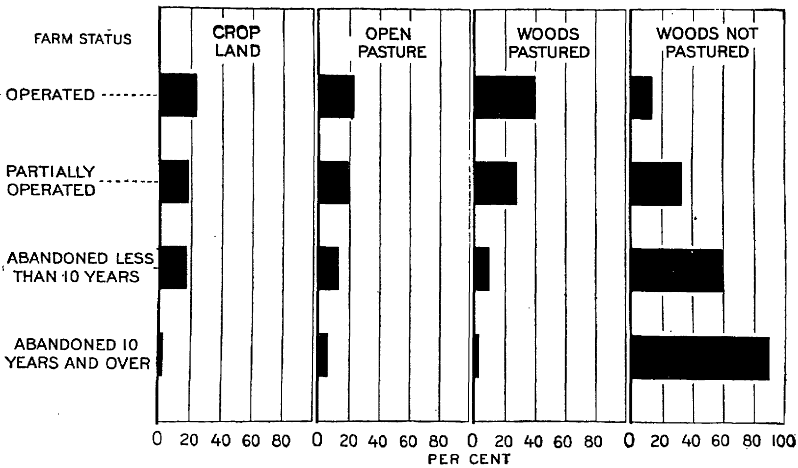

FIGURE 54.—As the status of a farm shifts from operated to partially operated to abandoned there is a parallel shift from the growing of cultivated crops and hay to hay only, from hay to open pasture, from open pasture to woodland pasture, and finally to woodland. The process is seldom reversed

to hay only, from hay to open pasture, from open pasture to woodland pasture, and finally to woodland.

This process is illustrated graphically in Figure 54. The crop land falls from 23.1 per cent of the farm acreage in operated farms to 2.3 per cent of the acreage of farms in the last stage of abandonment. On the other hand, the figures for woodland not pastured, which represents the use corresponding to the last stage of agricultural abandonment, increase with each succeeding stage of abandonment from 13.5 per cent of the total acreage of operated land to 89.9 per cent of the total acreage of land abandoned 10 years and over.

The question naturally arises as to the rate at which this reversion of agricultural land to woodland is proceeding in the 13 towns. On the assumption that woodland comprised the same percentage of the total acreage of land in each status in 1919 as in 1929, the area of woodland in farms in the 13 towns increased from 112,595 acres in 1919 to 118,413 acres in 1929. This estimate indicates that 5,818 acres of agricultural land reverted to woodland during the period 1919–1929. Less than 1,000 acres of this reforested area was planted.

In the past partially operated and abandoned lands ultimately have reverted to woodland. If this process continues, to reforest the 26,344 acres of open land now in partially operated and abandoned land in the 13 towns would require from 50 to 60 years at the rate of natural reforestation during the last decade. Of the 194,072 acres of agricultural land in the 13 towns in 1929, 118,413 acres, or over 60 per cent, was in woodland. More than one-third of the remaining open land is in process of reversion to woodland, as indicated by the fact that 26,344 acres of this open land are classed as partially operated or abandoned land.

Taking the 13 towns, crop land comprised 19.3 per cent of the land in farms, open pasture 18.8 per cent, woods pasture 30.3 per cent, woods not pastured 30.7 per cent, and farmstead and waste 0.9 per cent. Operated land comprised 54.6 per cent of the land in farms in the 13 towns; partially operated, 26.2 per cent; abandoned less than 10 years, 8.9 per cent; abandoned 10 years and over, 10.3 per cent.

For the decade 1919–1929 there were 697 farms classed as operated both at the beginning and at the end of the period. Of these farms, 676 had been operated continuously, 19 had been partially operated at some time during the period, and only 2 had been abandoned. Once abandoned a farm is seldom again operated. There were 154 farms classed as abandoned in 1919, and 152 of these were in the same status in 1929. One was classed as operated and one as partially operated at the end of the period.

Partially operated farms tend to continue as such until abandoned. Among 262 farms classed as partially operated in 1919 only 21 were in the operated status in 1929. But 78 had been abandoned. The sequence is from operated to partially operated to abandoned status. A reversal of this sequence rarely occurs. More than one-fourth of the farms operated in 1919 had passed out of that status in 1929, an average rate of 26.2 farms a year for the 13 towns.

Many of the partially operated farms probably will be abandoned. The buildings on these farms are fast falling into decay, natural reforestation is progressing rapidly, and two important sources of revenue, maple orchards and timber, are seriously reduced if not wholly eliminated. In some instances the farmhouses on these partially operated farms may be used for summer residences, but the probabilities are that the land will be used for growing timber.

During the next 10 or 20 years readjustments should be made in the 13 towns to meet the situation clearly indicated by the present trend in land use.

Bureau of Agricultural Economics.

FARM Income Changes Measured Roughly by Representative Reports

Nearly 12,000 farmers reporting to the Department of Agriculture each answered 36 questions related to their own farming operations in 1929. The questions asked the sums received and spent during the year for business purposes, the value of farm property, and other items descriptive of the farm and its business. The purpose of the inquiry was to ascertain direct from farmers the general results of farm operations during the year in different parts of the United States.

FARM Income Changes Measured Roughly by Representative Reports

Nearly 12,000 farmers reporting to the Department of Agriculture each answered 36 questions related to their own farming operations in 1929. The questions asked the sums received and spent during the year for business purposes, the value of farm property, and other items descriptive of the farm and its business. The purpose of the inquiry was to ascertain direct from farmers the general results of farm operations during the year in different parts of the United States.

In 1929 the 11,805 farmers reporting made an average of $1,298 from the farm business operations of the year, derived from cash sales amounting to $2,669, plus increase in value of property, $201, which might have been converted into cash or normally would soon be so converted, minus cash outlay for current farm expenses, $1,572. The farms which yielded these sums averaged 270 acres in size and were worth with buildings, stock, and equipment $15,242. The average ($1,298) is made up from individual reports, which ranged from $67,270 to a loss of $7,080; 65 per cent of the reports were below the average and 50 per cent below $861; 8 per cent showed net losses and only 3 per cent showed gains of more than $5,000. Averages for six major geographical divisions are stated in tables in the statistical section of this Yearbook.

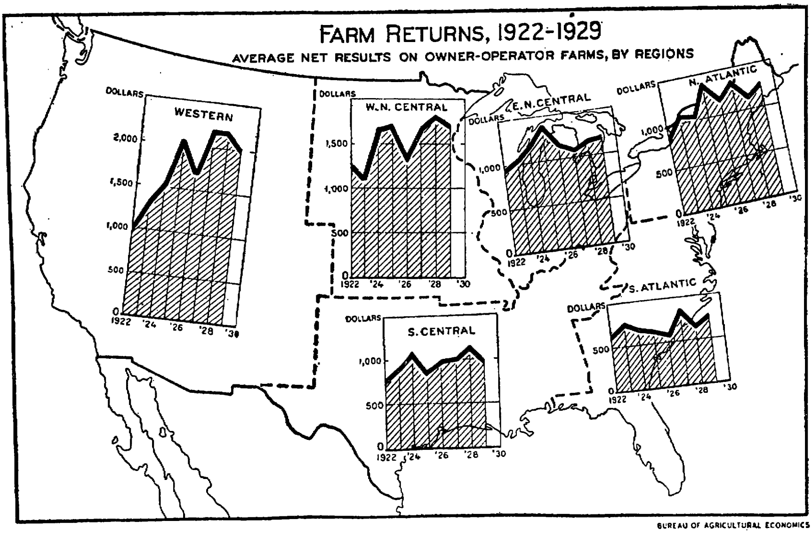

FIGURE 55.—Regional differences in farm returns result from differences in the size and value of farms and in prevailing types of farming. There is less annual variation in the averages of returns of all farmers reporting than in the averages of returns of farmers in the several regions

The return computed for 1929 ($1,298) is directly comparable with like figures for previous years in this series of reports. The list of correspondents to whom the inquiry is addressed has changed little in character and distribution during the period. The number reporting each year is large enough to render it probable that the average return obtainable from the 12,000 next neighbors of each reporter would be within $15 or $20 of the amount shown for those who did report in each of the years. The average returns in the several geographical divisions reflect real territorial differences in the results of farming. The average returns for the years 1922–1929 by regions are shown in Figure 55.

Reports Not "Average" But "Representative"

The farmers who report each year are "representative" rather than "average" in a sense that would permit using figures supplied by them as descriptive of the situation of all farmers. The report covers owner operators only, whereas owners constitute less than two-thirds of the number of farmers in the United States and smaller proportions in some of the States. Moreover, very few farms smaller than 50 acres are included, whereas small farms are numerous in some of the States. Presumably, however, economic forces affect groups of farmers in much the same way; tenants will have better crops and higher prices when owners have better crops and higher prices, and conditions hard for large farmers bear down also on small farmers. The adjustments necessary to convert farm-returns averages into average figures applying to all farmers or to tenants or to small farms have not been worked out. As an indication of the difference in levels between all farmers and the farm owners reporting their returns, the following comparisons of gross incomes from farming are made. Estimates by this department of the gross income of all farmers for the five years 1924–1928 give $1,840 per farm per year. Averages of cash receipts plus food produced on the farm and used by the farm family, as reported in the farm returns inquiry for the same period, amounted to $2,782, or 50 per cent more than the estimated average for all farmers. This proportion does not apply to subdivisions of the country nor to expenses or the net returns.

The computed net result ($1,298) is less than the income of the farmer under any of the usual definitions of income. Food used by the family out of farm production (averaging $262 at wholesale farm prices and perhaps less completely accounted for than the cash items), has not been included in the "net result," nor has any allowance been made for fuel available on most farms, or for house rent. Most farmers have some income from work done off the farm, and many have income from other property or contributions from the members of the family. These supplementary sources of income permit a higher standard of living among farmers than the meager cash returns from farming in some localities would support. On the other hand, the cash balance is not all available for family living, as part of it is paid out as interest on indebtedness, and part is spent for improvements or put into savings. Part of the earnings from the farm is shared by otherwise unpaid members of the farm family, so the farmer himself gets somewhat less than the indicated income of the family. These items, as yet unmeasured on a broad basis, must be considered in different combinations for comparisons of results of farming with results from other occupations. Surveys of farmers in selected areas have developed the relationships of part of the items at a time to the business results without yielding the key to their extension to all farmers or even to large groups of farmers differently situated.

Data Used in Other Studies

The items composing the farm-returns questionnaire are regularly used as supplementary information in several projects of the bureau where well-distributed replies to related questions are helpful. Thus, in the field of farm taxes the tax paid by the farmer for a farm of stated size and value yields rates which can be compared with rates obtained direct from local tax collectors and county officials, and something of the severity of the tax burden on income can also be indicated. In appraising the farm real estate situation, the acre values of real estate computed from groups of reports supplement those obtained from real estate dealers and other observers in working up the index numbers of values. In farm-management problems the results obtained in these inquiries are considered as significant supplementary information. Twelve thousand answers to the same questions year after year which reflect changes expected on logical grounds lead to confidence in changes observed in those items for which rigid proof is not currently available.

At a time when accurate information on the effect of economic problems is so important as it has been in recent years it is disappointing not to be able to get exact information on details of farm income in specified areas. The department must obtain such information from farmers, and farmers who do not have it can not give it to the department. Those who do not have the facts for their own farms well in mind can make little use of the summary information on incomes reported by the department. One of the accomplishments of the farm-returns inquiry has been that realization of inability to summarize the results of a year's effort has led a few hundred farmers each year to see for themselves what changing conditions mean to them.

Bureau of Agricultural Economics.

FEDERAL Meat Inspection Protects Consumers and Locates Animal Diseases The Federal meat-inspection service of the Bureau of Animal Industry, while engaged in its principal task of protecting the health of consumers of meat, also renders helpful assistance to other enterprises. As notable examples, it has made available to farmers and livestock sanitarians reliable information regarding the prevalence of livestock diseases and has contributed materially to knowledge concerning the spoilage and care of meats.

As a routine activity, all animals which are about to be slaughtered under Federal meat inspection are subjected to a thorough and searching veterinary examination for evidence of disease or other condition which would render the meat unfit for food. This is called the ante-mortem inspection. Later on, at the time of slaughter, or post-mortem inspection, each carcass with its viscera, is sytematically examined by scientifically trained inspectors. Carcasses and parts that are diseased, unsound, or otherwise unfit are conspicuously marked "U. S. Inspected and Condemned" and are destroyed for food purposes under official supervision. The sound carcasses and parts, after being appropriately marked "U. S. Inspected and Passed," continue on to other departments of the establishment for chilling and processing.

Each step in these processing operations, including packing and labeling of the finished product for shipment from the establishment, is closely scrutinized, and the meats are carefully inspected at the various stages by specially trained employees. The results of all inspections are recorded on report forms which not only show in detail the results of the activities but also constitute a fund of valuable data.

The magnitude of meat-inspection activities will be obvious when it is known that during the year ended June 30, 1930, nearly 75,000,000 animals were slaughtered and the resulting meat and meat food products processed in 804 establishments, located in 254 cities and towns.

In the administration of the meat-inspection acts, especially as they apply to post-mortem inspections, much effort has been necessary to after year which reflect changes expected on logical grounds lead to confidence in changes observed in those items for which rigid proof is not currently available.

The results of all inspections are recorded on report forms which not only show in detail the results of the activities but also constitute a fund of valuable data.

The magnitude of meat-inspection activities will be obvious when it is known that during the year ended June 30, 1930, nearly 75,000,000 animals were slaughtered and the resulting meat and meat food products processed in 804 establishments, located in 254 cities and towns.

In the administration of the meat-inspection acts, especially as they apply to post-mortem inspections, much effort has been necessary to coordinate the fundamental requirements of thorough inspection and sanitation with the speed of operation which the packer considers economically essential.

Mechanical Ingenuity Plays Important Part

Inventive genius, both within and without the service, has brought marked improvement in facilities for inspection and operations which are outstanding among the meat-inspection systems of the world.

In the modern meat-packing establishments the animals are hoisted to an overhead conveyer by means of which they pass in a suspended

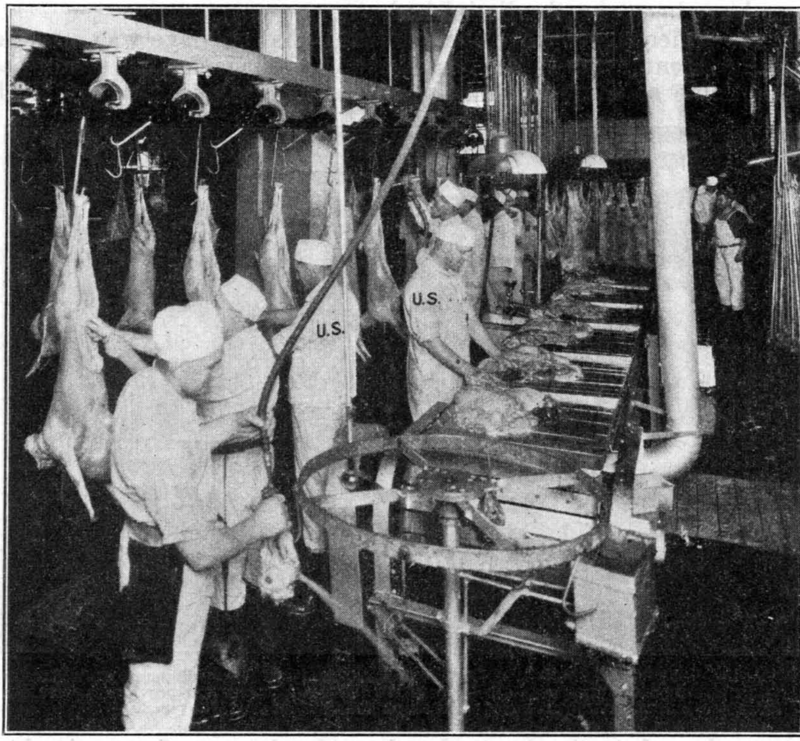

FIGURE 56.—Sheep-slaughtering department equipped with automatically cleansed, moving-top, all-metal inspection table with separate compartments for viscera and parts of each carcass. The movement of this equipment is synchronized with the rail mechanism which conveys the carcasses. Inspectors are indicated by the letters U. S.

position over a definite route with unvarying regularity through the various stages of the dressing operation and inspection. The viscera and parts are removed and placed for inspection on moving-top equipment which is synchronized in speed to that of the mechanical conveyer of the carcasses during the process of dressing. This is done in order to maintain accurate relationship and identification of the carcass and its viscera and detached parts until the post-mortem inspection is completed. (Fig. 56.)

The moving-top viscera-inspection table is constructed of corrosion-resisting metal, is automatically cleansed with pure water, and is also continuously subjected to sprays of scalding water. Good sanitation is thus assured as well as efficiency of inspection.

In both the slaughtering and processing departments where meats must be washed (fig. 57) the practice of spray washing under pressure up to 300 pounds is a recent and meritorious development in inspected establishments.

Improved Sanitation Reduces Spoilage

A study of assembled records shows that in the earlier years of meat inspection spoilage of meat was considerable and at times enormous, resulting in heavy losses. These conditions have from time to time been subjected to careful study and laboratory research in which the meat-inspection service contributed materially, with the result that the losses have been greatly diminished.

Much evidence was developed showing that spoilage was attended by and evidently due to the presence and propagation of certain bacteria. Some of these organisms, it was found, were present in the

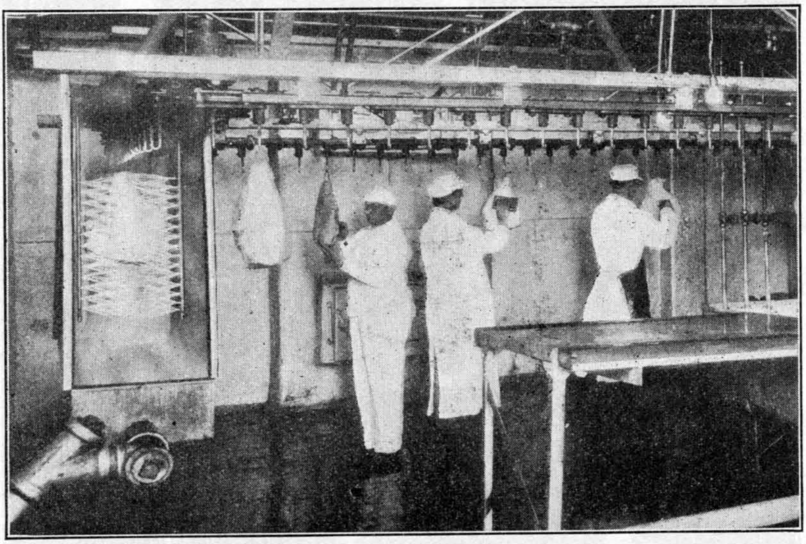

FIGURE 57.—Mechanical conveyer subjecting cured meats to spray washing in pure, tempered water under high pressure (approximately 300 pounds). This equipment also provides opportunity for inspection and branding of meats while suspended from the conveyer

tissues when the animal was slaughtered, whereas others gained entrance during the dressing of the carcasses and subsequent handling. Studies revealed the importance of good sanitation as a factor in preventing the spoilage of meat. They also proved that prompt and efficient refrigeration of meats would check the growth and propagation of those organisms which in some degree are present even when the best-known standards of sanitation are practiced. The soundness of these conclusions has been thoroughly demonstrated. When practiced with care the methods of prevention have greatly reduced spoilage losses, resulting in large savings and reaffirming the fact that a high standard of sanitation in packing houses is sound economically as well as hygienically.

Meat Inspection a Help to Livestock Producers

Diseases of animals, like weeds in growing crops, are a serious liability. Unlike weeds, however, the presence of which can readily be detected before much damage is done, communicable diseases are often insidious in nature, and may reduce or destroy the value of a herd or flock before their presence is apparent to the owner.

Probably no other agency is in a position to note and catalogue the livestock-disease situation so accurately as the meat-inspection service. The daily reports of diseased conditions found by inspectors assigned to ante-mortem and post-mortem duties, when assembled and tabulated, depict the general situation throughout the country.

These records furnish a reliable source of information for those interested in the control of animal diseases. An outstanding example may be found in reviewing the situation as it applies to bovine tuberculosis. Prior to the inauguration of the nation-wide campaign against this disease, the meat-inspection records showed a general increase in animals found on post-mortem inspection to be affected with tuberculosis. On the other hand the records of recent years indicate, with gratifying certainty, the retreat of the disease before the united efforts of livestock producers, assisted by the coordinated county, State, and national eradication forces.

As an added service to the livestock industry, when animals presented for slaughter are found to be affected with communicable disease, special reports are furnished to the State livestock sanitary authorities. These reports convey full information as to the character and extent of the disease found, thereby giving opportunity for measures of control and suppression to be applied as a protection to the owner against further loss, and to the community at large against the spread of infection.

W. C. Herrold,
Senior Veterinarian, Bureau of Animal Industry.

FERTILIZER Studies Show Manner of Distribution Is Extremely Important The expense incident to the use of any commodity is dependent not only on its purchase price, but also on its utility or length of service. Two distinct lines of endeavor are thus available for reducing the true cost of any commercial product. One of these, as applied specifically to fertilizers, is the economic improvement in manufacturing processes while the other involves increasing the returns from a given application of the fertilizer.

The new developments that have taken place since the war in the manufacture of fertilizers have greatly exceeded in importance those of any like period in the history of the industry. As an outcome of this work many new materials have been placed on the market at greatly reduced prices and the average cost of mixed fertilizers has therefore also been reduced. Comparatively little attention was given during the same period to the most effective use of fertilizers. Their efficiency remained about the same or actually decreased, owing to the poor mechanical properties of many of the new materials that were placed on the market. The question of the most effective use of fertilizers is, therefore, one of special importance at this time and one which seems to afford greater possibilities for reducing fertilizer expenses than is likely to result from further reduction in manufacturing costs.

The efficiency of fertilizers may be increased by (1) increasing the uniformity with which they are distributed in the field; (2) adjusting detected before much damage is done, communicable diseases are often insidious in nature, and may reduce or destroy the value of a herd or flock before their presence is apparent to the owner.

Probably no other agency is in a position to note and catalogue the livestock-disease situation so accurately as the meat-inspection service. FERTILIZER Studies Show Manner of Distribution Is Extremely Important

The expense incident to the use of any commodity is dependent not only on its purchase price, but also on its utility or length of service. Two distinct lines of endeavor are thus available for reducing the true cost of any commercial product. One of these, as applied specifically to fertilizers, is the economic improvement in manufacturing processes while the other involves increasing the returns from a given application of the fertilizer.

The new developments that have taken place since the war in the manufacture of fertilizers have greatly exceeded in importance those of any like period in the history of the industry. As an outcome of this work many new materials have been placed on the market at greatly reduced prices and the average cost of mixed fertilizers has therefore also been reduced. Comparatively little attention was given during the same period to the most effective use of fertilizers. Their efficiency remained about the same or actually decreased, owing to the poor mechanical properties of many of the new materials that were placed on the market. The question of the most effective use of fertilizers is, therefore, one of special importance at this time and one which seems to afford greater possibilities for reducing fertilizer expenses than is likely to result from further reduction in manufacturing costs.

The efficiency of fertilizers may be increased by (1) increasing the uniformity with which they are distributed in the field; (2) adjusting the position of the fertilizer in the soil with respect to the seed so as to secure the optimum balance between its burning effects and its availability to the roots of the plant; and (3) improving the quality of the fertilizer.

Fertilizer Distribution

Fertilizer distributors have been in use for many years but the first study of the uniformity with which they apply fertilizers was made only a few years ago in a cooperative investigation by the Fertilizer and Fixed Nitrogen Unit of the Bureau of Chemistry and Soils and the Division of Agricultural Engineering, Bureau of Public Roads. It was found that all distributors apply fertilizers more or less irregularly, and that the variation in distribution may sometimes be so great as to indicate toxic applications to some plants, whereas others are insufficiently fertilized for best results. This irregularity in the distribution of fertilizers is caused by (1) segregation of the components of the mixture; (2) poor drillability of the fertilizer; and (3) imperfections in the design or working parts of the machines.

The extent to which fertilizers segregate increases with the difference in the size and specific gravity of the individual particles. Fertilizer mixtures therefore segregate differently according to the materials used in making up the mixture. A powdered or damp fertilizer is not as drillable as a dry granular one. Many fertilizer materials cake or become sticky by absorbing moisture from the air and the uniformity with which they can be distributed may vary from day to day.

That uniform distribution is essential for best crop yields was clearly demonstrated in later cooperative experiments between the two bureaus already mentioned, the South Carolina Experiment Station, and a joint committee on fertilizer application appointed by a number of fertilizer and agricultural agencies. These experiments were made on cotton during the summer of 1929 in several places in South Carolina. Several plantings were made in which 800 pounds per acre of a 4–8–4 fertilizer, or 267 pounds of a 12–24–12 fertilizer, were applied by 22 different types of commercial distributors, and also with great care in a uniform manner by hand. All the distributors applied the fertilizer more or less irregularly along the row. When other conditions were equal the uniformly hand-distributed fertilizer produced from 20 to 50 per cent more cotton than that produced on an average by the use of fertilizer machines in every one of six tests, and the more irregular the distribution the lower were the yields.

Fertilizer Placement

These experiments on the distribution of fertilizers as well as field tests by others have also shown that the effectiveness of a fertilizer also depends on its position with respect to the seed. The results indicate that it should be more or less localized rather than widely distributed through the soil, and that it should be placed within a certain maximum distance from the seed, but not in contact with it.

The field tests that emphasized the importance of uniformity of distribution were followed in turn by a study of the drillability of fertilizers as affected by their tendency to segregate. It was found that the segregation of fertilizers can be entirely prevented by a granulating treatment which is applicable alike to soluble or insoluble materials and mixtures. This treatment not only prevents the segregation of fertilizers but also greatly improves their drillability by decreasing their tendency to cake or become sticky. Other experiments are in progress which should further improve the efficiency of fertilizers by securing a greater degree of uniformity in their distribution and proper placement with respect to the seed.

Fertilizer Quality

The efficiency of certain synthetic mixtures that have recently been placed on the market has frequently been too low to be explained by irregular distribution or placement of the fertilizer. The poor results were always obtained on sandy soils and were limited to mixtures containing alkali salts only. A careful investigation of the subject by the Office of Tobacco and Plant Nutrition, Bureau of Plant Industry, has demonstrated that the poor results obtained with fertilizers of this kind are due to an inadequate supply of calcium to counteract the toxic action of the alkali salts and to a deficiency of both calcium and magnesium below the normal requirements of the plants. When these were supplied, normal crop yields were invariably obtained. The addition of certain other elements now known to be essential to crops, such as manganese and sulphur, has also been found to increase the effectiveness of synthetic fertilizer mixtures when used on soils deficient in these elements.

It may therefore be concluded that the economic value of a fertilizer to the farmer is dependent not only on its original cost but also on its composition and on the manner in which it is applied.

Bureau of Chemistry and Soils.

FERTILIZER'S Value Much Affected by Method of Applying It to Soil

Fertilizers are used to increase crop production and quality and on this account have become an essential feature of farming in all countries practicing modern agricultural methods. It is probably true that there has never been in the history of the fertilizer industry a greater need than exists now of aiding farmers to secure the best possible profit from fertilizers. They represent a considerable share of crop-production costs and should therefore be bought and used with care. The method of applying fertilizer and fertilizer materials is of great importance and has much to do with their efficiency. This is particularly true since the introduction of so many new fertilizer materials of high plant-food concentration and the growing use of high-analysis and concentrated fertilizers.

Fertilizer Usage in Pioneer Days

The development of the fertilizer industry and of the raw materials upon which it depends has been a distinctly evolutionary process. It is admittedly a far cry from the days when "a fish to a hill of corn" was considered to be a first-class job of feeding plants to present-day methods of doing so. In pioneer days no thought had to be given to segregation of fertilizers but also greatly improves their drillability by decreasing their tendency to cake or become sticky. Other experiments are in progress which should further improve the efficiency of fertilizers by securing a greater degree of uniformity in their distribution and proper placement with respect to the seed.

Fertilizer Quality

The efficiency of certain synthetic mixtures that have recently been placed on the market has frequently been too low to be explained by irregular distribution or placement of the fertilizer. The poor results were always obtained on sandy soils and were limited to mixtures containing alkali salts only. FERTILIZER'S Value Much Affected by Method of Applying It to Soil

Fertilizers are used to increase crop production and quality and on this account have become an essential feature of farming in all countries practicing modern agricultural methods. It is probably true that there has never been in the history of the fertilizer industry a greater need than exists now of aiding farmers to secure the best possible profit from fertilizers. They represent a considerable share of crop-production costs and should therefore be bought and used with care. The method of applying fertilizer and fertilizer materials is of great importance and has much to do with their efficiency. This is particularly true since the introduction of so many new fertilizer materials of high plant-food concentration and the growing use of high-analysis and concentrated fertilizers.

Fertilizer Usage in Pioneer Days

The development of the fertilizer industry and of the raw materials upon which it depends has been a distinctly evolutionary process. It is admittedly a far cry from the days when "a fish to a hill of corn" was considered to be a first-class job of feeding plants to present-day methods of doing so. In pioneer days no thought had to be given to the application of materials of high plant-food content because they were unknown. In those days barnyard manure, wood ashes, lime or marl, gypsum, guano, bones, and tobacco stems constituted the chief supplies of fertilizer materials. Their application involved no special care and on account of large supplies fairly heavy applications were the rule. As these materials carried relatively low amounts of soluble plant food injurious effects were rarely observed.

Later on materials like sodium nitrate, ammonium sulphate, fish scrap, tankage, dried blood, cottonseed meal, castor pomace, and other nitrogen materials, superphosphate, and the various potash salts were employed for fertilizer usage. Complete fertilizers were manufactured out of these ingredients and for many years the fertilizer industry depended largely on them for raw materials. It was found that more care was required in applying such fertilizers, owing to their containing more active plant-food ingredients. Materials like tankage, fish scrap, and other organic-nitrogen carriers, while at one time used freely in fertilizers, are gradually being used less and less owing to their greater cost when compared to materials like sodium nitrate, ammonium sulphate, and other inorganic and organic salts. As the amount of inorganic nitrogen in fertilizer mixtures increases, it becomes necessary to exercise more care in the distribution and placement of the fertilizer.

World War Brought About Changes in Materials

Largely as a result of the World War, matters relating to fertilizer materials changed considerably. Extraction of nitrogen from the atmosphere for the manufacture of death-dealing explosives developed enormously. Huge plants were built in which to extract nitrogen and produce various salts therefrom. With the cessation of hostilities, it became necessary to find a peace-time outlet for these nitrogen products. The natural outlet was to dispose of them as plant-food materials to the fertilizer industry or to farmers direct. Not only nitrogen compounds, but also compounds high in phosphoric acid, such as double and treble superphosphate, ammonium phosphate, and a number of products of commercial origin containing two and three plant-food constituents are being produced synthetically for fertilizer usage.

The production of so many new materials of relatively great plant-food concentration led to another step, namely, the production of concentrated fertilizers. During the past decade, particularly the last five years, considerable progress has been made in the development and use of concentrated and high-analysis fertilizers. The necessity for greater precaution in applying modern fertilizers is therefore chiefly due to the diminished use of vegetable and animal organic-nitrogen materials, with a correspondingly greater use of inorganic and organic salts, and to a much greater plant-food content in fertilizer mixtures. Furthermore, there is a decided tendency to apply fertilizers at heavier rates which makes it more essential that care be exercised in their distribution.

Principal Factors Involved in Fertilizer Usage

The principal factors involved in the use of fertilizers are (1) what kind and how much to use, and (2) how to apply the fertilizer to insure uniform distribution and proper placement in relation to the seed or seed piece and to get it well mixed with the soil. In connection with the latter, the guiding principles are to apply the fertilizer uniformly so that every plant gets a proportionate share of plant food rather than suffer from an uneven distribution, and to avoid contact of fertilizer with seed or seed piece. In cases of uneven distribution some plants get too much fertilizer, frequently resulting in crop injury, while other plants get too little fertilizer and, as a result, fail to produce well.

Present-day methods of applying fertilizers include (1) broadcasting, (2) hill application, (3) drill or furrow application, (4) side dressing, and (5) combinations of the foregoing, such as applying part of the fertilizer broadcast and part in the hill or drill or partly in the drill and the rest as a side dressing after the crop is well established. Modern fertilizer practice utilizes distributing machines with which to apply fertilizers. Their design and construction varies in accordance with the method of application and the crop. Examples are as follows: Broadcasting, with fertilizer attachment on the grain drill or with lime distributor; hill application, made by means of fertilizer attachment on corn planter; drill or furrow application, with corn or potato planter; side dressing, by means of fertilizer attachment on cultivator. The main chance for injury to result from fertilizer application occurs when the fertilizer is applied in the hill or in the drill row, for the reason that these methods provide an opportunity for the fertilizer to come in contact with the seed which necessarily must be avoided if the method of application is to prove efficient.

Experimental Studies Being Made

Owing to the increasing use of high-analysis and concentrated fertilizers on crops and the fact that rates of application tend to increase, considerable interest is being taken by scientific investigators, fertilizer interests, and machinery manufacturers in the subject of efficient fertilizer distribution and placement. It is a mutual problem and one that is engaging the attention of varied interests. The fertilizer manufacturer who sells a good product in excellent physical condition is naturally desirous that whoever applies the fertilizer have a distributing machine that will do a first-class job. Otherwise, the blame for uneven distribution, poor stand, and lowered yield is apt to be charged to the fertilizer when the fault may have been due largely to the machine.

To furnish some idea of the situation in reference to fertilizer distributing machines it has been stated by specialists working on the problem that the faulty application of fertilizers to the soil causes serious losses to farmers and that the average fertilizer as applied to the land by present-day machinery is not always as effective as it should be. The various cooperative agencies attacking this important problem, including various State agricultural experiment stations, are not only making actual field trials with different crops to which the fertilizer is applied in different ways, but are working toward the improvement and standardization of fertilizer distributing machines and improvement of the drilling qualities of fertilizers.

Factors Affecting Fertilizer Distribution

The two main factors making for uneven distribution are, according to specialists, design and construction of implements and the variability of fertilizer properties, including tendency to absorb moisture, fineness or coarseness of particles, the degree of physical uniformity, and friction and cohesion between particles. In applying fertilizer a number of factors need to be considered. In the first place, it is undoubtedly true that all crops and all soils can not be given uniform fertilizer treatment, either as to amount or method of application. Crop plants vary in their growth characteristics, in-

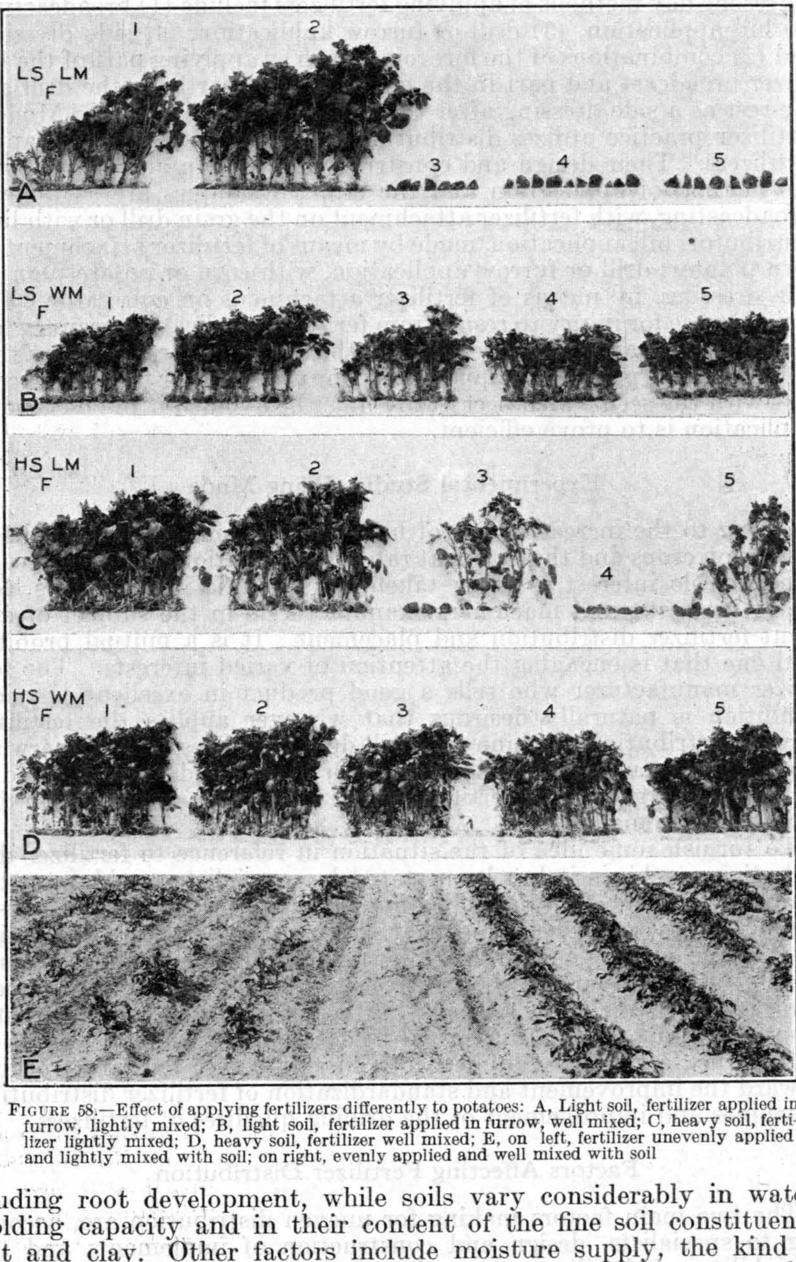

FIGURE 58.—Effect of applying fertilizers differently to potatoes: A, Light soil, fertilizer applied in furrow, lightly mixed; B, light soil, fertilizer applied in furrow, well mixed; C, heavy soil, fertilizer lightly mixed; D, heavy soil, fertilizer well mixed; E, on left, fertilizer unevenly applied and lightly mixed with soil; on right, evenly applied and well mixed with soil

cluding root development, while soils vary considerably in water-holding capacity and in their content of the fine soil constituents, silt and clay. Other factors include moisture supply, the kind of fertilizer and rate of application, the time of application, and weather conditions at and following planting time.

Effect of Applying Fertilizers Differently

Crops grown on light soils where drought may prevail will suffer most if the fertilizer is applied unevenly or is not well mixed with the soil. This effect is shown in Figure 58 in connection with the potato. Five fertilizer mixtures were used (1, 2, 3, 4, and 5) and applied in the drill. They were lightly mixed with the soil. (Fig. 58, A,) Fertilizer No. 1 was a 5–8–5 containing sodium nitrate, ammonium sulphate, superphosphate, and potassium sulphate. One-half of the nitrogen was derived from sodium nitrate, the rest from ammonium sulphate. In mixture No. 2, 50 per cent of the nitrogen was derived equally from fish scrap and tankage, the balance equally from sodium nitrate and ammonium sulphate. The effect of including organic materials is clearly evident. The other mixtures (3, 4, and 5) were concentrated fertilizers. Mixtures 1 and 2 were each applied at the rate of 2,000 pounds to the acre while Nos. 3, 4, and 5 mixtures were applied at the respective rates of 800, 700, and 900 pounds to the acre. In all cases the same amount of plant food was applied.

Figure 58, B shows what happened when the same fertilizers were well mixed with the soil. In Figure 58, C a much heavier soil, with greater water-holding capacity, was used. In the case of two of the concentrated fertilizers several seed pieces made an attempt to grow, although not effectually. Figure 58, D shows the advantage of having the fertilizer well mixed with the heavy soil. Figure 58, E affords an idea of the effect of poorly distributed fertilizer (left) on potato germination and stand. The plants on the right were uniformly fertilized. Such differences are reflected in the final yields.

No hard and fast rule can be established for applying fertilizer. The results of experimental work on different crops and soils will go far toward solving the problem. However, the following suggestions may prove helpful:

Never let fertilizer come in direct contact with the seed.

Get some of the fertilizer near the seed.

Mix fertilizer and soil together.

Use a distributing machine that provides an even distribution.

If fertilizer is applied by hand, as to the lawn, light applications frequently made are apt to prove better than heavy single applications.

Do not attempt to fertilize recently transplanted plants too soon or too heavily at first.

Do not expect fertilizer to do wonders when the soil is very dry.

B. E. Brown,
Senior Biochemist, Bureau of Chemistry and Soils.

FOOD and Drug Labels' Meaning and Value Are Shown in Radio Talks The most significant development of 1930 in the Federal Food and Drug Administration's campaign to educate the public regarding its regulatory activities were two series of "read-the-label" broadcasts, delivered through an eastern radio network by W. R. M. Wharton, chief of the administration's eastern district, and through a western network by W. W. Vincent, chief of the western district. Both series continued into 1931—Mr. Wharton's through a hook-up of 28 National Broad-

FOOD and Drug Labels' Meaning and Value Are Shown in Radio Talks The most significant development of 1930 in the Federal Food and Drug Administration's campaign to educate the public regarding its regulatory activities were two series of "read-the-label" broadcasts, delivered through an eastern radio network by W. R. M. Wharton, chief of the administration's eastern district, and through a western network by W. W. Vincent, chief of the western district. Both series continued into 1931—Mr. Wharton's through a hook-up of 28 National Broadcasting Co. stations; Mr. Vincent's through a chain of eight western stations of the same company.

These talks are an important development in the public-information policy of the Food and Drug Administration. They represent the first sustained attempt by the administration to use broadcasting to interpret for consumers those food and drug standards designed to conserve their health and protect their funds from frauds. While these standards have been developed through a period of more than 23 years, the administration has never before so vigorously attempted to inform the public as to their practical value and use. The "read-the-label" talks are written in popular form, designed to appeal to the busy housewife and husband. Letters from more than 8,000 listeners and comments in food and drug trade journals testify that both consumers and the ethical majority in the food and drug trades appreciate this effort and are thoroughly awake to its value.

Results secured through these radio talks surpassed expectations. Mr. Wharton had on his regular mailing list more than 10,000 listeners, Mr. Vincent's list passed the 3,000 mark. While a fair share of this success is attributed to the style in which the talks have been written and to the radio personality of Mr. Wharton and Mr. Vincent, the administration believes that the general public is becoming increasingly convinced of the actual dollars-and-cents and health value of concrete instructions on how to read food and drug labels more intelligently.

Mr. Wharton, the administration's pioneer in this public-instruction campaign, outlines his purpose in broadcasting his talks, as follows:

> The object is to teach consumers how to read labels in order that they may make their own selections from competing commodities with care. I want to help them to discriminate between relative qualities and relative values. Buyers should be in a position to exercise their indisputable right to know the product they pay for, and to use their collective influence to get more informative labeling on foods and drugs.

Trade Practices Much Improved

Many leading food and drug manufacturers have written the administration declaring their appreciation of the value of the talks. These letters indicate a vast change in business methods since the days when caveat emptor was a commercial rule. That principle was based upon an unsound economic supposition that the buyer was without the right to stand upon an equal footing with the seller. Under such a practice, the buyer had to protect himself with all the means at his command, while the seller's right to cheat was tacitly recognized. To-day, business is largely aware that protection of the buyer is commercially profitable. There is a noticeable tendency, particularly among food manufacturers, to tell even more than the pure food laws require on the labels of their products.

While the large majority of food and drugs manufacturers are trustworthy, there are differences among labels. Labels are often designed so as to be of great pictorial attractiveness but of questionable truth. The manufacturer who uses such a label, even when he makes an attempt to comply with the letter of the pure food laws, may fail to comply with their spirit. The label designer may try to hide an important fact from the buyer. He may attempt to camouflage the real facts in such a way that even the experienced buyer will be deceived. Administration officials have been aware of this practice for two decades and have done much to educate label designers and manufacturers in the strict legal requirements of the law and have constantly attempted to teach the buyer how to discriminate between honest labels and misleading labels. The "read-the-label" talks of the past year have been designed to inform the public as to the true meanings, the limitations, and the guidance value of labels in purchasing foods and drugs.

Many Commodities Covered

The "read-the-label" talks broadcast during the past year have outlined the requirements of the food and drugs act as regards scores of food and drug products. A few of the subjects covered are: Canned peas, tea, sirups, canned corn, vinegar, oysters, lard, flour and meal, drugs, vitamins, artificial colors, baking powders, flavoring extracts, pudding powders, canned fish, beverages, botulism, obesity cures, eggs, butter, jams and jellies, milk and milk products, cream, potatoes, and apples. In all cases, the general plan of procedure was the same. The administration officials each week told a story of a personal experience in the enforcement of the Federal food and drugs act to illustrate how this law safeguards the nation's food and drug supply. They followed this with a discussion of the meanings of labels on the different products under consideration that week. This was followed with a statement of just how the law protects the buyer of the products under discussion. The administration proposes to follow the same general plan during coming campaigns. A vast quantity of free printed matter has been distributed to listeners. The administration is now considering getting out a Farmers' Bulletin to cover the entire range of the subjects taken up.

SOLON R. BARBER,
Information Specialist, Food and Drug Administration.

FOOD and Drug Law Covers Preparations for Treating Livestock The Federal food and drugs act forbids false and fraudulent therapeutic claims on the labels of drug and medicinal preparations. For 23 years the department has directed its regulatory attentions to the drug industry, and so far as medical preparations designed for human use are concerned, the public is more or less aware of the extent of this work. But the administration is also charged, in the enforcement of this law, with removing from the channels of trade misbranded or adulterated medical preparations designed for treating domestic animals. Even the farmer, most directly concerned, is inadequately informed on just what the administration has done along this line. An efficient farmer naturally wants his livestock to be healthy. This desire, combined with ignorance of what constitutes a reliable treatment or cure for certain livestock diseases, has led him to spend much hard-earned money for quack remedies of no value whatever in the treatment of livestock diseases. So serious is this situation that the Food and Drug Administration has, during the past few years, directed as much of its attention to these drug products as its funds and personnel would permit.

It is imperative, the department believes, that misplaced public confidence in worthless remedies for livestock be destroyed. The department wishes at the same time to build sound public confidence in the drug products of those manufacturers who are really turning out reliable preparations for certain animal diseases.

The department wishes at the same time to build sound public confidence in the drug products of those manufacturers who are really turning out reliable preparations for certain animal diseases.

No Remedies Yet for Certain Diseases

Veterinary science recognizes that up to the present time there is no drug or mixture of drugs which can be considered effective in the treatment of the following diseases of poultry: Typhoid, cholera, coccidiosis, fowl pest, roup, pullorum disease or diarrhea of chicks, chicken pox, diphtheria, gapes, and blackhead of turkeys. But in spite of this recognition on the part of veterinary science, farmers see many advertisements of drug preparations which claim to be reliable in the treatment of these poultry troubles. Some of the above disease can be prevented by proper precautionary measures; but, once contracted, they do not respond to drug treatment. Drug preparations labeled for them create a false sense of security in the mind of the poultry man, and if he relies upon them he is apt even to encourage the spread of one or more of these diseases through an entire flock or community and to delay or prevent the application of suitable scientific methods of control. The Food and Drug Administration has removed from the market hundreds of preparations of this nature and has brought about the revision of labels of many others so that the purchaser will not be defrauded. But many such preparations are made locally and not entered in interstate trade and do not come under the jurisdiction of the food and drugs act. In many cases the administration has required the removal from the label of all untruthful and fraudulent claims, only to discover similar unwarranted statements in advertising over which the law has no control. The department believes it is a good practice not to place confidence in claims made in circulars or advertising matter which exceed those claims made on the printed matter which actually accompany the product shipped in interstate commerce.

Use of the Word "Health"

In recent years the country has been more or less flooded with scores of preparations which use the word "health" in their titles or on their labels. The Food and Drug Administration has investigated many of these and in the enforcement of the law has removed many of them from the market. The use of the word "health" on the label of a drug preparation to convey the impression that the use of the product will maintain or restore health is classed as misbranding under the law, since no drug or combination of drugs is capable of fulfilling such a promise.

In December, 1929, the courts rendered a judgment in favor of the department in a case against a preparation called "Liquid Hog Health." The manufacturer of this preparation claimed that oats treated with it would cure sick hogs and stimulate the growth of backward pigs and shoats. The Government alleged that the article was misbranded and proved to the satisfaction of the court that the preparation contained no ingredients capable of producing the effects claimed. The administration also takes exception to such words as "vital," "life," "vigor," "vim," in any form of spelling, when these words are used in names to imply far-reaching curative powers.

Alleged Worm Remedies

Farmers who have read the papers in recent months have probably noted a great many advertisements of "mineral mixtures," "tonics," and "conditioners," in which the manufacturers claim that such preparations control worm infestation in farm livestock. Such claims made for products of this character constitute misbranding under the law. Veterinary investigators have found that preparations of this nature have not proved effective in the control of worm infestation. Moreover, there is no drug or mixture of drugs known to science at this time which would be effective as an expeller of all types of worms which may infest animals, including poultry. The department has warned manufacturers of worm remedies or worm expellers to confine their claims in the labeling to the particular type of worm for which their product has proved to be effective. The unqualified use of terms such as "worm expellers" or "worm remedies" in labeling these preparations is a violation of the food and drugs act.

H. E. Moskey,
Veterinarian, Food and Drug Administration.

FOOD and Drugs Act Benefits Farmer as Producer and Consumer Pure-food legislation was considered by Congress for many years before the food and drugs act was passed in 1906. During all those years, the press continually carried stories which aroused public interest in the need for such legislation. During the years immediately preceding and following the passage of the pure food law, popular interest in the measure continued, largely because, in those days, the abuses which it was designed to correct were so sensational that they achieved a great deal of newspaper publicity. Scandalous abuses, such as the sale of dead horses as beef, promptly detected and stamped out under the law, caught and held the public interest. But as these startling types of adulteration and fraud were corrected, and as enforcement work under the law became more routinelike and better organized, the activities of the officials received less publicity and the general public, as well as the farmer, began to accept the protection afforded by the law as a matter of course. There is ample evidence to believe that, in many cases, people forgot it entirely.

Such forgetfulness is not justified. The work of the Food and Drug Administration, in enforcing the food and drugs act, is vitally important to the general consuming public, and particularly to the agricultural industries. Every American citizen is a daily consumer of food, and there are few so fortunate as not to be consumers, at one time or another, of medicines. The past 25 years have witnessed remarkable changes in food economics, one of the most striking being the gradual transfer of the manufacture of foods from the domestic kitchen to the factory. That transfer could not have occurred without the protection guaranteed by the food laws against adulterated and misbranded products. To-day, the farmer consumes almost as large a quantity of manufactured foods as the city dweller. He thus has a vital interest in those governmental activities designed to assure him pure, unadulterated, and honestly labeled foods.

Farmer Interested as Producer

But the farmer has an interest in food-law enforcement not shared by the city consumer. He is preeminently a producer. With the exception of our marine supply, the soil is the source of all our foods. There is, of course, little opportunity for adulterating commodities consumed rations control worm infestation in farm livestock. Such claims made for products of this character constitute misbranding under the law. Veterinary investigators have found that preparations of this nature have not proved effective in the control of worm infestation. Moreover, there is no drug or mixture of drugs known to science at this time which would be effective as an expeller of all types of worms which may infest animals, including poultry. The department has warned manufacturers of worm remedies or worm expellers to confine their claims in the labeling to the particular type of worm for which their product has proved to be effective. The unqualified use of terms such as "worm expellers" or "worm remedies" in labeling these preparations is a violation of the food and drugs act.

H. E. Moskey,
Veterinarian, Food and Drug Administration.

Food and Drugs Act Benefits Farmer as Producer and Consumer

Pure-food legislation was considered by Congress for many years before the food and drugs act was passed in 1906. During all those years, the press continually carried stories which aroused public interest in the need for such legislation. During the years immediately preceding and following the passage of the pure food law, popular interest in the measure continued, largely because, in those days, the abuses which it was designed to correct were so sensational that they achieved a great deal of newspaper publicity. Scandalous abuses, such as the sale of dead horses as beef, promptly detected and stamped out under the law, caught and held the public interest. But as these startling types of adulteration and fraud were corrected, and as enforcement work under the law became more routinelike and better organized, the activities of the officials received less publicity and the general public, as well as the farmer, began to accept the protection afforded by the law as a matter of course. There is ample evidence to believe that, in many cases, people forgot it entirely.

Such forgetfulness is not justified. The work of the Food and Drug Administration, in enforcing the food and drugs act, is vitally important to the general consuming public, and particularly to the agricultural industries. Every American citizen is a daily consumer of food, and there are few so fortunate as not to be consumers, at one time or another, of medicines. The past 25 years have witnessed remarkable changes in food economics, one of the most striking being the gradual transfer of the manufacture of foods from the domestic kitchen to the factory. That transfer could not have occurred without the protection guaranteed by the food laws against adulterated and misbranded products. To-day, the farmer consumes almost as large a quantity of manufactured foods as the city dweller. He thus has a vital interest in those governmental activities designed to assure him pure, unadulterated, and honestly labeled foods.

Farmer Interested as Producer

But the farmer has an interest in food-law enforcement not shared by the city consumer. He is preeminently a producer. With the exception of our marine supply, the soil is the source of all our foods. There is, of course, little opportunity for adulterating commodities consumed just as they come from the farm—the raw vegetables, the fruits, and the grains. But manufacturers to-day are more extensively engaged than ever before in utilizing these raw materials in the preparation of manufactured products. Without legal control, there would be ample opportunity to debase these materials in the course of manufacture. A prompt and inevitable loss to the farmer would result, (1) as a defrauded consumer, and (2) through lowered consumption of the products of the farm with decreased financial returns accruing to the farmer as producer. There is a very clear and direct relationship between the effective enforcement of the food laws and the economic welfare of the farmer, both as a producer and a consumer.

The canning industry, for illustration, to-day is one of the most important contributors to the national food supply. It utilizes vast amounts of raw vegetables and fruits produced by American agriculture. A generation ago, before the enactment of the pure food law, canned foods were of an uncertain and variable quantity. Their quality was seldom such as to commend them. With reason, they were looked upon suspiciously and employed only as a last resort where fresh fruits and vegetables were unobtainable. Too often, the can contained but a minimum of the fruit or vegetable and a maximum of liquid, for water has always been the cheapest and most prevalent of all adulterants.

This condition changed almost instantly with the passage of the food law. It was promptly announced that, under the law, the can must be full of the food it purported to contain and that the liquid content should be reduced to that minimum necessary for proper packing. Coincidentally, there was an insistence upon purity and cleanliness in the canned-food material. The enormous growth of the canned-food industry in the last 23 years has been the direct outcome of this principle of food-law enforcement. And to-day, the American consumer justifiably expects that when he purchases a canned-food product, he will receive a legal article, that is, a full can, honestly labeled, and packed in a clean and sanitary fashion. As a producer, it must be evident to the farmer that the demand by the canning industry for raw fruits and vegetables has been directly proportional to the insistence under the food law that a maximum of the food product shall be packed in the can. Not only has the demand for his product been increased through this cause, but also because increased public confidence has led to an increased consumption of canned-food commodities. It is evident that the American farmer as a consumer of canned foods and as a producer of the raw products for the canner, should emphatically insist upon a continued effective law enforcement so far as canned foods are concerned.

Farmers Benefited Through Butter Regulations

Let us consider the dairy industry. There would be a small profit to the dairy farmer if the creamery were permitted without restriction to incorporate excessive quantities of water in the butter which it markets, for with every pound of water incorporated in butter, the demand for butterfat would be correspondingly decreased. To-day, by special enactment of Congress, butter must contain not less than 80 per cent of butterfat and this requirement is rigidly enforced under the pure food law.

Concentrated commercial stock feeds are extensively used by dairy farmers and by livestock feeders. The value of these products depends upon their composition. Intelligent farmers buy according to the label guaranty of chemical constituents and net weight. Food officials, both Federal and State, annually analyze thousands of samples of such products for the protection of the farmers against the sale of feeding material of inferior value and of incorrectly labeled feeds.

The farmer is particularly victimized by the patent-medicine enterprise. In common with the rest of mankind, he is expected to fall a prey to the sale of fraudulently labeled medicines for human beings. He also offers the exclusive market for the sale of worthless livestock remedies. An amazing amount of superstition about the avoidance or treatment of serious livestock diseases prevails. Quackery capitalizes this fact. One of the big things the Food and Drug Administration has tried to do for the farmer has been to dispel dangerous illusions and protect him against the vendors of patent medicines with curative claims far in excess of their actual merit. Inspectors of the Food and Drug Administration are daily instituting action against fraudulent remedies purporting to cure cholera in hogs, heaves in horses, and many other serious livestock and poultry diseases for which no single drug or combination of drugs can properly be described as a competent treatment. Within the past few years, many hundreds of such preparations have been required either to go off the market or to revise their labeling so as truthfully to represent their real worth.

New Forms of Violation

Much work remains to be done by the administration under the food and drugs act, for new forms of violation are continually appearing. Nevertheless, the farmers of this country, as well as consumers in general, are being well repaid for the efforts that were made in 1906 to bring about the enactment of the food and drugs act. That law deserves the interest and support of all.

One point in conclusion. The law requires truthful labeling. It is the consumer's money that is being spent to enforce this requirement. But if the buyer does not take the trouble to read the labels which the law prescribes, he will not get the full protection he is entitled to. He will be well repaid for the small effort required to read the label of every food and drug he buys.

W. G. Campbell,
Director of Regulatory Work.

FOOD and Drugs Act Is Made Stricter by Request of Canners On July 8, 1930, Congress approved a new amendment to the Federal food and drugs act. This amendment, commonly known as the McNary-Mapes bill, or the canners' bill, is the fourth amendment since the enactment of that statute on June 30, 1906.

What is the purpose of this amendment? How did it originate? What is its significance?

The purpose of the canners' bill, briefly stated, is to authorize the Secretary of Agriculture to determine, establish, and promulgate, from time to time, a reasonable standard of quality, condition and/or fill of

He will be well repaid for the small effort required to read the label of every food and drug he buys.

W. G. Campbell,
Director of Regulatory Work.

FOOD and Drugs Act Is Made Stricter by Request of Canners On July 8, 1930, Congress approved a new amendment to the Federal food and drugs act. This amendment, commonly known as the McNary-Mapes bill, or the canners' bill, is the fourth amendment since the enactment of that statute on June 30, 1906.

What is the purpose of this amendment? How did it originate? What is its significance?

The purpose of the canners' bill, briefly stated, is to authorize the Secretary of Agriculture to determine, establish, and promulgate, from time to time, a reasonable standard of quality, condition and/or fill of container for each generic class of canned food, except meat and meat-food products and canned milk. It also authorizes the Secretary to prescribe a form of statement which must appear in a plain and conspicuous manner on each package or label of canned food which falls below the standard promulgated by him and which will indicate that such canned food falls below such standard.

It is a striking fact that this amendment to the law did not originate through the demand of consumers. Nor was it enacted through the initial recommendation of the Federal Government, but was framed and pushed to final congressional approval by the canning industry itself. In this fact lies the greatest significance of the amendment.

Before the enactment of the food and drugs act, there was a great deal of opposition to the legislation on the part of the food industries. It is needless now to enter into the many reasons for this opposition, but it is a fact that opposition to the law and to its rigid enforcement is almost unknown among the present generation of food manufacturers. There is plenty of evidence, in industrial support of the law, in the growth of better-business-bureau movements, in the advocacy of truth in advertising, and in other ways, that the food industry as a whole is to-day imbued with the conviction that profitable business depends on satisfied customers. Efforts to amend the food and drugs act by legislation tending to weaken it have met with strong opposition from the food manufacturers, and unquestionably there would be an overwhelming opposition to any move to repeal the measure. The peculiar significance of the enactment of the canners' bill lies in the fact that here we have an instance where an industry not only favors the law, but on its own volition secures an amendment proposing further legal restrictions upon its own operation. All of these restrictions are in the interest of the ultimate consumer of canned-food products.

Canning Industry's Position

The canning industry was not unselfish in seeking the passage of this new measure. After 23 years of experience, the industry has recognized that the food and drugs act has revolutionized its operations and that the enforcement of the act has eliminated much of the competition due to the marketing of unfit material, and has created public confidence by removing from the market a class of products so low in quality as to bring the entire output of the industry into disrepute.

The industry knows that glaring abuses in the manufacture of its products are rare to to-day. The industry knows that while the law is effective in protecting the public health and in curtailing offenses against decency and in materially influencing the economic welfare of the purchaser, border-line cases among canned foods still exist, which, though not definitely illegal, represent a degree of inferiority entitling the buyer to full and complete knowledge of their quality before he invests his money in products coming within this border-line group. The purpose of the canners' bill, then, is to authorize the formulation of such legal standards as will insure a product sold to be of at least a standard degree of excellence, while an article which has reached such a degree of inferiority as to offend the purchaser—even though that article be perfectly wholesome and nutritious—will be definitely labeled to show that it is substandard and therefore will not be bought at the ordinary price.

If a consumer has the money to buy a standard-grade article, he should be in a position to do so with full knowledge of the character of the product purchased. But if his means will not afford a product of that excellence, it should be possible, under the operation of the canners' bill, to secure a product within the range of his pocketbook which, while not so palatable, will nevertheless be pure and wholesome and carry a definite label declaration of its substandard quality. It is obviously the intent of Congress that this statement shall clearly inform the purchaser that the product does not conform to the standard, but it is also apparent that the designation is not to be of such a stigmatizing character as to convey the impression that the product is unfit for food.

Consumers naturally could be expected to favor any legislation which would guarantee them more wholesome food and food of a higher quality. And it is easy to see that the consumer would approve of any legislation which would cause food manufacturers to label their products in a way which the buyer could understand and profit by. But in the passage of the canners' bill, we have the paradoxical situation of an industry which 23 years ago was by no means united in its support of the enactment of the law, now seeking through appeal to Congress and obtaining the passage of legislation imposing more stringent regulation upon itself.

Necessity of Legislation

Leaders in the food industries recognize that the absence of legislatively authorized standards is a distinct handicap to uniform enforcement of the law and that the existence of such standards would facilitate good manufacturing practice. One of the most noticeable trends in recent trade views regarding food legislation is the tendency to favor legislation requiring even more extensive and stringent food standards. The reason for this is clear. In the absence of definitely established legal standards, the problem of enforcing the food and drugs act is materially increased. The industry realizes that food products coming under the border-line classification are potentially most demoralizing to honest competition. Leaders in the industry recognize, further, the high potential advertising value accruing through legislative standards which will standardize their products.

One of the most serious problems encountered in the enforcement of the food and drugs act is the determination of what actually constitutes a violation. The act is general in its language. With one exception, butter, there is no legislative standard for food products. After analysis, the general terms of the law must be applied to the commodity under consideration and a decision must be reached by the department, and later confirmed by the courts, as to whether a particular condition constitutes a violation within the general terms of the act. There is a legislative standard for butter. This was enacted by Congress in 1923 and requires butter to contain not less than 80 per cent butterfat. But before the butterfat standard was definitely established, there was considerable trade in a product which looked and tasted like butter, which to the layman was not distinguishable from butter, but which showed a deficiency of butterfat and a corresponding excess of water. If traffic in such a product were allowed to proceed unchecked, the consumer would pay the price of butter for this excess water; or, if a corresponding price reduction were made, honest competitors would be placed at an unfair trade disadvantage. It was not difficult, even without a legislative standard, to bring successful legal action against a so-called butter containing materially less butterfat than was recognized as proper in good commercial usage. But it was much more difficult to establish a violation where the deviation from accepted trade usage was comparatively small. Yet, in the aggregate, even small shortages in butterfat represent an enormous imposition upon consumers and honest manufacturers. Until a definite legal standard for butter was enacted, there was occasionally a question whether the enforcement officials, alleging butter with, let us say, 79 per cent butterfat to be adulterated, could establish to the satisfaction of the court that this product was actually in violation of the law. So far as butter is concerned, that problem no longer exists.

Probable Legislative Trend Indicated

The action of the canners to secure the enactment of the canners' bill is indicative of the probable trend of future legislation regulating the manufacture and sale of all manufactured food products. The preservers of the United States made an earnest attempt to secure the legislative enactment of standards for fruit preserves by Congress in the summer of 1930. Before the passage of the food and drugs act, there was no assurance that a commercial product sold as preserves would consist exclusively of fruit and sugar in the proper proportions, regardless of the fact that common understanding would lead the purchaser to expect such a product under that name. So-called preserves were found in which but an insignificant amount of the fruit ingredient was present, while excessive sugar or glucose, fruit substitutes like apple base, and artificial colors concealed the real character of the product. These articles might be wholesome and even nutritious if the purchaser was looking only for food value. The individual who can not afford a more palatable product undoubtedly received in many cases a valuable food. But he was entitled to receive it with full knowledge of the character of the product. On the other hand, the man who had the means to buy a pure preserve was likewise entitled to get the article he expected to get. While the passage of the food and drugs act has checked gross forms of violation in the preserve industry, there is still need for certain definite legislative standards which will make it possible to eliminate conditions unfair alike to consumers and competitive manufacturers. The attempt of the preservers to secure legislative standards for their products reflects their appreciation of this fact. As time goes on, it is to be expected that this trend in the direction of more definite legislative standardization of food products will become more pronounced. Congress, in fact, considered in its Seventy-first session a proposed amendment to give authority to the Secretary of Agriculture to establish legal standards for all food products. While the amendment was not acted upon by that session, it at least indicates the trend in thought on the part of the food industries and of Congress. The passage of the canners' bill in the summer of 1930 was an important step in that direction.

P. B. Dunbar,
Assistant Chief, Food and Drug Administration.

FOOD Composition Tables Revised to Meet Demand for More Adequate Data In recent years the public mind has become aware of the significance of diet in maintaining health and well being and in the control of certain diseases. This awareness is due not alone to the awakening of the public mind but to the making of new discoveries with regard to nutritional needs. Older theories emphasized only protein and energy requirements, but later investigations have brought to light requirements hitherto unappreciated, and have shown particularly the need for vitamins and for minerals.

In the light of the newer knowledge of nutrition, vegetables have acquired an important place among foodstuffs and they have been introduced into the diet in greater quantity and in much greater variety than formerly. Vegetables, particularly the green leafy ones, have been chiefly heralded because of their vitamin content, but their value has been further enhanced by their worth in bolstering up the mineral intake which all too often tends to fall short of sufficiency.

To many people it is enough to know that they have had three good meals a day with an ample supply of standard foods. There are many, however, who must make a quantitative estimate of the various components of their diet. The diabetic, for example, knows that he has but a limited tolerance for carbohydrate and that he can burn fat only in proportion to the carbohydrate he can utilize as fuel. For such an individual it is essential that he calculate the quantities of fat and carbohydrate in his diet, and it is important for him to obtain the carbohydrate from milk and fruits and vegetables because of the alkalinity of their ash, because of their vitamin content, and in the case of the leafy vegetables because of their indigestible fiber which constitutes the needed roughage for the diet.

Many Uses for Diet Studies

While tables on the composition of foodstuffs are indispensable to the diabetic, such tables are equally valuable to many others interested either in normal or in special diets. Figures used by the dietitian and the layman relative to the composition of foodstuffs have been taken for the last three decades from the compilations of the department. These tables, The Chemical Composition of American Food Materials, first published in 1896 and last revised in 1899, have served their purpose admirably, but are now inadequate, covering as they do but a part of the foodstuffs common to-day. Recently, certain sections of this bulletin have been revised so that up-to-date figures are now available on the composition of fresh fruits and on wholesale cuts of meat. Now new figures on fresh vegetables are available.

In the original compilation only 38 fresh vegetables are included. The reason for this is twofold. In the first place, the market or garden vegetables were far more limited in number in the nineties than they are at the present time. In the second place, vegetables did not hold such an important place in the early dietary studies as they do at the present time. In the revised tables data are given concerning the proximate composition of 110 different kinds of vegetables. Many of these, such as New Zealand spinach, Chinese cabbage, and sprouting broccoli, although in common use to-day were practically unheard of by many American gardeners a decade or so ago. Other vegetables not widely used but worthy of wider attention are included.

The new compilation presents additional information to suit the needs of various groups. Particular attention is given to nomenclature; each vegetable is described by the scientific name and the accepted common name. Data on different species are reported separately, and in a few cases the figures show the effect on composition of maturity differences. Data on the chemical constituents refer to the part analyzed as edible portion, but the averages are also calculated on the as-purchased basis. Since the data on composition refer to the edible portion a description of the edible part is given wherever there might be doubt, and refuse figures are likewise accompanied by a description of the refuse portion. The samples included are representative and varied, typical of vegetables as they would be bought on the open market or obtained direct from the garden, and the data are so presented as to give not only averages but also a picture of the variation to be expected.

While the revised compilation on the proximate composition of fresh vegetables will fill a long-felt want on the part of dietitians and all those making dietary studies it will also be of value to the layman who nowadays is gaining an appreciation of the value of diet both in health and disease.

FORAGE-CROP Seed's Regional Origin Often Revealed by Analysis The region of production of some kinds of forage-crop seed is important to the American consumer because of the inadaptability to American conditions of seed produced in some regions.

The culture of some forage crops is conducive to the undisturbed development of volunteer plants, such as weeds and occasional plants of other crops. The seed of such forage crops contains the seed of these volunteer plants under usual conditions. The extent to which the volunteer seed appears in harvested crop seed depends, first of all, upon the simultaneous development of the crop seed and volunteer seed and is influenced by the duration of the volunteer plants' seeding period. Finally, the occurrence and prevalence of volunteer seed in marketed crop seed is dependent upon the extent to which the crop seed is cleaned before marketing. The comparatively large or small size of certain kinds of volunteer seeds permits their practically complete removal from the crop seed by suitable screening. Other kinds of volunteer seeds having approximately the same size, form, and weight as the crop seed are not wholly removed from the latter by the methods of seed cleaning now in general use. These seeds and those remaining from incomplete preliminary cleaning are the seed analyst's guide in determining where the crop seed was produced.

Certain kinds of forage-crop seed, as that of red clover, alfalfa, also that of the bent grasses, are produced in widely separated regions possessing more or less different local volunteer floras. The resulting difference in kinds of volunteer seeds found in the crop seed from these regions provides what are sometimes designated as "characteristic" seeds, since they characterize the regions where they grew. Such seeds usually are accompanied by seeds of other plants so cosmopolitan that their seeds commonly appear in crop seed from many regions.

The new compilation presents additional information to suit the needs of various groups. Particular attention is given to nomenclature; each vegetable is described by the scientific name and the accepted common name. Data on different species are reported separately, and in a few cases the figures show the effect on composition of maturity differences. FORAGE-CROP Seed's Regional Origin Often Revealed by Analysis

The region of production of some kinds of forage-crop seed is important to the American consumer because of the inadaptability to American conditions of seed produced in some regions.

The culture of some forage crops is conducive to the undisturbed development of volunteer plants, such as weeds and occasional plants of other crops. The seed of such forage crops contains the seed of these volunteer plants under usual conditions. The extent to which the volunteer seed appears in harvested crop seed depends, first of all, upon the simultaneous development of the crop seed and volunteer seed and is influenced by the duration of the volunteer plants' seeding period. Finally, the occurrence and prevalence of volunteer seed in marketed crop seed is dependent upon the extent to which the crop seed is cleaned before marketing. The comparatively large or small size of certain kinds of volunteer seeds permits their practically complete removal from the crop seed by suitable screening. Other kinds of volunteer seeds having approximately the same size, form, and weight as the crop seed are not wholly removed from the latter by the methods of seed cleaning now in general use. These seeds and those remaining from incomplete preliminary cleaning are the seed analyst's guide in determining where the crop seed was produced.

Certain kinds of forage-crop seed, as that of red clover, alfalfa, also that of the bent grasses, are produced in widely separated regions possessing more or less different local volunteer floras. The resulting difference in kinds of volunteer seeds found in the crop seed from these regions provides what are sometimes designated as "characteristic" seeds, since they characterize the regions where they grew. Such seeds usually are accompanied by seeds of other plants so cosmopolitan that their seeds commonly appear in crop seed from many regions.

The volunteer seed content of commercial crop seed becomes complicated when seed of the same crop but from different regions becomes mixed in the trade. A representative sample of a pound or more of such mixed seed usually contains conclusive evidence of the mixture. In such cases other evidence sometimes is helpful. Individual seeds of most forage crops do not differ materially in form within the same kind, but a difference in size and in color sometimes is noticeable in seed of the same crop from different regions. Again, the quality of the crop seed, which affects its appearance, may happen to differ on occasions in different regions. When these conditions coincide with trade mixing, the latter sometimes is evident irrespective of the volunteer seed content.

Significance of the Volunteer Seed

As a rule, the volunteer-seed content of a pound of crop seed suffices to identify its source; often it is evident in a much smaller quantity. Occasionally a pound of seed affords insufficient evidence of origin. It might be thought that intentional addition or extraction of telltale seeds would be attempted to mislead the analyst. Removal of the volunteer seeds in a sample of crop seed submitted from test would result in a negative report upon its origin. Deliberate addition of characteristic seeds would necessitate knowledge of what kinds to use, the approximate proportions, and the possession of the seeds—a combination of conditions not at all likely to be provided. Such procedure is improbable, since true information usually is desired by those who submit seed for test.

Seed analysis is a branch of agricultural science so much in its infancy that existing books, except those relating to local floras, are but indirectly helpful to the analyst in determining the origin of crop seed. His main reliance is upon experience in the analysis of a great number of samples of crop seed of many kinds representative of the regions where they are produced, aided by fragmentary descriptive and illustrative matter helpful a little here and a little there, but mostly proving sound when well investigated. Many characteristic seeds are recognized by their appearance long before their botanical identity is determined; but their usefulness for the immediate purpose is not materially lessened by this fact. Their botanical identification eventually becomes an important factor in the thorough study of the subject and especially in making published statements. The origin-determining value of characteristic seeds present in a quantity of crop seed is materially strengthened by the absence of the characteristic seeds of other regions.

Identification of Unknown Seeds

The identification of unknown seeds is best attained by growing plants to maturity from them, that is, from seed to seed again, procuring enough plants for preservation to show the important stages of development and to display the plant habit, including root, leaves, flowers, fruits, and seeds. Named herbarium specimens and plant descriptions will be depended upon thereafter. This is not always easily accomplished with plants peculiar to some distant part of the world. Collections of named seed samples and certain published matter afford some preliminary help. The usual descriptive works on botany afford little help in making identifications of seeds, because most plant descriptions end where the seed analyst's need for information begins.

In deciding the origin of a sample of crop seed, all possible evidence is utilized. Rarely is a decision made upon the presence of a single kind of seed. As an instance of the latter, the origin of a small sample of alfalfa seed was designated upon the presence of seeds of an unknown kind of pigweed (Amaranth) not known to occur in seed from any region other than that designated. Further study of a larger portion of the same lot of seed afforded ample additional evidence of the accuracy of the decision made upon a single kind of characteristic seed. Determinations of origin based on this botanical evidence, contrary to persistent denial, have brought forth admission of the truth of the determination when court action threatened.

Associate Botanist, Bureau of Plant Industry.

FOREST Destruction and Soil Erosion Destroying Land Fertility Rapidly The comparatively recent advent of man upon the earth, dating back perhaps a few millions of years, has produced changes of a destructive nature, probably the greatest of which is the removal of forest cover by burning, purposely as well as accidentally, and by lumbering, followed usually by fires in the slashings and consequent destruction of young trees and other vegetation. This causes a rapid run-off of rainfall and soil erosion and filling of streams, with consequent flooding and destruction of wild life and wild-life refuge, including fish, and destroying navigation.

These conditions, with their dire results to human welfare, are most evident at the present time in China and parts of India and northern Africa, where floods and famine are more or less regular occurrences. Here man has upset those great natural balances that made it possible for him to live in comparative comfort and safety.

Japan and most European countries have long since learned the folly of such wastefulness and disturbance of natural conditions and have established policies of protection and reforestation that have made them able to support increasing populations.

Slow to Realize the Danger

On the American Continent and in our own country in particular we have been slow to realize the potential dangers of forest destruction and the destruction of the natural vegetation cover of the plains and nonforested lands.

Certain types of soils are particularly liable to erosion or washing, even though they are not on appreciable slopes and the run-off of waters is comparatively slow.

So-called sheet erosion over immense areas of overgrazed land is rapidly washing away the valuable humus layer that has required hundreds of years to form and is opening the way for more rapid erosion.

It is estimated that the loss in soluble fertility alone is double that removed by crops.

matter afford some preliminary help. The usual descriptive works on botany afford little help in making identifications of seeds, because most plant descriptions end where the seed analyst's need for information begins.

FOREST Destruction and Soil Erosion Destroying Land Fertility Rapidly

The comparatively recent advent of man upon the earth, dating back perhaps a few millions of years, has produced changes of a destructive nature, probably the greatest of which is the removal of forest cover by burning, purposely as well as accidentally, and by lumbering, followed usually by fires in the slashings and consequent destruction of young trees and other vegetation. This causes a rapid run-off of rainfall and soil erosion and filling of streams, with consequent flooding and destruction of wild life and wild-life refuge, including fish, and destroying navigation.

These conditions, with their dire results to human welfare, are most evident at the present time in China and parts of India and northern Africa, where floods and famine are more or less regular occurrences. Here man has upset those great natural balances that made it possible for him to live in comparative comfort and safety.

Japan and most European countries have long since learned the folly of such wastefulness and disturbance of natural conditions and have established policies of protection and reforestation that have made them able to support increasing populations.

Slow to Realize the Danger

On the American Continent and in our own country in particular we have been slow to realize the potential dangers of forest destruction and the destruction of the natural vegetation cover of the plains and nonforested lands.

Certain types of soils are particularly liable to erosion or washing, even though they are not on appreciable slopes and the run-off of waters is comparatively slow.

So-called sheet erosion over immense areas of overgrazed land is rapidly washing away the valuable humus layer that has required hundreds of years to form and is opening the way for more rapid erosion.

It is estimated that the loss in soluble fertility alone is double that removed by crops.

The Government, with the cooperation of the States, has begun a program of study of the situation, with the hope of suggesting practical means of stopping the losses.

Another aspect of the matter is the depletion of the readily available "organic content" of the soil. This is made up of decaying roots and vegetable remains accumulated through centuries. The vegetable material acts favorably on the physical structure of the soil, increasing its ability to admit air and to hold and give up water to growing plants. It is also the feeding ground of a host of organisms—protozoa, algae, fungi, bacteria, worms, insects, and other small animals. Most of these are beneficial and altogether they constitute what is popularly called the life of the soil. If the organic matter is unduly depleted these organisms die and the soil becomes dead and infertile.

This is taking place in millions of acres of what is now known as good agricultural land. Millions of acres more have been ruined for agricultural purposes by this process of organic-content destruction.

Eroded Soils a Menace

These soils wash and erode badly and soon become valueless for any purpose. In fact they become a menace as they fill up streams and watercourses, with the results described in earlier paragraphs.

The students of soils and agronomy are just waking up to the menace and are strongly advocating a strong cooperative program to articulate with the erosion program to halt these devastations.

A third category of destructive procedure consists in constantly taking from the soil the soluble compounds necessary for plant growth—lime, magnesium, potash, nitrogen compounds, phosphorus iron, manganese, copper, and the other essentials in plant nutrition.

Fertilizers Replace Loss Only in Part

To some extent these can be replaced by the use of fertilizers containing the necessary elements in available form.

The use of chemical fertilizers is increasing slowly but not as fast as the depletion of soils in these materials. Profitable crops depend upon maximum yield of high quality with the smallest expenditure of labor and investment. Numberless experiments and demonstrations by the Department of Agriculture and the State experiment stations have shown that this result can be obtained only where the highest fertility is maintained.

Finally, as economists and students of history and social science have repeatedly pointed out, the well-being of people and nations in the last analysis depends on the soil as a source of food and raw materials. In new countries we may for a time be oversupplied, but when population pressures reach a point where land must be divided into smaller and smaller portions and it becomes decreasingly difficult or costly to maintain an adequate food supply, standards of living decline until at last it is a life-and-death struggle, as it is in several Asiatic counties to-day. By foresight in planning, this day may be long delayed for America.

FOREST-FIRE Protection on Privately Owned Land Is a Cooperative Task

Who is responsible for the protection of privately owned forests from fire? It is obvious that many of the benefits of forest protection come to the public at large and not to the private owner as such. This is true of the great beneficial effect that fire prevention and control have upon the run-off and storage of water and upon the fixation of soil to prevent erosion. It is also true of the strikingly improved conditions for the production of fish and game and in recreational advantages. The public benefits directly through the stabilization of wood-using industries and through increased land values. The general economic development of the community and of the Nation depends in no small measure, in forest regions, upon the continual production of forest crops which is possible only when the forests are adequately protected from fire.

The public has a very real interest in the adequate production of wood materials of desirable quality and quantity wherever these wood materials are produced. Each fire loss effects a definite reduction in the prosperity of the Nation, and is a positive disadvantage to millions of people. Each single destructive fire attacks the economic and social well-being of the whole country.

The public generally benefits by forest-fire prevention and control and therefore has a large measure of responsibility for proper measures of forest protection. Furthermore the public is frequently to blame for the occurrence of fire. Of the 44,000 fires reported on protected areas in the United States in 1929, over 50 per cent were attributed to agencies over which the individual landowner had little or no control.

As the Nation and State benefit from forest-fire protection, so also, does the individual landowner. To him come the most direct results from the prevention of fire on his forest lands. In addition to sharing the general benefits, to him comes the gain from stimulated and sustained yield of forest products which he himself can sell. Like the public, also, he is not blameless in the matter of fire occurrence; nearly half the fires are caused by him. Is it not clear then that the Nation, the State, and the private owner have a community of responsibility?

Organized Effort Required

Prevention and control of forest fires can not be accomplished economically and effectively except by the joint efforts of public and private agencies. Group action is essential to success. Each effective protective working unit will, generally speaking, embrace not single but several ownerships. The planning and direction of the work very clearly can be best handled by the public, the State.

Fires must be prevented by education—State-wide and Nation-wide; they must be promptly located when they occur by adequate detection and communication machinery; and those who wilfully cause them must be apprehended. This work can be economically done only when handled on a State-wide basis. Fire must be fought promptly and without reference to property lines, under efficient leadership, by men who know how and who are organized in advance, with suitable equipment. Only through organized and united effort can forest fires be economically prevented and controlled. The public must take the leadership and responsibility.

Forest-fire protection has been recognized as a great cooperative undertaking by the Clarke-McNary law, act of June 7, 1924, under the terms of which the Federal Government, States, and private owners are to-day working together. The job, however, is scarcely more than half done. Of the 417,000,000 acres of forest or potential forest land in State and private ownership, 194,000,000 acres are at present receiving no systematic protection from forest fires although greatly in need of such protection. The completion of the task constitutes a challenge to the Federal Government, the States, and private owners.

A. B. Hastings,
In Charge of State Cooperation, Forest Service.

FOREST-FIRE Protection Presents Some Unusual Problems in Minnesota Among the unusual problems in fire protection faced by the United States Forest Service is that presented by physical conditions within the Superior National Forest in Minnesota. Visualize an area of 1,600,000 acres within which 1,000 square miles has been set aside as a primitive area, where there are no roads, and practically no trails—a wild country with little of human habitation, but abounding in game, such as moose, deer, bear, wolves, and other fur bearers.

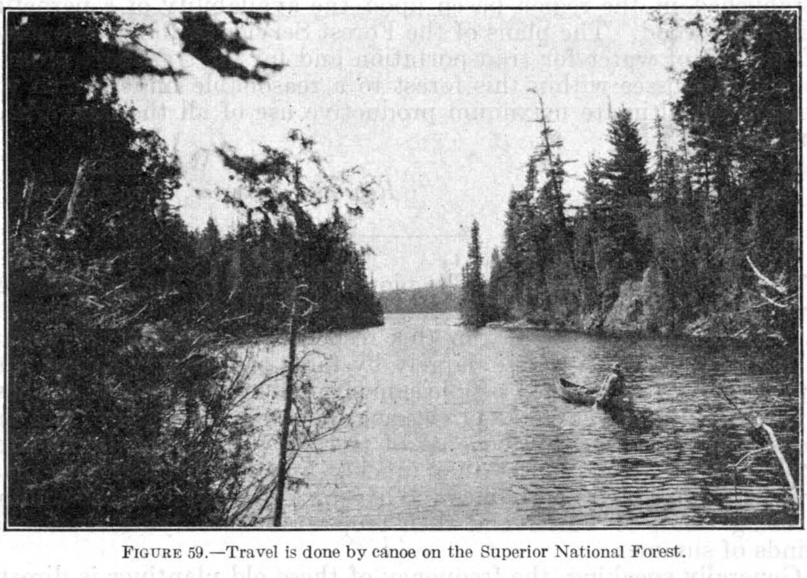

Figure 59.—Travel is done by canoe on the Superior National Forest.

Interlaced with a labyrinth of waterways, lakes, and great areas of spruce and muskeg swamp, this forest is almost impassable to foot travel in the summer. The cruising of timber and other similar activities of the Forest Service are carried on in winter, when the lakes, swamps, and streams are frozen, and dog teams can be used for transport. The usual method of travel during the summer season is by canoe and portage, a slow and laborious method, rendering forest-fire protection, where rapid movement of men and supplies is vital, extremely difficult.

Interlaced with a labyrinth of waterways, lakes, and great areas of spruce and muskeg swamp, this forest is almost impassable to foot travel in the summer. The cruising of timber and other similar activities of the Forest Service are carried on in winter, when the lakes, swamps, and streams are frozen, and dog teams can be used for transport. The usual method of travel during the summer season is by canoe and portage, a slow and laborious method, rendering forest-fire protection, where rapid movement of men and supplies is vital, extremely difficult.

Much work has been done to improve the portages to permit faster travel, and yet 1½ miles an hour is considered a high speed within the region. The transportation of men and equipment to fires at best is slow, hazardous, and difficult. Of a crew of 50 men, often not more than 4 or 5 are experienced in the use of canoes. Camp equipment, tools, and pumps must be transported by back pack over portages, and time after time reloaded into canoes along with men who are unappreciative of the hazard of travel in these fragile craft.

Plans Being Developed

To meet the situation, three plans are being developed:

(1) The improvement of portages, and on the primary travel routes the installation of light tracks over which fire equipment can be moved with greater speed.

(2) The use of hydroplanes for rapid transportation of small crews with essential equipment. This method has proved a great success, sometimes enabling the movement of a small crew to a fire in 30 minutes where previously it would have required a day and a half.

(3) The improvement of water routes by the installation of retaining dams, thus eliminating slow portage work.

The forest products produced within the Superior National Forest are of great value, because a permanent wood-using industry is being established in the region based upon the availability of a perpetual supply of wood. The plans of the Forest Service in the development of the use of water for transportation and for air transport promise to cut fire losses within this forest to a reasonable limit, which will permit the ultimate maximum productive use of all the land within the forest

Regional Forester, Forest Service.

FOREST Plantings in Central States Repay Their Cost Manyfold

The pioneer farmers of the Middle West were great tree planters. Their activity in this respect was encouraged perhaps largely by force of necessity rather than by choice. Most of these people came from districts lying to the east, where they had been actively clearing lands for agriculture, and had been accustomed to the benefits of tree growth around home sites. On the high, open prairies they quickly found it necessary to plant trees to shelter their new homes and livestock (fig. 60) from the chilling, freezing winds of winter and their crops from the drying, unchecked winds of summer.

Generally speaking, the frequency of these old plantings is directly in proportion to the area of prairie which originally existed. There are no accurate figures on the total planted area in the Middle West. Estimates show about 240,000 acres in Iowa where most of the area was treeless, about 40,000 acres in Illinois where there were also large areas of prairie, about 14,000 acres in Ohio, 10,000 acres in Missouri, and smaller areas in Indiana, Kentucky, and other States which were mostly wooded. A similar example on a small scale can frequently be seen in a country which is partly wooded and partly prairie. In

FOREST Plantings in Central States Repay Their Cost Manyfold

The pioneer farmers of the Middle West were great tree planters. Their activity in this respect was encouraged perhaps largely by force of necessity rather than by choice. Most of these people came from districts lying to the east, where they had been actively clearing lands for agriculture, and had been accustomed to the benefits of tree growth around home sites. On the high, open prairies they quickly found it necessary to plant trees to shelter their new homes and livestock (fig. 60) from the chilling, freezing winds of winter and their crops from the drying, unchecked winds of summer.

Generally speaking, the frequency of these old plantings is directly in proportion to the area of prairie which originally existed. There are no accurate figures on the total planted area in the Middle West. Estimates show about 240,000 acres in Iowa where most of the area was treeless, about 40,000 acres in Illinois where there were also large areas of prairie, about 14,000 acres in Ohio, 10,000 acres in Missouri, and smaller areas in Indiana, Kentucky, and other States which were mostly wooded. A similar example on a small scale can frequently be seen in a country which is partly wooded and partly prairie. In

Vermilion County, Ill., no plantings were found within the limits of natural woods, but they were immediately found in all portions which were originally prairie.

Shelter and Shade Most Pressing Needs

The need for shelter and protection has been the most impelling force toward tree planting. In a study of forest plantations which the Forest Service's Central States Forest Experiment Station is pursuing, data have been collected as far as possible on the purposes for which plantations have been established. Out of a total of 96 plantings, 39 were for windbreaks, 16 were for shade, 14 for timber, and the remaining planted groves were established for experiment, ornamentation, climatic control, and other purposes.

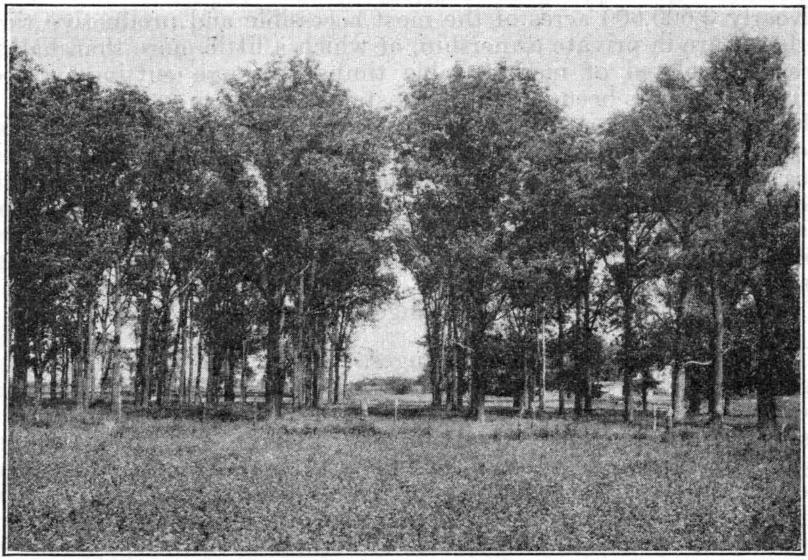

FIGURE. 60.—Black walnut, originally alternated with rows of cottonwood planted to protect a farm home from western and northern winds. The cottonwood has been removed. Many of these trees are now merchantable. (Champaign County, Ill.)

Additional advantages have been gained from the presence of planted trees on farms. Much fuel wood has been secured from trees which die or are removed. Poles, posts, and rough timbers have been cut, where the species originally planted was suitable for these uses. In the case of a valuable wood, like black walnut, the trees which remain have grown to merchantable size where the species has been suited to the soil, and growth has been continuous and rapid. To some farm owners, the ornamental and esthetic value of the windbreak is so great as to dwarf all cost of establishment and rental for the land area occupied. The statement is frequently made that the owner would not take several thousand dollars for his trees, solely because of their beauty and scenic value.

L. F. Kellogg,
Associate Silviculturist, Forest Service.

FOREST Problems Are Unusually Difficult in Idaho Panhandle In its efforts to help solve the forestry problems of the various regions, the Forest Service encounters many difficult and perplexing situations. One of the most baffling of these is found in the Idaho Panhandle, comprising that narrow strip of land in Idaho extending from the Salmon River Gorge northward to the Canadian boundary and containing the heart of the great white-pine forests of the West.

Of its entire extent of nearly 13,000,000 acres, approximately 10,000,000 acres is forest land, and more than 8,000,000 acres is suited to the growing of commercial timber crops; an area of slightly less than 4,000,000 acres still supports timber of commercial size. As against this large forest-producing area, less than 1,000,000 acres in the Panhandle is now producing farm crops, and the possibilities of further agricultural development are limited.

Nearly 3,000,000 acres of the most accessible and productive timberlands are in private ownership, of which a little more than half is already depleted of merchantable timber through cutting or fire. Much of this has been left in a devastated condition.

Ever since the great conflagrations of 1910 it has been realized that the prevention or prompt suppression of fires is fundamental to the success of any attempt to keep the forest lands of the Panhandle productive. There is, of course, much more to forestry in the region than mere fire control, but so long as fire still remains an unsolved problem it jeopardizes the results of any silvicultural measures that may be employed.

High Fire Danger in Region

The region is one of high fire danger. Long summer droughts, with high temperatures and low humidity are common. Over large areas the forest floor is crisscrossed with down timber, strewn with inflammable litter, and cluttered with dense undergrowth. Moss drapes itself from the trees, inviting the flames to climb into the tops where they form rapidly spreading "crown fires." Lightning sets fires in wholesale fashion, forming the chief cause of fires and one that is not preventable by any known means. All these conditions combine to aid the start and spread of fires and hinder control work. (Fig. 61.)

In the 18-year period from 1908 to 1925, inclusive, fire swept over nearly 5,000,000 acres of forest lands in the Panhandle and destroyed almost 10,000,000,000 board feet of timber. The estimated damage was more than $22,000,000, to which should be added the large sums expended in fire fighting by both public and private agencies.

It was early realized that slash from logging operations adds much to the natural fire hazards. Accumulated slash not only increases the chances of fires starting, but may be the cause of fires gaining such size and headway that control becomes well nigh impossible. From the start the Forest Service adopted piling and burning of slash on national forest sales of timber. The State later took up the same method on State lands, and a State law was enacted in 1925 requiring slash disposal on private lands except where the State Forester might direct otherwise.

Cut-Over Land Problem

The fate of cut-over and burned-over lands in private ownership is another important angle to the problem, the answer to which is not yet in sight. The burden of protection costs and taxes looms as a serious obstacle to continued private ownership. In spite of the fact that encouragement has been given through State laws favoring the formation of protective associations, in which the State assumes its share of costs, and in spite of the allotment of Federal funds under the Clarke-McNary law by which material contributions toward meeting pro-

FIGURE 61.—A typical mature stand of Idaho white pine

tection costs have been made, it became evident that further relief was necessary. The Idaho Legislature in 1929, therefore, passed the so-called reforestation law, providing for a flat valuation on cut-over and reforested lands of $1 per acre, with a 12½ per cent yield tax when the timber is cut. (Fig. 62.)

Coupled with these measures to alleviate fire losses and carrying charges has gone much educational effort, aimed at the prevention of man-caused fires and the cooperation of the public in rendering forest-land ownership less burdensome and hazardous. But large areas are still being burned over each year, and cut-over lands are becoming tax delinquent in some sections at a rather alarming rate. Difficulties are still being encountered in enforcing the slash disposal requirements, while the extent to which the tax relief contemplated in the 1929 reforestation law may be realized has not had time to prove itself. As if to complete the chain of obstacles to private ownership, there has recently been added the white-pine blister rust menace. This destructive disease has spread so rapidly in Idaho that it threatens to wipe out the most valuable commercial timber tree of the region unless control measures are extensively undertaken at once and completed within the next 10 years.

As a result of the study of this whole problem to date, there stands out clearly the fact that the next crop of timber in the Idaho Panhandle will not grow of its own accord as did the crop which is now being

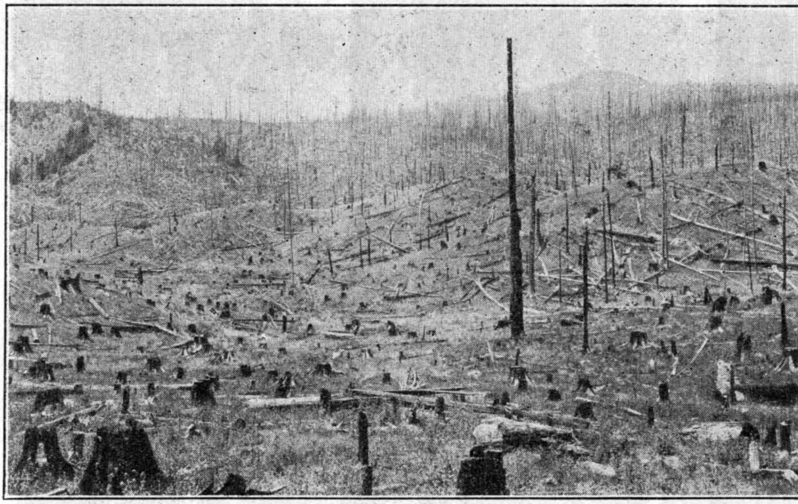

FIGURE 62.—Condition in which much of the cut-over lands of the Idaho Panhandle are being left

rapidly harvested. Fires, insects, blister rust, and unregulated cutting stand in the way. Man will have to grow the next timber crop, and he will have to do it by exercising control over these agencies, instead of allowing them to work on the side of forest destruction and denudation as in the past. Man has upset nature's scheme of forest rehabilitation in the Panhandle, and unless steps can be taken promptly to restore the balance between forest destruction and forest restoration the forests must perish.

Such are the forest problems of one of the Nation's timber storehouses; and into their solution must enter such ingredients as improved methods of cutting, better fire control, war against insect and parasitic enemies, increased public ownership of timberlands, and tax reform. Last, but underlying the rest, must go a vast amount of forest research. To meet these problems calls for courage, vision, patience, and a large amount of applied detail extending through the years to come.

THEODORE SHOEMAKER,
Assistant Regional Forester, Forest Service.

FOREST Roads and Trails Expenditure in Fiscal Year 1930 Was $8,500,000 Approximately $8,500,000 of forest-road funds was expended during the fiscal year 1930 for the construction and maintenance of roads and trails in the national forests of the United States. This sum covered the construction of 1,726 miles of roads, including 593 miles of motor ways; 6,176 miles of trails, including 4,601 miles of trail ways; and the maintenance of 65,785 miles of trail and 19,898 miles of roads.

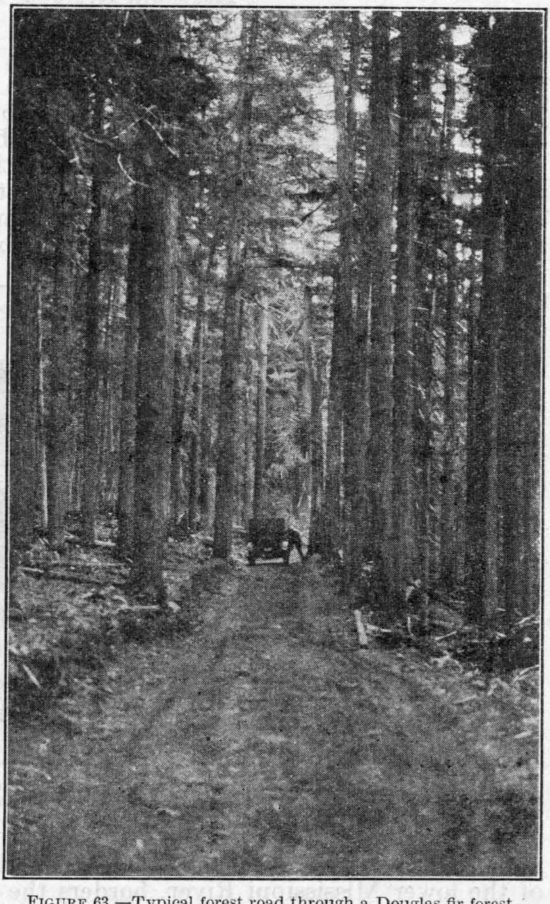

FIGURE 63.—Typical forest road through a Douglas fir forest, western Oregon

An adequate transportation system is required to facilitate the protection of the national forest resources from fire. Cheap construction is resorted to for secondary roads, but the roads are made safe. The requirements are so great that to construct only first-class roads would retard unduly the opening up of large inaccessible regions. To extend the mileage of roads and trails as rapidly as funds permit is the first consideration.

Many of the roads constructed are called "motor ways;" if they will permit a 2-ton loaded fire truck to pass over them safely, they meet the specifications. A "trail way" is the roughest kind of a trail through the woods. It must, however, be made reasonably safe for loaded pack animals. Trail ways are designed for use in case of fire only, and neither motor ways nor trail ways are constructed for public use.

When roads to be used extensively by the public or local settlers are constructed, the specifications provide for a 9-foot road with adequate turnouts, and a 7 per cent ruling grade. Forest roads are rarely surfaced as they are for the most part for summer use only. (Fig. 63.)

The crews engaged in road and trail construction are organized for fire suppression and constitute what is called the second line of defense. Trained men in the forest, subject to immediate call in the event of fires, mean reduced acreage burned and decreased fire suppression costs and damages.

Many years will be required for the completion of a transportation system that will afford adequate protection of the vast timber resources of the national forests of the United States, but a good start has been made on the system.

A. O. Waha,
Assistant Regional Forester, Forest Service.

FORESTRY Invoked to Aid Flood Control in Mississippi Uplands The influence of floods on the agriculture of the lower Mississippi Valley is well known, but the part which agricultural practices may have played in producing floods is less obvious. During the fall of 1929, erosion studies were initiated in the loess and silt loam uplands of Mississippi, by the Forest Service's Southern Forest Experiment Station. This

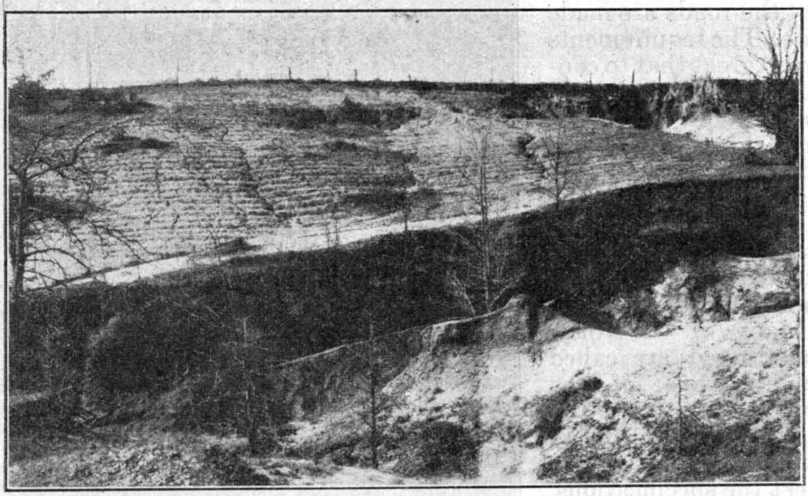

Figure 64.—The presence of small gullies on this cultivated slope means probable abandonment of the field in another year. The cultivatable life of such land is 5 to 10 years. The future appearance of this hillside is foretold by that of adjoining eroded areas

area, reported to be one of the heaviest contributors to the silt problem of the lower Mississippi River, borders the Mississippi Delta on the east and traverses the length of the State in a strip 35 to 50 miles in width.

Preliminary surveys show that the northern half of this area, comprising some 3,400,000 acres, is undergoing erosion in its most devastating and active forms. Near Oxford, Miss., a pasture which was a profitable cotton field in 1885 is now a maze of gullies, some of which are 50 feet in depth. In three months' time, during the winter of 1929-30, one of the deepest chasms had become filled to a depth of 10 feet with tons of loose soil which had sloughed from the gully banks. This soil was later flushed from the gully and carried into an adjacent stream by the heavy spring rains. Another gully 100 feet in depth, near Holly Springs, Miss., has resulted in a loss of approximately 2,000,000 tons of soil. It is, however, in the smaller gullies covering, fires, mean reduced acreage burned and decreased fire suppression costs and damages.

Many years will be required for the completion of a transportation system that will afford adequate protection of the vast timber resources of the national forests of the United States, but a good start has been made on the system.

Near Oxford, Miss., a pasture which was a profitable cotton field in 1885 is now a maze of gullies, some of which are 50 feet in depth. In three months' time, during the winter of 1929-30, one of the deepest chasms had become filled to a depth of 10 feet with tons of loose soil which had sloughed from the gully banks. This soil was later flushed from the gully and carried into an adjacent stream by the heavy spring rains. Another gully 100 feet in depth, near Holly Springs, Miss., has resulted in a loss of approximately 2,000,000 tons of soil. It is, however, in the smaller gullies covering, in the aggregate, thousands of acres in this region, that the most serious erosion is occurring.

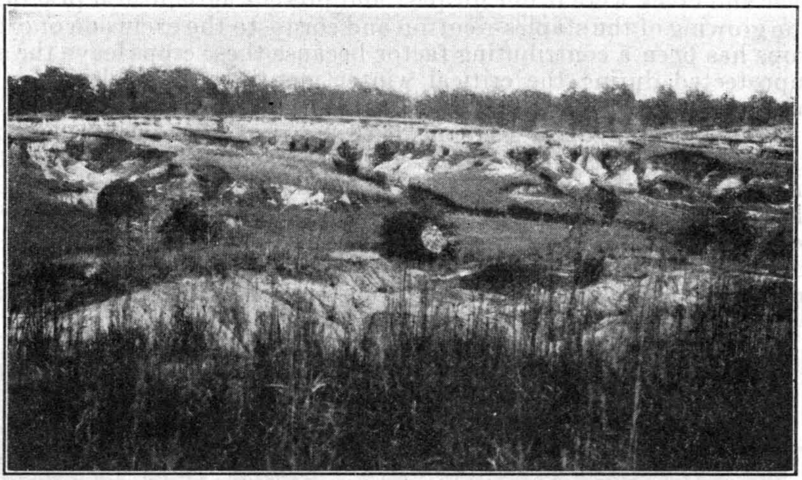

FIGURE 65.—Formerly a fertile cotton field, this intricate maze of rapidly enlarging gullies is typical of thousands of acres of abandoned land in north-central Mississippi

The decreasing value of eroded lands with a consequent shifting of the burden of taxation to other property and the high costs of maintaining public roads, represent losses perhaps as important as the loss of the valuable topsoil. Other losses result from the deposition of sterile sands and other débris on bottom-land farms. In some cases, driftwood dikes have been built along streams to protect adjacent fields from the sandy outwash carried by flood waters, but usually no adequate protection is possible.

FIGURE 66.—Portion of large gully showing extensive area of sandy outwash poured upon the timbered flood plain of an adjacent creek. About 2,000,000 tons of soil have washed from this chasm

Influence of Heavy Rainfall

The serious erosion problem in north-central Mississippi is due, among other things, to the heavy annual rainfall that averages about 50 inches, especially when these torrential rains follow the loosening effects of frost. The brown loam surface soils erode readily, but by far the most serious erosion is produced when the loose clay, gravel, or sands underneath are exposed.

But in spite of all the other conditions favoring erosion, the uplands of north-central Mississippi would not be pouring their sediments into river and creek were it not for past and present agricultural practices. The growing of the staples—cotton and corn—to the exclusion of other crops has been a contributing factor because these crops leave the soil unprotected during the critical winter months. The cultivation of unterraced steep hillsides has also favored the forces of erosion. Cultivated slopes having a gradient of 58 per cent were observed in one county. Erosion is not pronounced even on such slopes as long as the brown loam surface soil is kept in good physical condition. Shallow plowing, however, and careless cultivation, over a period of several years, allows run-off water to break through the furrows and form small gullies. These gullies are soon transformed into a network of larger washes which render cultivation difficult and the field is abandoned. Many gullies in abandoned fields might soon be controlled by the establishment of native vegetation were it not for the damage produced by annual or periodic fires.

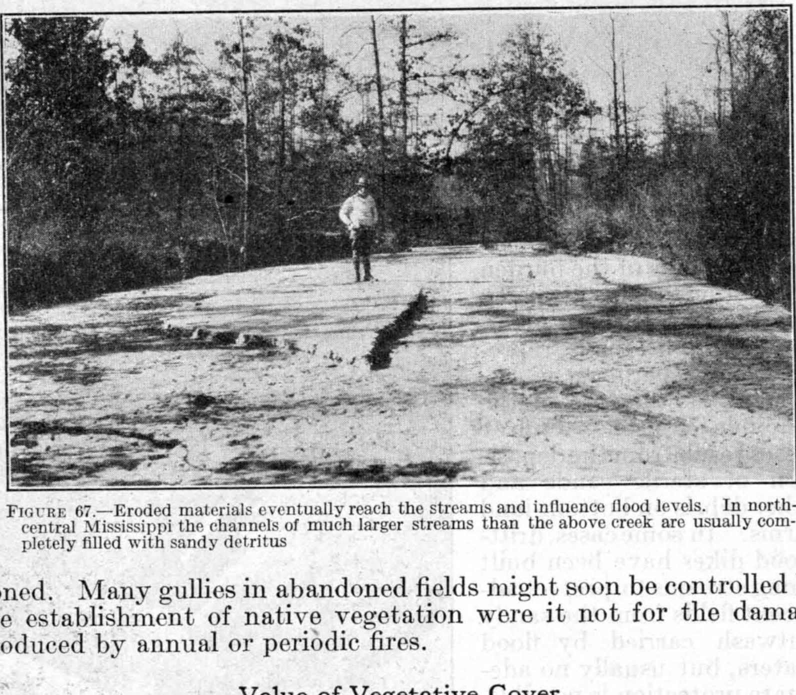

FIGURE 67.—Eroded materials eventually reach the streams and influence flood levels. In north-central Mississippi the channels of much larger streams than the above creek are usually completely filled with sandy detritus

Value of Vegetative Cover

The protective value of vegetative cover is well illustrated in north-central Mississippi. Only remnants of the once extensive upland hardwood stands occur in this region. Original virgin forest, through unregulated cutting and through the damaging effects of fires, has been replaced by an inferior second growth of scrub oaks and shortleaf pine, the protective value of which is far below that of well-managed woodlands. But even these timberlands, although they are usually burned over annually, are undergoing little or no erosion.

Studies have been started by the Southern Forest Experiment Station to work out the best methods of reclaiming, by tree planting, the waste lands of the Mississippi silt loam upland. Thousands of acres of gullied and waste lands are in such condition that their use, even for timber growing, will be made possible only through the solution of many perplexing problems.

FRUIT Juices Preserved by Various Methods Find Steadily Growing Market

Naturally the health movement slogan "Eat More Fruit and Vegetables" has carried with it the corollary "Drink More Fruit Juice," until within the past few years the consumption of fruit juices has increased enormously. Manufacturers of so-called fruit-juice beverages are required by Federal and many State food officials to use a substantial amount of actual fruit juice when the unqualified names of fruits are used on the labels.

The popularity of fruit juices comes largely from advertising campaigns extolling their healthfulness. These claims are in the main based on the results of sound research showing the high vitamin content of the popular juices. Thus orange juice contains the three vitamins, A, B, and C, so necessary to proper nutrition; lemon and grapefruit juices are rich in vitamins B and C. Apple juice also has vitamins A, B, and C, but in smaller quantities. Pineapple and tomato juices are equivalent to orange juice. Grape juice contains vitamins B and C.

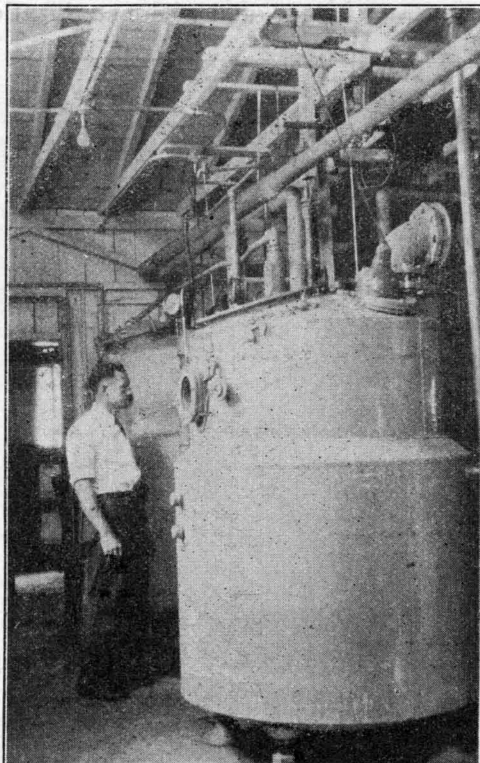

FIGURE 68.—Juice mixers

The preparation of fruit juice for consumption without loss of flavor is a matter of considerable difficulty. The first methods tried were those most familiar to the preservers, and depended upon heat. Some juices can be prepared in this way; others lose their fruity flavor and become objectionable. It is difficult to prepare orange, lemon, apple, and some other juices by the usual methods of heating.

Methods depending upon flash pasteurization are more satisfactory with most juices. This type of pasteurization consists in passing a relatively thin film of juice rapidly over the surface of the heating unit. A commonly used apparatus is a tube or coil of small diameter surrounded by hot water or steam. When the juice enters the coil, it timber growing, will be made possible only through the solution of many perplexing problems.

The first methods tried were those most familiar to the preservers, and depended upon heat. Some juices can be prepared in this way; others lose their fruity flavor and become objectionable. It is difficult to prepare orange, lemon, apple, and some other juices by the usual methods of heating.

Methods depending upon flash pasteurization are more satisfactory with most juices. This type of pasteurization consists in passing a relatively thin film of juice rapidly over the surface of the heating unit. A commonly used apparatus is a tube or coil of small diameter surrounded by hot water or steam. When the juice enters the coil, it reaches the temperature of the heating medium almost instantaneously and need be maintained at the proper temperature for a few seconds only. It can be bottled while still hot. The temperature of the water or steam, the length of the coil, and the rapidity of the flow of juice can all be used for controlling the pasteurization. When it is advisable to cool the juice immediately after pasteurization, it can be passed directly from the hot coil to one surrounded by cold water or brine. However, the problem of getting cold juice into the final containers without reinfection by yeasts or other organisms is one well-nigh impossible of solution under the usual commercial conditions. (Fig. 68).

Advantages of Coil Apparatus

The coil type of apparatus has the advantage of keeping the juice away from the air, and where sterilization can be carried on at sufficiently high temperatures, a part of the air dissolved in the juice is removed. As the juice is in motion while being heated, the danger of overheating the part in contact with the heating surface is reduced to a minimum.

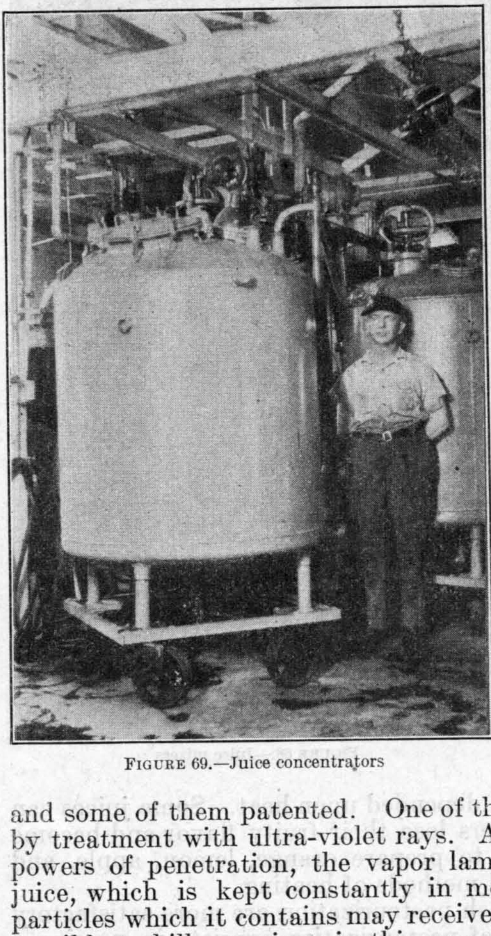

FIGURE 69.—Juice concentrators

Another method of preparation which has found favor is the concentration of the juices under high vacuum. This method not only sterilizes the juice but removes the air and evaporates the liquid at temperatures considerably below its boiling point. Where the acidity of the juices is normal, there is not much loss of vitamins during pasteurization or concentration under vacuum. When concentrated juice is diluted for consumption, however, it lacks the flavor and aroma of the original juice. (Fig. 69.)

Many methods of sterilization which avoid the use of heat and the resulting off-flavors have been devised and some of them patented. One of these is the preparation of juices by treatment with ultra-violet rays. As these rays have but slight powers of penetration, the vapor lamps are usually placed in the juice, which is kept constantly in motion, so that all sides of all particles which it contains may receive treatment. It is undoubtedly possible to kill organisms in this way, but the problem of getting the treated juice into sterile containers without contamination is a difficult one. The department has not yet demonstrated that the ultra-violet or electrical treatment of juices is successful.

There are a number of patents for treating fluids by passing electric currents through them. This is usually accomplished by running the liquid between a series of electrodes. The method is said to be satisfactory for use on milk, but not much is known about its use with fruit juice. There has also been some discussion as to whether the sterilizing is accomplished by the electric current or the heat generated.

Another set of methods employs gases under high pressure for sterilization. Carbon dioxide, oxygen, and sulphur dioxide (the gas given off by burning sulphur) have all been used. Where this is done, the excess of gas must be removed before the liquid is consumed, and in the juice treated with sulphur dioxide, only mere traces could remain without imparting an off flavor.

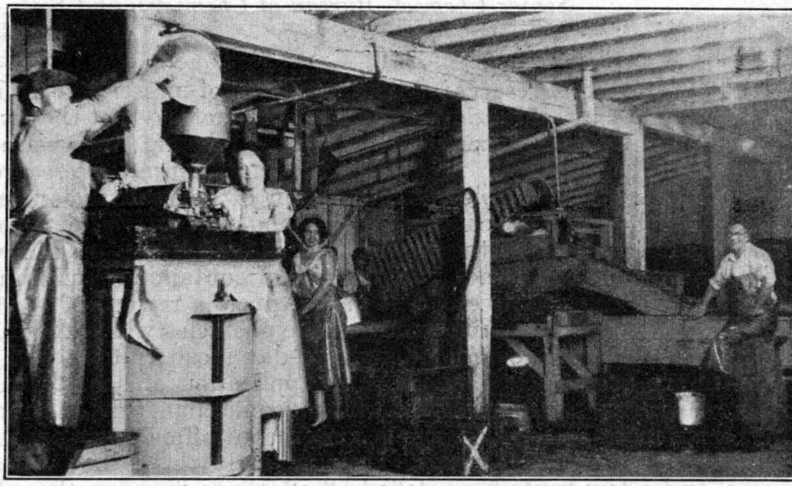

FIGURE 70.—Washing fruit and extracting juice

Preservation By Freezing

A very recent method of preserving juices does not depend on killing the organisms with which it is contaminated, but merely on checking their growth so that spoilage from this source is eliminated. Recently experimental work and shipments on a considerable scale have revealed that frozen juice may be held in cold storage and shipped under special refrigeration so that it can be delivered to large consumers in better shape than that put up by many methods of pasteurization. This development is still in its infancy, and much needs to be ascertained about its limitations, but with improvements in retail distribution and in home refrigeration, a new field for distribution of fruit juices may be opened. (Fig. 70.)

The problem of keeping juices is not altogether a biological one. Some chemical changes take place during the storage period. As yet no method of preventing these changes has been devised; we know, however, that cool storage retards them so that something can be done to lengthen the period during which they can be held.

Some juices keep best when they are kept from contact with air as much as possible, and the greatest possible amount of the air is removed from the container and from the juice itself. This is most often done by substituting an inert gaslike carbon dioxide for the air.

One phase of juice distribution has been neglected in this country, and that is the preparation of juice mixtures or blends. Small amounts of one juice added to another may greatly improve its flavor and appearance, and the mixture may be superior to either of the juices used. Thus, grapefruit juice is greatly improved by the addition of 15 to 20 per cent of Logan blackberry or pomegranate juice. Apple juice mixes well with many tart juices, and lemon juice is often used to take away the flat taste of other citrus juices. Pomegranate juice can be used with good effect, owing to its high color and rather neutral flavor. Even rhubarb juice has been sold as a beverage, and tomato juice is popular in many localities.

FRUIT Products Preserved Successfully by Freezing With Solid Carbon Dioxide

The problem of preserving fruits and fruit products so that they will be available during the periods when the fruits can not be secured fresh is one that has occupied the attention of housewives for centuries. Since the advent of canning as a method of preservation, a vast industry has been built on the sterilization of fruit by means of heat and its storage out of contact with sources of contamination. Since 1810, when the French Government gave Appert a reward of 12,000 francs for his work on canning, many of the obstacles which the canner has faced have been overcome, until to-day most fruits as well as vegetables are acceptably canned. The application of heat to fruit products can rarely be accomplished without some change in the flavor. In numerous instances this change is such that it offers an acceptable substitute for the original flavor. Unfortunately this is not always the case, and a few fruits have defied all efforts to preserve them by heat and retain a satisfactory flavor. It is also true that not a few fruits, although they may be very satisfactory when canned, are better when they are preserved without the use of heat.

Some 20 years ago, the berry packers of the Northwest began experimenting with cold-pack berries. At first the fruit was placed in 50-gallon barrels, mixed with sugar, and placed in cooling rooms. Too often, however, the package fermented and exploded before the temperature could be sufficiently lowered. To obviate this trouble, ice was placed in the package to keep the temperature down until the package reached the freezers. This was not successful, as the fermentation was only delayed and the product diluted. With better facilities for handling the fruit, these difficulties have been overcome. The berries are now washed in the packing shed in cold water, cleaning and cooling them in one operation, and are placed in the freezing rooms as soon as possible. That there is a large demand for this unheated product is shown by the fact that well over 100,000 packages of the 50-gallon size are being sold annually. Besides this package, 30 and 15 pound slip-cover cans are becoming popular, and in 1929 over 1,200-000 paper cartons containing 1 pound were sold.

Rapidity of Freezing Important

Until recently, it was thought that if a fruit product were cooled sufficiently to prevent fermentation, all had been done that was

The application of heat to fruit products can rarely be accomplished without some change in the flavor. In numerous instances this change is such that it offers an acceptable substitute for the original flavor. Unfortunately this is not always the case, and a few fruits have defied all efforts to preserve them by heat and retain a satisfactory flavor. It is also true that not a few fruits, although they may be very satisfactory when canned, are better when they are preserved without the use of heat.

Some 20 years ago, the berry packers of the Northwest began experimenting with cold-pack berries. At first the fruit was placed in 50-gallon barrels, mixed with sugar, and placed in cooling rooms. Too often, however, the package fermented and exploded before the temperature could be sufficiently lowered. To obviate this trouble, ice was placed in the package to keep the temperature down until the package reached the freezers. This was not successful, as the fermentation was only delayed and the product diluted. With better facilities for handling the fruit, these difficulties have been overcome. The berries are now washed in the packing shed in cold water, cleaning and cooling them in one operation, and are placed in the freezing rooms as soon as possible. That there is a large demand for this unheated product is shown by the fact that well over 100,000 packages of the 50-gallon size are being sold annually. Besides this package, 30 and 15 pound slip-cover cans are becoming popular, and in 1929 over 1,200-000 paper cartons containing 1 pound were sold.

Rapidity of Freezing Important

Until recently, it was thought that if a fruit product were cooled sufficiently to prevent fermentation, all had been done that was necessary. It has been found, however, that in preparing frozen fish for shipment and consumption in inland communities, the rapidity of freezing makes a difference in the physical condition or texture of the product after it is thawed and cooked. Very rapid freezing produces a firmer, finer texture than slow freezing. This is probably due to the fact that in rapid freezing, the ice crystals which are formed are very small and there is consequently less tendency to rupture the cells in the frozen food. Where the cells are ruptured, the product becomes mushy when thawed.

Some years ago an investigator of the Department of Agriculture showed that fruit juices could be concentrated by slowly freezing and separating the ice crystals formed in the juice. By refreezing the separated liquid and again removing the ice, a highly concentrated juice could be obtained. Unfortunately in not a few cases, it was found that during the process the concentrated juice lost its flavor and aroma. These juices, however, were frozen very slowly, usually 24 hours being required to produce a solid cake. Quite recently further studies have been carried out on both fruits and fruit juices, using the sharp-freezing methods applied to fish.

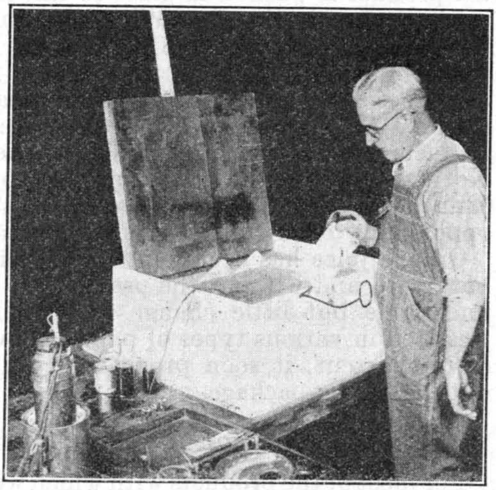

FIGURE 71.—Placing solid carbon dioxide in experimental freezer

By the use of what is known as "2-stage freezers" with a brine made of calcium chloride instead of salt, it is possible to obtain a temperature of −50° F. for commercial "sharp freezing." For experimental work, a comparatively new product is now available. Carbon dioxide can now be obtained in a solid condition. When this solid evaporates, becoming a gas, it produces a temperature of −110°. This solid carbon dioxide is known commercially as "dry ice" or "nu-ice." By constructing well-insulated coolers containing holders for this ice, around which the brine is circulated, the latter can readily be cooled to −50°. Such a cooler used in experimental work is shown in the illustration. (Fig. 71.)

The fruit or fruit juice to be frozen is placed in paper cups, tin cans, or glass jars or bottles. They are sealed before freezing and placed directly in the cold brine. With temperatures of −30° to −50° F., the juices become solid in about five minutes; the fruits require a longer time. Where pieces of fruit do not come into contact with the container over a considerable surface, the freezing is much slower. This difficulty can be overcome by filling the can with sugar sirup or fruit juice after the pieces have been packed in it, thus affording a satisfactory contact with the sides of the container. Grapefruit sections and orange slices become solid in about 30 minutes under these conditions.

Effecting Almost Instantaneous Freezing

Yet another possibility exists where temperatures as low as −80° F. can be obtained. The packages, cans, or bottles can be placed in direct contact with the solid carbon dioxide and an almost instantaneous freezing secured. This method has an advantage in the case of material which undergoes rapid change after its preparation for freezing. Some fruits, notably peaches, darken very rapidly after peeling, and it is desirable to get them frozen as quickly as possible. The danger zone for darkening seems to end at about 20° F., so that the sooner they reach that temperature the better.

Some advantage can be obtained in cases where air is responsible for the changes taking place after freezing, by filling the head space in the package with an inert gas such as carbon dioxide. The same gas which is used in its solid phase for the production of the low temperatures can also be used to take the place of air in the package. Where the product is packed in glass or tin, a vacuum closure can also be used to remove the air. With some products, this works with advantage; with others, little difference is found.

Among the products on which these new freezing methods can be used to considerable advantage are peaches, citrus fruits, and pineapples. All of these are changed to a greater or less extent by cooking. In fact, most citrus products are quite adversely affected by heat. Notwithstanding the fact that pineapple makes a very successful canned product, in the opinion of most of those who have had the opportunity of tasting it, the frozen material is much superior.

Orange juice has been kept frozen for months in cans and bottles, both with and without the use of inert gas in the container, and has undergone but little change in flavor. Where it has been stored wrapped in various types of paper, allowing contact with the air to a certain extent, it soon progressively deteriorates, beginning at the outside of the package.

Storage Temperatures Required

For most of the products with which we have experimented, a storage temperature up to 5° F. seems adequate. Much research is still before us on the problem and it is possible that higher storage temperatures can be used on some commodities, but they are not recommended as yet.

With further improvement in the retail distribution of frozen products, and in household refrigeration, it seems highly probable that the consumption of frozen fruit products will increase enormously in the next decade. Already frozen strawberries, raspberries, cherries, peaches, and orange juice are being placed on the market in considerable quantities.

FUR-TRADE Exposition Includes Special Exhibit of the U. S. Government

With the United States standing as the leading fur-producing and fur-consuming country in the world, it was entirely fitting that the Congress of the United States by a special act should enable this Government to participate in the International Fur-Trade Exposition and Congress held in Leipzig, Germany, during the summer of 1930. It was the purpose of the exhibit so to present all aspects of the fur industry that representatives of all countries should be better informed with respect to the source of supply of furs as well as with the nature and extent of the commercial manufacture of raw furs into finished wearing apparel, both in this country and abroad. (Fig. 72.)

Frank G. Ashbrook, in charge of the Division of Fur Resources of the Bureau of Biological Survey, was made commissioner general to represent this country at the exposition and congress. The Office of Exhibits of the Department of Agriculture cooperated not only with the Bureau of Biological Survey but with the Department of Commerce in designing and constructing the material that formed the governmental parts of the general exhibit. These comprised readily grasped statistics on the commercial aspects of the fur industry in continental United States and on the Pribilof Islands. Mounted specimens of native wild fur bearers were shown in natural habitats as well as on fur farms. Motion pictures, lantern slides, transparencies, charts, and other forms of visual information were prepared in a manner that fully illustrated every phase of the fur industry.

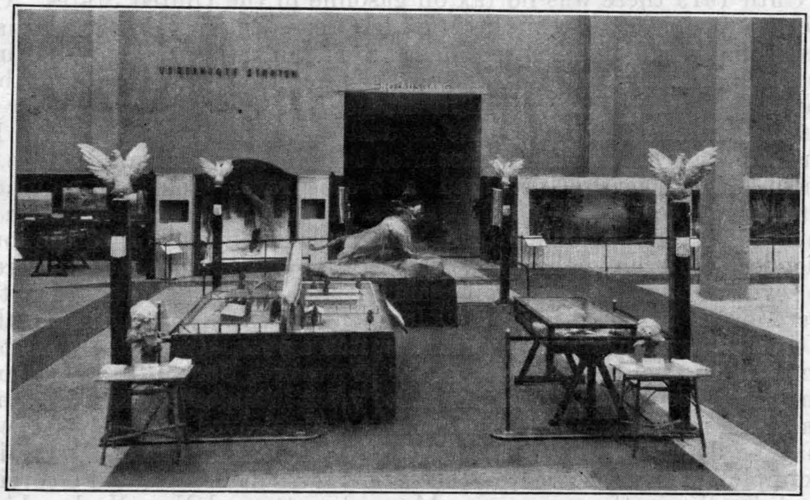

FIGURE 72.—Section of the United States Government's exhibit at the International Fur-Trade Exposition, held at Leipzig, Germany, June 1 to September 30, 1930

A large number of persons interested in the various angles of fur production and utilization viewed this country's exhibit. As a result of their studies and their reading of literature distributed by the department's representatives and others in attendance, they have been placed in a better position to arrange their transactions with fur-animal breeders in the United States, manufacturers of fur garments, and fur exporters. A special publication prepared by the Biological Survey and the Office of Exhibits of the Department of Agriculture and the Bureaus of Fisheries and Foreign and Domestic Commerce of the Department of Commerce, containing a foreword by the Secretaries of the two departments, was issued in both English and German editions to supplement the Government's exhibit.

While the exhibits of many countries demonstrated the commercial phases of the fur industry, that of the United States stressed methods of conservation of the fur bearers and of production and utilization of fur. Participation by the United States in this international exhibition should have a salutary effect on the fur industry in this country.

J. E. SHILLINGER,
Senior Biologist, Bureau of Biological Survey.

GASOLINE Taxes Nearly All Used for Building and Maintaining Roads Gasoline taxes paid by road users of the 48 States and the District of Columbia in 1929 reached the largest total in the 10-year history of this remarkable taxing measure. After deduction of refunds allowed by the State laws the tax netted in this tenth year of its existence $431,636,454 from levies on more than 13,400,000,000 gallons of motor fuel.

Until 1919 there was no tax on gasoline in the United States. On February 25 of that year the State of Oregon set in motion the small "snowball" which since has rolled through all the States and, swelling in size, has finally rolled up one of the largest of all revenues available for highway construction and maintenance.

Oregon's initial levy was the modest one of 1 cent per gallon. In the same year three other States tried the same experiment, and one of them—New Mexico—ventured a 2-cent rate. Colorado matched Oregon's 1 cent; but North Dakota decided to be content with a fourth of a cent per gallon. This was the beginning. By 1923 the four pioneers had been joined by 31 other States, and a 3-cent rate appeared in seven of them, with Oregon again in the van. In 1925 the 35 States were joined by the District of Columbia, and Arkansas celebrated the New Year by imposing a 4-cent rate; and a year later, with 44 States and the District of Columbia in the procession, South Carolina came out for a 5-cent tax. Then, for three years it appeared that the limit had been reached; but South Carolina again proved that appearances may be deceptive by laying down a 6-cent tax in March, 1929; its example quickly followed by the sister States of Florida and Georgia. And, finally, in the same year, Massachusetts and New York, which had previously held aloof, joined with the rest of the Nation, each levying a 2-cent tax.

Tax is Cheaply Collected

Regarded by tax experts as one of the most remarkable revenue producers ever devised, this tax is also one of the most cheaply collected of all imposts. In 34 States for which the costs of collection in 1929 are known, the net revenue produced, after deduction of all costs of administration was 99¾ cents for every dollar of tax collected.

It has also been one of the most willingly paid of all taxes. Devoted mainly to the work of road improvement, the road using public by which it is paid in proportion to the use of the highways, has in no case seriously opposed the imposition of the tax. Even at the 6-cent maximum rate now charged in three States there is still no definite indication of a diminishing return which would indicate approach to the limit of public tolerance.

How greatly the road improvement activity of recent years has depended upon this single source of revenue, and to what extent the rapid progress of the latter years has been made possible by the of conservation of the fur bearers and of production and utilization of fur. Participation by the United States in this international exhibition should have a salutary effect on the fur industry in this country.

J. E. SHILLINGER,
Senior Biologist, Bureau of Biological Survey.

GASOLINE Taxes Nearly All Used for Building and Maintaining Roads Gasoline taxes paid by road users of the 48 States and the District of Columbia in 1929 reached the largest total in the 10-year history of this remarkable taxing measure. Even at the 6-cent maximum rate now charged in three States there is still no definite indication of a diminishing return which would indicate approach to the limit of public tolerance.

How greatly the road improvement activity of recent years has depended upon this single source of revenue, and to what extent the rapid progress of the latter years has been made possible by the direct contributions of the road user in this form and in motor vehicle license fees can be shown by a few figures.

In 1919—the year the gasoline tax was adopted by the first four States—the whole expenditure on rural highways in the United States, by all agencies of government—Federal, State, and local—was $389,455,932. The total of gasoline taxes collected in that year was only $1,022,514. Motor-vehicle license fees produced an additional $64,697,255; so that the total contribution of the road user was $65,719,769, which was about 17 per cent of the comparatively small expenditure.

By 1929—just 10 years later—the total rural road expenditure had grown to an annual outlay of $1,444,668,985; and in support of this enormously increased expenditure the operators of motor vehicles contributed $729,791,055, or more than 50 per cent. Of their total contribution the road users paid $406,453,249 in the form of gasoline taxes and the balance in motor-vehicle license fees, permits, etc. In both instances these amounts are exclusive of the portions of the total contributions which were used to defray collection costs or diverted to other than rural highway uses.

Between the two years mentioned the yearly rural road expenditure increased slightly more than a billion dollars, and of this increase just about two-thirds was met by the increased contributions of the road user, made up in larger part of gasoline taxes. The remainder was met by increased revenue from real property taxation and bond issues.

Distribution of Gasoline Taxes

Of the $431,636,454 of gasoline taxes collected in 1929, $297,967,756 or 69 per cent was allotted for expenditure in the construction and maintenance of the main roads comprising the State highway systems. For the construction and maintenance of local roads of the counties and townships the allotment was $85,113,708 or nearly 20 per cent of the total. To meet necessary payments on State and county road bonds there was an allotment of $23,371,785, approximately 5 per cent of the total and the remainder of $24,405,027, or approximately 6 per cent was devoted to purposes other than the improvement of rural roads.

Of the amount thus diverted to other than rural road purposes, the greatest fraction, amounting in eight States and the District of Columbia to $14,548,106, was allotted to the improvement of streets in cities and towns; a further sum was diverted to the construction of schools and public buildings in three States in the amount of $9,270,562; one State allotted $90,000 to its Department of Commerce and Navigation; five States held $282,346 as a reserve for payment of tax refunds; one State devoted $210,093 raised by a special gasoline tax to the construction of a seawall for road protection; and the small balance of $3,920 was paid by one State into its general funds.

It will thus be seen that of the total amount of these taxes collected in 1929, nearly 98 per cent was devoted directly or indirectly to the construction and maintenance of rural roads and city streets. The diversions to other purposes, such as schools and public buildings, are as yet unimportant from the point of view of the country as a whole, though they represent very substantial sums in the few States involved.

This does not mean, however, that there have not been many efforts to appropriate the returns of the tax to other than the purposes for which it was originally designed. On the contrary there is scarcely a legislative session in any State at which there is not some effort, more or less strongly supported, to reap the benefits of the tax for other purposes.

Such attempts are stoutly and quite properly resisted by motorists as inconsistent with the character of the impost. They contend that, as a special levy on road users, the tax should be exclusively devoted to the benefit of the special class upon which it falls; and as a matter of equity, and public policy as well, their contention is fully justified.

Division Between Rural and City Uses

Whether the apportionment of the return on the present basis to State and county roads and city streets is entirely reasonable is a more debatable question. As originally levied in practically all States the tax was intended for the support of the State road program. Since the expensive investment in the main roads is necessitated by the heavy accumulation of motor-vehicle traffic which they must accommodate, there is peculiar fitness in this use of the tax.

In recognition of this fact, property taxes for main-road purposes have been greatly reduced or abandoned in all States, and now constitute less than 9 per cent of the total State highway revenue. The user taxes, including motor-vehicle license fees and gasoline taxes, constituting the bulk of the 91 per cent remaining, have thus become the main support of the important work of State road improvement; and the amount allotted to this purpose from the two special taxes can not be reduced without jeopardizing the continuance of this work which has made so great a change in the condition of the most important rural roads.

If, therefore, additional sums for county roads and city streets are to be raised by taxation of vehicle owners it is practically imperative that they be provided by increasing the tax rate; and proposals to that end affecting gasoline taxes should be very carefully considered. It is well to remember that additions have thus far been made to a falling price of gasoline and have thus been so absorbed that they have not been felt by the consumer. If the price of the fuel turns upward, as it doubtless will eventually, the higher tax rates already levied may become actually burdensome.

Principal Highway Engineer, Bureau of Public Roads.

GIFTS of Land Often Made to Government by Public-Spirited Citizens It is generally known that the Government is the owner of many lots of land utilized as sites for its various activities, and that in the past, due to its ownership of an empire of vacant public lands, the United States was one of the largest if not the largest and most active real-estate agency the world has ever known. While knowledge of its innumerable free grants is common, the fact that many tracts of land are given to the United States is probably known to comparatively few. Some of these gifts are by public-spirited citizens or organizations wishing to aid in the furtherance of projects conducted by the Government. Others are prompted in part by sentiment. Many for which it was originally designed. On the contrary there is scarcely a legislative session in any State at which there is not some effort, more or less strongly supported, to reap the benefits of the tax for other purposes.

GIFTS of Land Often Made to Government by Public-Spirited Citizens

It is generally known that the Government is the owner of many lots of land utilized as sites for its various activities, and that in the past, due to its ownership of an empire of vacant public lands, the United States was one of the largest if not the largest and most active real-estate agency the world has ever known. While knowledge of its innumerable free grants is common, the fact that many tracts of land are given to the United States is probably known to comparatively few. Some of these gifts are by public-spirited citizens or organizations wishing to aid in the furtherance of projects conducted by the Government. Others are prompted in part by sentiment. Many such gifts have been made to the United States through the Department of Agriculture. It is the policy of the department not to favor the acceptance of free transfers of land unless they can be used to advantage in the performance of the activities assigned to the department. This policy often leads to the necessity of rejecting gifts of land although they may have been prompted by the best motives.

Many may have heard of a tract of land in Warren County, Pa., known as "Heart's Content" and wondered at the significance of the name. This piece of land of 20 acres carries a highly valuable virgin stand of white-pine and hemlock timber, a rare combination in the East. It was given to the United States by a lumber company, Wheeler & Dusenbury. The tract is very accessible and has long been used for recreational purposes. In accepting this gift on behalf of the department, Acting Secretary Marvin said that it was planned to maintain this land in a virgin condition, to serve as a forest laboratory for the investigation of forest-soil problems. It was anticipated that this use would contribute to the rebuilding of the white-pine forests of the Northeastern States. The donation was one of the first of this kind of any magnitude made by a lumber concern to be used for the benefit of research and with the object of promoting a better development of forest lands in the future. The land is said to be worth more than $1,000 an acre. It was named "Heart's Content" 75 years ago by an old lumberman.

Morgan Horse Farm

The United States Morgan Horse Farm, located 2 miles north of Middlebury, Vt., in the town of Weybridge, was established in 1907 on land given to the Government by Joseph Battel, then owner of the American Morgan Register. Colonel Battel was one of the foremost breeders of Morgan horses and had spent much time and money in securing the best representatives of the breed. The land, a tract of 435 acres, was donated to the United States with the understanding that it should be used for the preservation and distribution of the Morgan breed of horses. This breed was established by a single stallion known as Justin Morgan, a horse renowned for beauty, symmetry, style, and strength. This farm, which has been enlarged, is still used in investigational work relating to Morgan horses. It is the only farm in America founded for the purpose of prepetuating a breed of horses. From this farm stock has been distributed for over 20 years throughout the United States and its overseas possessions and to many foreign countries.

In 1924 Secretary Henry C. Wallace accepted on behalf of the department 302 acres of land near Sisson, Calif., as a gift from Mary Burt Brittan. This land is of great value for forestry and recreation. In it is Castle Lake, from which a fine view of Mount Shasta may be had. It had been the custom of William Giles Brittan, formerly a judge of the Superior Court of California and a brother of the donor of this land, to pass much of his leisure time on this beautiful spot. His sister desired that it should continue to be used largely for recreational purposes, under the regulations of the department pertaining to national forests. The land was valued at approximately $15,000.

It quite often happens that none of the lands owned by the Government in a region are suitable for a particular purpose of the United States Forest Service. Some public-spirited citizen may then come forward and give the department land to meet its need. Recently the

Government needed a site for a fire lookout tower within the Sitgreaves National Forest, Ariz. Mike Chaco and his wife gave 10 acres of land to the Government for this purpose. This gift resulted in the erection of the Chevalon Butte fire lookout tower.

A short time ago the Colorado chapter of the Daughters of the American Revolution gave the Government a quarter section of land for a memorial forest planting tract.

Barbour Lathrop Plant Introduction Garden

The origin of the Barbour Lathrop Plant Introduction Garden is of interest. In 1918 the existence of a bamboo grove near Savannah, Ga., was called to the attention of an official of the department, with the information that the owner planned to cut it down. This would have meant the loss to the United States of one of its largest groves of timber bamboo. The situation was called to the attention of Barbour Lathrop, of Chicago, Ill., who had shown his unusual interest in bamboo plants by presenting a collection of them to the Government. Mr. Lathrop purchased the tract, which comprised 46 acres, and presented it to the United States to be used as a plant-introduction garden. The bamboo grove of this garden was derived from plants introduced from Japan. It was started with three small plants in 1890. While the most important plant in the garden is the Japanese timber bamboo, the general object of the project is the trial of new foreign plants and their propagation for distribution. At his death Mr. Lathrop left $10,000 to be used in connection with the station.

An outstanding example of cooperative effort between a local community and the Federal Government exists in the recent establishment of the United States pecan field station near Shreveport, La. The people of Caddo Parish, La., desired pecan investigational work. Parish authorities purchased 100 acres of land selected by representatives of the department and erected buildings thereon. The project involved an expenditure of approximately $41,000. This tract, together with the improvements and 42 acres of additional uplands donated by a public-spirited citizen, C. E. Ellerbe, was conveyed to the United States as a gift. The action required an amendment to the Constitution of the State of Louisiana. These lands have been taken over by the United States and work is progressing toward the organization of experimental activities which will include varietal testing, cultural and disease work, and consideration of soil problems.

A joint resolution approved in 1928 by President Coolidge authorized the Secretary of Agriculture to accept from James B. Munn, of New York City, on behalf of the United States, a gift of certain lands in Clayton County, Iowa, to become a part of the Upper Mississippi River Wild Life and Fish Refuge, which is administered jointly by the Bureau of Biological Survey, Department of Agriculture, and the Bureau of Fisheries, Department of Commerce. These lands, embracing a total area of 488 acres, estimated to be worth $30,000 or $40,000, were generously donated to the Government by Mr. Munn through his interest in the objects of the refuge.

Situated near McGregor, Iowa, the lands are more or less overgrown with original timber and are especially attractive for upland migratory birds. One parcel includes an excellent lookout point, known as Pikes Peak, that will be of great value in connection with fire protection, administrative uses, and other purposes on the refuge. Although adjacent to the lowlands embraced in the refuge much of the area is not subject to overflow, as it extends up into the hills bordering the river bottoms, and the inclusion of this high land will have the desirable result of lending variety to the refuge and attracting and protecting additional species of wild life.

Attorney, Office of the Solicitor.

GOAT Grass, a New Wheat-Field Weed, Is Growing Troublesome In recent years goat grass, *Aegilops cylindrica* Host., has become a troublesome weed in wheat fields of south-central Kansas and north-central Oklahoma. It was first reported from the vicinity of Trousdale, Kans., in 1917. The grass was not identified at that time and received no particular attention. Nothing was heard of it again until 1920, when it was identified. Its continued spread has forced a recognition of its importance as a weed in wheat fields.

Goat grass is a wild relative of cultivated wheat. It will even cross to a certain extent with wheat, although most plants arising from the hybrid seeds are sterile. Goat grass, like winter wheat, is a winter annual. The seedlings emerge in the fall, and the plants mature the following spring, about the time wheat is ready for harvest. Seedlings and young plants of goat grass are difficult to distinguish from wheat plants. The leaves of goat grass are narrower than those of wheat, however, and have hairs along the edges near the base, a character lacking in wheat. The grass tillers profusely, and when abundant it often crowds out the wheat. Plants with as many as 50 tillers are not of unusual occurrence, although in thick stands fewer tillers are developed. The grass is a vigorous grower, very winter-hardy, and has a distinct advantage over wheat where the latter is at all checked by unfavorable conditions.

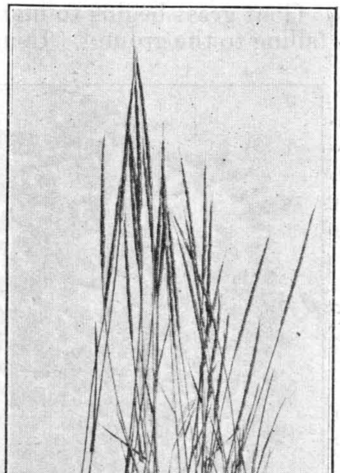

FIGURE 73.—A plant of goat grass showing its resemblance to wheat and its tillering habit

Goat grass produces a head or spike something like that of wheat, but more slender and cylindrical, as shown in Figure 73. Two varieties are found in the southern Great Plains, one with velvety chaff and the other smooth. Both varieties have beards only at the tip of the heads. At maturity the heads become very brittle and break up.

The grass is a vigorous grower, very winter-hardy, and has a distinct advantage over wheat where the latter is at all checked by unfavorable conditions.

Goat grass produces a head or spike something like that of wheat, but more slender and cylindrical, as shown in Figure 73. Two varieties are found in the southern Great Plains, one with velvety chaff and the other smooth. Both varieties have beards only at the tip of the heads. At maturity the heads become very brittle and break up.

The seed remains inclosed in the chaff with the latter attached to a portion of the head. The head ripens from the top downward, each portion falling to the ground as soon as mature. Mature heads are so brittle that a slight disturbance scatters the seed-bearing portions in all directions. The grass therefore reseeds itself very profusely. Each section of the head contains two seeds which resemble those of wheat in general appearance, but are much smaller. The sections of the goat-grass head are only slightly larger than well-formed kernels of wheat and about the same weight, making them difficult to remove from threshed grain. In appearance they resemble small pieces of straw or trash. (Fig. 74.)

Matures Before Wheat is Cut

Goat grass begins to mature slightly before the wheat, the ripe seed falling to the ground. Usually about one-half to two-thirds of the seed has been dropped before the wheat is cut. The remainder goes into the threshed grain.

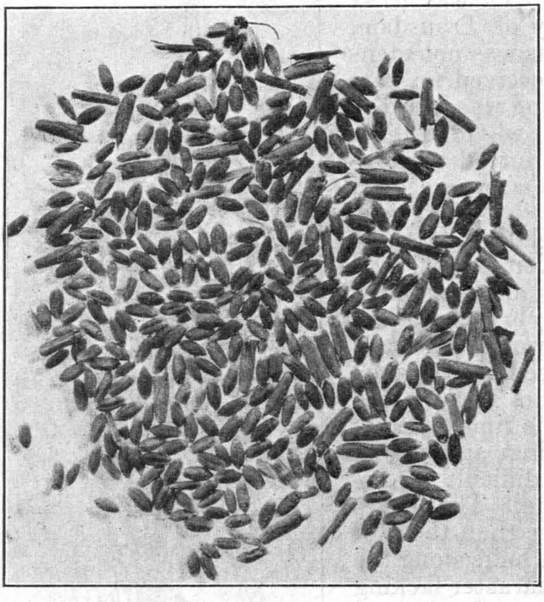

FIGURE 74.—Goat-grass seed in a sample of threshed wheat as it came from a Kansas farmer's field

Goat grass has been reported from 21 counties in central and southern Kansas and 2 counties in north-central Oklahoma. In individual fields the extent of infestation varies from a few scattered plants to solid stands of the grass several acres in extent.

Goat grass is not native to the United States, and it probably was brought into the area in seed wheat imported from southern Russia. Many Russian immigrants settled in central Kansas about 1873 and brought Turkey wheat with them. The most severely infested areas are in counties where these immigrants settled, or near by. The original Oklahoma infestation appeared in fields of Turkey wheat, the seed of which came from infested areas in Kansas. It is not clear why the grass did not make itself evident before 1918 if it was imported as early as 1873.

Where wheat is grown continuously, eradication is extremeiy difficult. Some farmers mow infested spots while the plants are still green and burn the straw as soon as dry. Others avoid infested spots in harvesting, and later pile straw on them and burn it. Still others disk fields as soon as the grass seedlings are well up in the fall and before the wheat is sown. None of these methods really controls the weed, however, and goat grass continues to spread slowly in the infested area where wheat is grown continuously.

Control of goat grass is not difficult where rotation with row crops is possible. It is easily killed by cultivation. The only complicating factor is the difficulty of killing plants growing in fence rows, roadways, and other waste places. The grass does not compete with native grasses in undisturbed sod.

GULLIED Land Reclaimed by the Use of Brush Followed by Terracing Preliminary to terracing land cut up with deep gullies that can not be crossed with farm machinery, it is sometimes advisable first to partly fill the gully by intercepting eroded soil in the run-off water. Where an abundant supply of brush is available, an ideal method for

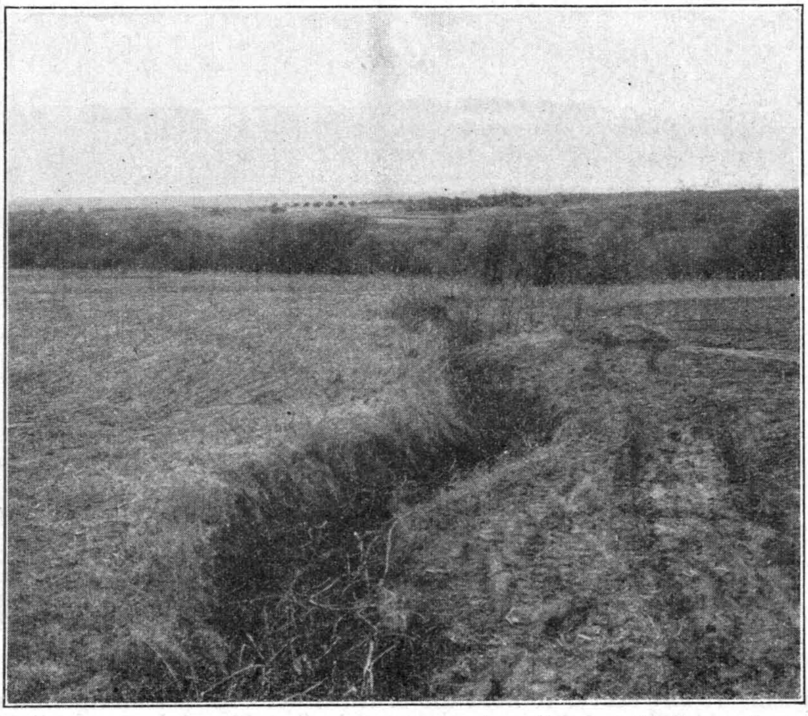

FIGURE 75.—Gully about half filled with brush to check erosion and intercept silt in the run-off water

collecting a deposit of soil is to partly fill the gully along its entire length with brush. This method has some advantages over the use of brush dams in that a greater proportion of the silt in the run-off water is caught and deposited in the gully, resulting in only small loss of soil from the field. The gully should be filled to about one-half its depth at the middle, and the brush should extend up the sides as near to the top of the banks as possible. This provides a passageway for the run-off water without permitting erosion on the sides of the gully. Two very common mistakes are to fill the gully so full of brush as to cause an overflowing of the banks and the eroding of a new parallel gully down the slope, and to neglect to protect the sides of the gully against the erosive action of the water.

Before laying the brush it is a good plan to cover the bottom and sides of the gully with straw, grass, or some other similar material to protect the soil from the eroding effect of water percolating through the brush. Starting at the lower end of the gully the brush should be laid with the butts downstream, overlapping it in a manner similar to that employed in shingling a house. This ties the brush effectively together throughout the length of the gully and reduces to a minimum any possible movement from the force of the run-off water. If rock is available it should be placed on top of the brush along the center line of the gully as an anchor and to prevent the movement of the top

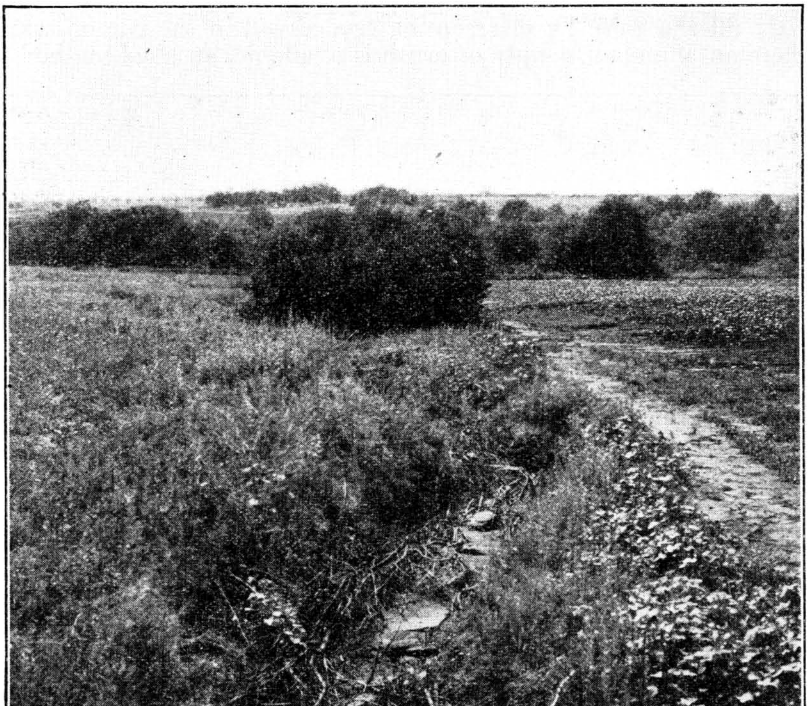

FIGURE 76.—Showing silt deposited to top of brush in gully shown in Figure 75

brush. It also serves to hold the brush closer together and permits a more rapid filling of the open spaces with silt. If rock is not available, stakes driven with tops tilting uphill and connected with cross poles will answer the same purpose.

Test at Erosion Experiment Farm

In the spring of 1929, on the department's soil-erosion experiment farm near Guthrie, Okla., a gully with a bottom width of from 2 to 7 feet, a top width of from 5 to 15 feet, and a depth of from 2 to 8 feet, was about half filled with brush as shown in Figure 75. During a period of about one month during which time four ordinary rains occurred, 1 to 2 feet of soil was intercepted by the brush and deposited in the bottom of the gully. Before the fall of the same year the gully had been filled with eroded soil practically to the top of the brush. (Fig. 76.)

In the fall the edges of the gully were plowed in and sufficient soil was scraped into the gully to permit crossing with tractors and terracing implements. The land was then terraced and, with some additional work between terraces consisting of plowing in the sharp edges of the banks, it was possible to cross the gully at any place with farm

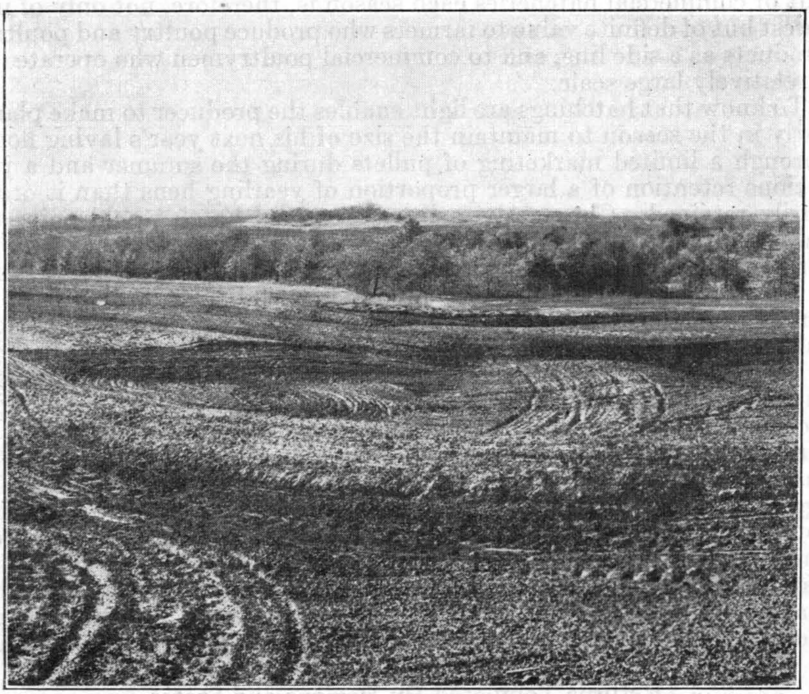

FIGURE 77.—View taken at same location as views in Figures 75 and 76 after land was terraced. Note disappearance of gully, all land being available for farming purposes

machinery. Figure 77 is a view taken in the same location as those in Figures 75 and 76 from which it is apparent that the gully has entirely disappeared and the former sharp edges have given way to smooth curves which can be readily crossed with farm machinery. All of the waste land formerly occupied by the gully is reclaimed for cultivable purposes.

C. E. RAMSER,
Senior Drainage Engineer, Bureau of Public Roads.

HATCHERY Reports, Issued Monthly, Aid Poultrymen to Regulate Production

Chicks hatched in the spring become either a part of the summer's supply of broilers or fryers or of the laying flocks that furnish the egg supply of the following season. A crop of baby chicks smaller than usual, therefore, is indicative of a smaller supply of young poultry for the summer markets, a reduction in the number of pullets in the bottom of the gully. Before the fall of the same year the gully had been filled with eroded soil practically to the top of the brush. (Fig. 76.)

HATCHERY Reports, Issued Monthly, Aid Poultrymen to Regulate Production

Chicks hatched in the spring become either a part of the summer's supply of broilers or fryers or of the laying flocks that furnish the egg supply of the following season. A crop of baby chicks smaller than usual, therefore, is indicative of a smaller supply of young poultry for the summer markets, a reduction in the number of pullets available for laying purposes the following fall, and a correspondingly lighter egg production for the next winter, spring, and summer than is usual in those seasons. Such a situation normally results in a higher level of prices for both eggs and poultry. On the other hand, a comparatively heavy hatch points to a substantial increase in the summer supplies of marketable young stock and a marked expansion of laying flocks the next fall. Such a situation may lead to a sharp decline in the prices for eggs and poultry. Information as to the size of the output of commercial hatcheries each season is, therefore, not only of interest but of definite value to farmers who produce poultry and poultry products as a side line, and to commercial poultrymen who operate on a relatively large scale.

To know that hatchings are light enables the producer to make plans early in the season to maintain the size of his next year's laying flock through a limited marketing of pullets during the summer and a judicious retention of a larger proportion of yearling hens than is ordinarily retained. Conversely, a heavy seasonal hatch would point to the desirability of a more liberal marketing of young stock and a stricter culling of old stock at the beginning of the next laying season. Such a program, if intelligently followed, would tend to modify to a large extent the extremes of the periodic cycles of production to which the poultry industry in the past has been subjected.

For the purpose of furnishing poultry producers with an index on the probable size of the season's chick crop, the Bureau of Agricultural Economics has for the past two years issued a hatchery report monthly during the main hatching season. This report contains information submitted by commercial hatcheries with incubating capacity of 10,000 eggs and over. Schedules sent to such firms each month request the total egg capacity of the hatchery on first of month, total number of chicken eggs set during month, and total number of salable chicks hatched during month. In order that proper comparisons may be made it is essential that reports be made not only for the current month under survey but also for the same month of the previous year.

Returns Tabulated By Regions and States

The returns are tabulated for the monthly hatchery report, (1) according to the principal geographic regions, and (2) according to States. While the poultry industry is conducted on a commercial scale to a greater or less degree in all States, the areas that furnish the principal proportion of the market supplies of eggs and poultry are rather definitely defined. General information on the changes occurring by areas is of interest and value to those concerned with the marketing of poultry and poultry products. Information on the changes by States is of particular benefit to hatcherymen and to the various State officials working with the poultry industry within the respective States. With facts on current changes before them they are in a much better position to measure the results of their efforts and to modify their programs if such a modification seems necessary.

In a short comment, written in popular style, the statistical data presented in the report are analyzed, and the most significant of the indicated changes pointed out and discussed.

The first year's results of the hatchery report indicate that it has excellent possibilities for roughly measuring early in the season the prospective supply of eggs and poultry. A summary of the 1929 reports at the close of the season showed a seasonal increase of 13.5 per cent in total incubating capacity, 29 per cent in the number of eggs set, and 31 per cent in the number of salable chicks hatched, over the same period in 1928. Such changes pointed to an increase in the supply of both eggs and poultry for the 1929–30 season. That this is what happened is borne out by the fact that receipts of fresh-killed dressed poultry at the four principal egg and poultry markets—New York, Boston, Philadelphia, and Chicago—for the last three months of 1929 and the first three months of 1930 were approximately 28,000,000 pounds, or 12 per cent, heavier than the receipts for the preceding comparable period. The receipts of eggs at the same markets for the period from January 1 to May 15, 1930, were larger by around 540,000 cases, or 8 per cent, than the receipts for the same period of 1929. The heavy supplies of both poultry and eggs for the 1929–30 season caused prices for both commodities to drop substantially under the prices for the corresponding period of the preceding year. These developments were fully indicated by the reports of commercial hatchery output during the midsummer of 1929.

Associate Marketing Specialist,
Bureau of Agricultural Economics.

HAYSTACKS' Content Is Measurable More Closely by New Rules

Requests for rules for computing the quantity of hay in stacks are frequently received by the Department of Agriculture from producers, stock feeders, and others, particularly in the Pacific and Intermountain States, who are interested in the marketing of hay for which actual weights can not be obtained because of distance from suitable scales, or for other reasons. In such cases it is necessary to have some means of estimating the weight of the hay. This usually is done by measuring certain dimensions of the stack and then computing the volume by one of several rules in common use. This volume is then divided by the accepted number of cubic feet required for a ton for the particular kind of hay in question. The result is the accepted number of tons in the stack, and settlement is made on this basis.

Rectangular Stacks

Recent studies show that the rules for determining volume of rectangular stacks in common use at present are not very accurate. In all the rules or formulas for computing the volume of rectangular stacks O equals the distance from the ground at one side of the stack over the stack to the ground at the other side, W equals the width of the stack at the ground, and L equals the average length of the stack. These measurements are taken in feet. The Frye-Bruhn rule or rule of two, $\frac{(O-W)W}{2}L$, which is commonly used, gave in some cases studied only 70 per cent of the actual volume of the stack and in other cases as high as 105 per cent of the actual volume. On an average this rule gave 86 per cent of the actual volume. The quartermaster or so-called Government rule, $\left(\frac{O-W}{4}\right)^2 L$, another rule in at the close of the season showed a seasonal increase of 13.5 per cent in total incubating capacity, 29 per cent in the number of eggs set, and 31 per cent in the number of salable chicks hatched, over the same period in 1928. Such changes pointed to an increase in the supply of both eggs and poultry for the 1929–30 season. That this is what happened is borne out by the fact that receipts of fresh-killed dressed poultry at the four principal egg and poultry markets—New York, Boston, Philadelphia, and Chicago—for the last three months of 1929 and the first three months of 1930 were approximately 28,000,000 pounds, or 12 per cent, heavier than the receipts for the preceding comparable period. The receipts of eggs at the same markets for the period from January 1 to May 15, 1930, were larger by around 540,000 cases, or 8 per cent, than the receipts for the same period of 1929. The heavy supplies of both poultry and eggs for the 1929–30 season caused prices for both commodities to drop substantially under the prices for the corresponding period of the preceding year. These developments were fully indicated by the reports of commercial hatchery output during the midsummer of 1929.

HAYSTACKS' Content Is Measurable More Closely by New Rules

Requests for rules for computing the quantity of hay in stacks are frequently received by the Department of Agriculture from producers, stock feeders, and others, particularly in the Pacific and Intermountain States, who are interested in the marketing of hay for which actual weights can not be obtained because of distance from suitable scales, or for other reasons. In such cases it is necessary to have some means of estimating the weight of the hay. This usually is done by measuring certain dimensions of the stack and then computing the volume by one of several rules in common use. This volume is then divided by the accepted number of cubic feet required for a ton for the particular kind of hay in question. The result is the accepted number of tons in the stack, and settlement is made on this basis.

Rectangular Stacks

Recent studies show that the rules for determining volume of rectangular stacks in common use at present are not very accurate. In all the rules or formulas for computing the volume of rectangular stacks O equals the distance from the ground at one side of the stack over the stack to the ground at the other side, W equals the width of the stack at the ground, and L equals the average length of the stack. These measurements are taken in feet. The Frye-Bruhn rule or rule of two, $\frac{(O-W)W}{2}L$, which is commonly used, gave in some cases studied only 70 per cent of the actual volume of the stack and in other cases as high as 105 per cent of the actual volume. On an average this rule gave 86 per cent of the actual volume. The quartermaster or so-called Government rule, $\left(\frac{O-W}{4}\right)^2 L$, another rule in common use, gave in some cases only 80 per cent and in other cases as high as 130 per cent of the actual volume. On an average, this rule gave 96 per cent of the actual volume. Several other rules in use to a limited extent were studied and results were even more unsatisfactory. (Fig. 78.)

Studies were then carried on for the purpose of developing rules or formulas for determining the volume of rectangular stacks that would be more accurate than those in use at present. The stacks were divided into three groups or types, based on the shape of the stacks. These types are (1) square flat-topped stacks similar to those built in certain parts of California; (2) high round-topped stacks similar to those built in the Intermountain States of Utah, Nevada, Idaho, and eastern Oregon; and (3) low round-topped stacks similar to those built in Montana South Dakota, Colorado, and Minnesota.

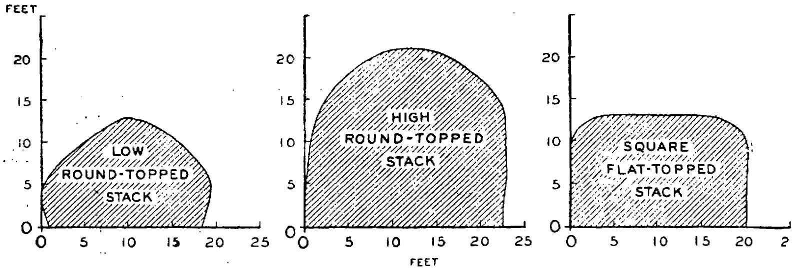

FIGURE 78.—Outline of three types of hay stacks

A formula was developed for each of these types of stacks that will give a volume within 5 per cent of the actual volume in practically all cases. All three of these formulas gave on the average 100 per cent of the actual volume. The formulas are as follows:

For square flat-topped stacks .... $(0.56\times O-0.55\times W)WL$.
For high round-topped stacks .... $(0.52\times O-0.46\times W)WL$.
For low round-topped stacks .... $(0.52\times O-0.44\times W)WL$.

Round Stacks

The rules in use at present for the purpose of determining the volume of round stacks were studied and found to be rather inaccurate. In the rules for round stacks O equals the average distance from the ground on one side of the stack over the peak to the ground on the other side; C equals the circumference of the stack at the ground. The quartermaster or Government rule for round stacks $\left(\frac{C}{4}\right)\times\left(\frac{O-\frac{C}{4}}{2}\right)$ was found on the average to give 95 per cent of the actual volume.

The following rule developed from the data obtained will give fairly accurate results for all round stacks:

$$\text{Volume} = (0.04\times O-0.012\times C)C^2$$

On the average this rule will give a result that is equal to the actual volume.

Cubic Feet per Ton

Many factors affect the number of cubic feet required for a ton, or the density of the hay in the stack. At present there are no methods for measuring this variation in density, but the following figures, which are the averages obtained from a large number of stacks, can be used with fairly satisfactory results:

Length of time in stacks	Number of cubic feet per ton of hay		
	Alfalfa	Timothy and timothy mixed	Wild
30 to 90 days	485	640	600
Over 90 days	470	625	450

These figures, when used with the new rules for determining volume stated above, will give more accurate results than can be obtained from the figures for cubic feet per ton now used in connection with present volume rules.

HEMP Fiber Losing Ground, Despite Its Valuable Qualities Hemp is one of the oldest of known textile fibers. There is a definite record that the hemp plant (*Cannabis sativa*) (fig. 79) was cultivated in China for fiber production 27 centuries before the Christian Era. For nearly 5,000 years it has been important and has won an honorable position because of its strength and durability and the well-established fact that it is dependable. Until less than a century ago hemp and flax were the principal fibers of vegetable origin. While flax was the aristocratic fiber for fine linens, laces, and embroideries, hemp was the strong and dependable fiber for ropes, cables, and sails. The name canvas is derived from the Arabic name for hemp. The Pilgrim Fathers at Plymouth and the Cavaliers at Jamestown planted hemp and flax among their earliest crops. The clothing of the men was hempen homespun, and it did not quickly wear out. The famous clipper ships that carried the merchandise on the seven seas until the middle of the last century were outfitted with sails, ropes, cables, halyards, and shrouds all made of hemp fiber. Many of the covered wagons that crossed the plains before 1860 had covers of real canvas.

For many of these uses of former days, hemp has been replaced by other fibers. In some instances fibers have been found that are better adapted for the particular purposes; for some temporary uses cheaper fibers have been found to serve the purpose quite as well; but in many cases hemp has been crowded out for uses where its strength and durability are desirable qualities.

Hemp for marine cordage has been superseded by abacá (Manila hemp) because the abacá ropes, cables, and hawsers are lighter and will float in water and this hard fiber is resistant to injury from salt water without being tarred. Hemp fiber is used in the marlines or twines with which the ends of the larger ropes are bound. The term for measuring this variation in density, but the following figures, which are the averages obtained from a large number of stacks, can be used with fairly satisfactory results:

Length of time in stacks	Number of cubic feet per ton of hay		
	Alfalfa	Timothy and timothy mixed	Wild
30 to 90 days	485	640	600
Over 90 days	470	625	450

These figures, when used with the new rules for determining volume stated above, will give more accurate results than can be obtained from the figures for cubic feet per ton now used in connection with present volume rules.

W. H. HOSTERMAN,

Bureau of Agricultural Economics.

HEMP Fiber Losing Ground, Despite Its Valuable Qualities Hemp is one of the oldest of known textile fibers. There is a definite record that the hemp plant (*Cannabis sativa*) (fig. 79) was cultivated in China for fiber production 27 centuries before the Christian Era. For nearly 5,000 years it has been important and has won an honorable position because of its strength and durability and the well-established fact that it is dependable. Until less than a century ago hemp and flax were the principal fibers of vegetable origin. While flax was the aristocratic fiber for fine linens, laces, and embroideries, hemp was the strong and dependable fiber for ropes, cables, and sails. The name canvas is derived from the Arabic name for hemp. The Pilgrim Fathers at Plymouth and the Cavaliers at Jamestown planted hemp and flax among their earliest crops. The clothing of the men was hempen homespun, and it did not quickly wear out. The famous clipper ships that carried the merchandise on the seven seas until the middle of the last century were outfitted with sails, ropes, cables, halyards, and shrouds all made of hemp fiber. Many of the covered wagons that crossed the plains before 1860 had covers of real canvas.

For many of these uses of former days, hemp has been replaced by other fibers. In some instances fibers have been found that are better adapted for the particular purposes; for some temporary uses cheaper fibers have been found to serve the purpose quite as well; but in many cases hemp has been crowded out for uses where its strength and durability are desirable qualities.

Hemp for marine cordage has been superseded by abacá (Manila hemp) because the abacá ropes, cables, and hawsers are lighter and will float in water and this hard fiber is resistant to injury from salt water without being tarred. Hemp fiber is used in the marlines or twines with which the ends of the larger ropes are bound. The term "hemp rope" has lost its significance for in America ropes are no longer made of hemp.

Cotton, which is adapted to a wider range of uses than other vegetable fibers, has replaced hemp for many purposes, and in most cases advantageously, for it can be spun more easily and with less waste, making smoother and more uniform yarns. Cotton twines, of course. are not as strong or as durable as hemp twines of the same size or weight.

Jute, which was first brought from India to Europe and North America about a century ago, is now used more than all other vegetable fibers combined except cotton. It is the cheapest and most easily spun of any of the soft fibers, and it is well adapted for purposes where strength and durability are of secondary importance but it is the weakest and least durable of the important textile fibers. Jute has replaced hemp for many temporary uses such as covering for cotton bales and

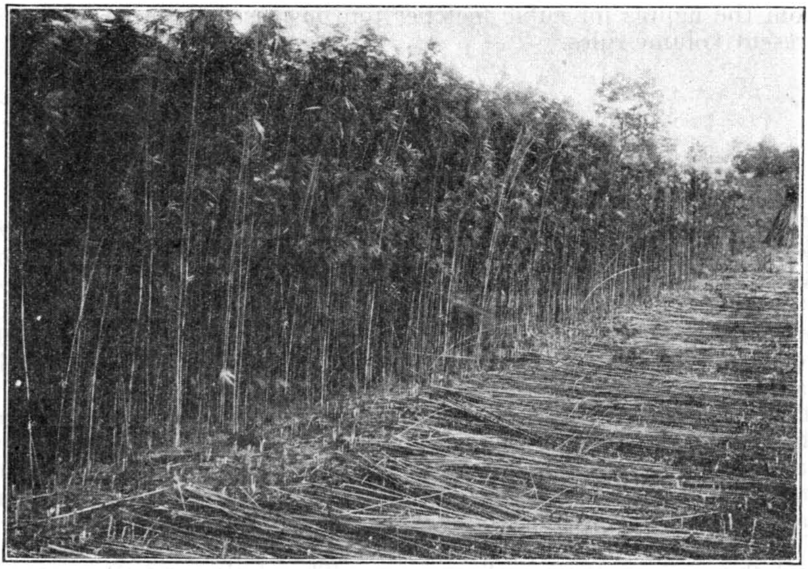

FIGURE 79.—Hemp (*Cannabis sativa*) grown in Kentucky from seed brought from China

packages of merchandise in transit and sacks for coffee, sugar, and grain where the cheaper fiber may give satisfactory service; but the weak and short-lived jute does not give as satisfactory service as the stronger and more durable hemp for twines for tying heavy packages, hop vines that must be exposed to the weather all summer, carpet warp that ought to last many years, or furniture webbing that should last a lifetime.

Owing partly to the resistant character of the fiber itself and partly to the lack of development of special machinery for spinning hemp, this fiber is not spun as efficiently and cheaply as cotton and jute. The average price per pound of scutched hemp fiber is nearly twice the average price of jute and less than the price of cotton, but hemp yarns are more expensive than those of cotton as well as jute.

The uses of hemp have thus been reduced by the competition of cheaper yarns made of other fibers. At the present time water-retted hemp imported from Italy and dew-retted hemp produced in Wisconsin, Illinois, and Kentucky are used for the following purposes:

Wrapping twines for heavy packages.
Mattress twine for sewing mattresses.
Spring twine for tying springs in overstuffed furniture and in box springs.
Sacking twine for sewing sacks containing sugar, wool, peanuts, stock feed, or fertilizer.
Baling twine, similar to sacking twine, for sewing burlap covering on bales and packages.
Broom twines for sewing brooms.
Sewing twine for sewing cheesecloth for shade-grown tobacco.
Hop twine for holding up hop vines in hop yards.
Ham strings for hanging up hams.
Tag twines for shipping tags.
Meter cord for tying diaphrams in gas meters.
Blocking cord used in blocking men's hats.
Webbing yarns which are woven into strong webbing.
Belting yarns to be woven into belts.
Marlines for binding the ends of ropes, cables, and hawsers to keep them from fraying.
Hemp packing or coarse yarn used in packing valve pumps.
Plumber's oakum, usually tarred, for packing the joints of pipes.
Marine oakum, also tarred, for calking the seams of ships and other water craft.

Other fibers are competing with hemp for even this limited list of uses, and for some of these uses increasing proportions of jute are mixed with hemp.

The annual importations of hemp into the United States in the last five years have ranged from only about 1,200 to 2,000 tons, compared with 5,000 to 8,000 tons previous to 1914, and the domestic production amounting to 800 to 1,100 tons per annum is only about one-half that of the years between 1908 and 1913.

HEREDITARY Mutations Induced in Plants by the Action of X Rays

The experimental modification of heredity is one of the oldest problems of science, but until very recent years there was no convincing evidence of the artificial production of hereditary changes in plants or animals. In 1927 Muller, of the University of Texas, in a remarkable series of experiments with the fruit fly, succeeded in demonstrating that mutations (fundamental changes in heredity) are produced in large numbers in that insect by treatment of the germ cells with X rays. It was soon found that mutations may be produced similarly in other animals and in plants, that body cells as well as germ cells may be caused to mutate, and that the radiations of radium produce genetic effects similar to those produced by X rays.

The phenomenon of mutation is fundamental to plant and animal breeding as well as to evolution, since it is the only process, so far as we now know, by which new hereditary determiners arise. Intensive experiments on heredity in plants and animals during the last 30 years have shown that the occurrence of hereditary qualities is dependent on the presence within the cell of minute determiners, or genes, one for each separately inherited modification of the type. Ordinarily the genes are very constant and are distributed with perfect regularity, so hemp imported from Italy and dew-retted hemp produced in Wisconsin, Illinois, and Kentucky are used for the following purposes:

Wrapping twines for heavy packages.
Mattress twine for sewing mattresses.
Spring twine for tying springs in overstuffed furniture and in box springs.
Sacking twine for sewing sacks containing sugar, wool, peanuts, stock feed, or fertilizer.
Baling twine, similar to sacking twine, for sewing burlap covering on bales and packages.
Broom twines for sewing brooms.
Sewing twine for sewing cheesecloth for shade-grown tobacco.
Hop twine for holding up hop vines in hop yards.
Ham strings for hanging up hams.
Tag twines for shipping tags.
Meter cord for tying diaphrams in gas meters.
Blocking cord used in blocking men's hats.
Webbing yarns which are woven into strong webbing.
Belting yarns to be woven into belts.
Marlines for binding the ends of ropes, cables, and hawsers to keep them from fraying.
Hemp packing or coarse yarn used in packing valve pumps.
Plumber's oakum, usually tarred, for packing the joints of pipes.
Marine oakum, also tarred, for calking the seams of ships and other water craft.

Other fibers are competing with hemp for even this limited list of uses, and for some of these uses increasing proportions of jute are mixed with hemp.

The annual importations of hemp into the United States in the last five years have ranged from only about 1,200 to 2,000 tons, compared with 5,000 to 8,000 tons previous to 1914, and the domestic production amounting to 800 to 1,100 tons per annum is only about one-half that of the years between 1908 and 1913.

LYSTER H. DEWEY,

HEREDITARY Mutations Induced in Plants by the Action of X Rays The experimental modification of heredity is one of the oldest problems of science, but until very recent years there was no convincing evidence of the artificial production of hereditary changes in plants or animals. In 1927 Muller, of the University of Texas, in a remarkable series of experiments with the fruit fly, succeeded in demonstrating that mutations (fundamental changes in heredity) are produced in large numbers in that insect by treatment of the germ cells with X rays. It was soon found that mutations may be produced similarly in other animals and in plants, that body cells as well as germ cells may be caused to mutate, and that the radiations of radium produce genetic effects similar to those produced by X rays.

The phenomenon of mutation is fundamental to plant and animal breeding as well as to evolution, since it is the only process, so far as we now know, by which new hereditary determiners arise. Intensive experiments on heredity in plants and animals during the last 30 years have shown that the occurrence of hereditary qualities is dependent on the presence within the cell of minute determiners, or genes, one for each separately inherited modification of the type. Ordinarily the genes are very constant and are distributed with perfect regularity, so that the distribution of hereditary characteristics in a progeny of known parentage may be predicted with statistical accuracy. In very rare cases, however, a gene changes, or mutates, and this is the mode of origin of new hereditary types.

Irregularities in the distribution of the genes also occur occasionally. The normal germ cell contains one complete set of genes and the normal body cell two sets (one from the father and one from the mother). The genes themselves are invisible, but each occupies a definite position in a microscopically visible body within each cell (the chromosome). In many species the appearance of the characteristic set of chromosomes has been closely studied. Various irregularities in the distribution of the chromosomes have been found, resulting in such abnormal conditions as the loss of a chromosome or section of a chromosome, the reduplication of a chromosome or section of it, or the development of an individual with only one set or with three or four sets of chromosomes instead of the normal two sets. These irregularities in distribution produce corresponding irregularities in inheritance.

Experiments at Missouri Station

Experiments on mutation in crop plants have been in progress for several years at the Missouri Agricultural Experiment Station at Columbia, Mo., in cooperation with the United States Department of Agriculture. These experiments involve a study of the frequency of gene mutation and of chromosomal irregularities under normal conditions, and of the effects of various genetic and environmental factors upon the mutation process. The ultimate objective is a definite knowledge of the physical nature of mutation and the physical constitution of the gene.

The normal frequency of mutation in eight genes or determiners for endosperm characters in corn has been measured in an extensive experiment begun in 1924. The frequency of mutation of a specific gene has not hitherto been determined in any plant or animal species, except in the case of genes selected for study because of their previously known high rate of mutation. The eight genes used in this experiment are genes of well-known and wholly normal genetic behavior, and are entirely unselected as regards mutation frequency, since none of them had previously been known to mutate.

The mutation rates were determined by the genetic testing of millions of germ cells. Mutation rate differs widely in different genes, the most mutable gene tested (*R*) yielding about 400 mutations per million, while the least mutable gene (*Wx*) has thus far yielded no mutations among about 2,000,000 germ cells or gametes tested. Mutations have been found in all the genes tested except *Wx*. There is also distinct and consistent variation in the frequency of mutation of the same gene in different families, and the rate of mutation may be increased or decreased by selection.

Mutations Induced in Various Plants

Mutations induced by X-ray treatment of barley were obtained in 1927, and in later experiments about 700 mutations in barley, oats, wheat, and corn have been obtained. The induced mutations appear to be identical with the mutations found in much smaller numbers in untreated material. The rate is proportional to the quantity of radiant energy absorbed and is independent of wave length within the limits of the X-ray spectrum available with present-day equipment. Mutations are induced similarly by beta rays of radium and radiothorium, and by cathode rays. Mutations are induced in dormant cells, but only about one-fifth as frequently as in similarly treated cells at a high level of activity. Mutations are induced readily by treatment of young embryos (seed germs), mature seed (whether dormant or germinating), young plants, or immature or mature germ cells.

The rate of induced mutation is very low in common oats and wheat, apparently because of a reduplication of genes involved in the increased chromosome number of these species. A number of other crop-plant species, including cotton and tobacco, have chromosome numbers similarly increased above those of more primitive related species. It is probable that this factor will limit the application of induced mutation in practical plant breeding.

The frequency of irregular chromosome distribution is also increased greatly by irradiation. A frequent result is the elimination of a chromosome or part of a chromosome. This occurs in early endosperm development in untreated material with a low but measurable frequency. X-ray treatment during early endosperm development greatly increases the frequency of its occurrence. Similar chromosomal deficiencies in the early development of the embryo have not been found in untreated material, but may be induced in large numbers by X-ray treatment. This results in the production of dwarfed and defective plants with at least 50 per cent of their germ cells aborted. The chromosomal deficiency is eliminated in the aborted germ cells, and the self-fertilized progeny of the defective plants are normally vigorous.

Transmission of Partial Sterility

Another type of chromosomal disturbance, occurring sometimes in as high a proportion as 40 per cent of the progeny of an irradiated plant, produces plants apparently normal except for the abortion of half of the germ cells. This semisterility is transmitted to half of the progeny. The same phenomenon had previously been found by other investigators in untreated plants of various species. The cause is apparently a transfer of a section of one chromosome to another, or an interchange of parts between two chromosomes, without any actual loss of genes.

An interesting type of chromosomal variant is the "haploid," a plant with only one set of chromosomes and genes instead of the usual two sets. Several haploid corn plants have been found in the progeny of X-rayed parents. Microscopic examinations have shown the absence of chromosomes or sections in the defective plants, the detachment of nonhomologous chromosomes in the transmissible semisteriles, and the presence of only one set of chromosomes in the haploids.

Practical application of induced mutation is now being attempted in the breeding of corn and certain fruit crops. It is probable, however, that the increased knowledge of heredity which will be secured in genetic experiments with this new technic will ultimately be of much greater value in practical breeding than the immediate applications now possible.

Senior Geneticist, Bureau of Plant Industry.

HIDES and Skins Require Prompt, Thorough Curing to Bring Best Prices

Promptness, thoroughness, and cleanliness are the reading, writing, and arithmetic of producers of properly salted and cured hides and skins. Fresh hides and skins must be cured because they are perishable. Curing is not a process of tanning. It is a treatment to keep hides and skins in a sound condition from the time they come off the animal until they reach the tanner.

Hide is the foundation of all leather. First-quality leather can not be made from a half-rotted hide. Sound hides and skins mean a sound foundation upon which the tanner builds the leather that makes up many of our daily necessities. The careless indifferent producer of poor, partly rotted hides and skins may be sure that they will result in shoes, belting, harness, and luggage that are less serviceable than they might have been had he done his part well.

There is no secret about curing. Except in the far southwestern section of this country, practically all hides and skins are cured with salt, the chemist's sodium chloride, and our common table salt. This does not apply to the skins used for fur. Salt is not required on these, as fur dressers and dyers prefer to have them cured by scraping off the excess fat, placing them on proper stretchers, and allowing them to be air-dried.

Promptness is essential in proper curing because fresh hide will spoil like fresh meat. The instant an animal is killed post-mortem changes and deterioration set in. The hide or skin should be removed quickly and salted promptly, as soon as the animal heat has escaped, which for cattle hides and calfskins usually requires about an hour in a cool place. Sheepskins require more time to cool off. Salting should not be put off or forgotten, as often is the case, until serious decay has occurred, and damage has been done. In hot weather especially salting should be done promptly.

Thoroughness Necessary in Curing

Thoroughness is a requisite of proper curing, because only those hides and skins that are thoroughly salted, or are saturated with salt, keep well. Cakes of salt have been used for money, and indeed to-day salt means money to producers and dealers in hides and skins. An excess of salt in the form of a continuous layer must be used. Folds, wrinkles, and spots that get little or no salt will rot. Two pounds of salt for every 3 pounds of hide or skin is a good proportion. To cure, the salt must get into the hide quickly and not simply on it, which means that the salt should be put on the flesh side.

Cleanliness plays a large part in the curing of hides and skins. Only clean hides and skins thoroughly cured with clean salt can come out with that bright, clean flesh side that the tanner always looks for and pays a premium to get. The exact origin and formation of many discolorations, grain defects, and other damages found in hides and skins is not known, but experience and scientific study of curing conditions have shown invariably that such damage is found to the least extent in those hides and skins that are handled with reasonable cleanliness. Many of these defects are the result in part, if not entirely, of the growth of bacteria and molds. Dirt, dung, blood, and other foreign matter, such as meat and fat, are excellent food for these microorganisms. Naturally the more of this foreign matter that is present the better the microorganisms thrive and the more damage they do.

The use over and over again of the same or recovered salt for curing is one of the worst evils in the production of "country" hides and skins. Used salt is contaminated with dirt, blood, hair, pieces of meat and fat, as well as bacteria and other microorganisms. It can not possibly do a good job of curing. Many small producers and those uninformed think it is economy to use old salt again and again. Such practice is indeed penny wisdom and pound foolishness. The money lost on a single hide damaged from the use of bloody, dirty salt might buy enough salt to cure about 10 hides. Yet some producers and dealers persist in using salt that contains so much dirt and filth that it is hardly recognizable.

If salt must be used again, it should at least be cleaned as much as possible. It should be screened to remove hair and other foreign matter, then piled and a stream of water played on the pile until the drainings run clear. Some salt will be lost in this way, but what remains will be fairly clean. If used, it should be mixed well with at least twice its bulk of new salt. Calfskins should never be cured with dirty used salt.

Kinds of Salt Used

Evaporated salt, rock or mined salt, and solar salt are all used for curing hides and skins. The first two, however, are more generally used because of their much greater production and wider distribution. Though evaporated and rock salt are widely used for both cattle hides and calfskins, many producers and dealers recommend for calfskins the use of evaporated salt only.

Salt is available in a range of sizes. A finer salt is required for curing calfskins than for cattle hides. Sizes G. A., F. C., and C. C. are extensively used for calfskins. (Fig. 80.) Salt of these sizes is slightly coarser than that used for curing meats. The individual particles range in size from grains about like granulated sugar to pieces as large as about one-third of a grain of ordinary polished rice. An even finer salt is better for curing sheepskins. The salt should be thoroughly rubbed into the flesh side of the skin with the hand until the salt "takes hold."

Size No. 1 and the next finer size are best for curing hides, and are widely used by experienced producers and dealers. The particles of size No. 1 will average slightly smaller than dried navy beans. No. 2 salt, which is about twice as large as No. 1, is too coarse to be used alone for curing.

Hides and skins should be cured in a place that is cool and watertight. Rain water dripping on salted hides will quickly wash out the salt and cause decay. A building partly under ground will maintain a more uniform temperature. An old root cellar with a plank floor makes a good hide cellar. A barn floor, if out of direct sunlight, can be used. A drain of some kind is a necessity. The best floor is one of concrete with sufficient slope to carry away all drainings. If a concrete floor is not available, one of heavy planking will do. Never put hides and skins on a dirt floor to cure.

Time Required for Curing

After they are salted, hides and skins should be left until cured, or at least until they become "salt hard" or "salt firm," which takes from 10 to 14 days. The usual time in cure for calfskins is from 2 to 4 weeks, and for cattle hides from 30 to 60 days. Hides and skins should not be rolled into a bundle immediately after salting as the falling away of the salt from parts of the hide or skin during the bundling will result in raw spots and rot.

Sheepskins, primarily because of their wool and grease, heat and spoil very quickly. Consequently they not only should be salted promptly and thoroughly but also should be marketed within five or

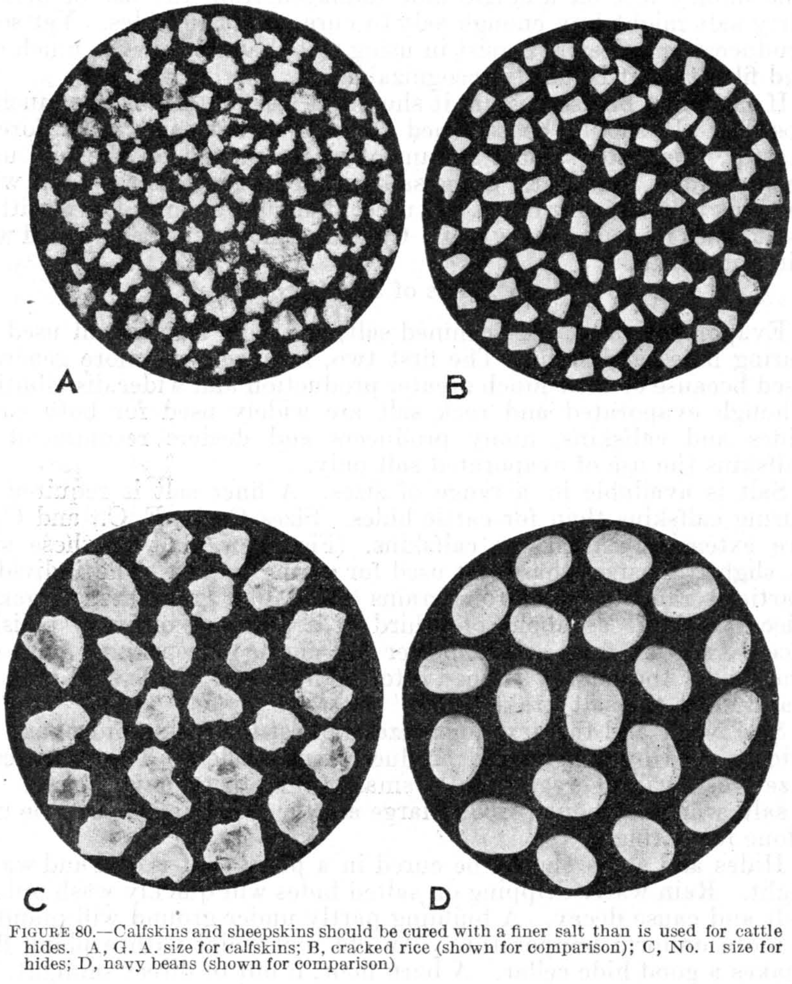

FIGURE 80.—Calfskins and sheepskins should be cured with a finer salt than is used for cattle hides. A, G. A. size for calfskins; B, cracked rice (shown for comparison); C, No. 1 size for hides; D, navy beans (shown for comparison)

six days. For the same reason not more than 10 sheepskins should be placed in one pile and if space is available, it is best not to pile them at all.

Producers and dealers in hides and skins should realize that they are handling a raw material essential for everyday necessities made from leather. The tanner buys hides and skins solely to make leather from them. He prefers those hides and skins that will make the best leather and the most leather, and he pays the best prices for them. Those who handle hides and skins should supply them in the best possible condition. They should learn to recognize condition and quality and thus know what they have for sale and should sell strictly according to the leather-making value of their products.

Since the clear product is also more concentrated the actual dosage represented is approximately four to one. Figure 81, which shows the yearly production of these types of serum, portrays both total output and the relative quantity of each.

Wider Interest in Prevention

The condition mentioned has been brought about by a combination of causes, including more general interest among farmers in protecting hogs against cholera and the requirements of the Bureau of Animal Industry, which supervises the production of all anti-hog-cholera serum authorized for interstate shipment. The bureau's requirements, besides insuring the effectiveness of the serum in protecting hogs against cholera, also safeguard the product against contamination with bacteria that may cause undesirable changes in it or unsatisfactory conditions in animals treated.

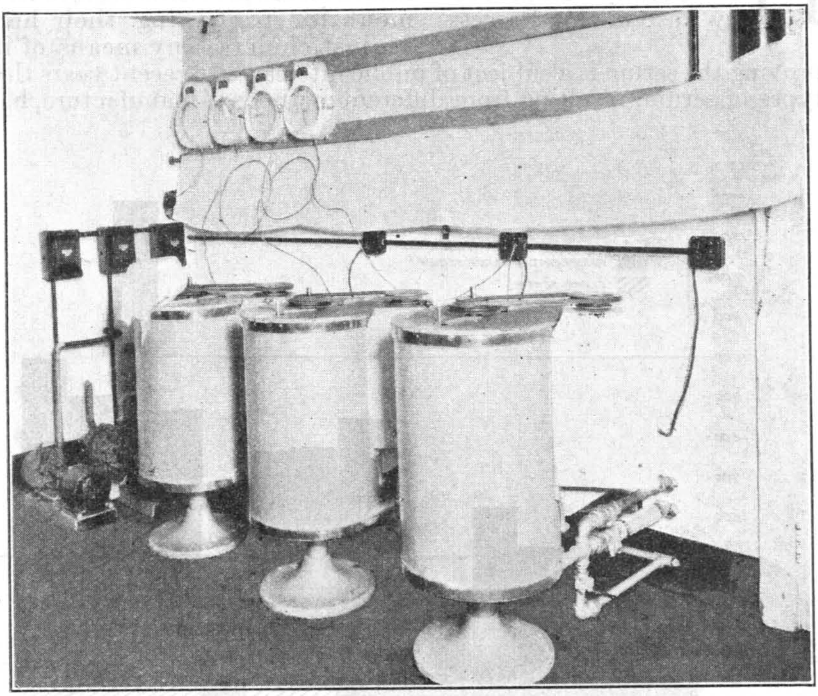

FIGURE 82.—Equipment for pasteurizing and cooling clarified anti-hog-cholera serum. Containers of serum are submerged within each unit shown. Temperatures are recorded by the clocklike devices on the wall

An important step now applied in the preparation of clear serum is efficient pasteurization, which involves heating the product to destroy any undesirable germ life that may be present. In this process the container of serum must be completely submerged in the heating fluid for a specified period. The required procedure is to heat the serum to 59°–60° C., maintain that temperature for at least 30 minutes and then reduce the temperature to 12° in the course of 20 minutes more.

In the development of the process it was necessary to provide new equipment which was devised at the bureau's request and under its direction. Besides providing for the entire submergence of the serum container during the entire heating process, the equipment includes power-driven agitators for thoroughly mixing the product, thus insuring uniform temperatures throughout the container. The equipment also makes use of automatic recording thermometers for registering temperatures continuously during the heating and cooling operations.

The entire procedure results in a product that is either sterile or of very low bacterial content when completed for marketing. Though designed primarily to safeguard the quality of serum and protect the swine industry, the system outlined also aids serum producers by enabling them to improve and standardize methods of production. The serum is handled in larger units than before, with less exposure to adverse influences, and with less cumbersome recording systems. The type of equipment now required for heating and cooling serum is illustrated in Figure 82.

Though all anti-hog-cholera serum produced under Federal supervision is dependable for the prevention of cholera, the clear product is considered superior in several important respects, as follows:

The concentrated product is reduced in bulk, thus enabling the purchaser to procure a given number of protective doses in smaller volume. This means that fewer containers are required for the same number of doses, compared with defibrinated-blood serum.

The clear product is absorbed somewhat more quickly after injection, making it especially suitable for use in herds exposed to the disease.

Its increased fluid character facilitates administration.

The smaller volume required for a dose and for treating a herd makes less filling of syringes necessary.

Advantage of Pasteurization

The most important advantage of clear serum is derived, however, from its pasteurization, which destroys possible sources of infection from infectious abortion, tuberculosis, and other communicable diseases. The pasteurization likewise improves the keeping qualities of the product, enabling serum producers to maintain larger reserve supplies for use in time of large demand.

It is noteworthy also that the strict Federal regulations surrounding the manufacture of the serum, together with hog-cholera virus and other veterinary biological products, have been favorably received and even welcomed by manufacturers of these products. The net result of these developments is the present high standard of purity and potency, thereby aiding materially in the suppression of hog cholera and other livestock diseases in the United States.

D. I. Skidmore,
Chief, Division of Virus-Serum Control,
Bureau of Animal Industry.

HOG Grades Shown Effectively by Use of Plaster Models

Carefully constructed plaster models are now being used as excellent substitutes for live animals in the demonstration of Government standards for grades of livestock, and, in many respects, they are superior to animals in effectiveness.

The greatest problem in livestock standardization work is to devise effective means of transferring the concept of a standard from one mind to another without impairment or modification of the standard. The standard for a Choice grade hog, for example, includes the relationships between the length, depth, and width of body; the proportion between length of legs and size of body; between the thickness of fat also makes use of automatic recording thermometers for registering temperatures continuously during the heating and cooling operations.

HOG Grades Shown Effectively by Use of Plaster Models Carefully constructed plaster models are now being used as excellent substitutes for live animals in the demonstration of Government standards for grades of livestock, and, in many respects, they are superior to animals in effectiveness.

The greatest problem in livestock standardization work is to devise effective means of transferring the concept of a standard from one mind to another without impairment or modification of the standard. The standard for a Choice grade hog, for example, includes the relationships between the length, depth, and width of body; the proportion between length of legs and size of body; between the thickness of fat and size of body, etc. A standard of this kind is rather easily grasped provided one has a concrete example of it, but any word description is always more or less incomplete and subject to different interpretations.

The models now in use are small, and can be taken anywhere for purposes of demonstration. They can be handled as much as one chooses and can be readily viewed from any angle. Finally, in making a model to illustrate a standard all conditions can be controlled. The advantages of this are many.

A grade standard represents uniform development in all respects or, in other words, uniform deviation from a certain point in all characteristics. In the case of hogs for example, there are six grades ranging from Prime to Cull. Good grade is the third from the top of the range and is the fourth from the bottom of the range. The standard for the

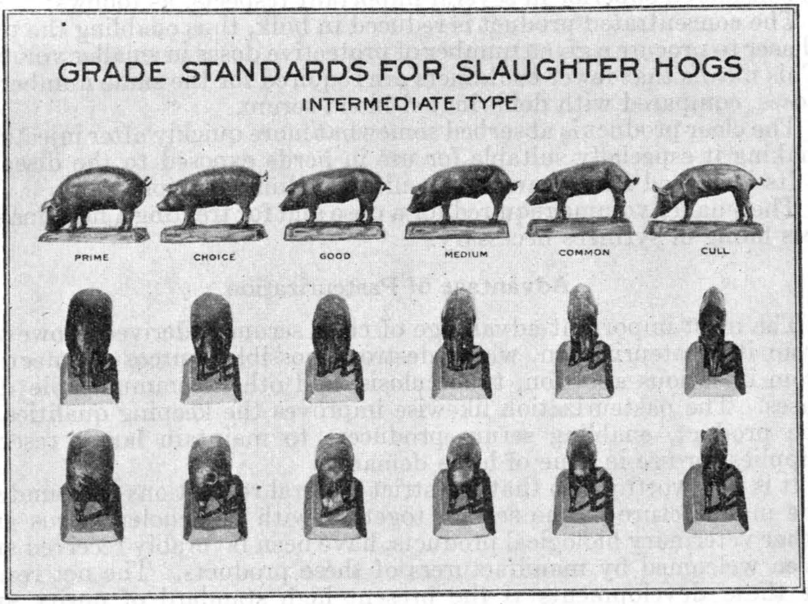

FIGURE 83.—Three views of six clay models illustrating standards for as many grades of intermediate-type slaughter hogs. Note how the bodies become narrower and shallower as they step down grade by grade from Prime to Cull. This means a decreasing proportion of edible flesh and an increasing proportion of bone. Note also a decrease in fat or finish from grade to grade which, within certain limits, means a decrease in tenderness, juiciness, and general palatability. (Models made by Justine A. Warner, Bureau of Agricultural Economics.)

Good grade therefore presupposes conformation that is three steps removed from the best and four steps above the poorest; it is likewise assumed that the finish in the standard for Good grade occupies a similar position in the scale of finish, and that the quality in the standard is similarly situated in the scale of quality.

In constructing a model this can easily be brought about, but in live animals it seldom, if ever, occurs. An animal usually is superior in certain respects and deficient in others. This fact offers little or no difficulty in grading, but it is a serious defect when the animal is used to represent a standard.

Artist's Collaboration Obtained

The value of models in presenting standards has long been appreciated, but it was thought that the services of a sculptor were required.

Collaboration between the livestock specialists and an artist worker in the Bureau of Agricultural Economics, however, recently resulted in an excellent set of clay models illustrating standards for six grades and three types of slaughter hogs. These were then used to make plaster casts which were painted to resemble live animals. (Fig. 83.)

Requests have been received from all parts of the country and from all branches of the swine industry for duplicate sets of the models. Shipping association managers and packer buyers expect to find them useful in maintaining uniformity in their grading and buying. Livestock market reporters find them an aid in reporting trade conditions and prices on a grade basis. Teachers and animal husbandry instructors plan to use the models in class work and in training judging teams. Presentation of standards by these models has attracted so much favorable comment that it is now planned to extend the scheme to cattle, sheep, and lambs.

Hogs That Produce the Best Export Pork Also Make Good Domestic Cuts

The American consumer is gradually demanding pork products that contain a larger amount of lean in proportion to fat. This is a development in consumer preference that the producer should keep constantly in mind. In days gone by, the big lumber and railway-construction camps used large quantities of dry salt sides of pork, but those days are over. The laboring man of the past drew a small wage and was practically compelled to buy cheap cuts of meat, but now the laboring man draws a good wage and demands a much better quality of meat than formerly.

A different type of hog weighing much less at slaughter is now in favor. When dry salt sides of pork were wanted, the demand was for a hog with a slaughter weight of 300 pounds or more; but the present demand is for a hog with a slaughter weight of about 200 pounds, rather long, fairly deep, fairly well finished, and carrying a good proportion of lean meat.

Every outlet for his product is of value to the American pork producer; consequently, he should be keenly interested in the foreign demand for pork products. Several European countries are buyers of pork products from the United States, but the English market is probably the most discriminating and pays the best price when it gets its favorite cut, the Wiltshire, cured as it wants it. This cut is the whole side of the hog, except the head and feet, cured as one piece.

Experiment Station Results

For several years investigators of the department have been experimenting at the United States Range Livestock Experiment Station, Miles City, Mont., to determine the methods by which American hog raisers can produce satisfactory Wiltshire sides from their own breeds receiving the feeds commonly grown in this country.

As the Chester-White hog most nearly represents the Landrace hog of Denmark, which is used in that country in the production of Wilt-

This cut is the whole side of the hog, except the head and feet, cured as one piece.

Experiment Station Results

For several years investigators of the department have been experimenting at the United States Range Livestock Experiment Station, Miles City, Mont., to determine the methods by which American hog raisers can produce satisfactory Wiltshire sides from their own breeds receiving the feeds commonly grown in this country.

As the Chester-White hog most nearly represents the Landrace hog of Denmark, which is used in that country in the production of Wiltshires, the Chester-White breed and the Yorkshire, which the Danes also use, were selected for this experiment. In the production of these hogs both the Chester-White and Yorkshire sows are bred to Chester-White boars and also to Yorkshire boars, resulting in four lots: Purebred Chester-White and Yorkshire pigs and crossbreds, both ways.

The hogs are fed and handled in very much the same manner as any good farmer would manage his hogs. They are full-fed barley and tankage and kept on alfalfa pasture from weaning until they reach about 200 pounds, live weight, when they are sent to market for slaughter.

The pigs raised from the spring litters of 1929 were slaughtered in Milwaukee, and a number of Wiltshires from each of the four lots were cured and sent to England for sale. There was some variation in the quality of the different sides in each lot and the prices showed this clearly. But the general results were highly satisfactory.

Representatives of the firm handling the shipment on the Liverpool market made the statement that the entire shipment was superior to any previous arrival of the same brand of Wiltshire received at that port, the type of hog being very much superior. They added:

> By this we mean long sides, leaner and quite equal to the best brands of Canadian bacon. We are delighted to see that the Government is taking such an interest in the future of the Wiltshire hog and we hope the production of this type will be considerably increased. We do feel there is a great future for American bacon provided you can get the farmers to produce the right type of bacon hog.

It is interesting to note that as good Wiltshires were produced from Chester Whites, a lard breed, as from Yorkshires, a bacon breed, and as from the crossbreds. Careful attention was given to the selection of breeding animals used in this experiment, but it is believed that equally as good results could be obtained from carefully selected individuals of any of the other lard breeds. Proper selection of the individual is of more importance than choice of breed.

In these experiments the investigators made domestic cuts from many of the carcasses, and it has been found that a hog making a good Wiltshire will also make a very satisfactory domestic cut. American hog men, therefore, with American hogs on American-grown feeds, can produce pork which will meet highest market favor both at home and abroad.

E. Z. Russell,
Senior Animal Husbandman, Bureau of Animal Industry.

HOME Demonstration Work is Democratic Education of Adults

Democracy in education is a fact in rural America. The United States Government and the rural woman have become partners in an endeavor of significance to all who are interested in physical, social, educational, and civic well-being. This principle of true democracy finds practical expression in home demonstration work, an endeavor whose objective is to make rural home and community life more satisfying and efficient.

Originally this service was conceived as a means of taking to rural home makers the vast accumulation of scientific facts which were in the possession of the United States Department of Agriculture and the experiment stations of the State colleges of agriculture, which would be of help to rural home makers.

shires, the Chester-White breed and the Yorkshire, which the Danes also use, were selected for this experiment. In the production of these hogs both the Chester-White and Yorkshire sows are bred to Chester-White boars and also to Yorkshire boars, resulting in four lots: Purebred Chester-White and Yorkshire pigs and crossbreds, both ways.

Home Demonstration Work is Democratic Education of Adults

Democracy in education is a fact in rural America. The United States Government and the rural woman have become partners in an endeavor of significance to all who are interested in physical, social, educational, and civic well-being. This principle of true democracy finds practical expression in home demonstration work, an endeavor whose objective is to make rural home and community life more satisfying and efficient.

Originally this service was conceived as a means of taking to rural home makers the vast accumulation of scientific facts which were in the possession of the United States Department of Agriculture and the experiment stations of the State colleges of agriculture, which would be of help to rural home makers.

Gradually, however, enlarged objectives developed as the technically trained representatives of the colleges and the department realized the valuable contribution which these home makers could make in vitalizing the endeavors of these State and Federal institutions.

To-day, there is a mutual give-and-take relationship. The representatives of the colleges and the department meet with the rural home maker on a coordinate basis, the home economists contributing the latest information of the research laboratories, the home makers contributing the practical judgment born of sustained rural home-making experience, plus knowledge of rural conditions based upon actual participation as members of rural communities.

This present plan is a sound but belated recognition of the educational value of practical experience and judgment born of repeated endeavor.

As a result of this united effort, the programs and plans evolved are not only scientifically accurate but they are psychologically sound, being based upon the knowledge of local people as to the needs, desires, and abilities of their communities. Such procedure has assured interested local cooperation and participation.

The Procedure Followed

The procedure followed in counties in many States is as follows: Each year approximately 15 to 20 home makers who are members of local home demonstration groups are chosen as a county home committee. The women so chosen continue as members of local groups to learn from the home demonstration agent or specialist such improvements in home-making activities as are included in the year's program, but they have additional duties. They are evaluating local needs. They are objectively observing conditions in their own homes and in those of their neighbors; they are evaluating the quality of home equipment and supplies to be found in the local stores; they are questioning members of their home demonstration groups as to their interests; they are analyzing the social and civic satisfactions of the community as a whole. They are seeking the viewpoint of merchants, bankers, editors, and others as to home and community needs. If needed facts are missing they make surveys to obtain them.

From time to time, these women meet with the home demonstration agent to discuss their observations. Once a year they meet to decide formally upon the county-wide program for the ensuing year. The agent, too, has been making observations. The State leader of home demonstration work from the agricultural college, who is usually present at this program-planning meeting, has also been making observations of the county, less intensively but with more perspective.

The meeting is opened by the county chairman. Discussion is general and informal. Analysis of local conditions is first considered. This is followed by decision as to basic needs. There is further discussion in relation to the viewpoint of local home makers, merchants, and others. The practicability of each suggestion is weighed by the trained staff and the home makers, and finally there emerges a program which is vitally related to local conditions and interests and which is of immediate value to home makers throughout the county.

The selection of the program is but one part of the duties of this committee. They also help to determine practical ways and means of interesting large numbers of home makers to follow the suggestions to be recommended. As a means to this end, consideration is given to the possibility of local tours, window displays, circular letters, exhibits, contests, special meetings, and the like, and a complete plan of procedure is determined with delegated responsibilities assigned to all concerned.

Home Makers Participate in Organized Work

In addition to the plans for the content and procedure for the home demonstration program, this committee helps to plan means of interesting more women in regular participation in the organized endeavors of these rural home makers, and to strengthen the groups already formed. They visit local group meetings; they check the publicity given to the work by local newspapers; they endeavor to increase the activities of each local group to include one matter of interest to all members of the community; they urge groups to sponsor a 4-H girls' club. Thus the group serves as a general efficiency committee to aid the home demonstration agent so to plan that a maximum of service and opportunity is given to the rural home makers of the county.

The constructive results of this democratic plan are manifold. It has vitalized the interest of home makers, for the plan and the program are their own. It has challenged their judgment to know that their viewpoint is of vital concern in planning an educational program. It has aroused the interest of increasing numbers of women and caused them to participate in the work. It has stimulated them to keen, impersonal analysis of their homes and their communities. It has made local merchants and others recognize the practical nature of home demonstration work. It has humanized educational methods. It has challenged educators to know conditions and to offer practical solutions to meet recognized needs. It has helped the colleges of agriculture and the Department of Agriculture to know the basic problems toward which these agencies may direct their endeavors.

Theory and Practice United

It is an example of true democracy. There is give and take. There is adjustment of the logical theory of the trained staff to the practical conditions of everyday life; and there is the challenge to the home maker from the trained staff as to her interests, standards, and practices.

This plan is a stimulating challenge to all concerned. It is a step in vitalizing educational procedure which is making of education a thing to be desired by home makers and a profession second to none for the trained staff. For the State and Federal institutions it is an efficient means of determining upon wise procedure in bringing about a maximum of service in their expenditure of public funds.

Grace E. Frysinger,
Senior Home Economist,
Office of Cooperative Extension Work.

HONEY Has Many Possibilities of Use as Yet Undeveloped Honey production in the United States is estimated at 200,000,000 to 250,-000,000 pounds annually, valued at between $20,000,000 and $25,000,000. In some States, such as California, production of honey is a considerable industry.

Exports of honey to foreign countries during 1929[4] amounted to almost 12,000,000 pounds, valued at over $1,000,000. This figure compares favorably with exports of honey for the past 12 years, being higher than for any year except 1918, when approximately 16,000,000 pounds of honey valued at about $2,500,000 was exported. From 1921, when only 1,112,015 pounds of honey was exported, until 1930, the general trend of exports has been upward. However, exports of honey in 1930 decreased to approximately 6,500,000 pounds. This decrease is very probably due in large measure to the action taken by certain foreign countries in protecting their own honey industries against outside competition. Germany, for example, increased the duty on honey from 4⅓ cents a pound net to 7 cents a pound gross, effective December 31, 1929. Exports of honey to Germany in 1930 were considerably less than in 1929. In the past Germany has been the largest consumer of American honey.

During the past two or three years a number of shipments of American honey to Germany were penalized as a result of claims by German importers that the honey was deficient in diastase. Until recently very little attention has been given in this country to the presence of diastase and other enzymes in honey, although in Germany some importance appears to be attached to their presence. German investigators have assigned a definite physiological value to diastase and other enzymes of honey, and honey that is deficient in these enzymes (either naturally or as a result of heating) is considered as being no longer "genuine" and is regarded as a "denatured" product.

Honeys Tested for Diastase Content

A large number of samples of unheated American honeys have been examined for diastase content by the Carbohydrate Division of the Bureau of Chemistry and Soils. These samples represented a great variety of floral types, and were obtained from practically every honey-producing region of importance in the United States. The results of this investigation showed that the diastatic activity of honey of most of the types examined was quite high, comparing favorably with German honeys in this respect. Orange and alfalfa honeys showed low diastase values, even when unheated, although the honeys themselves were excellent in quality. With this information available it should be possible for exporters to make a more suitable selection of honey for foreign requirements.

Stimulation of domestic consumption of honey is needed, however, to counteract the effect of a decline in exportation. Honey has some valuable properties not possessed by other saccharine materials used as a substitute for it. The flavor of honey is a valuable asset that is not duplicated by other products of somewhat similar sugar content. With such a great variety of floral types from which to choose, interest-

[4] The years for which exports are given are in each instance fiscal years, i. e., the annual period beginning July 1 and ending June 30.

ing possibilities suggest themselves for utilizing the individuality of each flavor. Featuring honeys of approximately individual floral source offers an opportunity of extending consumption of honey. Many persons to whom blended honey does not appeal might find honey of some particular flavor to their liking. The fact that honey exhibits such a great diversity of attractive flavors is an asset that is only imperfectly utilized in blended honeys.

Uses of Dark Honey

While there is produced, especially in the South, a large quantity of dark honey of fine quality and flavor, there are also produced in this country at the present time considerable quantities of honey the color and flavor of which restrict marketability for table purposes. This dark honey of inferior quality must be sold either in localities where people are accustomed to it, or to the baking trade. Large quantities of dark honey are used by baking concerns for increasing the retention of moisture by cakes and bread, thereby keeping these products soft and moist for longer periods of time. This effect is due to a great extent to the levulose present in honey, which, being extremely hygroscopic, has a pronounced effect in retarding the drying of baked goods. Furthermore, the hygroscopicity of the levulose is increased by certain nonsugar substances present in honey. The fact that honey usually contains a preponderance of the sugar levulose as compared with dextrose gives it a distinct advantage for use in baking and is a good illustration of the beneficial effect of certain specific constituents.

Difficulties arise in using honey for candy making, since many honeys possess poor cooking qualities. High temperature causes decomposition with resulting discoloration and off-flavor. Results of an investigation of various nonsugar constituents of honey being conducted by the Carbohydrate Division of the Bureau of Chemistry and Soils indicate that these substances have considerable influence on the behavior of honey when heated. Honey treated by a new and simple process whereby a large proportion of the colloidal substances in it are flocculated and removed showed considerable improvement in its ability to withstand elevated temperatures as shown by candy tests. These results promise to lead to a method of treatment of honey that will make it more suitable for use in candy making and for similar purposes, where heating to moderately high temperatures is required. It is to be understood, of course, that such treatment is applicable only to honey which is to be used for purposes for which heating to a fairly high temperature is required and that it is not needed for honey intended for table use.

Additional Research Necessary

There is also need for additional information on the suitability of honeys of various floral types for use in candy and for similar purposes. More honey could probably be used in this way if the manufacturer were certain that he could always obtain honey of suitable quality. Owing to the great variability of honey from different floral sources, considerable study will be required to reveal the underlying causes for the difference in behavior. Recent investigations of the nonsugar compounds present in honey and the effect of their removal on color and flavor promise to result in a method of treatment whereby some low-grade honeys can be converted into honeys suitable for table consumption.

In conclusion, it is believed that increased knowledge regarding the constituents of honeys of various types and the way in which they influence the suitability of honey for different specific purposes will lead to a greater appreciation of the merits of honey as a constituent of other foods and will point the way to its more extensive use in a number of food industries.

R. E. LOTHROP,
Assistant Chemist, Bureau of Chemistry and Soils.

HONEY Production in Mountain States Favored by Local Conditions The intermountain region is one of the important honey-producing regions of the United States. Many carloads of honey are shipped each year to both the eastern and Pacific coast markets as well as to foreign countries, only a very small part of the crop, up till 1930 at least, having been consumed locally. There is considerable demand for this honey, particularly for the honey-bottling trade, because of its uniformly fine qualities, such as light color, heavy body, and flavor due to type and purity of nectar source.

This region comprises primarily the States of Colorado, Wyoming, Montana, Idaho, and Utah, and parts of Nevada, although western Nebraska and the Dakotas, eastern Washington, and eastern Oregon should also be considered in this connection because in them a similar type of honey is produced. The main part of the region is traversed from north to south by the Rocky Mountains. There are many fertile valleys throughout the mountainous sections, while to the east is the Great Plains area crossed by numerous rivers having their sources in the mountains. The altitude of the various honey-producing centers varies from about 2,300 feet in parts of Idaho to 7,700 feet in the San Luis Valley of Colorado, with a large part of the region averaging around 1 mile above sea level.

Notwithstanding the differences in altitude, the rainfall is nowhere great, but is more or less variable owing to the effect of the mountain formations. It ranges from 6 or 7 inches annually in parts of Colorado and Wyoming to 18 or 20 inches in parts of Montana, but with a large part of the region averaging only from 10 to 15 inches. For this reason the agriculture of the region is almost entirely dependent upon irrigation for moisture, the water being obtained from streams arising in the mountains and fed by melting snow. Therefore the honey-producing areas of the various States are practically delineated by the irrigation projects. However, although the amount of rainfall is low and the air of the region is quite uniformly dry, the conditions are most favorable for nectar secretion where water is available because of the fertile soil, the high percentage of sunshine, and the fact that in these high altitudes there is sufficient variation between day and night temperatures to insure abundant nectar secretion.

Beekeeping Industry on Commercial Basis

Honey production is one of the well-recognized agricultural industries in this region. (Figs. 84 and 85.) A great majority of the bee-low-grade honeys can be converted into honeys suitable for table consumption.

In conclusion, it is believed that increased knowledge regarding the constituents of honeys of various types and the way in which they influence the suitability of honey for different specific purposes will lead to a greater appreciation of the merits of honey as a constituent of other foods and will point the way to its more extensive use in a number of food industries.

There are many fertile valleys throughout the mountainous sections, while to the east is the Great Plains area crossed by numerous rivers having their sources in the mountains. The altitude of the various honey-producing centers varies from about 2,300 feet in parts of Idaho to 7,700 feet in the San Luis Valley of Colorado, with a large part of the region averaging around 1 mile above sea level.

Notwithstanding the differences in altitude, the rainfall is nowhere great, but is more or less variable owing to the effect of the mountain formations. It ranges from 6 or 7 inches annually in parts of Colorado and Wyoming to 18 or 20 inches in parts of Montana, but with a large part of the region averaging only from 10 to 15 inches. For this reason the agriculture of the region is almost entirely dependent upon irrigation for moisture, the water being obtained from streams arising in the mountains and fed by melting snow. Therefore the honey-producing areas of the various States are practically delineated by the irrigation projects. However, although the amount of rainfall is low and the air of the region is quite uniformly dry, the conditions are most favorable for nectar secretion where water is available because of the fertile soil, the high percentage of sunshine, and the fact that in these high altitudes there is sufficient variation between day and night temperatures to insure abundant nectar secretion.

Beekeeping Industry on Commercial Basis

Honey production is one of the well-recognized agricultural industries in this region. (Figs. 84 and 85.) A great majority of the beekeepers are commercial honey producers, deriving their chief income from this source. Most of the honey produced is in the form of extracted honey, although there still are some sections, notably parts of Idaho, where considerable comb honey is produced.

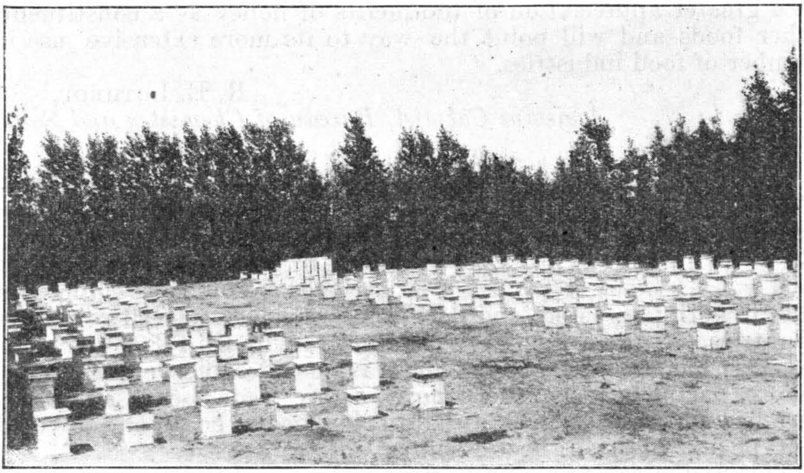

FIGURE 84.—A well-located Wyoming apiary surrounded by an excellent windbreak

The outstanding characteristics of the honey from the Intermountain States are its uniform delicate flavor, light color, fine texture, and heavy body. Practically all of the honey from these States and from parts of the surrounding States is derived from alfalfa and sweet clover. Alfalfa is one of the principal crops of the irrigated sections, while

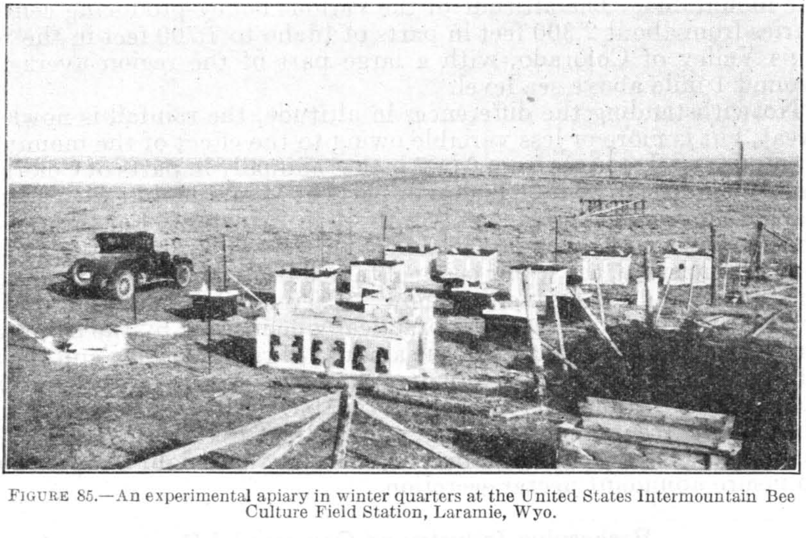

FIGURE 85.—An experimental apiary in winter quarters at the United States Intermountain Bee Culture Field Station, Laramie, Wyo.

sweetclover thrives in abundance along the ditch banks and near-by waste places where not actually grown as a seed or forage crop. Dandelion and fruit bloom serve as excellent stimulating sources for the bees in the spring, but the surplus from these does not produce good commercial honey. Other sources of nectar are negligible, and in most cases the bees will desert other plants to work on the alfalfa and sweetclover when they come into bloom. This accounts for the purity of flavor and color of the honey from this region.

Another characteristic of alfalfa and sweetclover honeys is the rapidity with which they granulate and the fine texture of the granulation when the honey has not been heated sufficiently to retard the process. This granulation presumably is due, at least in part, to the fact that there is a slightly higher percentage of dextrose than levulose in these honeys. Granulation is an advantage for extracted honey, particularly where the honey has to be shipped long distances.

HORTICULTURAL Practice Greatly Changed in Last Quarter Century A 25-year period is a short space of time, relatively, by which to measure fundamental changes in an art that is as old as the human race, yet within that period science and the application of sound business principles have effected some notable changes in horticulture.

In orcharding, pruning practices and the use of fertilizers have undergone great changes as a direct result of scientific investigation. Though these two operations are very diverse, they have close relationships in their effect on the nutritional condition of the tree, especially with respect to stored-up food supplies within the tree. The plant physiologist, by means of biochemical methods, has found out something about what the tree does under different conditions as affected by pruning and feeding; he has determined the plant-food content of fruit spurs and twigs and its relation to fruit-bud formation and the setting and development of fruit; also that these factors may be decidedly influenced both by pruning and by fertilizing.

In line with the earlier understanding of pruning principles, the regular pruning for young fruit trees consisted of severely heading them back each year, in the belief that it made them stocky and well-branched. But such pruning, as a rule, undoubtedly delayed by years the time when the trees came into bearing; and if summer pruning was done, the expected resultant formation of fruit buds was more likely than otherwise not to be realized.

It is now known that heavy cutting back of the annual growth of young trees removes large quantities of stored-up plant-food materials otherwise available in the future development of the tree and that in summer pruning the removal of a large amount of leaf surface commonly deprives the tree of needed food-elaborating apparatus just when it is required for the proper functioning of the tree. The practical effect of this newer knowledge of the physiology of tree growth has been to reduce the pruning of young trees to the minimum consistent with corrective training.

In close relationship with this is the matter of food requirements and supplies as affected by the application of commercial plant foods. The present understanding of such requirements involves the practice now widely followed in the regular use of quickly available forms of nitrogen at certain periods in the season. Earlier teachings cautioned against the use of nitrogen except very sparingly.

commercial honey. Other sources of nectar are negligible, and in most cases the bees will desert other plants to work on the alfalfa and sweetclover when they come into bloom. This accounts for the purity of flavor and color of the honey from this region.

HORTICULTURAL Practice Greatly Changed in Last Quarter Century A 25-year period is a short space of time, relatively, by which to measure fundamental changes in an art that is as old as the human race, yet within that period science and the application of sound business principles have effected some notable changes in horticulture.

In orcharding, pruning practices and the use of fertilizers have undergone great changes as a direct result of scientific investigation. Though these two operations are very diverse, they have close relationships in their effect on the nutritional condition of the tree, especially with respect to stored-up food supplies within the tree. The plant physiologist, by means of biochemical methods, has found out something about what the tree does under different conditions as affected by pruning and feeding; he has determined the plant-food content of fruit spurs and twigs and its relation to fruit-bud formation and the setting and development of fruit; also that these factors may be decidedly influenced both by pruning and by fertilizing.

In line with the earlier understanding of pruning principles, the regular pruning for young fruit trees consisted of severely heading them back each year, in the belief that it made them stocky and well-branched. But such pruning, as a rule, undoubtedly delayed by years the time when the trees came into bearing; and if summer pruning was done, the expected resultant formation of fruit buds was more likely than otherwise not to be realized.

It is now known that heavy cutting back of the annual growth of young trees removes large quantities of stored-up plant-food materials otherwise available in the future development of the tree and that in summer pruning the removal of a large amount of leaf surface commonly deprives the tree of needed food-elaborating apparatus just when it is required for the proper functioning of the tree. The practical effect of this newer knowledge of the physiology of tree growth has been to reduce the pruning of young trees to the minimum consistent with corrective training.

In close relationship with this is the matter of food requirements and supplies as affected by the application of commercial plant foods. The present understanding of such requirements involves the practice now widely followed in the regular use of quickly available forms of nitrogen at certain periods in the season. Earlier teachings cautioned against the use of nitrogen except very sparingly.

Changes in insect and disease control have occurred both in insecticides and fungicides and in spraying equipment, but they have been less revolutionary than changes in many other aspects of horticulture.

Breeding and Selection

In the improvement of horticultural varieties by breeding and selection the period covered by this article has witnessed material advancement. While most horticultural varieties of fruits originated as chance seedlings, the planting of selected seeds with a view to obtaining better varieties was both advocated and practiced many years ago, but the principles of plant breeding and heredity were not then understood. In fact, the whole science of plant breeding is new. During the period under consideration great advancement has been made through the application of the laws of genetics, though most of the results are still too new to be as yet fully appraised.

Some of the striking improvements of varieties by breeding are in the field of olericulture and in the direction of disease resistance—for example, the Washington strains of asparagus, which are resistant to rust; disease-resistant tomato varieties that have superseded older sorts susceptible to wilt and other diseases; cabbage varieties resistant to yellows; and new lettuce varieties that have contributed largely to the vast expansion of a regional industry.

Fruit improvement by bud selection has been carried far in recent years. Prior to 20 years ago little attention was given to the bud variations or mutations occasionally seen in fruit trees. Their significance for "weal or woe" was not recognized. The fact that bud variations occur on fruit trees (perhaps more often than is commonly realized) has been established; also the fact that such variations are perpetuated in progeny trees propagated from them. These mutations may represent either much of value or utter worthlessness.

Very much the same idea is involved in the seed potato improvement plan which in recent years has become generally adopted in the commercial potato-growing regions of the country. It recognizes superior yielding strains within the variety. In many cases the superiority is in the absence of virus diseases which deplete the vigor of the plants. Such strains may be "certified" by properly constituted authorities. The use of certified seed by the growers has undoubtedly been by far the most potent factor in increasing the average acre yield of potatoes for the country by nearly 20 bushels since about 1900.

Self-sterility or self-unfruitfulness in fruit varieties has become recognized within the last 20 or 25 years as a basic orchard problem of far-reaching purport. Though much research work remains to be done in this field, the fact is now widely recognized that cross-pollination for fruitfulness is the rule rather than the exception in the majority of tree fruit varieties.

Influence of Rootstocks

In the matter of rootstocks used in propagating fruit trees and other plants, the conception, long prevailing, to the effect that the stock as a rule had little or no influence on the characteristics of the top has largely given place to the view that the rootstock greatly influences the top and its behavior. Much effort is being put forth to find better stocks. The use by commercial propagators of domestically grown fruit stocks in place of imported stocks is in rather rapid transition.

Improved roads and motor-truck transportation have done much to eliminate the distance factor in the geography of production. Formerly a grower of perishable crops who was more than 4 or 5 miles from market or shipping station was seriously handicapped. Now transportation of horticultural products 50 or 100 miles or more by motor truck is not unusual. Adequate transportation facilities and other agencies have made possible the winter-garden industry whereby tomatoes, lettuce, peas, snap beans, and other vegetables are grown in extensive quantities in some of the warmer sections such as southern Florida, southern Texas, and the Imperial Valley in southern California, not to mention the development on the west coast in Mexico, and supplied fresh to the markets of the country throughout the winter months. The extensive growing of other crops in some of these sections is in reality a part of the same enterprise; for instance, the thousands of carloads of muskmelons produced annually in the Imperial Valley. Not only has the geography of production been changed, but meanwhile the greenhouse industry in which some of these winter-garden crops were grown under glass in the North has undergone considerable modification.

Roadside marketing as a real factor in the disposal of horticultural commodities has largely come during the past decade. It may be noted in passing that many thousands of dollars in the aggregate are invested in roadside marketing facilities, and hundreds of thousands of dollars worth of produce are sold annually from roadside stands.

Ornamental horticulture has experienced marked expansion in some directions in recent years, while other fundamental changes in horticulture have been made and are still taking place.

ICE-WELL Refrigeration for Dairy Farms Works Well at Mandan, N. Dak. Ice wells for cooling and storing milk and cream on the farm may be a satisfactory solution of the refrigeration problem on many dairy farms where the usual methods are too expensive or impracticable.

The ice-well "refrigerator" consists primarily of a pit in the ground in which a large solid cake of ice is formed by running a small quantity of water into the hole daily during freezing weather. The method has been tried to some extent on dairy farms in Canada, but no information regarding its adaptation in the United States had heretofore been available.

Following closely the plans suggested by the Saskatchewan Department of Agriculture, the Bureau of Dairy Industry, in cooperation with the North Dakota Agricultural College, constructed an ice well in the fall of 1928 at the United States Dairy Experiment Station at Mandan, N. Dak., to test the possibilities of the method under conditions there.[5] (Fig. 86.)

On a well-drained spot near the milk house and convenient to a well a pit was dug 8 feet square and 9½ feet deep. The sides were boarded up with cheap lumber and the bottom covered to a depth of 1½ feet

[5] A. L. Watt, superintendent of the U. S. Dairy Experiment Station at Mandan, N. Dak., collected the data presented here.

with coarse gravel to insure good drainage. A small house was built over the pit. (Fig. 87.) The floor was of two thicknesses of planking with building paper between the layers, and it was built in sections to permit easy removal during freezing weather. Windows in the house provided air circulation in the winter, but were closed during the summer. A wooden rack or basket suspended from a pulley overhead served for raising and lowering the cans of cream and other food products held in storage. (Fig. 88.)

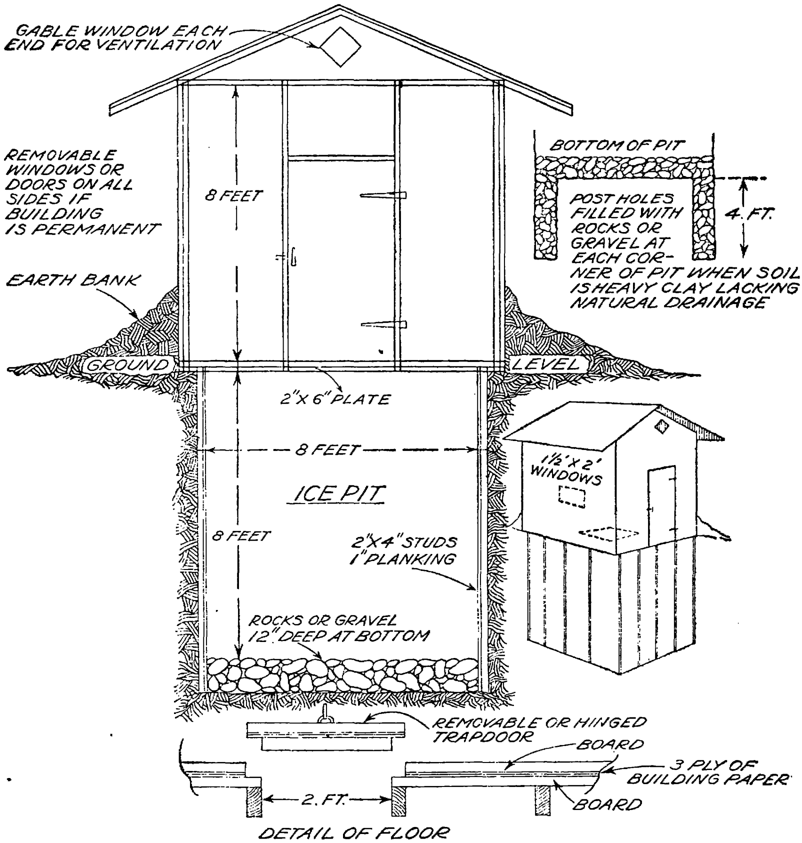

FIGURE 86.—Details of ice well and shelter building. There seems to be no reason why the well can not be of any size that is practical; the measurements above are only suggested

Freezing was started in January, 1929. Two to four gallons of water were run into the pit each day and allowed to freeze until a layer of ice was started. Some difficulty was experienced in getting the first layer of ice to form because the water drained out rapidly. After the formation of the first layer sufficient water was added each day to make a layer of ice from 1 to 3 inches thick, depending upon the outside temperature. By the end of February a solid cake of ice 8 feet square and 6½ feet deep had formed. When freezing weather was over, the house was closed tightly and the floor replaced.

Mean Winter Temperatures

The mean average temperature in this vicinity for January and February was $-2.9°$ and $4.6°$ F., respectively. The highest temperature for the two months was 38°, and the lowest was $-43°$.

Storage of cream was started May 25 and the ice lasted until September 28, a period of 126 days.

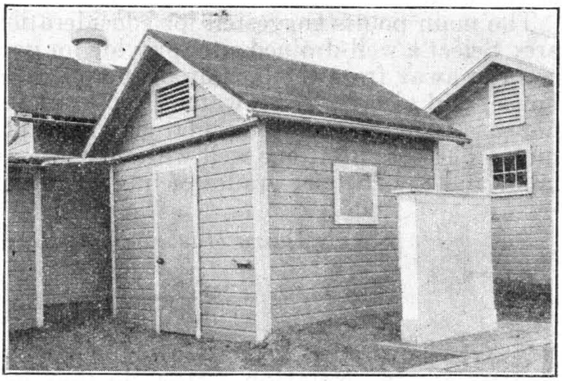

FIGURE 87.—Shelter house over ice well. Doors and windows are kept open in freezing weather and closed as much of the time as possible in summer. The scales at right had no part in the ice-well experiments

Careful records were kept throughout the summer. Cream cooled with well water to 56.5° F. and placed in the rack in the pit at 8.30 a. m. was cooled to 48° within three hours and to 42° by 4.30 p. m. Cream in cans placed directly on the ice was cooled to 34° in the same period. Cream was kept perfectly sweet for 14 days in July, the hottest part of the summer. The cream was in small lots, varying from 20 to 25 pounds. The temperature in the pit an inch above the ice varied from 32° to 42°. Six inches above the ice it varied from 44° to 50°; and a foot above the ice the temperature was never higher than 50°.

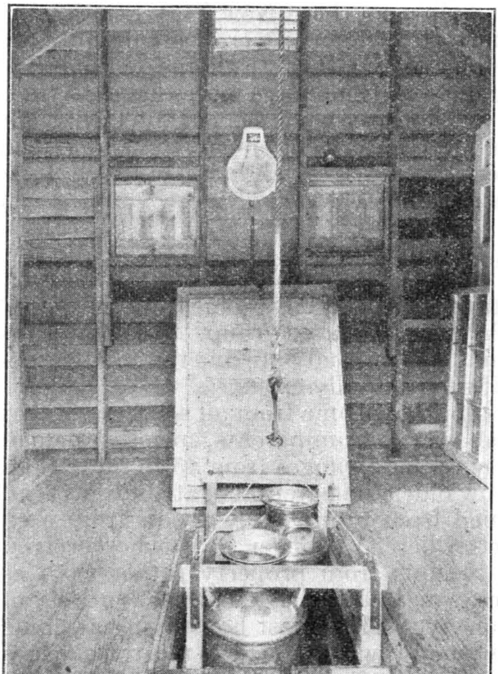

FIGURE 88.—Inside of the shelter house over the ice well. Note opening through floor leading to pit. Milk cans, on rack, are being lowered to the ice in the well. On the wall is the dial of the self-recording thermometer, which kept a record of the temperatures in the well

The mean average temperature for this locality for June, July, and August was 62.9°, 73.6°, and 70.6° F., respectively. The highest recorded temperature for the three months was 106°, in July. On 14 days in July and 10 days in August the maximum temperature was 90° or higher.

Meat, fruit, and vegetables, as well as milk and cream, were stored in the pit and kept perfectly. No offensive odors were detected at any time throughout the summer in the well or in any of the stored products.

The results seem to indicate that the ice well will prove to be a satisfactory means of refrigeration on many farms in the regions having sufficiently low temperatures for the freezing of ice in winter. The work is being continued, with some slight variations in the construction of the well.

The main points suggested for consideration in building an ice well are: Select a well-drained site; provide for good drainage, so the water can run away from the bottom of the pit; locate the pit near the milk house, and also near the water supply; and see that the floor of the house is tight, so the air circulation will be at a minimum in the summer. The cost of an ice well will vary, of course, but by using home labor and the cheaper grades of lumber it can be very low.

INCOME of Farm Boys Studied in Relation to 4-H Club Activity How much money do farm boys have? How do they get it? What do they do with it? Do 4-H club members have a more favorable economic standing than nonclub members in a community? These and other questions are answered in a recent study made in a southern New York State dairy region.[6] Two hundred and thirty-two families were visited and data obtained for 304 boys 10 to 20 years of age, living at home on the farm. Boys living at home but working away from home more than half time were not included in the study. Thirty-six per cent of the boys were 4-H club members; 33 per cent were former club members; and 31 per cent had never belonged to the 4-H clubs. Two hundred and five were 15 to 20 years of age, and 99 were 10 to 14 years of age.

Amount and Source of Income

The fact that a large percentage of the 4-H boys come from the better families might indicate that they are a selected group. It is not probable that all the differences found by the study are due to the superiority of 4-H families, however, if such actually exists.

If all boys are taken as a group, the income from all sources—wages received for definite services, allowance from parents, spending money given by parents, and property owned—ranges from $5 to more than $500 per boy. As the boys grow older the parental contributions tend to decrease, and more is earned from property owned or from cash wages received at home or elsewhere. Younger boys who received higher incomes got them as receipts from property rather than as wages. The source of incomes over $400 consisted almost entirely of the boys' own produce or property. Thus most boys living at home and working away part of the time for wages, or boys receiving wages at home, did not receive as large incomes as most of the boys who got receipts from their own property.

400 and over	1	21	1	10
Total	99	205	100	100

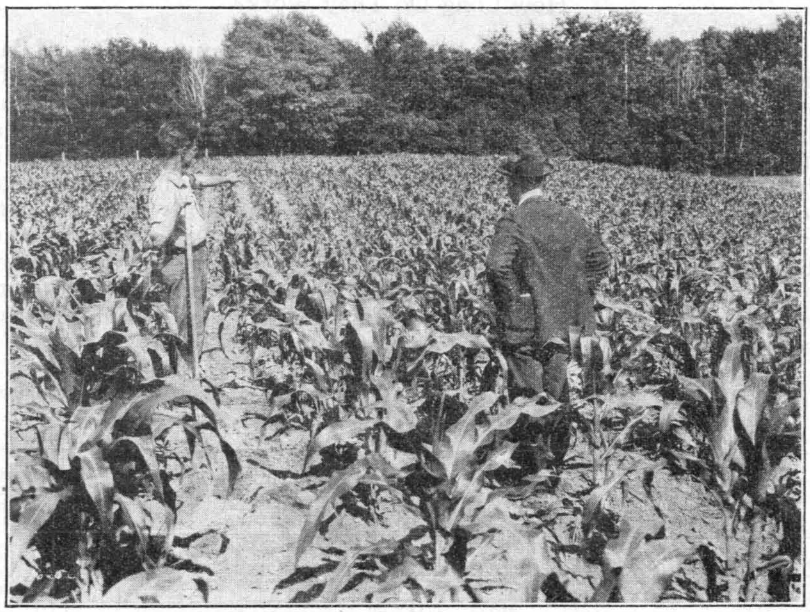

FIGURE 89.—Club boy showing his field of corn from which he made a profit

Spending money given at irregular intervals by parents is the source of income for 56 per cent of all the boys, and wages earned from home is the source of income for 21 per cent. A decreasing importance of spending money and an increasing importance of income from property exists among the 4-H membership, especially for boys under 15. Thus 4-H club members have to earn and handle and expend money at an earlier age than nonclub boys. Both present and former club members had more property than nonmembers. The average property value for all boys was $95. Boys connected with junior extension or 4-H club work have more savings than nonmembers, and these varied with income.

How is the Money Used?

Fifty-three per cent of the boys had no responsibility for their own clothing, school expense, and spending money. Seventeen per cent of all boys were responsible for all clothing and school expense and spending money, and 19 per cent were responsible for part of these expenses. As the farm boy's money income is increased he assumes responsibility for more and more expenditures that have to be made for his clothing, schooling, and other needs.

Only 3 per cent of the boys were responsible for spending money alone! This fact reverses the common notion that if a boy has money the first items of expense he is responsible for are items calling for spending money. These farm boys are responsible for spending money only when they are also responsible for other items of expense.

On the whole, the boys who had the highest independent incomes were most decidedly favorable to farming as a vocation. Where father-son partnerships were known, other fathers were initiating similar partnerships in these communities.

How Long Do They Work?

On the average the boys under 15 worked 2.27 hours per school day, and those over 15 worked 2.96 hours per school day. The figures for city boys, from a study [7] made in Lincoln, Nebr., in 1928, show that they spent 43 minutes per day in work at home and 47 minutes per day in work for pay. Those boys who worked more than an hour per day were near the average of school attainment, whereas those working an hour or less were in higher school grades. The study indicates that school advancement limits the amount of farm work done rather than that farm work retards school attainment. The boys on farms of better economic status tended to work more than boys on farms of poorer economic status; and those on dairy farms, particularly grade A farms, worked more than boys on nondairy farms.

TABLE 9.—*Relation of age to work done by 237 farm boys in school, Chenango and Otsego Counties, N. Y., 1929*

15	55	5.61			
16	42	5.69	Total and average	237	5.10

The Fathers' Incomes When Boys

None of the fathers reported having received allowances when boys, and only five received any kind of wages before they were 21. Seven reported having had a share in the farm business, and two had property of their own from which they derived an income. The remainder of the 272 fathers received any money they had, or spending money, at irregular intervals for special occasions.

The significant facts of this study indicate that 4-H club work tended to influence the way in which boys received their money income, increasing with the importance of the boys' own property and decreasing

[7] COOK, J. M., and GOODRICH, T. V. HOW HIGH-SCHOOL PUPILS SPEND THEIR TIME. School Review, v. 36, p. 771. Dec. 8, 1924.

the importance of wages and spending money received from parents. Club work tended to increase the size of the money income and the amount of property owned by boys and exerted a positive influence upon the size of the savings.

Thus this one bit of research tends to substantiate one of the fundamental objectives of 4-H club work—that of aiding farm youth to solve satisfactorily their most pressing economic problems to the end of better living. Each boy who, through property ownership, learns to earn, invest, and save money wisely has acquired a training that is the basis of good citizenship.

ROBERT G. FOSTER,
Senior Agriculturist, Office of Cooperative Extension Work.

INCOMES from Farms in the Appalachian Region Added to in Many Ways

When incomes from farming in the up lands of the Appalachian region are compared with those in more favored farming regions of the United States, farm families within the Applachian region apparently are at a considerable disadvantage.

Farm business studies for 1926 and 1927 on 959 farms located within the Appalachian upland region of Ohio, West Virginia, Kentucky, and North Carolina, were made in cooperation with the agricultural experiment stations of the respective States. Data obtained show sales of farm products, including inventory changes, averaging $630 per farm. Of this amount $236 were left for family living, savings, and other expenditures after deducting expenses of operating the farm, excluding any charge for unpaid family labor. Similar data for 1,102 farms in Illinois for 1927 show sales of $4,067 per farm, with $2,307 left for family living, savings, and other expenditures.

As figures such as these become available from studies in localities within the upland Appalachian region, the question is often asked, "How do these people live?"

Probably the families in the aggregate accept lower standards of living as measured in the number of dollars spent than do those in better agricultural regions, but their standards are not so low as is indicated by the amount of money available through the sales of farm products alone.

Data for 503 farm families within the Appalachian upland region of Ohio and Kentucky for 1926 and 1927 show that these families spent an average of $448 annually for their living, while comparative data for 1,557 families in more favored agricultural regions show an annual expenditure of $961 per family. The average amount from the sales of farm products available to the 503 families for family living and other expenditures was $272, or a deficit of $176 in meeting their cost of living.

Other Sources of Income

These families, like other families of the United States, endeavor to piece out their incomes to have more money to spend or to save. Many of the farmers and frequently other members of the family contribute to the income in ways other than from the sales of farm products. It can not be supposed, of course, that on the whole and year after year their expenditures exceed their incomes. As a matter of the importance of wages and spending money received from parents. Club work tended to increase the size of the money income and the amount of property owned by boys and exerted a positive influence upon the size of the savings.

Thus this one bit of research tends to substantiate one of the fundamental objectives of 4-H club work—that of aiding farm youth to solve satisfactorily their most pressing economic problems to the end of better living. Each boy who, through property ownership, learns to earn, invest, and save money wisely has acquired a training that is the basis of good citizenship.

INCOMES from Farms in the Appalachian Region Added to in Many Ways

When incomes from farming in the uplands of the Appalachian region are compared with those in more favored farming regions of the United States, farm families within the Applachian region apparently are at a considerable disadvantage.

Farm business studies for 1926 and 1927 on 959 farms located within the Appalachian upland region of Ohio, West Virginia, Kentucky, and North Carolina, were made in cooperation with the agricultural experiment stations of the respective States. Data obtained show sales of farm products, including inventory changes, averaging $630 per farm. Of this amount $236 were left for family living, savings, and other expenditures after deducting expenses of operating the farm, excluding any charge for unpaid family labor. Similar data for 1,102 farms in Illinois for 1927 show sales of $4,067 per farm, with $2,307 left for family living, savings, and other expenditures.

As figures such as these become available from studies in localities within the upland Appalachian region, the question is often asked, "How do these people live?"

Probably the families in the aggregate accept lower standards of living as measured in the number of dollars spent than do those in better agricultural regions, but their standards are not so low as is indicated by the amount of money available through the sales of farm products alone.

Data for 503 farm families within the Appalachian upland region of Ohio and Kentucky for 1926 and 1927 show that these families spent an average of $448 annually for their living, while comparative data for 1,557 families in more favored agricultural regions show an annual expenditure of $961 per family. The average amount from the sales of farm products available to the 503 families for family living and other expenditures was $272, or a deficit of $176 in meeting their cost of living.

Other Sources of Income

These families, like other families of the United States, endeavor to piece out their incomes to have more money to spend or to save. Many of the farmers and frequently other members of the family contribute to the income in ways other than from the sales of farm products. It can not be supposed, of course, that on the whole and year after year their expenditures exceed their incomes. As a matter of fact the 503 families had average total family incomes of $578, and total family living expenditures of $448. Therefore, the former question might better be put in the form, "What else do these people do to make a living?"

In studies of 678 families in Ohio, West Virginia, and Kentucky, the sources of the total family income, or the amount available for family living, savings, and other expenditures after farm expenses were paid, were grouped in three classes—income from sales of farm products, from outside work of the farmer, and from other sources. (Fig. 90.)

Were all the facts known, it probably would be an endless task to enumerate all the ways in which the incomes from farming in the Appalachian upland region are supplemented. Facts and figures, however, from two studies—one in southeastern Ohio for the year 1926 and one in southeastern Kentucky for the year 1927—covering 503 farm

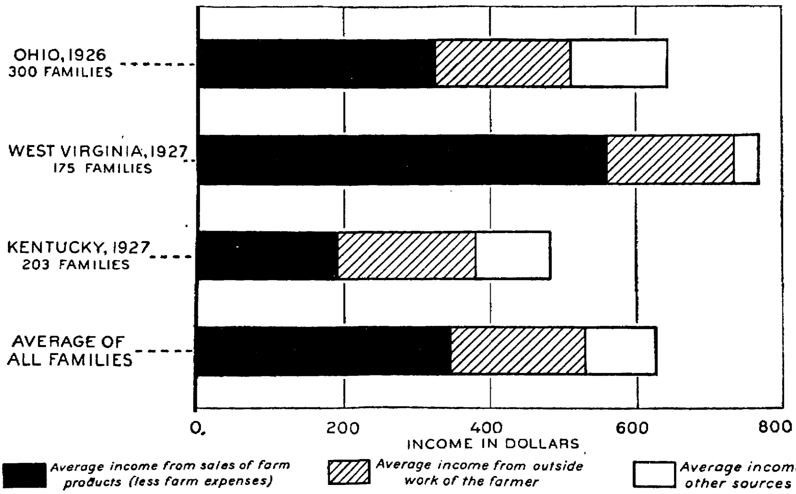

FIGURE 90.—Sources of family cash income

families, serve to illustrate what is more or less common, although subject to modifications, in many other farming communities within the region.

Of the 300 farm families in the Ohio study only 49 obtained all their income from the farm, and 33 of these received income from coal or oil leases. Many of the other 251 families (57 per cent) also received income from coal or oil leases. Of the 203 families in the Kentucky study only 20 obtained all income from the farm, and two of these received income from coal leases. Of the other 183 families, only one received income from a coal lease.

In addition to the income from coal or oil leases, the income of the 251 Ohio families and the 183 Kentucky families were supplemented in one or more of the following ways:

Outside work of farmer:	Number of families
Road work	65
Farm work	61
Work in woods	38
Mining coal	34
Carpentry	23

Outside work of farmer—Con.	Number of families
Official work	13
Hauling coal	8
Dealing in livestock	7
Selling	7
Teaching	7

Outside work of farmer—Con.	Number of families
Blacksmithing	6
Painting	5
Baling hay and straw	4
Work in railroad shops	4
Work in oil fields	4
Hauling school children	3
Auto trucking	2
Buying furs	2
Buying wool	2
Grinding feed	2
Work on railroad	2
Postmaster	2
Rural mail carrier	2
Work in iron foundry	2
Tractor work	1
Threshing outfit	1
Butchering	1
Trapping	1
Making sorghum sirup	1
Grading tobacco	1
Pulling hearse	1
Driving taxi	1
Work for telephone company	1
Bricklaying	1

Outside work of farmer—Con.	Number of families
Stone masonry	1
Holding barn dances	1
Plumbing	1
Stationary engineer	1
Railroad agent	1
Surveying	1
Life insurance business	1
Work in grain elevator	1
Work in steel mills	1
Preaching	1
Practicing medicine	1
Unspecified work	54
Other income:	
Family earnings	181
Interest	40
Pensions	31
Other property	17
Life insurance annuity	1
Insurance on buildings	1
Inheritance	1
Bonus for taking back real estate sale	1
Unspecified sources	17

Other Members of Family Help

In the several kinds of outside work of the farmer, as in woods, road work, farm work, and work in oil fields, the farm team was frequently used. Family earnings include earnings of members of the family other than the farmer himself. Usually these members live at home and work off the farm. Sometimes children who have left home send money to help support the family. The kinds of work done are many. Sometimes children—both boys and girls—do farm work on other farms. Children, especially girls, and sometimes the wife teach school. Girls and sometimes the wife do housework in other homes in the community and in towns or cities. Girls are stenographers, clerks, cashiers; they work in restaurants or hotels. Boys work on roads, in the woods, and in mines; they have various jobs in towns or cities.

To make the picture more complete, recognition should be made of the part these upland farms play in furnishing food, fuel, and shelter to the families. While the value of these items, when figured at farm prices for food products and fuel, and at 10 per cent of the value of the house for house rent, is less than for the better agricultural regions, it is larger in proportion to both the sales of farm products and the amount spent for the family living than in the better regions.

For the 503 families in Ohio and Kentucky the value of the farm-furnished items averaged $386 per family, made up of $316 for food, $12 for fuel, and $58 for house rent, while for 1,557 families in more favored agricultural regions it averaged $660, made up of $389 for food, $35 for fuel and $236 for house rent. The family living furnished to the 503 families averaged $386 as compared with sales of farm products amounting to $272 after the farm expenses were paid.

INSECT Resistance in Wheats and Sorghums a Heritable Character

For about 15 years, members of the departments of entomology and agronomy of the Kansas State Agricultural Experiment Station, cooperating with the Bureau of Plant Industry of the United States Department of Agriculture, have been actively interested in the subject of insect resistance in crop plants and have been studying the reaction of varieties of corn, sorghum, and grasses to chinch bugs and of wheat to the Hessian fly.

No varieties of corn have been found that are immune from chinch-bug injury, but repeated tests have shown that varieties well adapted to Kansas are more tolerant than those introduced from Northern States where chinch bugs do not occur. Pride of Saline resists chinch-bug attack as well as or better than any other Kansas variety that has been tested.

In order to test the resistance of sorghums to chinch-bug injury, special plantings are made at one edge of a wheat field. When the wheat

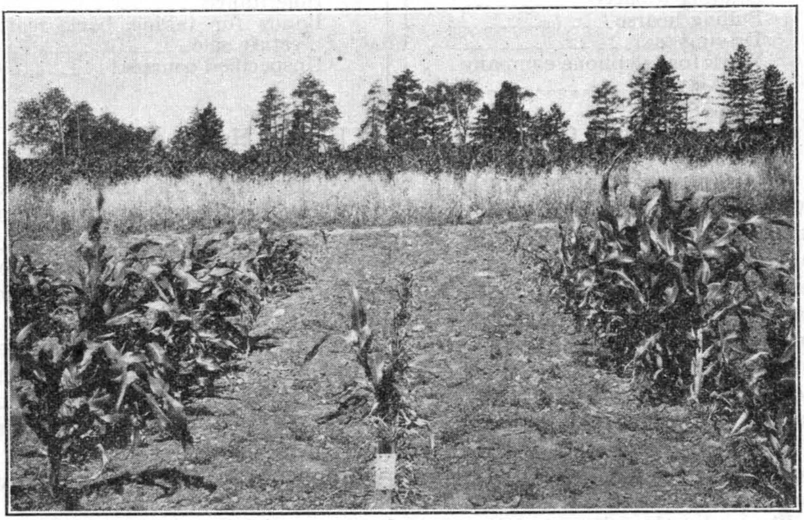

FIGURE 91.—A row of Dwarf Yellow milo (center) mostly destroyed by chinch bugs, and two resistant hybrid selections showing little injury

is cut the chinch bugs migrate to the sorghums, where the injury to the different varieties can be watched carefully. The basis or cause of chinch-bug resistance in sorghums is not known, though it is known to be a heritable character and one that can be combined through hybridization with other desirable characters such as dwarfness, erect heads, and smut resistance.

There are very distinct differences in chinch-bug resistance among the sorghums. The milos are very susceptible. Feterita and some of the kafirs and sorgos are more resistant. Dwarf Yellow milo (very susceptible) and Kansas Orange sorgo (resistant) have been crossed, and hybrid selections that are much more resistant to chinch bugs than the milo parent are now on hand. A row of Dwarf Yellow milo and two very resistant hybrid selections are shown in Figure 91. Nearly all the milo plants have been killed by the chinch bugs, while the resistant hybrid plants are much less injured.

INSECT Resistance in Wheats and Sorghums a Heritable Character

For about 15 years, members of the departments of entomology and agronomy of the Kansas State Agricultural Experiment Station, cooperating with the Bureau of Plant Industry of the United States Department of Agriculture, have been actively interested in the subject of insect resistance in crop plants and have been studying the reaction of varieties of corn, sorghum, and grasses to chinch bugs and of wheat to the Hessian fly.

No varieties of corn have been found that are immune from chinch-bug injury, but repeated tests have shown that varieties well adapted to Kansas are more tolerant than those introduced from Northern States where chinch bugs do not occur. Pride of Saline resists chinch-bug attack as well as or better than any other Kansas variety that has been tested.

In order to test the resistance of sorghums to chinch-bug injury, special plantings are made at one edge of a wheat field. When the wheat

FIGURE 91.—A row of Dwarf Yellow milo (center) mostly destroyed by chinch bugs, and two resistant hybrid selections showing little injury

is cut the chinch bugs migrate to the sorghums, where the injury to the different varieties can be watched carefully. The basis or cause of chinch-bug resistance in sorghums is not known, though it is known to be a heritable character and one that can be combined through hybridization with other desirable characters such as dwarfness, erect heads, and smut resistance.

There are very distinct differences in chinch-bug resistance among the sorghums. The milos are very susceptible. Feterita and some of the kafirs and sorgos are more resistant. Dwarf Yellow milo (very susceptible) and Kansas Orange sorgo (resistant) have been crossed, and hybrid selections that are much more resistant to chinch bugs than the milo parent are now on hand. A row of Dwarf Yellow milo and two very resistant hybrid selections are shown in Figure 91. Nearly all the milo plants have been killed by the chinch bugs, while the resistant hybrid plants are much less injured.

Different species of grasses show different degrees of resistance to injury from chinch bugs. Native perennial species with harsh tissues are able to survive chinch-bug injury and show the most ability to recover.

Early experiments on Hessian-fly injury showed one hard red winter wheat of the Turkey type (Kansas No. 2132) and one soft red winter wheat, Illini Chief, to be resistant. More recent studies have shown that wheat varieties may be placed in three classes, according to Hessian-fly infestation—(1) low, (2) medium, and (3) heavy. The following varieties in class 1 have had only 0 to 3 per cent of infested plants in a series of trials, using Hessian fly from the hard-wheat area of Kansas: Michigan Wonder, Red Rock, Honor, Dawson Golden Chaff, Illini Chief selection, Shepherd, Beechwood, Gypsy, Purkof, Kawvale, and Fulhard. In the same tests from 40 to 60 per cent of the plants of Kanred were infested. All of these fly-resistant varieties except Fulhard, a hard-kerneled selection from Fulcaster made at the Kansas station, are soft or only semihard wheats. The following varieties placed in class 3 have had from 45 to 65 per cent of the plants infested: Minturki, Sherman, Hussar, Nebraska No. 6, Nebraska No. 60, Kharkof, and Turkey.

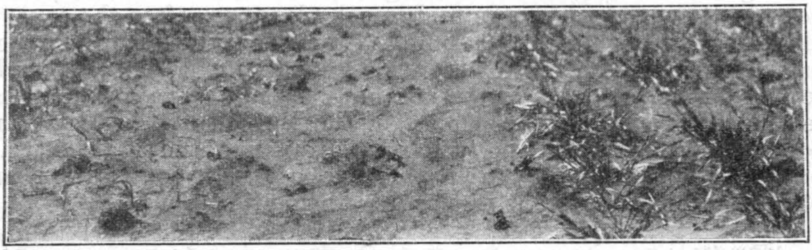

FIGURE 92.—A variety of wheat nearly destroyed by Hessian fly (left), and one tolerant to fly injury (right)

There is no question as to the significance of the difference in resistance to Hessian fly of the varieties in classes 1 and 3. Blackhull and Superhard Blackhull, which are grouped in class 2, may be described as more or less tolerant to Hessian fly, that is, they carry an intermediate amount of infestation, but the larvae and "flaxseed" sometimes do not develop normally and the plants are not always injured by the fly as much as those of Turkey and Kanred.

A very striking difference between a hard red winter wheat, very susceptible to Hessian fly, and a variety tolerant to Hessian fly, observed under field conditions in south-central Kansas in 1928, is shown in Figure 92.

The exact cause of resistance to Hessian fly is not known, but fly resistance is known to be a heritable character. It has been transferred and combined with other desirable characters in crosses between the resistant Illini Chief and Kanred, Marquis, and other susceptible varieties. The several selections of Kanred × Illini Chief have an average fly infestation of only 2 to 3 per cent in a series of tests in which the susceptible Kanred parent had 45 per cent and the resistant Illini Chief parent had 1.7 per cent.

Agronomist, Bureau of Plant Industry.

INSECTICIDAL Plants Investigated as Possible Farm Crops Thousands of people who derive their livelihood from agriculture are vitally interested in means to stay the progress or diminish the destructiveness of the insect pests with which they reluctantly share their crops. As crop production becomes more intensified, the biological balance is disturbed, and insects multiply at a rate faster than ordinary natural checks can control. As the insects increase, man is compelled to seek and develop additional means of warfare to maintain his supremacy or at least his equilibrium in the world of living things. These unbidden and unwelcome boarders of the farmer and the orchardist levy an annual toll estimated at about $100 for every thousand dollars worth of crop value. Research of a chemical, entomological or mechanical character to supply the ammunition needed in this fight has, therefore, tremendous economic significance.

Nowhere else are insecticidal operations more widely practiced than in the United States. Yet a census of both foreign and domestic poisonous plants reveals the surprising fact that few of these plants are utilized commercially as insecticides. With few exceptions, the potentialities of our domestic poisonous plants in this direction have been ignored. Instead of increasing crop returns to the farmer, which perhaps they might be made to do, such plants are often the cause of direct loss through stock poisoning. There may be lurking in these unwelcome plants the ideal insecticide—one that will be cheap, deadly to insects, harmless to vegetation, and will not leave a toxic spray residue. To a group of chemists in the Bureau of Chemistry and Soils has been assigned the task of isolating and studying the active principles of these plants. Knowledge of their constitution and physiological properties is essential to their utilization.

Drawbacks of Pyrethrum and Tobacco

Of the plants now used as insecticides pyrethrum and tobacco approximate the ideal, but each has objectionable features. Pyrethrum is effective against many insects, does not injure foliage, and is not poisonous to man and animals, but its price is high. Moreover, American fruit and vegetable growers are dependent largely upon foreign supplies. The crude pyrethrum and its chemically active components, the pyrethrins, are in great and rapidly increasing demand, and as the domestic supply is wholly insufficient, it is necessary to import annually from Japan and Europe more than 11,000,000 pounds valued at $2,500,000. Efforts are being made to produce pyrethrum in America at a cost to compete commercially with the production of Japan and Dalmatia, the principal sources of foreign supply.

The midribs of the tobacco leaves, leaf scrap, damaged leaves, and the refuse from cigar manufacture furnish the chemical compound nicotine, one of the most valuable insecticides which kill by contact. But the chemically extracted nicotine, nicotine sulphate, and the nicotine dusts are by-products of the tobacco industry, and their supply is limited by the use of tobacco. The demand for nicotine exceeds the supply available from the products of tobacco and the price is correspondingly high. The nicotine content of available tobacco material is usually rather low and its extraction is costly. Consequently producers of nicotine are able to pay only a relatively low price for tobacco material in spite of the high price of the finished product. Other domestic plants of lesser value that are used as insecticides include hellebore, sabadilla, and larkspur, all of which have chemical components which are actively destructive of insect life.

Since the need for harmless but effective insecticides is urgent, scientists of the United States Department of Agriculture have turned their attention recently to the known fish-poisoning plants of the Tropics and through the consular agents of the State Department have procured much material for investigation. Three of these tropical plants have proved to be promising sources of the insecticidal component rotenone. They are Derris, cube, and haiari.

The poisonous character of Derris, a plant grown on the rubber plantation of Sumatra and the Malay Peninsula, has long been known to the natives who throw the crushed roots into streams to kill or stupefy fish, which are then easily taken in nets. In the insecticide division of the Bureau of Chemistry and Soils the roots of cube, a plant native of Peru, have been found to contain the remarkable quantity of 7 per cent of rotenone. Other species of Lonchocarpus, such as timbo and haiari, are believed to be possible dependable sources of a commercial supply of this poison.

Toxicity of Rotenone

Preliminary results indicate that rotenone is more toxic than pure nicotine as a contact insecticide. It rivals pyrethrum in toxicity to many insects, and gives promise as a possible agent to replace arsenic as a stomach insecticide for use against chewing insects. The annual consumption of arsenates in the United States is approximately 60,000,000 pounds with a retail market value of about $7,000,000. From this fact, the potential market for an effective organic material like rotenone can be imagined.

Since rotenone or some of its chemical derivatives give promise of filling the requirements of the ideal insecticide, intense efforts by chemists of the department are being made to produce it synthetically. While this difficult work is under way, consideration should be given to the growing of plants which contain this interesting chemical component, in the warm regions along the Gulf coast and in our insular possessions where tropical conditions prevail.

Crop diversification is badly needed in the Virgin Islands, where large areas of unusued lands are available and unemployment is a problem. The cultivation of insecticidal plants in the Virgin Islands, in Porto Rico, and in the Philippines might possibly provide the the farmer of the United States with a powerful weapon wherewith to fight the insects. The chemists of the department are studying many plants which produce these complex poisonous organic substances, in the hope of finding one or more which can be grown as a field crop in a temperate climate, such as prevails in the United States.

W. W. Skinner,
Assistant Chief, Bureau of Chemistry and Soils.

INSECTS Captured by Airplane Are Found at Surprising Heights

Chasing insects with airplanes sounds like a far-fetched idea, but in reality the Department of Agriculture is actually doing just this in a very serious way in connection with studies on the migration of various insects, particularly those affecting the cotton crop. Different species of insects have their peculiar habits as regards migration; one may move only from plant to plant, another from field to field, while still others have distinct migratory movements extending hundreds or even thousands of miles. It frequently becomes of the utmost importance to have a thorough understanding of these migrations, the facts influencing them, and their direction and extent. Such knowledge aids in preventing the spread of new insects, in checking migrations at their source, or in predicting outbreaks so that proper control measures may be taken.

Many observations have been made on migration by using such equipment as field screens, and there have even been a few cases where such screens have been erected at some height from the ground, but for all practical purposes these gave information only on conditions within the fields and the first few feet of air above them. In making such studies in connection with some of the cotton insects, their travels could not be correlated with the ground wind conditions and were apparently more closely allied with the travel of hydrogen balloons, which were known to blow across country at high altitudes. It is a well-known fact that as we go higher in the air, the wind direction frequently or, in fact, usually changes from that on the ground, and the wind a few thousand feet up may be blowing in an opposite direction from that on the ground. It was obviously of the utmost importance, therefore, to know the altitude at which the various insects traveled, and plans were made to try to catch them with airplanes.

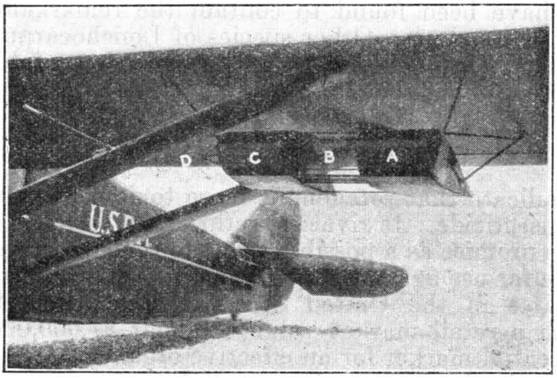

FIGURE 93.—Insect collecting trap attached to wing of monoplane. The unexposed trays are carried in compartment A. At B a tray is shown pulled into position for exposure. After exposure, the tray is pulled into compartment C. These movements are controlled by wires (D) leading to the cockpit of the plane

Special Trap Devised

A special trap was devised as shown in the accompanying illustration. (Fig. 93.) This contained two insect-proof compartments, one at each end, with the center section open. A battery of screen trays were arranged so that they could be stored in one compartment and, whenever the operator desired, any tray could be pulled out to the center section, where it was exposed to the air, left there as long as necessary, and then slipped into the second closed compartment where insects could not reach it. These screens were coated with a light application of a sticky substance which caused any insects striking the screen to remain fastened thereto. When ready to commence operations, the plane was flown to any desired altitude, then a screen would be pulled out and exposed for any desired length of time, following which it was pulled into the protected compartment and the insects were removed after the plane reached the ground. (Fig. 94.) Preliminary flights with such equipment quickly showed that the results were greatly influenced by conditions such as temperature, rainfall, air pressure, and time of day. Consequently, it was necessary to carry out a systematic series of flights to be made at all times of the day and all seasons of the year (figs. 95 and 96), as well as to visit various localities in order to trace out migrations.

As a standard for comparison, all of these records are computed on the basis of the number of cubic feet of air sampled. The ordinary

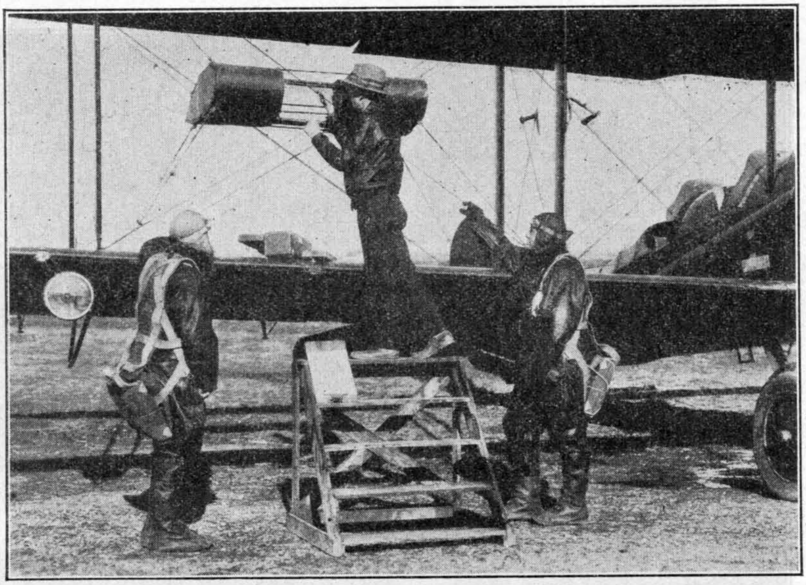

FIGURE 94.—Removing insects from screen trays after the landing of the plane. On account of the low temperatures experienced at high altitudes, heavy flying clothing is necessary

screen tray utilized is 1 foot square, and by computing from the duration of the exposure and the known forward speed of the ship it is easy to figure the volume of air through which this tray has passed for each sample. In this way the insect populations at various altitudes can be computed.

Many Insects at High Altitudes

In these studies the insects below 50 feet altitude are not considered, and the number found in the air above that level is surprising. Of course, the population is denser closer to the earth, but many insects reach a previously unsuspected height. All collections have been made at various altitudes, ranging from 50 feet to 14,000 feet, and insects have been collected at all of these altitudes. Undoubtedly they will be found even higher. The densest population is found in the first 1,000 feet from the ground, but at 2,000 feet we find approximately half as many as at 1,000, and at 3,000 feet we find half as many as at 2,000. From about 3,000 to 5,000 feet there is comparatively little difference, and from 6,000 feet upward the population is considerably lighter, but there are still a remarkable number of insects present. To give some idea of this abundance, computations have been made of the number of insects in a column of air 1 mile square starting 50 feet from the ground and extending 14,000 feet high. Computing from several hundred collections which have been made, it is shown that under all conditions for all seasons of the year in the vicinity of Tallulah, La., an approximate average of 25,000,000 insects is to be found in the upper air over this square mile of ground. The lowest ebb is during January, when the population drops to about 12,000,000, and the highest is during May, when it rises to 36,000,000.

A study of the various species collected at different altitudes reveals many interesting facts, only a few of which can be mentioned here.

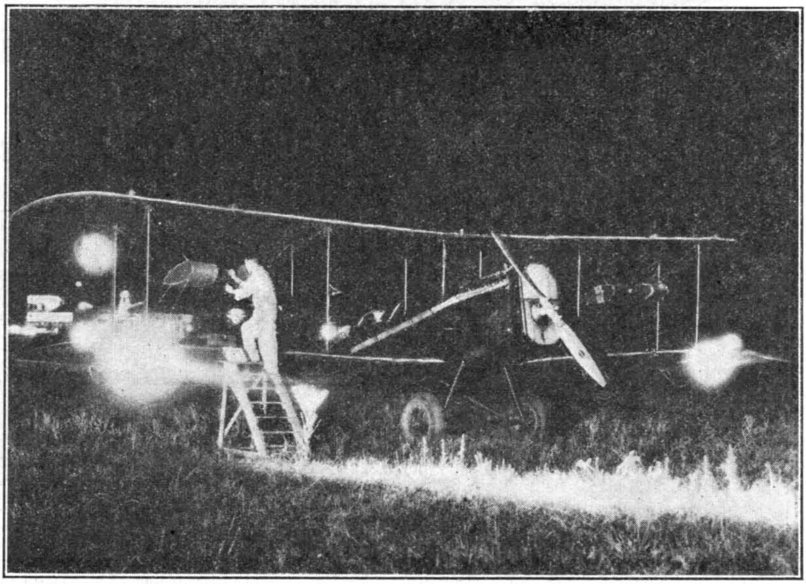

FIGURE 95.—Removing insects from trays following a night flight. Some insects are found in the air only at night

As a rule the larger, stronger flying insects are collected closer to the earth and the smaller, weaker ones at higher altitudes. It is particularly interesting to note that many absolutely wingless insects are collected at very high altitudes; for example, the balloon spiders, which have no powers of flight but are carried entirely by air currents, have been collected as high as 10,000 feet, and numerous other small forms, including mites, are found at similar elevations. Consequently, it is obvious that we are dealing with two distinct classes of air travel. One of these is the voluntary movement of strong flying insects which have sufficient powers of flight to enable them to travel at will and more or less overcome atmospheric conditions. The other extreme is the purely involuntary travel of the weaker-flying insects which are picked up and carried by the rising air currents caused by convection and which do not have sufficient powers of flight to offset these. Between these two extremes we have the intermediate condition of travel which is partly involuntary and partly by actual flight. Generally speaking, the strong-flying insects, such as the cotton leaf-worm moth and similar species, are found at 3,000 feet or lower, although occasional individuals are found as high as 5,000 feet. Boll weevils have been collected only as high as 1,000 feet, tarnished plant bugs up to 3,000 feet; and cotton flea hoppers up to 5,000 feet. Above these we find such insects as the leaf hoppers extending up to 7,000 feet, and still above these we find the minute parasitic flies, wasps, plant lice and similar light, small-bodied insects extending up to 14,000 feet and probably considerably higher. The pink bollworm moth, which had been supposed to be a comparatively weak flier with a decided tendency to remain down among the plants, was found as high as 3,000 feet in the air.

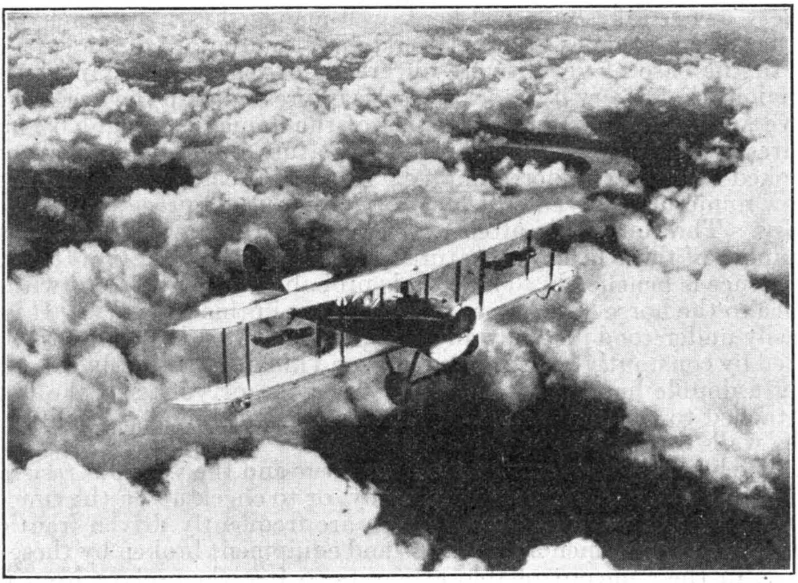

FIGURE 96.—Plane collecting insects at high altitude above clouds. Only small, light-bodied insects are collected at such altitudes

Findings Important to Pest Control

These findings have a most important relation to many of the problems of insect repression or control, and there is no question that as the work is continued and extended they will be even more useful by throwing entirely new light on the manner and method of travel of many insect species. Air currents at the higher altitudes frequently become extremely swift as compared with winds normally experienced on the ground, and it is easy for insects reaching such currents to be carried forward on them for hundreds of miles within a comparatively short time, and then, upon meeting descending currents, return to the earth where they may spread new infestations.

B. R. COAD,
Principal Entomologist, Bureau of Entomology.

INSECTS Harm Livestock to an Extent That Is Frequently Unsuspected

The reduction of losses caused by insect pests of livestock is one of the problems with which stock raisers are seriously concerned. Practical methods of control of several of these pests have been developed, and those farmers who familiarize themselves with these methods and put them into practice are securing substantial returns for the investment in time and equipment.

Some of these insect problems of the stockman, or poultryman, can be met by modifying farm and range practice with little or no added expense or labor. Such modifications often result in the conservation of by-products of the stock farm and substantial increases in crop yields. Others require improvements in building and equipment which add to the attractiveness of the farm and the feeling of pride which every owner takes in a well-kept, well-managed farm or ranch. Still other insect enemies require special direct action or equipment.

In the case of very severe outbreaks of insects the damage is so obvious that every livestock owner is impressed with the need of decisive action. Unfortunately, much of the damage wrought by insect parasites of livestock is of an insidious nature and either entirely overlooked or greatly underestimated. In fact, the determination of just how numerous a given pest must be to produce appreciable loss is not easy. The thought is often expressed that the presence of a certain number of these insects is natural, and some even maintain that their presence is beneficial. This idea is probably more prevalent with refence to the horse bot than any other insect in this category. It is not easily understood just why anyone should assume that a horse is benefited by constantly biting, switching, and kicking at a botfly or by having a double handful of the spiny maggots, or young of the botfly, attached to the stomach and intestine by mouth hooks deeply set in the walls of these organs.

One has only to observe the intense fear and the vigorous resistance of a horse attacked by the nose botfly, or to check up on the time lost by farmers in working horses which are frequently driven frantic by these pests, or in mending harness and equipment broken by these animals in their uncontrollable attempts to free themselves from their annoyers to be thoroughly convinced of the fallacy of such ideas. The improvement in condition of heavily infested horses which have been freed of bots by dosing with carbon disulphide leaves no doubt in a farmer's mind that bots are a positively injurious pest and that a greater output of work on the same feed is assured by elimination of bots from the digestive tract.

Fallacy About the Cattle Grub

The same erroneous idea of benefits accruing to cattle from infestations by the cattle grub, or warble, seems to be held by some. Here again one is forced to conclude that even a smattering of knowledge of the life history and habits of this insect would dispel such a notion. In the case of this pestiferous insect few people are fully aware of the many ways in which injury is produced, because of the fact that the heel fly, which is the parent of the grub, is seldom seen and the stampeding and wild excitement produced by its attack are not attributed to it. Furthermore, the eggs are inconspicuous, and the penetration and migration of the small grubs throughout the bodies of the cattle is, of course, unobserved. The presence of the grubs becomes evident only when, after seven or eight months of burrowing about in the body, they reach the backs of the cattle, cut holes through the skin, and enter upon their final stages of development there. The hide damage in the case of this pest is obvious, but the dockage on account of it is not usually brought to the attention of the producer at the time of marketing. Hence but few livestock raisers or feeders realize that in the matter of defective hides alone a loss of approximately $5,000,000 for our entire country is being sustained each year. It is certain that the loss caused in reduced milk flow, retarded development of young stock, lowered flesh condition, and actual death loss due to cattle stampeding or miring down in their frantic efforts to escape heel-fly attack far outweighs the hide and leather damage.

Either the removal of grubs from the backs of the cattle, or their destruction by applying insecticides, such as Derris or tobacco powder, is an effective method of breaking the heel fly's vicious life cycle. The fact that several such treatments must be given during the winter and spring to accomplish satisfactory control makes these methods rather difficult of practical application, especially on range cattle, but in regions where the grubs are abundant the cost of the treatment involved appears to be fully justified.

The hordes of blood-sucking flies surely account for the loss of millions of dollars in milk and condition. Furthermore, they may carry dangerous diseases, such as anthrax. While no accurate figures on the losses sustained have been obtained, the marked effect of serious outbreaks of stable flies, horn flies, horse flies, mosquitoes, and buffalo gnats on all classes of livestock leaves no room for doubt as to their economic importance. Observations indicate that a few flies of any of these destructive forms are of no material consequence, but that where they become very abundant losses are inevitable.

Stable Flies in Grain Belt

Stable flies are present throughout the country, but are a notorious pest in the grain belt, where they have been found to breed in accumulations of stable manure and especially in straw stacks which ferment upon getting saturated with rain. The spreading of manure at intervals not to exceed three days on fields to be cultivated, the proper stacking of straw, and the elimination of old scattered straw stacks will greatly reduce the numbers of these troublesome bloodsuckers. Manure should not be spread on pasture lands because of the danger of infecting such pastures with internal parasites of livestock.

Horn flies of cattle breed in cow manure. Frequent cleaning of yards and the use of killing fly sprays will hold this pest in check about dairies and farms.

Drainage of marshy areas and pools will do much toward eliminating the horsefly and mosquito pests, and oiling of undrained pools where mosquito wrigglers occur will prevent their breeding.

House flies are dangerous pests on farms as well as elsewhere. They annoy livestock, carry certain parasitic worms, and contaminate dairy and other farm products. Prompt disposal of manure and garbage to prevent breeding, the use of flytraps, the application of killing sprays where the flies congregate, and the protection of food products by screening will give almost complete relief if these steps are consistently carried out.

The screw worm and wool maggot in the Southwest are held by many ranchmen to be the most serious problem with which they have to deal. The damage caused by these pests is dependent very largely on climatic conditions. Warm weather with frequent showers is highly favorable to their multiplication in carcasses and their infestation of every wound, however slight. The prompt destruction of carcasses by burning and the use of flytraps are of much importance in lessening the number of screw-worm flies. During the fly season the number of wounds on animals which give opportunity for the flies to attack should be reduced to a minimum. This can be accomplished by branding, marking, and dehorning out of fly season, using care in handling stock to prevent injuries, practicing dehorning or the breeding of muley strains, and controlling breeding so as to have the offspring dropped when flies are not abundant.

Losses Caused By Lice

The losses caused by biting and sucking lice are widespread and at times exceedingly heavy. Here again, unless very severe, the damage is not easily recognizable or determinable. Sometimes louse infestations of all classes of livestock and poultry become very heavy before the presence of the parasites is noticed. Marked reduction of flesh, decreased milk flow, damaged wool and mohair, and curtailment of egg production are inevitable in such cases. Even when livestock are freed of such heavy infestations, complete recovery from the ill effects is often slow.

These parasitic insects live continuously on the animals which they infest. Dipping the animals in suitable insecticides at proper intervals will completely eradicate the insects from a herd or flock. Since the pests reproduce rapidly it is essential that every animal or fowl be dipped at the same time or that the untreated individuals be kept separate.

Ticks and mites, which are related to insects, are notorious pests of all classes of animals and birds. Some are important carriers of diseases, such as the cattle-fever tick. Others are persistent and serious pests, either sucking blood or living in or on the skin, as in the case of the various itch or scab mites. As persons familiar with itch mites infesting man well know, the annoyance from the presence of these mites is almost intolerable. The decline in flesh and the general debility or even death of animals heavily infested with similar mites is not surprising.

The difficulty of detecting the presence of a few of the small mites, or even of the much larger ticks, makes it hard for even a trained inspector to say with certainty from a single examination when an animal is entirely free. This makes the spread of these pests on infested animals from herd to herd or from one locality to another comparatively easy, and necessitates the application of rigid quarantines against the more dangerous kinds.

The efficacy of insecticides applied as dips and of State and Federal quarantines in eradicating scab from cattle and sheep has been fully demonstrated, and the inconvenience and cost of such eradicative efforts are far outweighed by the results accomplished.

No serious effort has been put forth to restrict the spread or stamp out the fowl tick, chicken mite, or scaly-leg mite. The last two pests are nation-wide in distribution and cause heavy losses to poultry raisers, but the ease with which they can be controlled on individual premises has led most poultry raisers to ignore them until serious infestations have developed. The fowl tick, however, is more difficult to control, as it is a pest of unusual hardihood, living as it may for more than three years without food and being very resistant to insecticides. The fact that it is spreading to new regions and becoming more generally distributed in old territory makes more evident the necessity of the application of known control and restrictive methods.

Not only does the control of insect enemies of livestock give increased returns on the investment, but the comfort and appearance of the stock is a source of great satisfaction to the owner; and the relief from annoyance to man by the direct attack of some of these pests and the peace of mind made possible by their control is in itself perhaps ample remuneration.

Principal Entomologist, Bureau of Entomology.

INTER-AMERICAN Meeting on Agriculture Plans Scientific Cooperation

The first Inter-American Conference on Agriculture was held in the Pan American Union Building in Washington, D. C., from September 8 to 20, 1930, at the invitation of the United States Government in accordance with the recommendations of the Sixth International Conference of American States at Habana in February, 1928. Fifty-four official delegates representing the 21 Governments, members of the Pan American Union, and 168 consulting delegates, were registered. The conference organized by electing A. F. Woods, director of scientific work of the Department of Agriculture, as permanent chairman, and his assistant as secretary general.

The program provided for round-table discussions on a series of topics grouped as follows:

Surveys and inventories of soils, forests, pastures, irrigation, plant and animal diseases and pests, censuses, and other statistical surveys.

Problems relating to land, their classification, erosion, and fertilizers.

Forestry problems, systematic management, selective logging, prevention of fires, reforestation, the testing of American woods, and utilization of waste and by-products.

Animal-industry problems, such as breeding for special purposes, nutrition, diseases, sanitation, quarantine, and control service.

Plant-industry problems, introduction of promising plants from foreign countries, breeding and selection of improved varieties, seed testing, weeds and their control, forage crops for warm climates, diseases and insect pests and their control, and production problems of special crops, such as cereals, cotton, tobacco, sugar, rubber, fibers, coffee, cacao, tropical fruits, and vegetables.

Agricultural education, experimental and demonstration stations, extension services, and a proposed central agricultural research station for all the American Republics.

Agricultural economics, competition, cooperative agricultural credit systems, marketing, transportation, standardization and grading, present and future food supply, farm management, and overproduction problems.

Seventy-one Resolutions Adopted

The conference adopted 71 resolutions, recommending: That a second Inter-American Conference on Agriculture be held within five years and a permanent inter-American committee be appointed to prepare for it; that a permanent technical advisory board be appointed to study problems of paramount importance to agriculture, to discuss raisers, but the ease with which they can be controlled on individual premises has led most poultry raisers to ignore them until serious infestations have developed. The fowl tick, however, is more difficult to control, as it is a pest of unusual hardihood, living as it may for more than three years without food and being very resistant to insecticides. The fact that it is spreading to new regions and becoming more generally distributed in old territory makes more evident the necessity of the application of known control and restrictive methods.

Seventy-one Resolutions Adopted

The conference adopted 71 resolutions, recommending: That a second Inter-American Conference on Agriculture be held within five years and a permanent inter-American committee be appointed to prepare for it; that a permanent technical advisory board be appointed to study problems of paramount importance to agriculture, to discuss and formulate plans for future work, to cooperate with the Pan American Union in carrying out the resolutions of the conference, and to collaborate in preparing for the second inter-American conference; that the Division of Agricultural Cooperation in the Pan American Union be strengthened and organized as a coordinating center of agricultural coöperation in research; that cooperating committees and national agricultural congresses be organized in each Pan American country; that regional conferences be held between representatives of governments having common problems and interests for the purpose of cooperating in the technical study and possible solution of problems common to the group; that each country appoint a special official delegate to be in constant communication with the national committees, with the Pan American Union, and with all other official and private organizations dealing with agriculture in the respective countries; that the various governments cooperate in listing all the agricultural scientific institutions, exchange of publications, and the propagation and exchange of economic plants; that coöperation shall be encouraged between agricultural experiment stations and international agricultural organizations of the various countries; that at the second inter-American conference special consideration shall be given to the study of plant and animal diseases and pests; that a plan be formulated for the establishment of a central Pan American research station and substations for consideration at the next inter-American conference; that annual reports of advances in agricultural scientific research be published; that a Latin American association for the advancement of science be established; that provision be made for the interchange of research workers; that the organization of private associations interested in agriculture be fostered; that a technical commission study the standardization of surveys, terminology, and Spanish equivalents; that soil, forestry, and other surveys be undertaken; that an inter-American livestock advisory board be established and provision made for the exchange of laws relating to livestock and for telegraphic reports of outbreaks of animal diseases; that cacao production be investigated by a commission of experts; that the Pan American Governments provide for the training of agricultural specialists; that the various governments cooperate in developing and perfecting statistical services, in the adoption of standard weights and measures, in promoting better farm management and crop diversification, and in the study of overproduction problems; that a Pan American agricultural bank be established with headquarters in New York; that international committees be formed to advertise coffee and yerba mate and that steps be taken to stabilize coffee production; that special consideration be given to the appointment of agricultural attachés; that Pan American countries modify their customs tariffs so as to encourage the introduction and commercial exchange of insecticides, fungicides, machinery, and equipment for applying them; that plants in American agriculture be listed, with the authorized Latin name for each species and authentic common names in each of the official languages of the American republics; that the bibliographical agencies, libraries, agricultural, and other agencies cooperate in the formulation of a bibliography of agriculture; that the educational films of the United States Department of Agriculture be loaned to the different countries represented in the conference; and that the conference express its high appreciation of the valuable services of the late W. A. Orton and other research workers in tropical agriculture.

Papers and Proceedings Published

The technical papers that were prepared in advance of the conference for the information of the delegates and as bases of the round-table discussions were published in a volume entitled "Documentary Material on the Inter-American Conference on Agriculture, Forestry, and Animal Industry," in English, Spanish, and Portuguese editions; the resolutions and rules of procedure were published in the Final Act, in four languages; and the proceedings were published in the Report of the Delegates of the United States of America to the Inter-American Conference on Agriculture.

From the foregoing it will be seen that the conference was well attended, that the discussions covered a wide range of topics, and that definite and permanent provision was made for continuing cooperation in promoting scientific research in agriculture throughout the American Continent. Among the intangible results of the conference were the contacts made between research workers and institutions of the different countries, and the spirit of good will, mutual respect, understanding, appreciation, and cooperation that developed from the exchange of views and discussion of problems common to many countries. These results will have an important bearing on the future agriculture of the United States, because many problems of agricultural production and marketing, of plant and animal diseases and pests, and of scientific research in connection therewith, are international in scope, are not limited by national boundaries, and can not be successfully solved, confined, or controlled within the boundaries of a single country.

LEON M. ESTABROOK,
Assistant to the Director of Scientific Work.

INTERNATIONAL Action to Aid Agriculture Is Gaining Headway This is an international age. War and postwar experiences have emphasized the economic interdependence of nations. International congresses, conferences, and meetings, by their very number, have become commonplace incidents. The League of Nations in its Handbook of International Organizations published in 1926 listed some 470 international associations, offices, and committees. Agriculture figures conspicuously in the movement. Twenty-six years ago—June 7, 1905—42 nations pledged themselves by treaty to cooperate in promoting the welfare of agriculture, and created the International Institute of Agriculture. Of the thirty-odd international groups directly concerned with agriculture, the greater number have come into being within the last decade. Their activities and scope may be illustrated by special consideration of three of their number.

The idea of the International Institute of Agriculture was conceived by a California merchant—David Lubin. In bringing his plan to fruition Mr. Lubin attempted to enlist the cooperation of the United States as well as that of other nations in the organization of an international clearing house for agricultural information. Failure attended these efforts until the King of Italy, Victor Emanuel III, embraced the proposal and called an international conference to consider it. The conference resulted in the founding of the institute at Rome in 1905. The treaty establishing the institute provided that it should

International congresses, conferences, and meetings, by their very number, have become commonplace incidents. The League of Nations in its Handbook of International Organizations published in 1926 listed some 470 international associations, offices, and committees. Agriculture figures conspicuously in the movement. Twenty-six years ago—June 7, 1905—42 nations pledged themselves by treaty to cooperate in promoting the welfare of agriculture, and created the International Institute of Agriculture. Of the thirty-odd international groups directly concerned with agriculture, the greater number have come into being within the last decade. Their activities and scope may be illustrated by special consideration of three of their number.

The idea of the International Institute of Agriculture was conceived by a California merchant—David Lubin. In bringing his plan to fruition Mr. Lubin attempted to enlist the cooperation of the United States as well as that of other nations in the organization of an international clearing house for agricultural information. Failure attended these efforts until the King of Italy, Victor Emanuel III, embraced the proposal and called an international conference to consider it. The conference resulted in the founding of the institute at Rome in 1905. The treaty establishing the institute provided that it should promote the welfare of agriculture in the international sphere. Its principal task was the collection and dissemination throughout the world of information from as many countries as possible on acreages sown, crop conditions, harvest yields, numbers and kinds of livestock, prices, and market supplies.

At the World Economic Conference, held by the League of Nations in May, 1927, agriculture for the first time was placed on the same footing with commerce and industry in the deliberations of that body. Since then the league has given increased attention to agriculture. Its economic consultative committee meeting in Geneva in May, 1928, and in May, 1929, gave a large place to agriculture in its deliberations. In January, 1930, and again in January, 1931, a committee of agricultural experts from 21 countries was convened by the league to discuss the agricultural depression.

A Farmer-Controlled Organization

The International Commission of Agriculture is an organization composed of 92 national farm associations located in 27 countries. This is the only international agricultural group controlled and financed by the organized farmers themselves. Its history illustrates the difficulty of getting unity of action among farmers. For more than 40 years there had been a well-developed movement in Europe to found some sort of international agency controlled by and representing the organized farmers of the world. Rivalry between national groups, and conflicting opinions as to the form this organization should take, presented seemingly insurmountable difficulties. It was an American proposal that resulted in action. The American delegation to the 1924 General Assembly of the International Institute of Agriculture proposed that the farm organizations of all nations should consider the advisability of establishing an international agency to represent the interests of the organized farmers of the world. An organization committee was created which two years later obtained the adoption of a plan whereby the International Commission of Agriculture (an existing body with headquarters in Paris) revised its constitution, and turned its control over to representatives of affiliated national farm groups. The commission has since taken a prominent part in the agricultural meetings held by the League of Nations. It cooperates with the International Labor Office and with the International Institute of Agriculture. Its program deals largely with the extension of the cooperative movement and with the analysis of the causes of the present world-wide agricultural depression.

Cooperation on an international scale in the field of agriculture is not confined to the three agencies mentioned above, but perhaps enough has been said to indicate the substantial nature of the movement, which promises to grow. In many respects agriculture's problems are international in scope and origin. Frequently they suggest international action. Government action designed to benefit farming in one nation may work a hardship to growers in another country. Acts of one country often call forth counter acts in another. Bounties and subsidies in one nation may bring forth countervailing duties elsewhere. The Government of the United States recommends a reduction of wheat acreage. The Government of Australia encourages an expansion of Australia's area in wheat. The wheat-acreage problem interests all wheat-growing countries. Germany and Poland have reached an accord in the cooperative disposal of rye on foreign markets. Unity of action for the relief of agriculture is now being considered seriously by eight eastern European countries. It is reported that Hungary, Yugoslavia, and Rumania have agreed to set up machinery for the joint disposal of grain for export. The question whether international agreement affords an effective means of aiding agriculture is before the statesmen of many countries.

Bureau of Agricultural Economics.

IRRIGATION Water Supply Increased by Storing Flood Water Underground There are many parts of the West where profitable crop production depends upon irrigation and the principal or only supply of water is from under-ground sources. Where this condition prevails a deficiency in the precipitation or an increased demand, or both, have sometimes depleted the supply to such an extent that the cost of irrigation has approached or even exceeded the economic limit, and the source of supply has sometimes been threatened with exhaustion.

This is especially true of certain portions of southern California. Ground water is found at various depths in all of the valleys, and the extent and depth of the supply are of prime importance, since a lowering of the water table may increase the cost of pumping to the point where it is no longer profitable to irrigate crops with the pumped water.

The original source of the available water, even of that conveyed for long distances, is, of course, precipitation. Under the climatic conditions prevailing in southern California the precipitation falling in the rainy seasons often comes in the form of torrential rains and a large part of it runs off quickly and hence does not reach the water-bearing strata. However, certain geological formations found at the bases of the mountains serve to some extent, even without artificial assistance, to hold back a part of the run-off, and these formations become natural reservoirs from which the water drains slowly. These porous formations occur as cones and fans created by the sand and gravel washed down by streams and deposited at the foot of the mountains. (Fig. 97.) The materials thus deposited are not consolidated or cemented but for the most part are loose and spongy and often occupy the lower stretches of alluvial valleys where ground water is near enough to the surface to permit of profitable pumping. Table 10 illustrates how an increase or a decrease in the supply furnished by feeder streams was directly reflected in a corresponding rise or fall of the water levels in the irrigation wells of a typical southern California area. It will be noted that the pumping lift became greater each year during several successive dry years.

The amount of the precipitation that is stored depends upon a number of conditions, such as the quantity and intensity of rainfall, the character of the watershed surfaces, the topography, the rate of run-off, and the percolation and porosity factors of the strata in which the water is stored. Obviously, any retardation of the run-off tends to increase the penetration to the subterranean reservoirs and, consequently, the quantity of water made available for irrigation. Methods of holding back the run-off have therefore long been sought and among those now in use is that generally known as "water spreading."

The practice of water spreading is not new. Records show that as long ago as 1889 the city of Denver used a modified form of spreading in order to supplement its water supply and tide it over a threatened water famine. In 1896 the practice, on a much broader scale, was adopted in southern California, and now water is spread over large

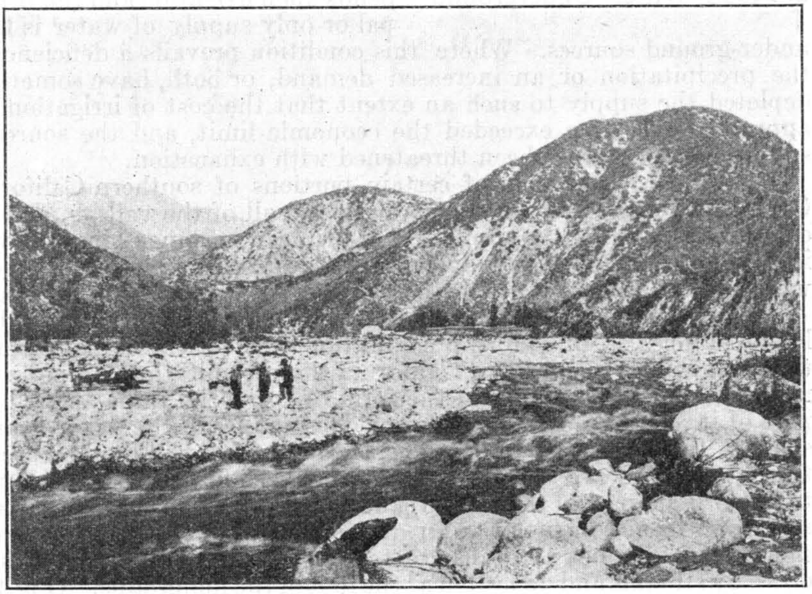

FIGURE 97.—Head of gravel cone at mouth of Santa Ana Canyon, near Mentone, Calif.

areas with complete success. The city of Los Angeles, for example, maintains well-devised spreading and storage works in the San Fernando Valley. Orange, San Bernardino, and Riverside Counties have pooled their interests and formed a tri-county water conservation association with a view to the storage of the flood waters of Santa Ana River and have been more or less successful each year since about 1911. The records of the association show a maximum storage for one year, that of the season of 1921–22, of 81,000 acre-feet. Another association spreads water, whenever enough is available, over an area of about 1,000 acres of the Lytle Creek cone, and there are extensive spreading works in the San Antonio and Cucamonga Creek areas.

The great value of water spreading in the conservation of the run-off of southern California is well illustrated by the fact that the quantity of water thus stored in the San Gabriel cone on a wetted area of not to exceed 40 acres was over 12,000 acre-feet in the season of 1929–30, although that season was one of low precipitation.

Different methods of spreading are employed in different localities. One is to run the water through ditches constructed in porous materials, diverting the streams into smaller and smaller channels from

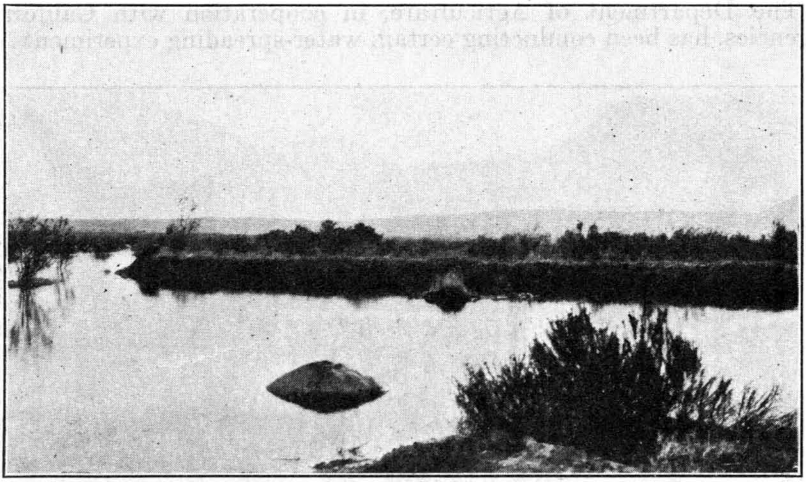

FIGURE 98.—Basins formed by check or contour dams built on the flatter slopes of the gravel cones serving the double purpose of stimulating percolation and settling the storm waters

which the water is distributed in thin films over gravelly areas. In the basin or check method (fig. 98) the water is held in numerous shallow percolation basins created through the construction of low

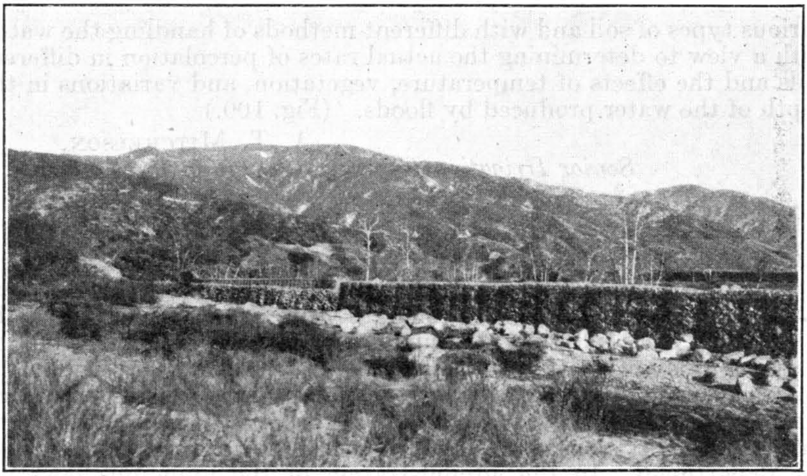

FIGURE 99.—One of the spreading or retarding dams built across the stream bed. Note the construction of this dam, formed by encasing bowlders in a binder of hog wire. The low section on the left end of the dam serves as a spillway thereby causing the overpour to meander over the higher portions of the gravel cone in its passage back to the stream bed. This, of course, stimulates percolation.

rock and earth dams. (Fig. 99). Still another method is to use horizontal tunnels or vertical shafts, or both, to conduct the water to the underground gravel deposits that serve as reservoirs.

Usually all of the works needed for the complete and efficient storage of water by spreading can be quickly and cheaply constructed. The areas utilized are generally of little or no value for other purposes and water thus stored is subject to little loss from evaporation.

The Department of Agriculture, in cooperation with California agencies, has been conducting certain water-spreading experiments on

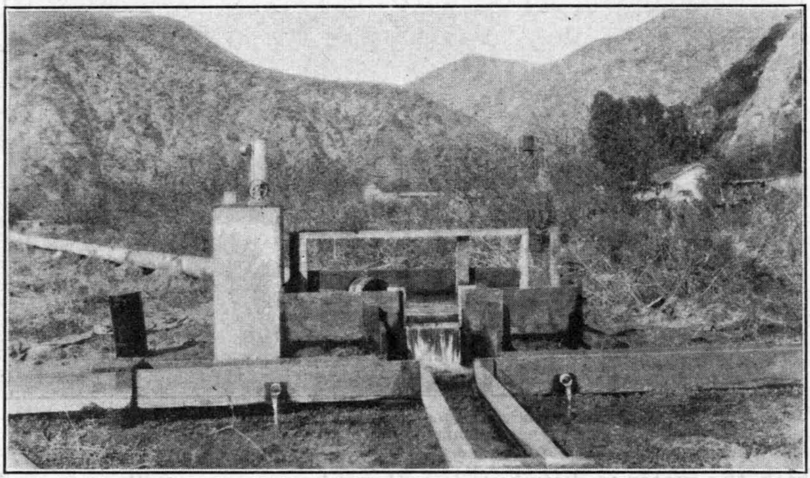

FIGURE 100.—Supply and metering system on the experimental plot of the Department of Agriculture near Azusa, Calif. The water is distributed over the accurately measured area in such a manner as to get an even film of water over the entire surface. Instruments for determining the percolation rate per day, the soil and water temperature, and the evaporation or transpiration losses are installed here

various types of soil and with different methods of handling the water, with a view to determining the actual rates of percolation in different soils and the effects of temperature, vegetation, and variations in the depth of the water produced by floods. (Fig. 100.)

LAW Administration by the Department Raises Important Legal Issues By direction of Congress the legal work of the United States Department of Agriculture is performed under the supervision of the solicitor who, by virtue of this authority, acts as legal adviser to the Secretary and to the various administrative officers. The solicitor is assisted in the performance of his duties by a corps of attorneys who are attached to various office divisions, each of which specializes in certain activities of the department. In the administration of the numerous laws enacted by Congress and the regulations promulgated thereunder relating to agriculture and allied subjects, legal questions and controversies of many kinds must necessarily be considered. Some of these controversies are sensational in their developments while others, although lacking in sensational factors of interest, are determinative of questions of great importance to the individual or to the country at large.

On occasions in the enforcement of public rights the Government becomes involved in cases which also concern private interests and at times these private interests far outweigh in monetary considerations the interests of the United States. The participation of the Government in such cases is not due to any desire to take part in private differences but to maintain those principles of justice and equity having for their object impartial enforcement of the laws, which are so necessary to the prosperity and success of an ever-advancing sovereignty.

Many thousands of acres of land in the public-land States of the country are embraced in our national forests which are administered by the Department of Agriculture. Such lands although withdrawn for forest purposes are subject to disposal to individuals under the mining laws of the United States which are administered by the Department of the Interior. This is occasioned by a desire to encourage the development of our mineral resources. But to be so acquired a tract of land must be of a substantial mineral character. Recently a mineral application was filed for a tract of land within the boundaries of the Beaverhead National Forest, Mont. Upon an examination of the land by the forest officials it was found that the land itself was nonmineral in character but supported a vast pile of mineral tailings from mining operations on other lands, confined by a cribbing made of logs and bags. It developed that these tailings had been placed on the land many years ago by a mining company to await improved methods for the extraction of the mineral values remaining in them. Although much precious metal had been recovered from the ore years ago it was estimated by mining engineers that the material is now worth in excess of $1,000,000.

Mineral Character of Land Asserted

While it was evident that the mineral applicant was seeking to acquire possession of valuable mineral tailings, he sought to prove the mineral character of the land itself in support of his claim. Anticipating failure in this respect he also alleged an abandonment by the owner of the tailings in which event it was urged that they would have ceased to be personal property and become a part of the realty thereby rendering the land upon which they rested mineral in character and subject to disposition under the mineral laws of the United States. If successful in this it meant that the United States would lose its land and the successor to the mining company a fortune in the tailings. The applicant sought to show that the cribbing erected was for the purpose of preventing the tailings from contaminating the water in the creek, which was used by cattle, and that the mineral tailings had been abandoned years ago. However, after extended proceedings it was held by the Interior Department that the land in its natural condition was nonmineral in character and that under the circumstances shown no mineral character was imparted to it by the deposit of the tailings. The claim on June 9, 1930, was declared void, the ownership of the land remaining in the United States and the tailings retaining their true character as personal property.

When Congress deems it necessary to regulate a business it is not unusual for those who are restricted in their activities to seek to tie the hands of the executive officers charged with the administration of a particular law. The packers and stockyards act of 1921 was passed to secure the free and unburdened flow of livestock from the ranges and farms to consumers of meat and meat products, or still as livestock to other parts of the country. Then it was desired to provide against the exorbitant charges, duplication of commissions, and deceptive practices in the passage of livestock through the stockyards made possible by collusion between the stockyards, the commission men, the packers, and the dealers. The act declares that persons engaged in the business of buying or selling in interstate commerce, livestock at a stockyard on a commission basis are market agencies; requires such agencies to furnish their services upon reasonable request, without discrimination and at reasonable rates and confers upon the Secretary of Agriculture the power to determine what are just and reasonable rates and charges for their services.

Secretary's Action Upheld

The Secretary of Agriculture prescribed a tariff of maximum charges for such services at the Omaha Union Stockyards. An attempt was made in the courts to enjoin enforcement of this order and to set it aside by 58 concerns comprising the entire membership of the Omaha Livestock Exchange. It was urged by the plaintiffs that the packers and stockyards act does not purport to confer upon the Secretary power to prescribe commission rates and that if it does it is unconstitutional because it provides for the fixing of charges for personal services, in a manner constituting a denial of the liberty guaranteed to the plaintiffs by the Federal Constitution. The Supreme Court of the United States on February 24, 1930, however, pointed out that the plaintiffs enjoyed a substantial monopoly at Omaha of an indispensable service in interstate commerce in livestock, having eliminated rate competition and substituted for it rates fixed by themselves. The court said that there was nothing in the nature of monopolistic personal services which makes it impossible to fix reasonable charges to be made therefor and that there is nothing in the Constitution which limits the Government's power to regulate the businesses which employ substantial capital and that inasmuch as the Secretary's order prescribes only the charges to be made in individual transactions it is not an attempt to fix a maximum wage or net income for anyone. The court upheld the power of the Secretary to prescribe reasonable rates for the buying and selling of livestock at public stockyards and approved the rates prescribed for services at the Omaha Union Stockyards, and the method employed by the department in determining those rates.

Again in the case of Ambruster *v.* Mellon et al., an attempt was made to enjoin the Secretaries of the Departments of Treasury, Agriculture, and Commerce from permitting the importation into this country of certain qualities of ergot of rye which were claimed to be under the legal standard and dangerous to the public health. It was said that such importations resulted in irreparable injury to Ambruster, who was the importer and owner of quantities of ergot of rye of the standard character. It was urged that the duty of the departmental executives was mandatory and permitted the exercise of no official discretion in the determination of the admissibility of drugs. The Court of Appeals of the District of Columbia on May 5, 1930, held, however, that the authority of these executives is not simply ministerial in character in the particular under discussion but calls for a finding of fact and the exercise of judgment upon the facts when found, and stated that the exercise of this authority will not be reviewed by the courts unless it has been capriciously or arbitrarily exercised.

Execution of Road Agreements

Recently the authority of the Secretary of Agriculture under the Federal highway act to withhold approval of contracts for Federal-aid road projects until a particular contractor had made an adjustment with a State under a previous closed contract for road building which the Secretary had found had not been properly performed, was questioned. The contractor denied the right of the Secretary to reopen the question of the contractor's past performances in respect to the execution of road agreements. The Supreme Court of the District of Columbia on May 31, 1930, stated, however, that if the Secretary should be of the opinion that the contractor had failed properly to perform his work in the past and had failed to make good the losses occasioned thereby, it would seem to be common business procedure on the part of the department to decline to approve any further contracts with that particular contractor until he had made good the losses due to his faulty work.

Peaceful and lawful means to determine the legality of acts performed by representatives of the department are not objectionable. But unfortunately recourse is sometimes had to force on the part of those who seek to avoid the requirements of law. An employee of the United States Department of Agriculture in company with other inspectors went to several farms in a middle-western State for the purpose of applying the tuberculin test to cattle in accordance with State and Federal laws. Approximately 1,900 cattle owners out of 1,952 in the particular county had requested this test. The remaining cattle owners opposed a compulsory testing of cattle. The inspector was denied permission to examine the cattle of certain of these owners who stated that they would oppose by force and arms if necessary any attempt to examine their cattle or to apply the tuberculin test. These farmers were reported to have been armed with shotguns and farm implements and to have accompanied their actions with threatening and abusive language. The ringleaders were indicted by a Federal grand jury; convicted on May 5, 1930, in the United States District Court and fined in amounts varying from $100 to $350. The court in pronouncing sentence stated that it did not impose incarceration, because of the novelty of the case, but intimated that further cases of a similar nature would be dealt with more severely.

Attorney, Office of the Solicitor.

LEATHER Injured by Mud, Water, and Heat; Preserved by Grease

Leather, although tough, is responsive and an investment of a reasonable amount of attention and treatment in the care of leather goods yields a profitable dividend in greater satisfaction and service.

The arch enemies of leather are mud, water, strong acids and alkalies, extreme dryness, and prolonged exposure to heat and direct sunlight. Among its best friends is oil or grease, preferably of animal or vegetable origin. Oils and greases help to protect the fibers against decay and to lubricate them so that they are flexible and can slide back and forth without cracking or breaking.

To get the most service out of leather goods treat them promptly and periodically. All too often no thought is given to preservation until the leather is cracky, brittle, and powdery and has practically no strength left. It is then really too late. (Fig. 101.) The aim should be to keep the leather in its original sound and serviceable condition.

When oiling leather, use judgment and care. To do any good, the oil must get into the leather—not simply on it. This means that enough oil must be used to satisfy the leather. On the other hand, an excess of oil, which would leave the surface greasy and smeary, usually is undesirable. It is safest to apply but a little oil at a time while carefully noting how the oil is taken up by the leather. Applications should then be repeated until the leather is well oiled. Uniform light applications can be conveniently made with a small wad of oily cheese-cloth. For general oiling, neat's-foot oil, castor oil, lanolin, olive oil, and winter sperm oil, or mixtures of them, are good. It should be remembered that any oil or grease will darken tan or light-colored leathers.

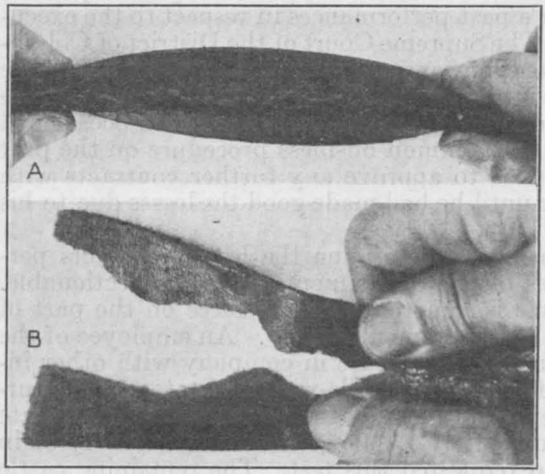

FIGURE 101.—Too late—when leather gets cracky (A) and tears easily (B), treatment will do but little good

Effects of Water

Many leather articles are ruined by the way they are mistreated when wet. In the first place, unless made for continuous use in water, leather goods should not be worn or used while wet any longer than is absolutely necessary. Wet leather wears away rapidly. It is easily stretched out of shape and readily cut through by thread. Much damage is done to wet leather by the way it is dried. Surprising as it may seem, wet leather burns much more readily than dry leather. A temperature hotter than the hand can bear is destructive.

Wet leather should be dried slowly and never at a temperature too hot for the bare hand. Wet shoes and other leather articles should be reshaped as much as possible and kept so with forms or pads while drying. If a polish or shine is not desired, an application of oil to the leather while it is still damp but not wet will make it more pliable and soft when dry.

Many leather articles such as brief cases, suit cases, bags, and upholstery leather can be improved in appearance and condition by dressing them with a saddle-soap preparation according to directions on the container. After treatment, the leather should be thoroughly polished and rubbed until it no longer stains a white cloth.

Direct sunlight is harmful to leather of certain types. Leather-bound books, leather-upholstered furniture, and leather articles destined for long service should be kept out of direct sunlight.

Mildewing of Leather

The molding or mildewing of leather is a frequent occurrence. There are no commercial leathers that under favorable conditions of moisture and heat will not develop mold growth. This is not, however, a condemnation of leather. Molds are present everywhere, and when conditions are right they will grow if they can find a medium on which to live. Molds can not grow without a certain amount of moisture, and the surest way to prevent mold growth on leather articles is to keep them in a dry, well-ventilated, well-lighted place. As a rule, the use of poisons to prevent mildew is not recommended. Molds seldom seriously injure leather. They do, however, frequently change its color. Mildew should be removed with a damp cloth.

Because a high polish and finish is desirable for shoes for street and dress wear, these can not be heavily oiled and greased. Such shoes should always be kept polished not only because of appearance but also because polishing leaves a thin film of wax that helps to turn water to keep the pores of the leather from becoming filled with dirt, and to prevent staining of the uppers.

Old shoe uppers on which polish has accumulated can be improved by scrubbing them thoroughly with clean gasoline or naphtha and then polishing twice.

The uppers of street shoes can be made more pliable, if desired, and more resistant to wetting by oiling them with castor oil. Castor oil is the only oil that can be used if the uppers are to be polished afterward and even castor oil must be applied in very small quantities and the shoes left in a warm place overnight before being polished.

The soles of street shoes can be made more water and wear resistant by brushing them with warm neat's-foot oil, castor oil, or lanolin, being very careful, however, that the oil does not touch the uppers.

Patent leather uppers probably are kept in the best condition by simply washing them when necessary with a soft, wet cloth, without subsequent use of polishes and dressings. A very light oiling of the uppers once or twice a month with castor oil or vaseline will help to prevent cracking.

Work shoes for winter or wet wear will last longer and be more of a protection if waterproofed. A mixture of 8 ounces of neutral wool grease, 4 ounces of petrolatum, and 4 ounces of paraffin wax, or one consisting of 16 ounces of petrolatum and 2 ounces of beeswax makes a good waterproofing compound.

Care of Harness and Belts

Harness should be kept clean and in a soft, pliable condition. It should be washed and oiled from two to four times a year, depending upon its use and condition.

A driving belt can not do its best and last as long as it should if not properly installed. Belts, like harness, should be kept clean, flexible, and nourished. Pasty mixtures of butterlike consistency made from neat's-foot oil, castor oil, tallow, and neutral wool grease are good belt dressings.

Leather bookbindings will last longer if kept well oiled and dressed. Dry, powdery, cracked, and broken leather bindings, starving for oil, are a familiar sight. This condition can be forestalled for many years by keeping the bindings well oiled, using pure 20° C. cold-test neat's-foot oil, United States Pharmacopœia castor oil, United States Pharmacopœia anhydrous lanolin, or a mixture of about equal parts of the lanolin and neat's-foot oil. A good dressing in emulsion form may be made of the following: Anhydrous lanolin, 30 parts; castor oil, 12 parts; Japan wax, 5 parts; powdered sodium stearate, 3 parts; and distilled water, 50 parts. The sodium stearate is dissolved in the water by gentle heating; the lanolin, oil, and wax are melted together and then poured in a thin stream into the sodium stearate solution while the whole is being stirred. When cold, the mixture is beaten or whipped into a cream. An emulsion such as just described can also be used to clean the surface of old, soiled vellum bindings.

Oils and dressings must be worked well into the bindings and as much oil applied as is possible without leaving the binding greasy.

Old powdery and dusty bookbindings can be made more pleasant to handle and more serviceable by lacquering them with a clear, flexible, "soluble-cotton" or cellulose-nitrate brushing lacquer. Before lacquering, such bindings should be oiled as heavily as possible without leaving the surface greasy for they can not be oiled after lacquering. Furthermore, if not well oiled, some of the lacquer is taken up by the leather, which increases its brittleness and consequently promotes breakage, especially at the hinges.

Chemist, Bureau of Chemistry and Soils.

LEGUME Inoculation by Cultures Depends Finally on Field Test

The practice of treating soil with soil for the growth of legumes is not new. Just when this procedure was found to be beneficial is not known but records indicate that it was practiced in Holland, Finland, Italy, and Germany over a hundred years ago. And prior to this—more than a thousand years—historians report that legumes were considered important for their fertilizing value. This early knowledge of certain of the legumes shows that the function of these plants in agriculture was recognized although the underlying principles were unknown.

Nitrogen assimilation by plants was a much discussed question in the early part of the nineteenth century. Boussingault, a Frenchman, in 1838 partially solved this problem by demonstrating that clover could obtain nitrogen from the air but wheat could not. This was only a small advance and did not uncover the agency responsible for the fundamental difference between legumes and nonlegumes. In 1879 it was shown that nodules on legumes could be prevented by sterilizing the soil in which they were to be grown. This indicated that an influence in unsterilized soil was responsible for their formation. It remained for two German investigators, Hellriegal and Wilfarth, in 1886 to show that nodules of legumes are caused by bacteria and by virtue of this invasion of plant roots nitrogen is fixed and the plant benefited. This discovery marked a great advance in the science of agriculture.

Natural Inoculation

The nodule-producing bacteria are found in the soil as well as in the nodules. This explains why the earlier farmers obtained beneficial results by transferring soil from one field to another. While these foot oil, United States Pharmacopœia castor oil, United States Pharmacopœia anhydrous lanolin, or a mixture of about equal parts of the lanolin and neat's-foot oil. A good dressing in emulsion form may be made of the following: Anhydrous lanolin, 30 parts; castor oil, 12 parts; Japan wax, 5 parts; powdered sodium stearate, 3 parts; and distilled water, 50 parts. The sodium stearate is dissolved in the water by gentle heating; the lanolin, oil, and wax are melted together and then poured in a thin stream into the sodium stearate solution while the whole is being stirred. When cold, the mixture is beaten or whipped into a cream. An emulsion such as just described can also be used to clean the surface of old, soiled vellum bindings.

Oils and dressings must be worked well into the bindings and as much oil applied as is possible without leaving the binding greasy.

LEGUME Inoculation by Cultures Depends Finally on Field Test

The practice of treating soil with soil for the growth of legumes is not new. Just when this procedure was found to be beneficial is not known but records indicate that it was practiced in Holland, Finland, Italy, and Germany over a hundred years ago. And prior to this—more than a thousand years—historians report that legumes were considered important for their fertilizing value. This early knowledge of certain of the legumes shows that the function of these plants in agriculture was recognized although the underlying principles were unknown.

Nitrogen assimilation by plants was a much discussed question in the early part of the nineteenth century. Boussingault, a Frenchman, in 1838 partially solved this problem by demonstrating that clover could obtain nitrogen from the air but wheat could not. This was only a small advance and did not uncover the agency responsible for the fundamental difference between legumes and nonlegumes. In 1879 it was shown that nodules on legumes could be prevented by sterilizing the soil in which they were to be grown. This indicated that an influence in unsterilized soil was responsible for their formation. It remained for two German investigators, Hellriegal and Wilfarth, in 1886 to show that nodules of legumes are caused by bacteria and by virtue of this invasion of plant roots nitrogen is fixed and the plant benefited. This discovery marked a great advance in the science of agriculture.

Natural Inoculation

The nodule-producing bacteria are found in the soil as well as in the nodules. This explains why the earlier farmers obtained beneficial results by transferring soil from one field to another. While these bacteria may live indefinitely in a soil suited to their growth, it is believed that in most cases the soil will be better populated with them if the host plant upon which they function is grown from time to time. In the nodule, the bacteria are insulated from other bacteria and propagate therein in the absence of competition from without. When the plant dies or becomes dormant the nodules rot and the bacteria pass back into the soil to await another chance to associate with their particular host.

Since the bacteria which cause nodules are adapted to certain legumes only and are present in soils usually on account of the growth of their specific plants it quite often happens that certain strains of organisms are not present. Sometimes they may have been eliminated by conditions under which it was impossible for them to live.

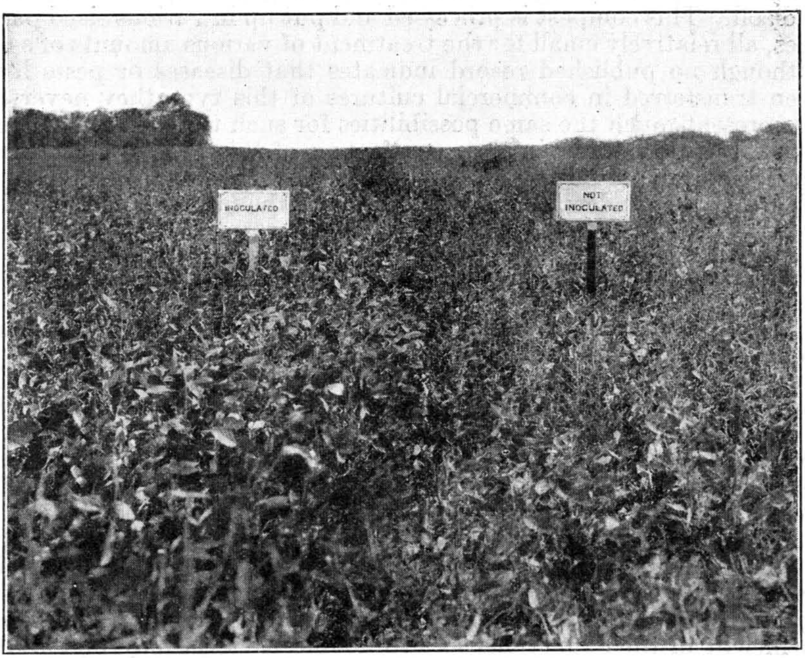

FIGURE 102.—Soybean field which shows the effect of nodule bacteria and of the lack of them

These are mainly acidity, heating, drying, and lack of aeration. The absence of the proper organism makes it necessary for best results to introduce them, correcting, of course, the conditions which are detrimental, in advance of their application. (Fig. 102.)

When the inoculation question was first studied in the United States about 25 years ago the use of naturally inoculated field soil was commonly advised and where satisfactory material and labor for its preparation is available, its use is often recommended to-day. In certain ways the transfer of soil is objectionable; it requires much labor for its collection and distribution; it may be the cause of distributing diseases and pests.

To obviate the extensive drilling of soil over the whole field the Illinois Agricultural Experimental Station proposed in 1904 a method by which seed is treated lightly with a 10 per cent glue solution and then dusted with a small quantity of naturally inoculated field soil. Through this process the soil is glued to the seed and the proper nodule bacteria it contains are in a position to enter the roots promptly when they form. The glue method has been widely practiced and is still used. A modification of this method involves the shaking of naturally inoculated field soil with water and applying the muddy suspension to the seed. In either method the seed is allowed to dry before sowing. Naturally inoculated field soil also has been used by mixing it with an equal part by volume of the seed at the time of sowing. Other ratios of seed to soil have been used, the soil usually being of smaller volume than the seed.

A number of commercial concerns have utilized the fact that in favorable soils the numbers of legume bacteria may be greatly increased by growing legumes and composting plants, roots, nodules, and soil. This compost is processed and put up in various sized packages, all relatively small for the treatment of various amounts of seed. Although no published record indicates that diseases or pests have been transferred in commercial cultures of this type they nevertheless present much the same possibilities for such transfer as field soil. It is also evident that in the manufacture of this type of culture not much equipment beyond that available on the farm is necessary. With a proper understanding of the subject the farmer is in a position to make his own inoculation of this character.

Artificially Prepared Inoculation

Nodule bacteria are found in soil or nodules and from the latter source it has been found possible to isolate them in pure culture. A pure culture of bacteria is a growth of one kind only, usually maintained on a sterile solid nutrient, shielded from external invasion by glass and sterile cotton. Cultures may be maintained pure in sterilized soil and liquid nutrient but for purposes of study and observation a jellylike substance called agar made from certain kinds of seaweed is used. The organisms grow on the surface of this material.

After a pure culture is obtained it is necessary to determine whether it will produce nodules satisfactorily on the plant for which it is intended. This is usually accomplished by tests on plants in large bottles or protected sterile pots. Just as occasional animals and plants are inefficient in their functions so also nodule bacteria may be variable in their ability to fix nitrogen for the benefit of the plant. Some organisms have been found which produce nodules but are detrimental to the plant. It is therefore very necessary that a culture be thoroughly tested before it is distributed for inoculation purposes.

Thirty-four years ago Nobbe and Hiltner of Germany began the commercialization of the pure cultures by distributing them in glass containers to farmers. The Department of Agriculture in 1902 began the preparation of pure cultures after a study of this work by one of its investigators. The first method consisted of adding pure cultures to absorbent cotton and slowly drying this impregnated material at a very gentle heat. Pieces of this inoculant with sugar and other chemicals were sent to farmers for development on the farm. At that time an effort was being made to establish a source of inoculation on the farm for transfer to other local areas.

The preparation of cultures of this type on the farm was not satisfactory and was abandoned in favor of a liquid pure culture. The liquid type of culture is satisfactory for rather prompt usage and has the advantage of being ready to apply without further preparation. More than a half million packages of nodule bacteria for the treatment of more than a million bushels of legume seed have been distributed to farmers for experimental purposes by the department in the last 25 years.

Commercial inoculation derived from pure cultures first appeared in the United States on cotton, then agar and liquid followed, agar being still widely employed. Peat and sand are also used as carriers for legume bacteria, the former finding a wider application than the latter presumably on account of its lightness and ability to retain water.

For selling as an article of commerce, especially over large territories, it is necessary to have a material that will withstand conditions of transit and storage in seed stores for at least the growing season and certain of the manufacturers use ventilated stoppers to help keep alive the organisms on agar in bottles. A number of the producers of inoculation place a date on the package after which it is not desirable to use it.

The method of applying inoculation of the commercial type has not varied greatly in 25 years. The intent is to put the organisms in position to enter the roots when they form. A suspension of the organisms found in a soil, sand, peat, or agar culture is obtained by shaking with water. This mixture applied lightly to the seed dries quickly and permits of prompt sowing which practice is preferable because of the inability of certain strains of nodule bacteria to live very long on dry seed.

Experiments With Dry Applications

A recent development endeavors to put the organisms on the seed by means of dry dusts thereby eliminating water altogether in the process. It is well known that legume bacteria are very susceptible to drying so that one would not expect them to live satisfactorily in carriers containing only a little moisture. Of course, the real test of a culture is the result it will produce in the field. Evidence from this source has at least indicated that quite often the dry applied inoculants do not compare favorably with good quality material prepared for liquid application used according to directions.

With the appearance of the dry inoculants has come seed inoculated at the seed store. It is quite probable that some of the surviving bacteria in the dusts will live on the seed just as natural dirt on seed often retains them alive and is the means of their occasional transferance. However, since the preliminary work shows unfavorable results when dusts are applied at the time of planting no improvement in the efficiency of the bacteria is to be expected by storing on dry seed. Until more evidence is available dry inoculation must be considered in the experimental stage and those who desire to use them may find it advantageous to compare their efficiency with that of those applied with moisture.

Regulation of Commercial Legume Inoculants

In the period during which commercial legume bacteria cultures have been sold there have appeared materials which were rather worthless. Sometimes this condition may have been due to treatment subsequent to leaving the manufacturer, although quite as often it has been traced to faulty handling in the preparing laboratory.

The farmer has no means of telling whether a culture is good or bad. A date on the package may show how old it is, but it gives no idea of its quality. This can be determined only by planting treated and untreated seed side by side on the same soil—a very advisable practice. The only immediate criterion of satisfactory material available to the farmer is the past reputation of the firms which make and sell it, respectively. But this is not entirely sufficient with material of such a perishable nature.

In 1906 an inspection of commercial cultures by the Department of Agriculture revealed that many of them on the market at that time were worthless. Since that time the department has made annual inspections of samples of commercial inoculating materials, and while there has been a more or less gradual advancement in quality there is still much room for improvement. Information concerning materials included in this inspection is available in the form of a sheet which gives the names of the firms whose samples have given satisfactory results as well as the names of public institutions which are engaged in the distribution of inoculating material.

Certain of the States have endeavored to regulate the sale of commercial legume inoculants. New Jersey started in 1919 to make annual tests of material found on sale within the State; Wisconsin put a law to control these materials on the books in 1921; Maryland followed with a similar law in 1922. A Kansas law dealing with inoculants appeared in 1927. Several other States have considered laws for this purpose, but they are not yet on the statute books. All of these efforts in behalf of better quality material are commendable and tend to weed out the deficient manufacturers. However, the farmer should not depend entirely upon those regulatory agencies but should determine for his own circumstances the effect of the culture he purchases by comparing plants from treated seed with those from untreated.

LEWIS T. LEONARD,
Bacteriologist, Bureau of Chemistry and Soils.

LESPEDEZAS Introduced from Asia Thrive in Widening Area in U. S.

In 1846 Thomas C. Porter, of Monticello, Ga., found a plant that was new to him. He sent it to the Gray Herbarium and learned that it was *Lespedeza striata* and that as it was not native to the United States, it must in some way have emigrated from Japan. This plant became known as Japan clover, but the more desirable name of Lespedeza has of late become more common.

How rapidly it spread during the next 20 years there is no way of knowing, but it certainly was noticeably more common and spread over a wider territory after the Civil War than before. Since that time the plant has steadily spread north and west until to-day it is found from eastern Kansas to the Atlantic and from central Indiana to the Gulf. Even during the last few years it has obtained a foothold farther north in Indiana and Ohio than where it was known to have grown 10 years earlier.

This spread of the species northward has resulted from variations in the seeding habits of individual plants. If seed produced in Louisiana to leaving the manufacturer, although quite as often it has been traced to faulty handling in the preparing laboratory.

The farmer has no means of telling whether a culture is good or bad. A date on the package may show how old it is, but it gives no idea of its quality. This can be determined only by planting treated and untreated seed side by side on the same soil—a very advisable practice. LESPEDEZAS Introduced from Asia Thrive in Widening Area in U. S.

In 1846 Thomas C. Porter, of Monticello, Ga., found a plant that was new to him. He sent it to the Gray Herbarium and learned that it was *Lespedeza striata* and that as it was not native to the United States, it must in some way have emigrated from Japan. This plant became known as Japan clover, but the more desirable name of Lespedeza has of late become more common.

How rapidly it spread during the next 20 years there is no way of knowing, but it certainly was noticeably more common and spread over a wider territory after the Civil War than before. Since that time the plant has steadily spread north and west until to-day it is found from eastern Kansas to the Atlantic and from central Indiana to the Gulf. Even during the last few years it has obtained a foothold farther north in Indiana and Ohio than where it was known to have grown 10 years earlier.

This spread of the species northward has resulted from variations in the seeding habits of individual plants. If seed produced in Louisiana is seeded at the Arlington Experiment Farm near Rosslyn, Va., most of the resulting plants, while making a good growth, will not mature seed; but some will, and it is these earlier plants that establish the species at a new point. There will doubtless be a limit to this northward spread, since the Lespedezas are hot-weather plants and besides appear to be strongly influenced in seed production by the length of day—the longer the summer day the less freely do the plants seed.

On good soil, especially in the more southern part of its range, the common Lespedeza grows tall enough for hay, but on most soils it is useful only for pasture and soil improvement. The giant varieties generally make more hay.

The tendency to vary, referred to above, also is displayed in other directions, and this fact was taken advantage of some years ago when S. H. Essary of the Tennessee Agricultural Experiment Station made

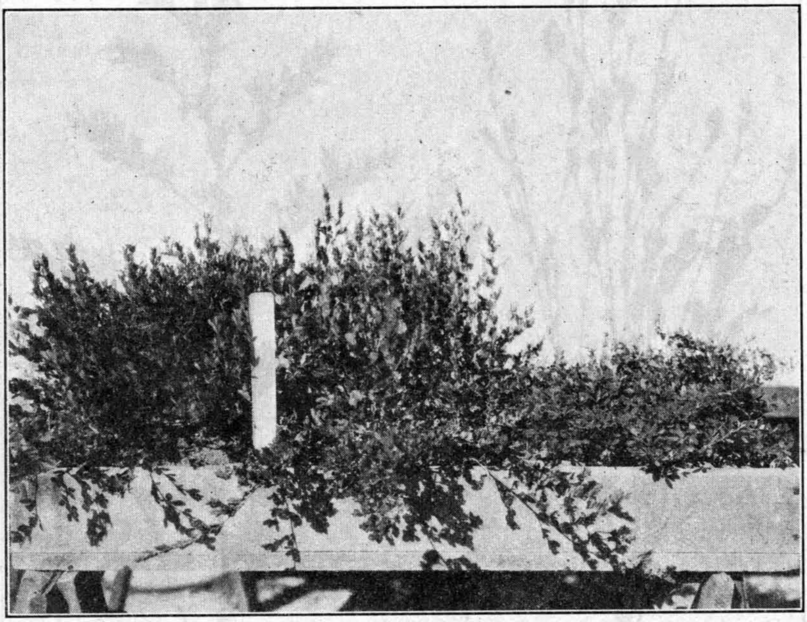

FIGURE 103.—Left to right Kobe, Korean, and common Lespedeza. At Washington, D. C., the Korean grows taller than the other

a number of selections out of the common run of *Lespedeza striata*. Several selections were made, but only one was considered valuable enough to introduce. This is a tall, upright-growing form, especially suited to haymaking, and is now in use as Tennessee 76. Other varieties have been found, and one of these, known as Kobe from the city in Japan where it was found, also has been introduced into the United States. It most nearly resembles Tennessee 76, but lacks the naturally erect habit of that variety and has slightly larger leaves and strikingly larger seeds. Both of these varieties may be called giant forms of the common Lespedeza of the South.

A Species From Korea

Another closely related species has been introduced from Korea, though it also is found in Japan and in China. This is *Lespedeza* *stipulacea,* known in the United States as Korean Lespedeza. This, like the Japanese Lespedeza, is an annual, but it has larger leaves, is much earlier, and has also a distinctive seed. The Korean Lespedeza will ripen farther north than any of the other varieties and is a heavy seeder. One plant has been known to produce 14,799 seeds.

All of these Lespedezas are among the most valuable forage plants for the South. (Fig. 103.) While they respond to lime, they get along

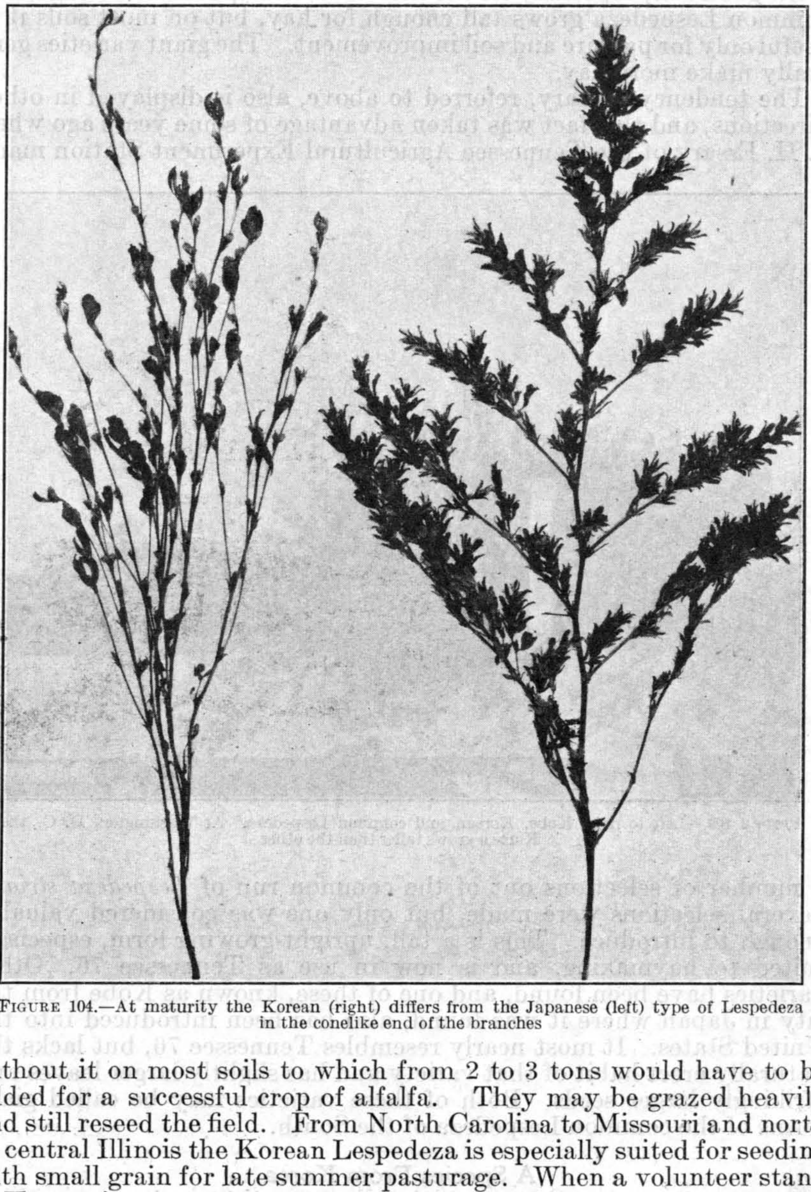

FIGURE 104.—At maturity the Korean (right) differs from the Japanese (left) type of Lespedeza in the conelike end of the branches

without it on most soils to which from 2 to 3 tons would have to be added for a successful crop of alfalfa. They may be grazed heavily and still reseed the field. From North Carolina to Missouri and north to central Illinois the Korean Lespedeza is especially suited for seeding with small grain for late summer pasturage. When a volunteer stand of Korean is secured it is ready to graze a week or two earlier than the later varieties, because of its more rapid growth. Late in the season, however, the late varieties have the advantage, since in the latitude of Washington, D. C., the Korean has matured and died long before the late sorts are killed by frost.

At maturity there is a striking difference between Korean and the other annual Lespedezas (fig. 104), and this is of importance in connection with the harvesting of seed. In the Korean the seeds are borne 1 to 3 in the axils of the leaves near the ends of the branches. The leaves then turn forward at maturity and inclose the seeds, thus making a conelike end to the branch. The protection thus afforded results in less shattering of seed at harvest. The common, the Kobe, and the Tennessee 76 must be harvested with a seed pan if much seed is to be secured. With the Korean a seed pan will catch some seed, especially if the crop is overripe, but frequently this can be dispensed with. There is also a wider latitude in the time at which the Korean may be cut for seed than is the case with the other varieties of Lespedeza.

FIGURE 105.—*Lespedeza sericea*, an oriental perennial species

First-class hay may be made of any of these Lespedezas, but when cutting is delayed until a large part of the seed is ripe the hay is inferior. There seems no reason why Lespedeza hay should not be widely used and be a standard hay in the southern markets which now bring in thousands of tons. To make Lespedeza hay a standard and desirable product, however, it must be cut long before the seed is ripe. Fortunately it is possible to do this and still get seed by cutting early so that a second growth will develop and ripen seed. Unless the season is very dry, enough seed will be made on such second growth at least to reseed the field.

Wild Species Are Perennial

There are wild species of Lespedeza in the United States, but they are all perennial, and, so far as is now known, none are of value in agriculture. There are also many perennial species in the Orient. It is an interesting fact that the genus Lespedeza is found almost exclusively in eastern North America and in eastern Asia. There are no native species on the Pacific coast and none in Europe, Africa, or South America. When, therefore, the Japanese Lespedeza emigrated to the southeastern United States some time before 1846 it was quite at home and proceeded to establish itself firmly. Whether this will happen with the perennial species, some of which have been introduced experimentally, remains to be determined. Some, such as *Lespedeza sieboldi* and its more showy horticultural variety known as *L. japonica*, are offered by nurserymen as ornamentals. They are woody, shrublike herbs, the year's growth in the latitude of Washington, D. C., being killed nearly or quite to the ground and the new growth coming from a permanent crown.

All Lespedezas will thrive on land too poor and too sour for such plants as alfalfa or red clover. Some of the oriental perennials are being experimented with for forage. (Fig. 105.) Whether any one of them will ever become as widely popular as the annual forms remains to be seen.

Principal Agronomist, Bureau of Plant Industry.

LETTUCE Breeding for Disease Resistance Progresses Rapidly A surprisingly large percentage of the lettuce used in the United States is grown in California and Arizona. It is sold everywhere under the trade name "Iceberg" lettuce. To seedsmen and growers the variety is known as New York or New York Special, of which there are now several similar but distinct strains. In 1929 the car-lot shipments of lettuce for the country were 53,000 cars, of which California shipped 35,000 and Arizona 8,000, making 81 per cent of the total for the country from these two States. In California the two important producing areas are the Imperial Valley, which in 1929 shipped 12,000 cars from December to March, and the Salinas-Watsonville district, which shipped 19,000 cars from April to December, 1929.

Brown Blight

In 1922 the United States Department of Agriculture undertook the investigation of a threatening new disease in the Imperial Valley, now known as brown blight. Affected plants become stunted and yellow and gradually turn brown and die. The trouble was soon found to be a soil-borne disease which increases rapidly from year to year. In the Imperial Valley only one or two crops of lettuce could be grown before the soil became so badly infested that it was necessary to shift to new fields where lettuce had never been previously grown. So far as known lettuce is the only crop attacked by brown blight. The growing of other crops, like alfalfa, for five or six years on infested soil has, however, repeatedly failed even to reduce the disease in the soil. A large part of the lettuce land in the Imperial Valley is now heavily infested with brown blight. In the Salinas-Watsonville district the disease had until recently developed less rapidly, but is now increasing at an alarming rate, with indications that lettuce soils will become generally infested within the next few years. In Arizona the disease is bad in some sections, while there is little or none in others. So far as known brown blight occurs only in California and Arizona.

In the hope of finding resistance to brown blight, about 100 varieties of lettuce were grown on diseased soil in 1923. Two varieties, Big Boston and White Chavigne, proved to be entirely immune, but they are commercially useless in California and Arizona. These varieties were then crossed with the New York variety in order to combine their mentally, remains to be determined. Some, such as *Lespedeza sieboldi* and its more showy horticultural variety known as *L. japonica*, are offered by nurserymen as ornamentals. They are woody, shrublike herbs, the year's growth in the latitude of Washington, D. C., being killed nearly or quite to the ground and the new growth coming from a permanent crown.

All Lespedezas will thrive on land too poor and too sour for such plants as alfalfa or red clover. Some of the oriental perennials are being experimented with for forage. (Fig. 105.) Whether any one of them will ever become as widely popular as the annual forms remains to be seen.

It is sold everywhere under the trade name "Iceberg" lettuce. To seedsmen and growers the variety is known as New York or New York Special, of which there are now several similar but distinct strains. In 1929 the car-lot shipments of lettuce for the country were 53,000 cars, of which California shipped 35,000 and Arizona 8,000, making 81 per cent of the total for the country from these two States. In California the two important producing areas are the Imperial Valley, which in 1929 shipped 12,000 cars from December to March, and the Salinas-Watsonville district, which shipped 19,000 cars from April to December, 1929.

Brown Blight

In 1922 the United States Department of Agriculture undertook the investigation of a threatening new disease in the Imperial Valley, now known as brown blight. Affected plants become stunted and yellow and gradually turn brown and die. The trouble was soon found to be a soil-borne disease which increases rapidly from year to year. In the Imperial Valley only one or two crops of lettuce could be grown before the soil became so badly infested that it was necessary to shift to new fields where lettuce had never been previously grown. So far as known lettuce is the only crop attacked by brown blight. The growing of other crops, like alfalfa, for five or six years on infested soil has, however, repeatedly failed even to reduce the disease in the soil. A large part of the lettuce land in the Imperial Valley is now heavily infested with brown blight. In the Salinas-Watsonville district the disease had until recently developed less rapidly, but is now increasing at an alarming rate, with indications that lettuce soils will become generally infested within the next few years. In Arizona the disease is bad in some sections, while there is little or none in others. So far as known brown blight occurs only in California and Arizona.

In the hope of finding resistance to brown blight, about 100 varieties of lettuce were grown on diseased soil in 1923. Two varieties, Big Boston and White Chavigne, proved to be entirely immune, but they are commercially useless in California and Arizona. These varieties were then crossed with the New York variety in order to combine their brown-blight resistance with the New York type. This method of obtaining resistance involves the slow procedure of selecting plants that show the sought-for combination of characters over several generations in order to purify strains. It is only now, after several years' work, beginning to give the desired strains of lettuce.

A quicker method of obtaining brown-blight resistance was undertaken at the same time. Diseased fields were searched in the hope of finding resistant individual plants of the New York variety from which resistant strains could be developed. This method yielded quick results, and in 1926 two resistant strains were introduced under the names Imperial No. 2 and Imperial No. 3. (Fig. 106.) A third resistant strain was distributed in 1928 as Imperial No. 6. These strains make normal crops on the most severely diseased soils and have rapidly come into general use in the Imperial Valley. In 1930 they were

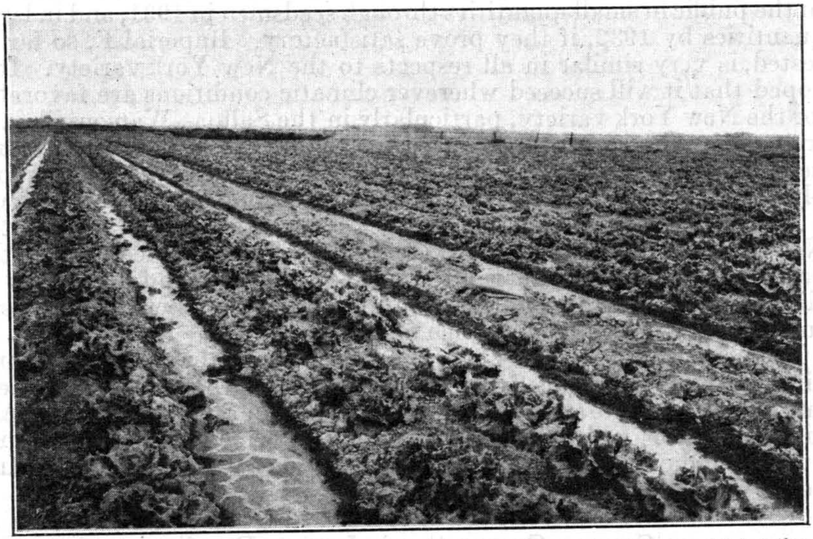

FIGURE 106.—Brown blight resistant lettuce. At right one double row (cap between rows) of the New York variety with all plants attacked by brown blight and dead or dying. All other rows are Imperial brown-blight-resistant strains with all healthy plants

planted on more than 75 per cent of the 38,000 acres in that area. It is generally agreed that without resistant strains, instead of increasing each season, the lettuce industry in the Imperial Valley would be rapidly declining, owing to the exhaustion of disease-free soil. These resistant strains are particularly adapted to the Imperial Valley, where they usually far outyield the original New York variety, even on disease-free soil. Unfortunately, they have proved to be more or less unsatisfactory in other sections.

Lettuce Mildew

Lettuce mildew, caused by the fungus *Bremia lactucae*, frequently injures the quality of the crop in California by attacking and yellowing or browning the outer leaves, although attacked plants usually make marketable heads. The New York variety and the brown blight resistant strains mentioned above are all highly susceptible to mildew.

In 1922 crosses were made between New York and a highly mildew-resistant Cos or Romaine variety from France. Considerable progress had been made in selecting mildew-resistant New York types from this cross when the most promising selections were again crossed in 1925 with the brown blight resistant Imperial No. 2 and Imperial No. 3 strains. Continued selection from these double crosses has finally, in 1930, given strains of the New York type which are highly resistant to both brown blight and mildew, or "double resistant."

"Double-Resistant" Lettuce

Early in 1930 small amounts of seed of the two most promising double-resistant strains, or strains that are resistant to both brown blight and mildew, were distributed to lettuce-seed growers under the names Imperial C and Imperial F. These strains should be available to the public in small quantities through seedsmen in 1931, and in large quantities by 1932, if they prove satisfactory. Imperial F, so far as tested, is very similar in all respects to the New York variety. It is hoped that it will succeed wherever climatic conditions are favorable for the New York variety, particularly in the Salinas-Watsonville district, where there is a pressing need for adapted resistant strains. Imperial C resembles the Imperial Nos. 2, 3, and 6 strains and will probably succeed best under Imperial Valley or similar climatic conditions.

All the disease-resistant strains are of the same general type as the New York variety and are marketed as "Iceberg" lettuce. With the possible exception of Imperial F, however, they respond differently to climatic and cultural conditions and must not be unwittingly substituted for New York by seedsmen or growers.

Lettuce-breeding work is being continued with the purpose of combining disease resistance with further improvements in quality, yield and adaptation to various cultural and climatic conditions. Additional strains will be named according to scheme, Imperial with a number indicating a strain resistant to brown blight only, and Imperial with a letter indicating a double-resistant strain.

Growers Cooperating in Lettuce Breeding

Much of the comparatively rapid progress in this lettuce-breeding work may be attributed to two causes. (1) Numerous growers have taken an active interest and have cooperated by furnishing land and labor for growing, breeding, and trial plots on a large scale. (2) A unique combination of climatic conditions has made possible the growing for breeding purposes of two generations of lettuce seed each year. The crop is planted in the Imperial Valley in September and October and harvested through the winter. The spring season in this reclaimed desert inland valley is warm and bright, maturing seed from the winter lettuce crop in May. This seed, planted immediately only 120 miles distant under the equable coastal climate of southern California, makes a summer crop of lettuce which matures seed in time to plant back in the Imperial Valley in September and October.

LIVESTOCK Are Healthier Than Formerly, According to Meat-Inspection Data Remarkable progress in the control and eradication of livestock diseases has taken place in recent years through the application of science. It is also gratifying to know that the improved health of domestic animals which scientific discoveries and methods have brought about is being observed at the livestock markets. Because of the millions of animals slaughtered each year and examined in a uniform manner under Federal meat inspection, the records of this service are of particular value in showing the relative extent and importance of each malady. This inspection represents about two-thirds of the estimated total slaughter.

From a commercial standpoint it is noteworthy that of nearly 75,000,000 food animals inspected at the time of slaughter, during the year ended June 30, 1930, only 1 out of 282 was condemned entirely because of disease, parasites, or other abnormal condition. The condemnations consisted principally of parts of carcasses since, in most cases, the abnormal condition was localized in the body. This information is typical of that obtained in other recent years. Although in percentage the loss in 1930 was small, the total quantity of meat condemned amounted to more than 50,000,000 pounds. Moreover, an animal malady is not stationary. Most diseases have a tendency to spread if not recognized promptly and either eradicated or controlled; and the trend of those that can be observed at time of slaughter may be readily portrayed graphically by the use of Federal meat-inspection records. Such a portrayal for the principal cattle diseases is shown in Figure 107. Especially noteworthy is the prominence of tuberculosis, against which an energetic campaign of eradication is now in progress. The reduced extent of this disease since 1926 is distinctly encouraging.

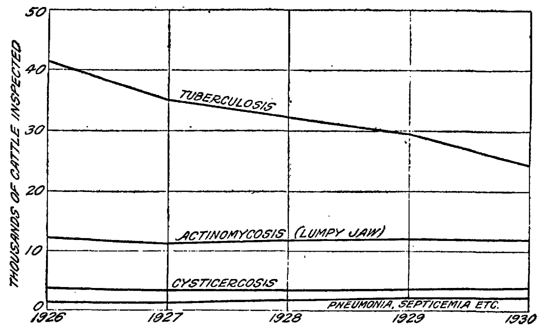

FIGURE 107.—Trend of the principal diseases affecting cattle at time of slaughter, as indicated by Federal meat-inspection records, 1926–1930

It will be noted that actinomycosis, more commonly known as lumpy jaw, has decreased slightly in the last five years, though this malady is of relatively minor economic importance. The disease nevertheless bears watching. The other maladies, cysticercosis and the so-called inflammatory group which includes such diseases as pneumonia, peritonitis, pleurisy, and enteritis, are of less economic importance, though a slight increase in recent years is regrettable.

The diseases in that group are largely incurred by animals while en route to stock centers. Greater care in handling and feeding cattle before shipment, loading proper numbers in cars, and other precautions should help to decrease losses of this kind.

In the case of swine, as with cattle, tuberculosis overshadows all other causes for the condemnation of hogs slaughtered under Federal inspection. Fortunately, many of the lesions are extremely minor, and condemnations are limited to parts rather than to entire carcasses. Though hog cholera, pneumonia, septicemia, and other maladies are observed, each of these, in recent years, has affected less than one hog in every thousand inspected, which makes the loss so small as to be scarcely visible on the same scale with swine tuberculosis in Figure 108. Accordingly, these diseases have been combined, for convenience in graphic portrayal, and the line for them shows the trend of the total infection.

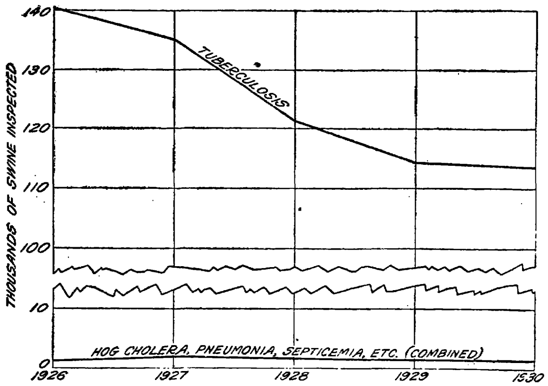

FIGURE 108.—Trend of the principal diseases affecting swine at time of slaughter as indicated by Federal meat-inspection records, 1926–1930. (Note break in scale)

The noticeable decrease in tuberculosis of cattle and swine becomes even more impressive when the condemnations are converted into the value of the meat represented. Such calculations show a saving of approximately $2,000,000 worth of beef and $1,500,000 worth of pork in 1930 as compared with the year of greatest former loss.

Of the maladies affecting sheep at the time of slaughter (fig. 109) caseous lymphadenitis is the most important, but it occurs in less than three per thousand. This disease, peculiar to sheep, claims more victims than the three next important combined.

From these data, which represent the actual findings by trained inspectors of abnormal conditions in animals sent to slaughter, one can readily see that tuberculosis of cattle and swine should be the object of particular concern. This one malady is more important from a meat-inspection viewpoint than are all others combined. Though the charts are based on inspections, during the five years, of more than 335,000,000 food animals, they do not, however, furnish the entire picture of the livestock health situation. Many animals, such as those lost through outbreaks of hog cholera on farms, do not reach the principal markets and consequently are not included in meat-inspection records. Yet the losses on farms are familiar, and the meat-inspection service supplements that knowledge by revealing conditions that otherwise would be obscure.

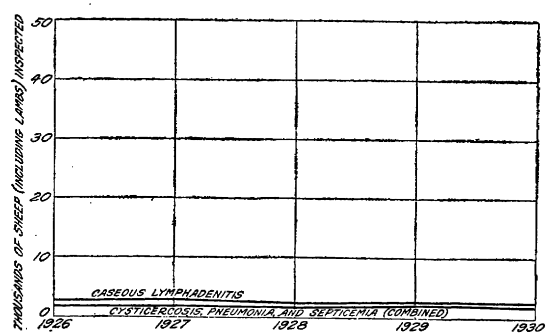

FIGURE 109.—Trend of the principal diseases affecting sheep (including lambs) at time of slaughter as indicated by Federal meat inspection records, 1926–1930

The following comparison summarizes the relative extent to which cattle, swine, and sheep were affected with disease or other abnormal condition in the fiscal years 1926 and 1930, according to Federal meat-inspection records. The figures represent the number of affected animals per 1,000 inspected:

Year	Cattle	Swine	Sheep
1926	58.97	141.63	4.56
1930	42.46	115.44	4.89

It is reasonably clear from the foregoing data that the last five years have witnessed a general improvement in the health of food animals at time of slaughter, chiefly because of less tuberculous infection. Besides being of public interest, this progress is distinctly creditable to all who are engaged in the livestock industry.

Chief, Bureau of Animal Industry.

LIVESTOCK Parasites in Manure Can be Killed by Means of Heat Generated The control of internal parasites of livestock which cause heavy mortality in young animals and often stunt those that survive, involves, among other practices, the proper disposal of stable and barnyard manure. While the average farmer can do little to overcome pasture pollution resulting from manure deposited by animals on pastures, he can dispose of stable and barnyard manure in a sanitary manner. If he spreads fresh manure on pastures and on fields to which livestock have access, serious consequences may follow, particularly when the manure comes from animals which are heavily infested with internal parasites. Such manure is usually teeming with eggs and larvae of parasitic worms. A heavy intake of such infective material by grazing animals usually leads to serious parasitic infestations, with their attendant evils of stunted growth, lowered vitality, and increased death rate.

Recent investigations carried out in the Bureau of Animal Industry have shown that manure may be stored in a manner which insures the death of a part or of all parasite eggs and larvae present. These investigations, which are still in the experimental stage, have shown, moreover, that certain methods of storing manure are more effective than others in killing eggs and larvae of parasitic worms. The more effective methods require more labor and more expense than the less effective procedures. The additional effort and expense are justified, however, by the good that is accomplished in keeping livestock parasites down to a level where they can do relatively little harm.

The open manure pile which one sees on the average farm has some advantage as a parasite control measure. The interior of such a pile becomes very hot, and the heat which is spontaneously generated kills parasite eggs and larvae. The surface manure, however, is cooled so rapidly by the air that few, if any, parasites there are killed. Thus, while the open manure pile does some good, it has rather

LIVESTOCK Parasites in Manure Can be Killed by Means of Heat Generated The control of internal parasites of livestock which cause heavy mortality in young animals and often stunt those that survive, involves, among other practices, the proper disposal of stable and barnyard manure. While the average farmer can do little to overcome pasture pollution resulting from manure deposited by animals on pastures, he can dispose of stable and barnyard manure in a sanitary manner. If he spreads fresh manure on pastures and on fields to which livestock have access, serious consequences may follow, particularly when the manure comes from animals which are heavily infested with internal parasites. Such manure is usually teeming with eggs and larvae of parasitic worms. A heavy intake of such infective material by grazing animals usually leads to serious parasitic infestations, with their attendant evils of stunted growth, lowered vitality, and increased death rate.

Recent investigations carried out in the Bureau of Animal Industry have shown that manure may be stored in a manner which insures the death of a part or of all parasite eggs and larvae present. These investigations, which are still in the experimental stage, have shown, moreover, that certain methods of storing manure are more effective than others in killing eggs and larvae of parasitic worms. The more effective methods require more labor and more expense than the less effective procedures. The additional effort and expense are justified, however, by the good that is accomplished in keeping livestock parasites down to a level where they can do relatively little harm.

The open manure pile which one sees on the average farm has some advantage as a parasite control measure. The interior of such a pile becomes very hot, and the heat which is spontaneously generated kills parasite eggs and larvae. The surface manure, however, is cooled so rapidly by the air that few, if any, parasites there are killed. Thus, while the open manure pile does some good, it has rather definite limitations as an effective control measure for parasites. The surface manure remains unsafe for spreading on pasture, is a source of parasite contamination to livestock because it may be carried by wind to feeding lots and to pastures, and is, moreover, a breeding bed for flies and other insects which are directly or indirectly injurious to livestock. Where the open manure pile must be used, the manure on the outside should be turned over every week or so and buried under the inner material.

Storing manure in closed containers, before spreading it on pastures, appears to offer a more satisfactory solution to the problem of sanitary manure disposal. In this connection, one naturally thinks of a concrete pit as a sanitary structure. Unfortunately this device has been found to be inadequate because the manure in contact with the walls and floor of the pit remains cold, as does the surface manure of the open pile. While the concrete pit eliminates the danger of spreading manure with its parasite content by wind and rain, it falls far below the desired level of effectiveness in the destruction of worm eggs and larvae.

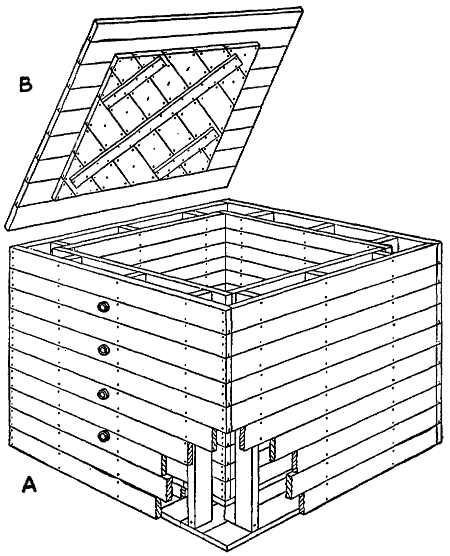

FIGURE 110.—Insulated experimental manure box. Note the double walls and the holes on one side for inserting a thermometer

In the course of experiments with different types of wooden boxes, an insulated box was constructed and tested for a period of about two years, including all seasons. The box, shown in Figure 110, was built of tongue-and-groove lumber. It was 5 feet square, and was provided with double walls and a double floor. The framework was built of 2-by-4's. The 4-inch space between the walls and floor was filled with fine sawdust, and the top was covered with a well-fitting lid made of two layers of ¾-inch tongue-and-groove lumber and covered with substantial composition roofing. This box had a capacity of 2 wagonloads of manure. After being filled with manure, the box was covered with the lid, and a set of holes on one side, designed to admit a thermometer for recording temperatures, were plugged with tight-fitting corks.

Both horse manure and cow manure were placed separately in the box during the various tests, and temperature records were obtained at different times. The maximum temperatures recorded were close to 170° F. but the larvae of parasites present in horse and cow manure are killed after 10 minutes' exposure to a temperature of 125°. After a few days' storage, sufficient heat was developed in the manure-filled box to kill worm eggs and larvae in practically all parts of the box. The box was finally emptied and samples of manure were taken from various parts of the box, so as to cover a wide range of locations. The samples were examined for parasite eggs and larvae.

The results of these tests showed conclusively that after about two weeks' storage, horse manure and cow manure, which were originally infested with live parasite eggs and larvae, no longer contained this infestive material. Such manure was safe for spreading on pastures. In several cases a few live larvae were found in the corners at the bottom of the box. The few larvae which escaped death were negligible as compared with the millions which perished.

While it has not as yet been determined whether the above experimental procedure is applicable to farm practice, it is probable that the principle of storing manure in insulated wooden containers can be utilized to advantage, particularly on farms where valuable purebred stock is raised. In view of the great damage which parasites are capable of producing, it is important that progressive stock owners exert every effort to avoid exposing their stock to the ravages of parasitic worms. An attack on pasture pollution resulting from contamination with stable and barnyard manure is a step in the right direction and is, moreover, a rational control measure which will pay good dividends.

LIVESTOCK Performance Is Best Indication of True Breeding Ability

Two kinds of records—pedigree and performance—are used in measuring the breeding value of livestock. The pedigree record indicates what an animal may do. The performance record tells what an animal does. Together, they are a reasonably accurate indication of the value of the animal for breeding purposes.

Many breeders attach undue value to pedigrees. They also fail to interpret them accurately. As a rule remote ancestors in an animal's pedigree have little influence on the breeding value of that animal. For instance, in a 4-generation pedigree showing no inbreeding, and therefore containing 30 individual ancestors, the chance that a great-great-grandparent (fourth generation) will dominate the inheritance of a mating is less than 1 in 30. Even the likelihood that a grandparent will have a great influence is not more than 1 in 6, and the usual influence is very much less, if we assume that all ancestors are equally prepotent. It is mathematically illogical, therefore, to expect an outstanding beef bull, for example, to have any material influence on beef calves which are his remote descendants. In a pedigree covering 10 generations there are 2,046 ancestors, more than half of which are in the tenth generation. Yet cattle sometimes are sold at a premium because an excellent cow or bull appears in the pedigree several generations back, regardless of the merit of animals much more closely related.

On the other hand, if a beef bull is known to have as his dam a cow of outstanding, blocky conformation, approaching the ideal of beef type, and if he has sired a large number of daughters which are of better beef type than their own dams, it is reasonable to say that this bull has proved his worth.

Inheritance sometimes manifests itself in strange ways. The record of performance, however, is always convincing. Geneticists may have

Inheritance sometimes manifests itself in strange ways. The record of performance, however, is always convincing. Geneticists may have difficulty in explaining why one bull sires uniformly good bull calves, whereas another excels in the quality of his heifer calves. But when such results are obtained they are worthy of being recorded and often prove useful in interpreting pedigrees.

Pedigree Breeding With Poultry

Pedigree breeding is practiced with poultry at the United States Animal Husbandry Experiment Farm at Beltsville, Md. Yet the value of each pedigree is interpreted in the light of the performance of the individuals contained in it. Not only numbers of eggs laid but size and quality of eggs are recorded. Recently one of the best layers at this farm, a Rhode Island Red pullet, produced 306 eggs in one year but was culled from the flock because her eggs were small and poorly shaped. A minimum weight of 2 ounces for each egg, making 24 ounces to the dozen, is used as a standard in this breeding work. If a pullet lays 200 eggs of good shape, good shell quality, and standard size, she is prized much more highly as a breeder than another that lays 50 or 100 more eggs which are undersized and of poor shape. The principal reason is that it is much simpler to breed up a flock for large numbers of eggs than to increase the size and market quality of that flock's eggs.

It may be contended that keeping the necessary performance records is well enough for experiment farms but impractical for the average farmer. Such does not seem to be the case. Farmers who are conspicuously careless about their record keeping are almost invariably the ones who show no profit at the end of the year. And it is rarely the case that a farmer keeps an itemized account of his year's operations without showing a profit. He learns, through records, which are the unprofitable animals and the unsound enterprises. No farmer will willingly throw away feed. If record keeping will show him, as it did investigators at one of the Government experiment farms, that each time one of his sows farrows a dead pig he is in reality losing 140 pounds of feed, he will be more likely to look into the cause of such a loss. Even a simple set of records showing the number of pigs farrowed and raised by each of the sows on his farm will be of great value to the owner. When he increases his breeding herd he will save gilts from those sows which have proved to be good mothers in addition to possessing other desirable qualities.

Performance records are doubly important to a sheepman because of a sheep's two crops a year—wool and lambs. Many sheepmen do not appreciate this. Some specialize on lamb production and regard the fleece merely as something to be clipped once a year and sold for what it will bring. Others give little attention to such carcass characteristics as width of loin and fullness of the leg of mutton in their flocks, and regard the carcass merely as a means of growing the fleece. Still others, and these are usually the successful ones, appreciate that the most profitable type of sheep must produce a fleece of high quality and one or two meaty lambs each year.

Method of Herd Improvement

The value of any herd or flock is the aggregate worth of its individual members. It can be improved by weeding out the poor producers and retaining and breeding from the high producers. This can be accomplished only through careful performance records, honestly interpreted and rigidly followed. Without them there can be no sure progress in the field of livestock improvement. With them one can determine and retain the prepotent sires and high-producing dams. Very often the excellence of a great sire or dam has not been discovered until the animal had been slaughtered, frequently before its usefulness had been exhausted.

Individual excellence and breeding excellence unfortunately are not always synonymous. Some of the best animals at stud, for instance, have never won a prize in the show ring. Records of performance disclose the ability in sires and dams to produce those qualities for which they are fed and bred, not mere beauty of form and carriage, but, in beef cattle, for instance, a large quantity and a desirable quality of flesh.

The breed associations could do nothing more constructive in the field of livestock development than to set up standards of excellence for superior breeding animals, based upon performance. Such standards should be reasonably uniform for each class of livestock. Not only quantity of market product but also quality should be taken into account because both influence the final judgment of purchasers as to merit in our domestic animals.

E. W. Sheets,
Chief, Animal Husbandry Division,
Bureau of Animal Industry.

MANGANESE and Other Less Common Elements Have Fertilizer Value

The 10 elements—nitrogen, phosphorus, potassium, calcium, magnesium, sulphur, carbon, hydrogen, oxygen, and iron—have been considered necessary for the growth and maturing of our agricultural crops. In fertilizer practice we have chiefly applied nitrogen, phosphorus, and potassium to our soils, with lime to correct soil acidity and not as plant food, on the assumption that soils, fertilizers, and manures supply sufficient of the other mineral elements for profitable crop production. Modern research has shown that magnesium, iron, sulphur, and manganese deficiencies can exist in large soil areas. It has shown that a marked phosphorus deficiency exists in some middle-western soil regions of the United States devoted to sugar-beet culture, and that the application of even small amounts of this element produces large increases in sugar-beet production, and in the sugar content of the beets.

Agricultural chemists naturally give first attention to those elements present in plants and animals in largest amount. Recently the less common elements, considered previously as nonessential, have been found to be most important factors in plant and animal nutrition and health. Reference is made especially to the part which manganese, copper, boron, iodine, zinc, and other elements play in the newer research in plant and in animal physiology.

The use of manganese in agriculture has been increased in the last few years as the result of some practical demonstrations with tomatoes and other truck crops in southern Florida. Research by the Bureau of Chemistry and Soils over a period of years tended to show that manganese was essential to plant growth. Without it plants showed abnormal symptoms, analogous to disease conditions.

MANGANESE and Other Less Common Elements Have Fertilizer Value The 10 elements—nitrogen, phosphorus, potassium, calcium, magnesium, sulphur, carbon, hydrogen, oxygen, and iron—have been considered necessary for the growth and maturing of our agricultural crops. In fertilizer practice we have chiefly applied nitrogen, phosphorus, and potassium to our soils, with lime to correct soil acidity and not as plant food, on the assumption that soils, fertilizers, and manures supply sufficient of the other mineral elements for profitable crop production. Modern research has shown that magnesium, iron, sulphur, and manganese deficiencies can exist in large soil areas. It has shown that a marked phosphorus deficiency exists in some middle-western soil regions of the United States devoted to sugar-beet culture, and that the application of even small amounts of this element produces large increases in sugar-beet production, and in the sugar content of the beets.

Agricultural chemists naturally give first attention to those elements present in plants and animals in largest amount. Recently the less common elements, considered previously as nonessential, have been found to be most important factors in plant and animal nutrition and health. Reference is made especially to the part which manganese, copper, boron, iodine, zinc, and other elements play in the newer research in plant and in animal physiology.

The use of manganese in agriculture has been increased in the last few years as the result of some practical demonstrations with tomatoes and other truck crops in southern Florida. Research by the Bureau of Chemistry and Soils over a period of years tended to show that manganese was essential to plant growth. Without it plants showed abnormal symptoms, analogous to disease conditions.

As manganese is widely distributed throughout the United States, most soils contain sufficient for profitable crop production, but in certain sections where manganese is rare in rocks and soils, or where conditions are such that the manganese is unavailable to plants, serious difficulties are experienced.

Large areas south of Miami, Fla., are periodically covered with water each year. This soil is composed almost entirely of calcium carbonate deposited from the sea water. These areas, known as glades, are being used largely for the production of tomatoes.

A chlorotic condition of the foliage of the tomato plants grown on this soil showed itself in white spots and areas between the veins. Analysis of the soil showed that the difficulty was a lack or a deficiency of manganese. This could not be remedied with liberal applications of ordinary fertilizer salts, but the addition of minute quantities of manganese—50 pounds of manganese sulphate per acre—produced strong, vigorous plants, deep green in color, with luxuriant blossoming and greatly increased fruit production. In fact, without manganese there is no fruit production, and the plants soon fade and die. In all of these tests the commercial fertilizers were used at the rate of 2 tons per acre. Even with 2 tons of fertilizer to the acre the tomatoes would not grow and flourish unless the manganese was present.

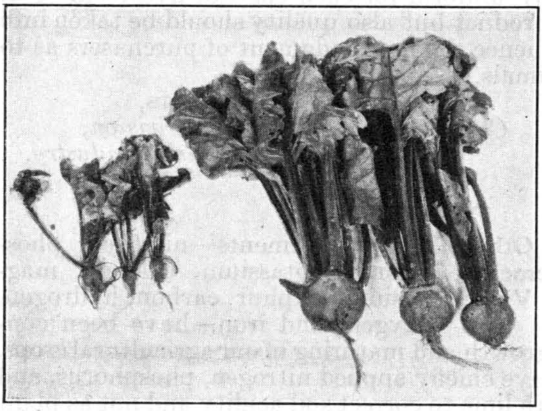

FIGURE 111.—Beet plants grown on calcareous glade soil, Dade County, Fla. Both plots received liberal applications of ordinary commercial fertilizer. The plants on the right were fertilized with a small amount of manganese sulphate; those on the left received no manganese

Manganese Sulphate for Tomatoes

Tomato growers of southern Florida have begun to use manganese sulphate on a large scale within the last two years, and this has replaced stable manure to a large extent. Formerly, train loads of compost were carried to the fields where to-day a few carloads of manganese sulphate are giving the same results. Growers who till these calcareous glade soils haul out a few bags of manganese sulphate instead of truck loads of manure.

Manganese sulphate is now also used generally in the area south of Miami in the growing of beets, carrots, lettuce, cabbages, corn, potatoes, beans, ornamentals, and forage crops. Formerly these crops were considered failures on this land. All the crops grown without manganese were chlorotic and mottled, made a poor growth, and produced little or no marketable vegetables. The growth was very good where manganese was used. Only 50 pounds per acre were required to produce this remarkable difference in yield. (Fig. 111.)

Another interesting case of manganese deficiency has occurred in a section on the east coast of Florida. This section produces beans and peppers. The soil is sandy and the surface slightly acid. At intervals in the section, small areas occur which contain shell deposits. These shell areas appear as pockets and lie slightly lower and are alkaline. Both beans and peppers were found to fail in the pocket areas. The plants became yellow, were dwarfed, failed to grow, and produced no vegetables. A small amount of manganese overcame the trouble. The crops grew normally and produced as much as the surrounding section which showed no chlorosis.

Throughout eastern North Carolina there occur in fields unproductive spots on which corn, and also soybeans, show symptoms of chlorosis resembling manganese deficiency. These soil spots are approximately neutral or alkaline, while adjacent soils in the same fields, bearing normal crops, are acid. These spots often result from local overliming, due to lime piles, when spreading lime on the fields, or to the burning of brush heaps in clearing. The chlorotic poor growth of the soybeans can be completely obviated by the application of manganese sulphate.

It is of some importance to bear in mind that soluble manganese in the soil may easily become a source of trouble when the soil reaction is allowed to become too acid. Thus we have the practical situation that if the soil becomes too alkaline, symptoms of manganese deficiency may develop, while on the other hand when the soil becomes rather strongly acid in reaction, manganese toxicity may result even though this element is not included in the fertilizer.

Observations in Australia

Comment on the action and essential character of manganese has recently been made by some Australian investigators. They found that the plants might grow with the amount of manganese stored in the seed, in certain cases for weeks, and that then the manganese deficiency symptoms developed with diseaselike suddenness. They obtained astonishing differences in growth as a result of the complete absence of manganese on the one hand, and the presence of mere traces on the other, amounting to from three to fifty times the weight. Different plants require different amounts of manganese to enable them to complete their development. Therefore, certain types of soil, which do not possess sufficient available manganese for the growth of cereals, may support an apparently normal growth of pasture plants and weeds, but such plants nevertheless contain less manganese than when grown on normal soil, which fact, according to these investigators, may be found to have some connection with certain animal diseases which occur on these manganese-deficient soils in South Australia.

Here a word of caution should be added against too liberal use of manganese. Not only is this uneconomic, but a too liberal supply of manganese will cause harm.

Results have been obtained thus far only with soluble manganese salts. The sulphate is the most effective. Manganese is well distributed in nature and most soils contain some of it. Manganese occurs in a number of localities of the United States where it can be mined. When sufficiently pure, it is manufactured into the various manganese preparations used in the arts and industries. Manganese sulphate, pure or containing iron and some other metals, is frequently obtained as a by-product, which can be used in fertilizers for supplying water-soluble available manganese to soils deficient in manganese.

With the utilization of modern pure fertilizer materials of chemical manufacture, especially in the leachy sandier soils, the problem may be extended to include not only manganese but also such elements as zinc, copper, nickel, boron, and so forth, the relation of which to plant growth is not yet so fully understood.

There are many troublesome and little-understood plant diseases which may be directly traced in the future to manganese deficiency or to a deficiency of some other little-understood essential element. There are many so-called physiological plant diseases which have baffled the pathologists. A disease of oats occurring in South Australia on certain soil types and also on alkaline soils in Germany and Sweden is a manganese-deficiency disease. Although manganese occurs in the Australian soil, it is not soluble and available in sufficient quantity. This condition, no doubt, occurs on many of our own soils. A small amount of soluble manganese may become desirable in fertilizers as a kind of insurance against unfavorable climatic factors.

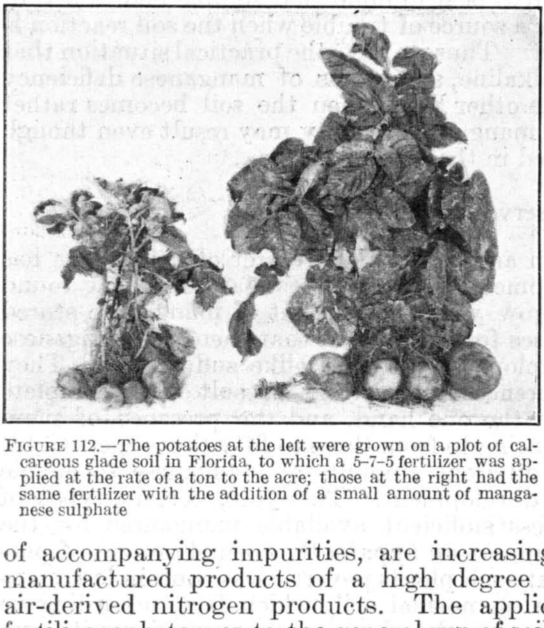

FIGURE 112.—The potatoes at the left were grown on a plot of calcareous glade soil in Florida, to which a 5-7-5 fertilizer was applied at the rate of a ton to the acre; those at the right had the same fertilizer with the addition of a small amount of manganese sulphate

Probable Relation to Fertilizer Practice

These problems are likely to become more pressing as pure and concentrated chemicals supplant the older ordinary fertilizers. The older fertilizers, consisting of plant and animal by-products, and even the inorganic fertilizer salts originating in natural deposits and containing greater or less amounts of accompanying impurities, are increasingly being supplanted by manufactured products of a high degree of purity, especially the air-derived nitrogen products. The application of these chemical fertilizer substances to the general run of soils containing sufficient reserves of the lesser inorganic constituents is not likely to involve any problem of deficiency. On the other hand, in soils, especially sandy soils, where the amount of these less-common constituents may be small or unavailable, deficiency will probably be noticed in time if pure chemicals only are used.

Recent experiments have also shown that small quantities of other less common elements are important in crop production. A striking illustration of the effect of minute quantities of copper occurs in the work of the Florida Agricultural Experiment Station on Everglades peat lands. These lands present many problems, among them a lack of response to fertilizers. Plant growth responses have been obtained on a long list of plants by using such unusual fertilizing elements as zinc, antimony, nickel, tin, barium, copper, and manganese. (Fig. 112.) The most favorable results were obtained with copper. By the use of copper, plant growth has been enormously stimulated. The treatment of Everglade peat lands with copper sulphate has reached commercial proportions. A considerable acreage devoted to sugarcane is now thus treated in the region south of Lake Okeechobee. Previous attempts to grow sugarcane on a large scale in the Everglades north of Miami practically failed. Experiments using all possible combinations of fertilizers gave no promising leads. The new treatment, together with the use of proper fertilizer, is giving very encouraging results.

Interesting in this connection also is the now common practice of applying copper sulphate to citrus trees suffering from die-back, which is considered a physiological disease. The symptoms of die-back are many, among them chlorosis or mottled leaf, gum pockets in the new shoots, multiple buds, and split fruits. Originally, the crystals of copper sulphate were inserted under the bark with only moderate success. For the last 10 years or more, the copper sulphate has been applied in fertilizers or separately to the soil. Beneficial results are obtained often enough to encourage citrus growers in the practice of using copper sulphate as a cure for die-back.

Double Benefit From Copper

The use of Bordeaux mixture which contains copper, as a spray for potatoes, citrus, and numerous other plants, has been followed by crop improvement as well as disease control. It seems probable that the increased growth is due to the specific action of the copper on the plant functions. Some very valuable work has been done on the effect of the less common elements on plants at the University of California and the University of Minnesota laboratories. Copper is proving absolutely essential for the normal growth of sunflowers and tomatoes. The amount necessary is exceedingly small. Yet mere traces of copper in the culture solutions caused an increase in growth of tomato plants over 10 times that produced with copper absent. A single leaf of the copper-treated plant was often greater than the entire plant without copper.

Research has also been done with boron and with zinc. Experiments with zinc suggest that it too may be essential to growth. The evidence, however, is rather conflicting, and no agricultural value can as yet be assigned to its compounds.

Boron illustrates the principle that these rarer plant foods must be handled with care and understanding. Without boron there is no plant development, no maturation, no fruition. Excessive amounts, however, cause damage and crop failure. Scientific control of the amounts supplied in seed, soil, irrigation water, and fertilizer are essetial and show us that the old ways of haphazard experimentation and practice are not possible, when these new forces and factors are brought into play. The subject has since been very ably investigated at Rothamsted in England. It has been studied also by scientists in California and in Maryland, and by specialists in the United States Department of Agriculture.

Work at Rothamsted with leguminous plants showed the necessity of boron to plant growth, and demonstrated that, in the broad bean, boron is absolutely essential in the production of the ducts which enable the plant to obtain nitrogenous matter from the nodule, and in return to supply sugars and other food substances to the bacteria in the nodules. This is a truly remarkable system of cooperation.

Effects of Minute Quantities

Boron has been shown to be essential to a long list of plants. Experiments with the tomato have been conclusive. An interesting growth effect was noted with boron-free potato plants, in which the leaves showed the characteristic symptoms of what is known as the potato leaf-roll disease. All the abnormal symptoms are obviated by adding as little as one part per two million to the solution; but toxicity was reached with as little as five parts per million.

Boron is so widely distributed in minute amounts throughout natural soils and fertilizer materials, that its addition for agricultural use is probably nowhere necessary except possibly in sandy soils with high rainfall where purely synthetic nitrogen and other fertilizer salts are used continuously. This boron question from a fertilizer viewpoint is a problem of the future rather than the present, but it illustrates the accurate scientific control that must be exercised in the study and use of some of these less common but nevertheless essential plant food substances.

The rarer elements are of tremendous value to human and animal life. Freedom from disease may depend on their presence in human food and in the feed given to livestock. Iodine is essential to prevent goiter in man, abortion in cattle, and hairlessness in young pigs. Copper and manganese play their part in the formation of blood, and in the prevention of anemia. These constituents are stored up in the unborn child or animal to enable it to function properly until it can get its own supply later, since mother's milk or cow's milk does not supply them. Liver, which contains copper compounds, is prescribed for pernicious anemia. Low calcium and phosphorus content, cause many serious diseases in cattle. The best and normal way to supply these elements, to animals and to man, is through their feed and food—through plants, vegetables, and fruits, grown on well-fertilized soils.

OSWALD SCHREINER,
Chief, Division of Soil Fertility,
Bureau of Chemistry and Soils.

MANURE Substitutes Are Made from City Wastes by Various Processes

Roses and sweet peas, glorious rhododendrons, and lowly asparagus and celery, meet on common ground in their need for organic matter in the soil of their beds. Their response to soil enrichment is well known, and the confirmed home gardener will almost jeopardize his next winter's coal supply to buy manure for his flowers. And, if his home is close to one of our great cities, he pretty nearly has to. With makeshift substitutes for barnyard manure not uncommonly bringing $25 a ton, in the vicinity of New York City, the suburban gardener is often hard pressed to obtain adequate supplies of suitable organic material for preparing his beds and mulches.

It has long been common knowledge that properly cared for barnyard manure makes an excellent fertilizer; and the demand for it has far exceeded the available supply, particularly in the great urban districts. There, gardeners, florists, and truck growers are using various substitutes. Peat, composted with a substantial amount of manure, "artificial manure," prepared by rotting straw; the more expensive

MANURE Substitutes Are Made from City Wastes by Various Processes

Roses and sweet peas, glorious rhododendrons, and lowly asparagus and celery, meet on common ground in their need for organic matter in the soil of their beds. Their response to soil enrichment is well known, and the confirmed home gardener will almost jeopardize his next winter's coal supply to buy manure for his flowers. And, if his home is close to one of our great cities, he pretty nearly has to. With makeshift substitutes for barnyard manure not uncommonly bringing $25 a ton, in the vicinity of New York City, the suburban gardener is often hard pressed to obtain adequate supplies of suitable organic material for preparing his beds and mulches.

It has long been common knowledge that properly cared for barnyard manure makes an excellent fertilizer; and the demand for it has far exceeded the available supply, particularly in the great urban districts. There, gardeners, florists, and truck growers are using various substitutes. Peat, composted with a substantial amount of manure, "artificial manure," prepared by rotting straw; the more expensive dried manures, and organic ammoniates like cottonseed meal, have helped to stop the gap. But the prices paid for satisfactory substitutes are evidence enough that the supply is far from adequate.

By an interesting working of the law of compensation, prospects for producing large quantities of organic materials, that may in part take the place of barnyard manure, are brightest just where this commodity is scarcest. Our larger cities must continually dispose of great quantities of organic waste in the form of garbage and sewage, and these are potential sources of fertilizer materials.

Fertilizer Material From Municipal Garbage

Attempts to utilize raw garbage as fertilizer have proved decidedly unsatisfactory in this country. Such disposal is conducive to the breeding of flies and vermin, and, on truck farms, to the spread of truck-crop diseases by infected parts of vegetables in the garbage.

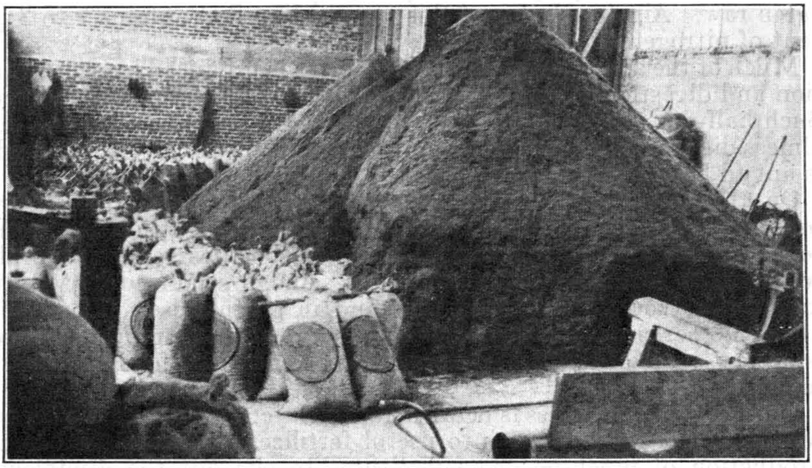

FIGURE 113.—Garbage tankage dried, ground, and screened, when used in mixed fertilizers, furnishes some nitrogen and improves the physical condition and drillability of the mixtures

But, a number of large cities steam-render their garbage for the production of household grease, and the residual tankage is useful fertilizer material. The steaming kills disease germs, and removal of the grease improves the product for fertilizer purposes. Garbage tankage is low in plant-food value, however, since the dry material contains only about 3 per cent of nitrogen, 5 to 10 per cent of bone phosphate, and 1 per cent of potash. When used in mixed fertilizers, dried, ground, and screened garbage tankage improves their physical condition and drillability. (Fig. 113.)

Moist garbage tankage, degreased but not heat dried, has been used direct in fairly large quantities as a makeshift substitute for farm manure. With a water content of 50 per cent, it contains two to three times as much total plant food as manure, but its nitrogen is less readily available. However, a well-decomposed compost of moist garbage tankage and manure will more than equal the latter alone, in plant-food content; and such a compost fortified with superphosphate and potash salts should make a satisfactory fertilizer as well as manure substitute.

Humuslike material is being produced directly from raw garbage by an adaptation of the Beccari reduction process, which depends on high-temperature fermentation in closed concrete cells. Chemical analysis shows that the air-dried "humus" contains very nearly the same amount of total plant food as equally dry garbage tankage, and about 10 per cent of calcium oxide derived from added lime. Some of this humus has been used in lieu of manure in the vicinity of New York City.

Sewage Sludge Fertilizers

The composition and fertilizer value of sludges obtained in municipal sewage disposal vary rather widely, and depend chiefly on the type of process used in purifying the sewage.

Sludges produced by plain sedimentation, or in septic tanks, are usually foul-smelling and septic—possibly unsafe for use as fertilizer on certain truck crops, particularly on vegetables that are customarily eaten raw. Air-dry sludge of this type ordinarily contains 1 to 3 per cent of nitrogen of low availability.

Much of the sewage sludge in this country is produced by sedimentation and digestion in Imhoff tanks, followed by draining on sand beds. Such half-dry sludge contains but little more nitrogen than manure. Unless digestion has been long continued and thorough, Imhoff sludge is apt to be offensive and unsuited to use in the home garden.

On the other hand, sludge produced by the "activated-sludge" process of sewage treatment is rapidly gaining recognition as satisfactory organic fertilizer material. State authorities report favorable results with the heat-dried "activated" sludge produced at Milwaukee, and advocate its use on turf and in greenhouses. Containing about 5.6 per cent of nitrogen and 2 per cent of phosphoric acid of satisfactory availability, it has several times the plant-food strength of manure.

On the whole, progress is being made in the conversion of the organic wastes of our large cities into useful fertilizer materials, and in the production of much-needed substitutes to eke out the diminishing supplies of barnyard manure.

MARKET News Services Specially Adapted to Various Requirements Increasing demand for authoritative agricultural market news reports has led to some extension and specialization of the official information services of the Bureau of Agricultural Economics and to more attention to adapting the market information to readers in the various producing areas and to requirements of the different news mediums.

There are two general classes of agricultural market news readers: Producers and dealers who wish to follow reports promptly and closely, who may keep in touch currently with the market through the daily press and radio; and producers who are not operating in the market throughout the season and whose needs are met by the weekly, monthly, quarterly, or seasonal summary or review.

The first class of readers want original facts and figures on conditions, grades, shipments, and prices and must depend upon the prompt and accurate work of market reporters and upon quick distribution. The second class of readers relies on the studies of these reports as checked, compared, summarized, and reviewed by the bureau's editorial specialists, their work supplemented with reports from field representatives and special news correspondents.

The completed market news articles or reviews are circulated mainly through the farm papers and trade periodicals; also, through standard newspapers having large country circulation. Some of the smaller trade papers use rather sectional matter or that on specific products, arranged and treated somewhat according to the demand. Many publications are served by press associations, which send out material in syndicated form. Some press associations, news syndicates, and various private market writers prepare reviews of their own, based on the official news information. The radio service uses market news material somewhat like the articles prepared for the press, but preferably adapted for reading aloud, and usually arranged with regard to location and interest of the majority of the station listeners.

Combined Summary Issued

A recent development in market news reviews is a combined summary of market news features for all of the leading farm products, including the more significant items, stated in one or two paragraphs for each class of products, whether grain, livestock, dairy and poultry products, or fruits and vegetables. This type of review of special market news has been found suitable for many of the representative agricultural weekly or monthly periodicals, for the trade and commercial journals, and for a number of news agencies and large newspapers. Since the whole range of farm production is considered in the space of a column or less, these articles are acceptable to papers which devote only limited attention to agricultural market material. The short general reviews, including the whole list of leading farm products, are suitable for readers who most of the time do not wish to follow the day-to-day markets closely but who desire to keep in touch with the general agricultural market situation and its bearing on future developments.

For the preparation of the various forms of market literature, the larger branch offices of the bureau are manned by a group of reporters and writers, each a specialist in his particular field. These reporters collect information in the various markets and supply the material for the daily reports. Editorial writers at Washington headquarters of the bureau, or in the principal branch offices, prepare reviews based on these reports. The writers are equipped with charts, graphs, and tabular statements of receipts, prices, supply, and distribution over long periods, arranged for easy comparison. Long experience enables them to prepare promptly the market reviews or special news articles which are ready for distribution soon after the close of the markets for the period under review.

Leased telegraph wires, air mail, and regular mail service complete the work of distribution. Each of the various commodity divisions within the bureau prepares special reviews on the various classes of farm products during the season, and in some instances the distribution is assisted by State marketing agencies which reproduce the reviews, and sometimes combine them with local material.

40442°—31——24

Distribution of Market News

Distribution of market news depends somewhat on its nature. Information relating to shipments, receipts, condition and price, and present state of the market require prompt action and the use of telegraph, telephone, radio, and the daily press. The long-range studies, comparisons, and conclusions may still be useful even if delayed a little in getting to the reader, and such material is well suited to distribution by mail and through periodicals of various kinds. This part of the service almost assumes that the public already has the underlying facts given from day to day regarding the market. It is implied further that the reader desires to have the meaning of the facts brought out by comparison of conditions on the different markets and with the market of the past week or the previous season. To be considered also in this connection and to be included perhaps in the summary is the market bearing of the current news about crops, production, business conditions, foreign trade, and the like.

The total circulation of market material through these various means is not easy to estimate closely. One commodity division which had been adding up the circulation of its reviews and market articles through the news press, counting only the periodicals actually printing all or part of the material, concluded that their reviews found at least 9,500,000 takers, according to the circulation rating by the directories. Two other divisions each reckoned a total of fully 4,000,000 press circulation. Reviews of one line of farm products were being used by from 200 to 300 papers, and by numerous radio stations, and were posted by 4,000 country banks, and in the offices of numerous boards of trade, county agents, and State officials. Members of the writing staff also send out special signed reports to a dozen representative trade papers. Another division has depended greatly upon the radio stations and has supplied material, daily or weekly, to about 80 of these stations, covering nearly the whole country in a network of direct publicity.

All the market news material is distributed by substantially the same means, the main difference being in the relative emphasis placed upon the different agencies for reaching the public, according to the nature of the product, the apparent demand, and the style in which the material is prepared. All the news services on the various farm products make extensive use of local, metropolitan, and commercial papers, press associations, news agencies, mail distribution, and the radio; but emphasis placed on each of these differs somewhat, according to the nature of the products and the scope of its marketing field, the general availability of reliable news from normal sources, and the proved effectiveness in each instance of the methods of publicity employed.

The long-range studies, comparisons, and conclusions may still be useful even if delayed a little in getting to the reader, and such material is well suited to distribution by mail and through periodicals of various kinds. This part of the service almost assumes that the public already has the underlying facts given from day to day regarding the market. It is implied further that the reader desires to have the meaning of the facts brought out by comparison of conditions on the different markets and with the market of the past week or the previous season. To be considered also in this connection and to be included perhaps in the summary is the market bearing of the current news about crops, production, business conditions, foreign trade, and the like.

The total circulation of market material through these various means is not easy to estimate closely. One commodity division which had been adding up the circulation of its reviews and market articles through the news press, counting only the periodicals actually printing all or part of the material, concluded that their reviews found at least 9,500,000 takers, according to the circulation rating by the directories. Two other divisions each reckoned a total of fully 4,000,000 press circulation. Reviews of one line of farm products were being used by from 200 to 300 papers, and by numerous radio stations, and were posted by 4,000 country banks, and in the offices of numerous boards of trade, county agents, and State officials. Members of the writing staff also send out special signed reports to a dozen representative trade papers. Another division has depended greatly upon the radio stations and has supplied material, daily or weekly, to about 80 of these stations, covering nearly the whole country in a network of direct publicity.

All the market news material is distributed by substantially the same means, the main difference being in the relative emphasis placed upon the different agencies for reaching the public, according to the nature of the product, the apparent demand, and the style in which the material is prepared. All the news services on the various farm products make extensive use of local, metropolitan, and commercial papers, press associations, news agencies, mail distribution, and the radio; but emphasis placed on each of these differs somewhat, according to the nature of the products and the scope of its marketing field, the general availability of reliable news from normal sources, and the proved effectiveness in each instance of the methods of publicity employed.

Associate Editor, Bureau of Agricultural Economics.

MARKETING Legislation Calls for Federal and State Cooperation

Marketing work now conducted by the Bureau of Agricultural Economics had its legislative origin in an item in the appropriation act for the fiscal year 1914. This authorization was "to enable the Secretary of Agriculture to acquire and diffuse among the people of the United States useful information on subjects connected with the marketing and distribution of farm products * * * ."

Soon after the organization of the marketing work in the Department of Agriculture, requests began to be received from the States for assistance in the formation of an effective bureau of markets in which to conduct the State work. As a result, a draft of a State law was prepared and with minor changes remains as a model upon which it is believed the States may rely in shaping their marketing work. This draft of bill was designed to include only the more general powers necessary for conducting the work. Provision was made for investigational, educational, and demonstrational work in marketing, but, broadly speaking, regulatory features were not included. Such regulation as might be deemed necessary, as of warehousing, cold storage, commission merchants, etc., was left for treatment in separate laws.

As the work has progressed and as the results of the bureau's investigations, as well as the practical application of the principles involved, have become known and recognized, there has been an increasing call from the States for assistance and cooperation in the shaping of policies and the working out of their marketing problems. This is evidenced by the cooperative projects now in effect with the States, representing a substantial proportion of the bureau's marketing undertakings. It is logical to expect that the States will cooperate and will desire to take advantage of the careful study given the subject by the Federal Government. This applies particularly to standards for agricultural products, the market inspection of such products, and the market news service. Development of these activities has continued steadily, and they are perhaps as well known as any of the phases of marketing work.

Two Classes of Standards

Standardization and grading, from the inception of the marketing work, has held a prominent place. Standards fall within two classes—mandatory and permissive. Except in the cases of grain and cotton, it is with the latter type that the larger part of the work in marketing is conducted. The use of these standards is optional—that is, there is no law which compels their use and makes it obligatory upon shippers and others to designate their products as falling within a certain grade. The permissive feature allows for latitude and makes it possible for one to dispose of his products, regardless of grade, as "unclassified."

Upon this point there has arisen a difference of opinion. Some of the State officials hold out for mandatory grades and insist that the surest way of improving the quality of agricultural commodities is to permit them to be marketed only by recognized definite grades. On the other hand, with permissive grades it is possible to market every part of the crop which is marketable or adaptable to any purpose.

The character of a law, whether mandatory or permissive, is determined by its object—that is, whether some regulatory action is to be enforced or a service is to be rendered. Both types of laws are administered by the bureau.

The farm products inspection service is an example of a permissive service which is meeting the needs of the industry. While authorization exists for the inspection of perishable agricultural products at shipping points and at central markets under rules and regulations of the Secretary of Agriculture, it applies only to those interested parties who may wish to have their products inspected.

The question of jurisdiction has at times been raised—that is, whether the Federal Government under some of its marketing laws has not encroached upon the functions of the States. Apparently some apprenhension existed in the minds of certain State enforcement officers as to the attitude of the Federal officials, but it is now well understood that there is no thought of undue assumption of authority, that the dominant idea is cooperation, that friction in enforcement or administration is unnecessary, and that wherever there is a job to be done which requires action by both State and Federal officials their duty is to do it in the most efficient and helpful manner, rendering such service, if it be a permissive law, or such enforcement, if it be a mandatory statute, as will best serve the interests of the public.

Federal Legislation Welcomed

Limited jurisdiction of the States sometimes acts as a preventive of thorough treatment of a particular situation where remedial action is necessary. In such cases there is now a growing recognition of the desirability of Federal legislation in a field already occupied by the States. This is exemplified in the recently enacted perishable agricultural commodities act of 1930, approved by the President on June 10, 1930, under which commission merchants, dealers, and brokers in fresh fruits and fresh vegetables are required to be licensed by the Secretary of Agriculture. The so-called commission merchants' laws have been on the statute books in several of the States for a number of years. By reason of the limited jurisdiction of the States, however, it has been felt that they have not been fully effective; that the unjust and fraudulent practices of certain members of the fruit and vegetable industry have not been nor could not be stamped out without a jurisdictional authority embracing both the shipping point and the receiving end of a transaction.

Demand for agricultural marketing legislation continues. A large number of bills are introduced at each session of Congress having for their purpose the amendment of existing laws or the enactment of provisions covering additional features considered desirable by their proponents. Such bills are invariably subjected to close scrutiny, and rarely does one pass without undergoing careful examination and full discussion.

The Trend in State Legislation

The States continue to cooperate with the Federal Government legislatively. A perusal of their session laws for any of the recent sessions will indicate such a trend with respect to agricultural legislation and a disposition so to shape their laws as to profit by the investigations or the experience of the Federal Government. A potent factor in this trend toward amity and understanding between the State and Federal officials has been the National Association of Marketing Officials, an organization composed of representatives of the State marketing bureaus and of the Federal Government. At the eleventh annual meeting of this association held in December, 1929, 25 States and the District of Columbia were represented, as well as research associations, producers, shippers, dealers, etc. This association is filling an important rôle in the field of marketing in bringing together the various public marketing officials for discussion of the many problems that confront them in the performance of their duties.

H. F. Fitts,
Assistant to the Chief, Bureau of Agricultural Economics.

MEAT Keeping in Home Refrigerators Studied in Varying Conditions The keeping of meat in the household refrigerator is a subject of concern to the housewife. It is one of the foods which normally is digestible, palatable, and nutritive. When proper care is not exercised in its production and storage, decomposition takes place which renders it unpalatable, and harmful toxins may be formed.

The money loss incurred through the spoilage of food by improper storage is high. The possible injury to health and life is of greater consideration and can not be estimated. In the past, many cases of food poisoning have occurred due to the use of meat. This possibility has been greatly reduced through the thorough inspection of livestock and meat products by Federal and local authorities. The protection thus afforded, however, loses its value if the meat is not properly stored from the time of purchase until it is used.

Local health authorities are responsible for the conditions under which the meat is handled in its local distribution. The housewife's responsibility commences with its choice at the local store and the handling of the meat after it reaches home. In connection with the refrigeration investigations of the Bureau of Home Economics, a series of studies has been made to determine the conditions of home storage which will help preserve the quality of the meat.

Bacterial activity is responsible for the advancement of spoilage of meat. The housewife can only by choice safeguard the contamination of meat before it reaches her. She does have a responsibility, however, in choosing meat of good quality and in handling the meat after it reaches her, (1) to prevent contamination, and (2) to provide storage conditions which will retard the development of the bacteria present.

Temperature plays the most important part in controlling the development of microorganisms in food. To determine the temperatures desirable for home refrigeration of meat, a study was made of the effect of different temperatures on the increase of bacteria in meat. The temperatures used were 35°, 40°, 45°, 50°, and 55° F. for periods of one to four days. The meat selected for this work was a good grade of the top round of beef—uncooked—cut in solid cubes. It was stored in covered and uncovered containers, since preliminary studies had shown that spoilage proceeded more rapidly in tightly covered dishes. In making the tests, samples were taken from 10 different places on the cube and the results given represent the averages from 24 series. The comparative rate of growth taking place at each temperature is shown in Table 11.

TABLE 11.—*Effect of storage temperature upon the number of bacteria in meat*

Meat stored in uncovered containers

Temperature	Original sample	Rate of increase in—			
		24 hours	48 hours	72 hours	96 hours
° F.					
35	2	1	2	4	4
40	2	3	3	5	11
45	2	5	20	143	1,301
50	2	12	92	2,929	9,145
55	2	21	3,356	22,261	97,294
Meat stored in covered containers					
35	2	3	2	7	8
40	2	3	4	24	221
45	2	11	32	2,083	4,894
50	2	32	137	7,420	24,197
55	2	32	4,525	18,879	390,130

From these results, it will be seen that not only was the increase greater at the higher temperatures but it was also greater in the covered dishes as compared with the uncovered. Table 11 shows the rate of bacterial increase taking place in the meat stored in uncovered and in covered containers at temperatures of 35°, 40°, 45°, 50°, and 55° F. It is of particular interest to note the quickened rate of growth taking place in the uncovered container at 50° as compared with that at 45°. The meat in the covered containers shows a more advanced state of spoilage than meat in the uncovered containers—signified in large measure by a greater acceleration in bacterial growth—as may be observed in the table. The use of a covered container for meat was found to enrich the conditions favoring the growth of bacteria, and produced a quickened growth rate equal, in many instances, to that produced by a 5° rise in temperature.

The Temperatures Required

A study of Table 11 indicates that the home refrigerator, if the meat is to be kept for more than 24 hours, should provide a temperature of below 50° F. and wherever possible a temperature of 45° or below. If the meat is to be kept longer than two days, a temperature of 45° or below ought to be provided. These temperatures coincide with those which are recommended for the safeguarding of milk. That means that meat should be placed in the milk compartment or in that portion of the refrigerator which is quite as low in temperature as the milk compartment.

These studies also show that fresh meat should have the wrapper removed and be placed in a clean vessel, loosely covered if at all. A slight drying out of the surface of the meat does not interfere seriously with its palatability and certainly retards bacterial development. Cooked meat has the number of bacteria reduced markedly. It should be loosely covered so as to prevent unnecessary drying out, which does interfere seriously with its palatability. While the temperature is not so important in its storage, it should be placed in the coldest portion available and care should be taken to avoid holding it too long. It is especially important that ground-cooked meat should be handled with care, for in the process of grinding there is so much opportunity for recontamination that food poisoning may result from its use. This is especially important in salads and sandwiches where there is no heating after grinding or chopping to kill the bacteria which may be introduced, and in the case of recooked meat, like croquettes, that may be simply heated through but not cooked to a temperature which would help destroy the bacteria or toxins present. Especially to be avoided are situations in which meat is ground or chopped while still warm and allowed to stand without proper refrigeration—as refrigeration retards development, higher temperature stimulates it.

MEATS (Fresh) Graded and Sold in Packages Win Consumers' Favor

Distribution of nonperishable food products from manufacturer to consumer has undergone a complete change in the last 20 years. Retailers have found that the inducements to handle large and unwieldy containers have progressively diminished in favor of the convenience of handling packaged goods. Consumers generally prefer small, neat, original packages.

In the case of nonprocessed and perishable products, which require constant refrigeration at relatively low temperatures, packaging has been somewhat slow in developing. The distribution of frozen meats precut in convenient consumer packages received attention by commercial interests for the first time during 1929. It is still in the experimental stage.

Beef bearing the Government grade stamp has been available in many sections of the country since May, 1927, but it was not until April, 1930, that cut and packaged fresh meats (unfrozen) bearing the official grade label were available to consumers. At that time a large meat-packing company with slaughtering plants in eight cities started an experiment in the sale of precut and packaged fresh meats of all kinds in New York City.

The aim of the company is to provide meats of uniformly high quality in convenient size packages to meet the needs of consumers. To insure a high degree of uniformity in quality, the department's grading service is used. Government graders select all meats and place the official grade stamp on them before they are sent to the cutting room. Only meats that meet the requirements of the official grade choice are used. From these are cut rib roasts, chuck roasts, steaks, cutlets, chops, and in fact practically all cuts which might be purchased in any modern retail market. Practically all bone and surplus fat are trimmed off before putting the cuts into packages. The retail cuts are neatly wrapped in cellophane and placed in attractive cardboard containers with "window" arrangement for the convenience of customers. The process of packaging is supervised by Government employees who see that the package carries the correct grade label. Packages containing two pork chops, two lamb chops, or one small steak are always available for the needs of the small family; likewise larger packages of all well-known cuts are on sale constantly.

Careful Refrigeration Needed

The need for suitable display and the highly perishable nature of the product required special attention in the matter of refrigeration. Specially constructed cases were built in which relatively low uniform temperatures ranging between 32° and 34° F. could be maintained. After a 3-month experiment in which approximately 30 refrigerated cases have been placed in retail stores, the plan promises to become a factor of considerable importance in retail meat distribution generally. The reaction of consumers has been highly favorable and no criticisms resulting from dissatisfaction with purchases have been received.

From the economic side the plan also has much in its favor. All meats are cut at a central point by experienced meat cutters under the direction of a competent supervisor. Special attention is given the matter of trim, thickness, and uniformity of size between cuts, especially the smaller cuts such as chops and steaks, when several are placed in the same package. Savings which would result from centralized cutting operations are greater conservation of trimmings and fats for conversion into edible products than has been possible under the old system in the average small market.

Another economic factor which should receive consideration by the retailer who handles precut, packaged meat, is that of lower operating costs. Under the new plan, the services of meat cutters in the market are dispensed with. No racks, blocks, or other equipment including butcher tools are necessary. Full time of employees can be given to selling. The Government grade label on each package gives the consumer an index of quality, and largely eliminates the possibility of consumer dissatisfaction. Reports from satisfied customers and constantly increasing sales are indicative of what can reasonably be expected when precut, packaged, fresh meats bearing the Government grade label are made available to consumers generally.

Bureau of Agricultural Economics.

MEDITERRANEAN Fruit-Fly Eradication Program Is Making Rapid Progress

The attempt to exterminate the Mediterranean fruit fly in Florida, one of the most extensive pest-eradication programs ever undertaken, has shown remarkable progress in the direction of eliminating this insect completely from the United States. From the conditions existing during the early summer of 1929, when 1,000 properties were found infested and serious commercial losses were being experienced within the center of the infested area, the work has progressed to a point where now (October, 1930) no fly-infested fruit whatever is found.

The Mediterranean fruit fly is an accidentally imported pest, which, before 1929, had never been present in the United States. It is probably the worst of all fruit pests, having a long record of serious damage to the tropical and subtropical fruit industries of southern Europe, South Africa, Hawaii, Australia, and other countries. When first found in Florida, in April, 1929, the grapefruit crops on several premises in the center of the infested area at Orlando were already practically a complete loss. Surveys to determine the extent to which the fruit fly had already spread in the State showed its presence in 20 counties on approximately 1,000 properties. While the manner in which it reached this country is not known, the spread in Florida was clearly due to the general distribution of fruit from infested groves, and to the carrying of adult flies with the wind.

Suppressive Measures

In other countries, Mediterranean fruit fly invasions have resulted so disastrously to fruit-growing interests that total eradication appeared to offer the only hope of protecting this industry in the United States. Under generous appropriations promptly made available by Congress and by the State of Florida, suppressive measures were accordingly undertaken at once.

The methods used to exterminate the fruit fly included (1) the clean-up of infested properties as rapidly as found, and the removal of such host fruits and vegetables as appeared necessary to eliminate infestation on the infested properties; (2) the application to trees in infested localities of sweetened poisoned bait to destroy the adult flies; and (3) the destruction of all summer-ripening host fruits and vegetables in the infested zones (areas 1 mile in radius around points of costs. Under the new plan, the services of meat cutters in the market are dispensed with. No racks, blocks, or other equipment including butcher tools are necessary. Full time of employees can be given to selling. The Government grade label on each package gives the consumer an index of quality, and largely eliminates the possibility of consumer dissatisfaction. Reports from satisfied customers and constantly increasing sales are indicative of what can reasonably be expected when precut, packaged, fresh meats bearing the Government grade label are made available to consumers generally.

Senior Marketing Specialist,
Bureau of Agricultural Economics.

MEDITERRANEAN Fruit-Fly Eradication Program Is Making Rapid Progress

The attempt to exterminate the Mediterranean fruit fly in Florida, one of the most extensive pest-eradication programs ever undertaken, has shown remarkable progress in the direction of eliminating this insect completely from the United States. From the conditions existing during the early summer of 1929, when 1,000 properties were found infested and serious commercial losses were being experienced within the center of the infested area, the work has progressed to a point where now (October, 1930) no fly-infested fruit whatever is found.

The Mediterranean fruit fly is an accidentally imported pest, which, before 1929, had never been present in the United States. It is probably the worst of all fruit pests, having a long record of serious damage to the tropical and subtropical fruit industries of southern Europe, South Africa, Hawaii, Australia, and other countries. When first found in Florida, in April, 1929, the grapefruit crops on several premises in the center of the infested area at Orlando were already practically a complete loss. Surveys to determine the extent to which the fruit fly had already spread in the State showed its presence in 20 counties on approximately 1,000 properties. While the manner in which it reached this country is not known, the spread in Florida was clearly due to the general distribution of fruit from infested groves, and to the carrying of adult flies with the wind.

Suppressive Measures

In other countries, Mediterranean fruit fly invasions have resulted so disastrously to fruit-growing interests that total eradication appeared to offer the only hope of protecting this industry in the United States. Under generous appropriations promptly made available by Congress and by the State of Florida, suppressive measures were accordingly undertaken at once.

The methods used to exterminate the fruit fly included (1) the clean-up of infested properties as rapidly as found, and the removal of such host fruits and vegetables as appeared necessary to eliminate infestation on the infested properties; (2) the application to trees in infested localities of sweetened poisoned bait to destroy the adult flies; and (3) the destruction of all summer-ripening host fruits and vegetables in the infested zones (areas 1 mile in radius around points of infestation) and in parts of the surrounding protective zones which were 9 miles wide.

These measures were especially adapted to destroying the fruit fly, many of the details of the life history and habits of which were well-known from its record in foreign countries. Nearly all kinds of fruits, both citrus and deciduous, and several kinds of vegetables, are attacked. The adult flies puncture the rind or surface of the fruit or vegetable to deposit eggs. The eggs hatch into small larvae or maggots which burrow into the fruit until they reach maturity. The fruit soon drops to the ground and the larvae leave it to rest in a pupal stage in the soil.

Larvae Killed By Destruction of Fruit

The destruction of fruit in infested and surrounding groves killed the larvae which were working in the fruit at the time. Since no satisfactory soil disinfectant was discovered, it was necessary for such insects as were in the soil to develop through the pupal stage into adult flies before they could be killed. Their destruction was then accomplished by means of the poisoned bait sprays mentioned, and in the absence of fruit and fruit juices in the infested zones, this spray was especially attractive to the flies and effective in destroying them. The removal of the fruit in the infested zones accomplished the further purpose of providing no near-by fruit within which the flies could breed, and most of those not poisoned by the bait lost their lives before they reached fruit in which breeding could be continued.

This work was pressed vigorously by the United States Department of Agriculture in cooperation with the State Plant Board of Florida from April, 1929, to January, 1930. By that time clean-up activities had covered the 120,157 acres of citrus groves in the infested zones an average of approximately four times, and had involved the destruction of the equivalent of approximately 608,864 boxes of citrus fruit. The infested zones included all properties within 1 mile of the point of infestation. Over 60,000 acres outside these zones were covered, an average of two and three times. The poisoned bait spray was used within the infested zones so far as possible each week throughout the winter and was resumed again this past summer. Spray applications in other parts of the eradication area were made at greater intervals.

The eradication program has been so successful that since August 27, 1929, up to the time of the writing of this article, only three infestations were found, one each in November, 1929, and March, 1930, respectively, near Orlando; and one at St. Augustine in July, 1930. Only one, two, or three fruits were involved in each of these cases. The St. Augustine infestation consisted of only two puparia found in the soil below an orange which had fallen to the ground. While these three infestations, meager as they are and scattered over a period of more than a year, show that the fruit fly can not as yet be considered exterminated, the record indicates that great strides have been made in that direction and that the suppresive measures employed promise to be completely successful if they can be continued.

Prevention of Spread

When the fruit fly was first found in Florida more than three-fourths of the fruit of the district concerned had already been shipped out of the State. This situation meant that there was danger that the pest had already been carried to many other points in the United States. To determine whether these shipments had resulted in the widespread establishment of the fly, as much as possible of such fruit was examined wherever it was still held at local markets or in storage. The quarantine officers and extension services of the Cotton Belt States were especially active in making these inspections. The work resulted in the discovery of 17 shipments of infested fruit distributed to 12 localities in Arkansas, Georgia, Louisiana, North Carolina, Texas, New York, and Ohio. The infested materials were in all cases destroyed and the containers and locations cleaned up, with the result that so far as can be determined the Mediterranean fruit fly did not become established at any point outside Florida.

The shipment of further infested fruit was prevented by the issuance of a Federal plant quarantine, bringing under control the transportation of host fruits and vegetables from all parts of the State. From May 16 to November 21, 1929, no such fruits or vegetables from any part of Florida were permitted to be shipped into Southern and Western States, as the previous record of the fruit fly in other parts of the world showed that it was in these States that the Mediterranean fruit fly promised to become especially injurious if established.

Treatment of Host Fruits for Shipment

Similarly, throughout the summer of 1929 and until the new crop was ready to move that fall, no host fruits or vegetables were permitted to be moved to any destination or sold locally, if they had been produced within 1 mile of points of infestation. All such material was required to be destroyed. Early in the fall shipping season of 1929, however, experimental work had shown that it was possible to eliminate risk of infestation either by refrigerating it to 28° F. or by heating it to 110°. Thereafter infested-zone fruit was allowed to be moved under sterilization, and sterilization was also required for fruit shipped from most other parts of the 20 counties concerned, except as to fruit moved into the extreme Northeastern States where there was the least possibility of the establishment of infestation. During midwinter, from the latter part of November to the end of February, sterilized fruit was also allowed to be shipped into the Southern and Western States. Sterilization was never used as a measure to authorize the shipment of infested fruit, all of which has been consistently destroyed from the time the fruit fly was first discovered, but was employed to eliminate risk of infestation from fruit which had been more or less exposed to fruit-fly attack.

The quarantine measures adopted to prevent the spread of the fly were highly successful. Not a single case of the discovery of infestation in fruit moved after the Federal quarantine became effective, on May 1, 1929, has been reported.

The Mediterranean fruit fly eradication campaign in general has been so successful as to give great encouragement to the possibility of eradicating new outbreaks of insect pests when they are discovered soon after their first appearance in this country. The most economical method of fighting a foreign insect pest is never to permit it to reach the United States. If it eludes the protective measures set up against it and becomes established in this country, an eradication program may be an expensive and difficult undertaking, but, in the case of the Mediterranean fruit fly, the work thus far has cost so much less than the losses which could have been anticipated from the permanent establishment of the pest in this country, that the eradication campaign has been a highly profitable one. The disastrous results to fruit-growing in other countries which have followed Mediterranean fruit fly invasions in the past, and the severity of its attack in the center of the infested section of Florida in 1929, showed how great a drain it might have become on the horticultural resources of the country.

Principal Plant Quarantine Administrator,
Plant Quarantine and Control Administration.

MEXICAN Bean Beetles' Spread Checked in 1930 by Drought and Heat

Few insect pests of its type are so susceptible to the influence of climatic conditions as the Mexican bean beetle. After surviving the winter in large numbers over most of the infested territory of the eastern part of the United States and causing much damage during the spring and early summer of 1929, the infestation decreased in many areas during dry, hot summer weather.

This natural check on reproduction of the beetle has been observed almost annually in the Southeastern States at some time during each season since it has been studied there. The tendency of bean leaves to turn upward during hot weather, when moisture is insufficient, exposes the eggs and immature stages to the heat from the sun. Recent research has shown that when the temperature reaches 101° F. the beetle is killed within three hours if the relative humidity of the air is low or very high. At 109° the beetle is killed at any humidity. This work confirms the field observations that either hot dry weather or extremely wet weather in summer reduces the numbers of the insects.

Probably the most conclusive demonstration of the effect of climate on the Mexican bean beetle was evident in the spring and summer of 1930. After a favorable winter (1929–30) in general for hibernation over much of the eastern infested area, reproduction was almost entirely checked by the prolonged droughts and unusually high spring temperatures. Large numbers of eggs were deposited by the female beetles, but only a very small percentage survived and hatched. As a result, injury by the beetle was reduced to a point below commercial damage in areas where defoliation of untreated beans had occurred in 1929 and undoubtedly would have occurred in 1930 had not the dry, hot weather prevailed.

Survival in Spring of 1930

Survival from hibernation in the spring of 1930 reached the high percentage of 33.33 in eastern Virginia and a still higher percentage in southeastern Virginia. In southeastern Ohio more beetles survived the winter than in the previous winter. Field observations in other sections indicated a high survival and emergence. Emergence from hibernation, which depends largely on rainfall for a stimulus, after required temperatures prevail, was delayed by dry weather, although the beetles emerged earlier than in 1929.

The susceptibility of the insect to high summer temperatures undoubtedly accounts for its failure to thrive in the southern portions of Mississippi, Alabama, Georgia, and South Carolina and explains its the losses which could have been anticipated from the permanent establishment of the pest in this country, that the eradication campaign has been a highly profitable one. The disastrous results to fruit-growing in other countries which have followed Mediterranean fruit fly invasions in the past, and the severity of its attack in the center of the infested section of Florida in 1929, showed how great a drain it might have become on the horticultural resources of the country.

S. B. FRACKER,
Principal Plant Quarantine Administrator,
Plant Quarantine and Control Administration.

MEXICAN Bean Beetles' Spread Checked in 1930 by Drought and Heat

Few insect pests of its type are so susceptible to the influence of climatic conditions as the Mexican bean beetle. After surviving the winter in large numbers over most of the infested territory of the eastern part of the United States and causing much damage during the spring and early summer of 1929, the infestation decreased in many areas during dry, hot summer weather.

This natural check on reproduction of the beetle has been observed almost annually in the Southeastern States at some time during each season since it has been studied there. The tendency of bean leaves to turn upward during hot weather, when moisture is insufficient, exposes the eggs and immature stages to the heat from the sun. Recent research has shown that when the temperature reaches 101° F. the beetle is killed within three hours if the relative humidity of the air is low or very high. At 109° the beetle is killed at any humidity. This work confirms the field observations that either hot dry weather or extremely wet weather in summer reduces the numbers of the insects.

Probably the most conclusive demonstration of the effect of climate on the Mexican bean beetle was evident in the spring and summer of 1930. After a favorable winter (1929–30) in general for hibernation over much of the eastern infested area, reproduction was almost entirely checked by the prolonged droughts and unusually high spring temperatures. Large numbers of eggs were deposited by the female beetles, but only a very small percentage survived and hatched. As a result, injury by the beetle was reduced to a point below commercial damage in areas where defoliation of untreated beans had occurred in 1929 and undoubtedly would have occurred in 1930 had not the dry, hot weather prevailed.

Survival in Spring of 1930

Survival from hibernation in the spring of 1930 reached the high percentage of 33.33 in eastern Virginia and a still higher percentage in southeastern Virginia. In southeastern Ohio more beetles survived the winter than in the previous winter. Field observations in other sections indicated a high survival and emergence. Emergence from hibernation, which depends largely on rainfall for a stimulus, after required temperatures prevail, was delayed by dry weather, although the beetles emerged earlier than in 1929.

The susceptibility of the insect to high summer temperatures undoubtedly accounts for its failure to thrive in the southern portions of Mississippi, Alabama, Georgia, and South Carolina and explains its disappearance from some sections of those States which have been invaded from time to time.

The northern limits of the insect are becoming more definite as its spread into new territory continues. After being present in parts of southern Michigan and New York and southern Canada since 1927, it has not survived the winter in those areas in sufficient numbers to become a pest. Relatively little damage occurs in northern portions of Ohio and Indiana. In explaining the northern limits, results obtained to date indicate that low temperature during the winter is one of the critical factors.

The history of the Mexican bean beetle proves that it varies in abundance from year to year, owing in part to the factors mentioned. However, the likelihood of its eradication by natural or other causes over much of the infested area is extremely slight. With such great capability of rapid reproduction, heavy infestations can be and are built up in one or two seasons. The beneficial effects of climatic control can be further enhanced by continuous repressive methods. The destruction of crop remnants after the bean crop is harvested is very important, but the importance is not as generally recognized as it should be. Spraying should be practiced even during seasons of light infestations in areas where damage occurs at intervals and where it is known that the beetle thrives under normal conditions. An infestation may be too light to cause an appreciable loss, or may occur too late to reduce the yield, but still may harbor sufficient beetles to cause a heavy infestation on later plantings.

Senior Entomologist, Bureau of Entomology.

MEXICAN Fruit-Fly Invasion Fought by Novel Eradication Plan

Crop diversification is such a common and effective method of reducing insect losses that a Mexican fruit fly eradication plan now in use in southern Texas appears strikingly novel. It consists of confining fruit production in the lower Rio Grande Valley almost solely to citrus, although such fruits are the most favored products attacked by the insect. The plan is based on the fact that oranges and grapefruit ripen during the fall and winter and leave no fruit on which the pest can breed during the spring and summer.

The southern and western portions of the United States have for many years been almost the only parts of the world in which oranges and grapefruit can be grown without a certain amount of fly infestation within the fruit itself. Accordingly, the citrus growers have watched with concern the gradual spread northward in Mexico of an insect at first known as the Morelos orange maggot which was originally discovered southwest of Mexico City over 70 years ago. Through the shipment of infested fruit this pest has spread to other sections of the Republic until eventually it reached the border of the United States.

Meanwhile, beginning in 1907, a citrus-growing industry of large proportions has been developing in the lower Rio Grande Valley of southern Texas. The region was found especially adapted to grapefruit, and grove planting has continued until there are now about 6,000,000 citrus trees in the area, of which less than one-fourth have disappearance from some sections of those States which have been invaded from time to time.

The northern limits of the insect are becoming more definite as its spread into new territory continues. After being present in parts of southern Michigan and New York and southern Canada since 1927, it has not survived the winter in those areas in sufficient numbers to become a pest. Relatively little damage occurs in northern portions of Ohio and Indiana. In explaining the northern limits, results obtained to date indicate that low temperature during the winter is one of the critical factors.

The history of the Mexican bean beetle proves that it varies in abundance from year to year, owing in part to the factors mentioned. MEXICAN Fruit-Fly Invasion Fought by Novel Eradication Plan

Crop diversification is such a common and effective method of reducing insect losses that a Mexican fruit fly eradication plan now in use in southern Texas appears strikingly novel. It consists of confining fruit production in the lower Rio Grande Valley almost solely to citrus, although such fruits are the most favored products attacked by the insect. The plan is based on the fact that oranges and grapefruit ripen during the fall and winter and leave no fruit on which the pest can breed during the spring and summer.

The southern and western portions of the United States have for many years been almost the only parts of the world in which oranges and grapefruit can be grown without a certain amount of fly infestation within the fruit itself. Accordingly, the citrus growers have watched with concern the gradual spread northward in Mexico of an insect at first known as the Morelos orange maggot which was originally discovered southwest of Mexico City over 70 years ago. Through the shipment of infested fruit this pest has spread to other sections of the Republic until eventually it reached the border of the United States.

Meanwhile, beginning in 1907, a citrus-growing industry of large proportions has been developing in the lower Rio Grande Valley of southern Texas. The region was found especially adapted to grapefruit, and grove planting has continued until there are now about 6,000,000 citrus trees in the area, of which less than one-fourth have yet reached bearing age. The commercial citrus crop of 1929–30 in that section was reported as 4,854 carloads shipped to outside points and about 57 carloads utilized locally in canning and bottling plants.

After the Morelos orange maggot, now known as the Mexican fruit fly, reached northern Mexico, first on the local fruit markets and later attacking the fruit on dooryard trees, it finally made its way to the Texas side of the river. The insect was found there by representatives of the Texas Agricultural Experiment Station in March, 1927, and a few days later was picked up independently in another part of the valley by collaborators of the United States Department of Agriculture.

Threatened Untold Damage

When, in April, the specimens were definitely determined by specialists as this insect, it was at once recognized that the fruit fly not only seriously endangered the prosperity of the expanding grapefruit industry of that section but also might spread to the other citrus-growing districts of the United States and cause untold damage. Total eradication of the outbreak was proposed as the only satisfactory solution of the problem, and the State and Federal Governments joined hands with the growers to accomplish that end.

Surveys at that time showed the pest in 12 orchards located at various points in Cameron and Hidalgo Counties. These groves were so scattered as to involve more or less the whole irrigated section of the lower valley, a region about 90 miles long by about 30 wide. The only fruits found infested there were grapefruit and some oranges, although the insect in Mexico attacks nearly all citrus fruits (except lemons and sour limes), as well as such other fruits as peaches, plums, pears, apples, apricots, and various tropical products such as guavas and mangoes.

The first step in eradication consisted of the destruction of all citrus fruit remaining on the trees in commercial orchards and the clean-up of other possible host fruits. This program was undertaken in May and June, 1927, and was followed up in July. Through the hearty cooperation of the citizens of the valley the needed measures were most faithfully carried out.

The eradication program in 1927 was apparently successful, and no further specimens of the pest were seen in the valley for about two years. In 1929 it was twice accidentally reintroduced from Mexico, once in April in the western end of the valley and once in the fall at Brownsville. Each time eradication measures were promptly undertaken and these appear to have eliminated the infestation successfully. In the case of the Brownsville outbreak, the suppressive measures previously employed were supplemented by using a poison spray to kill the adult flies.

Infested Fruit Reaches Markets

While the agricultural authorities of Mexico are heartily cooperating by assisting in the maintenance of a continuous control and spraying program in the Mexican towns on the south side of the Rio Grande, infested fruit repeatedly reaches the markets there from interior points. This means that a permanent plan of grove management must be maintained which so far as possible will prevent the establishment of the fruit worm and will tend to eliminate the pest automatically whenever it reaches the Texas plantings. The maintenance of the fruit-free period throughout the area from the first of March to the end of September, to a large extent, fills this requirement. The fact that the insect breeds more or less continuously, normally passing through about four generations a year, makes such a plan of attack effective.

The adult of the Mexican fruit fly is a small fly (*Anastrepha ludens*) scarcely larger than a house fly but of brownish color and with the wings crossed by oblique dusty bars. This fly places its eggs directly in or through the skin or rind of fruits, and these eggs hatch into larvae or "worms" which work inside the fruit. They leave scarcely an indication on the outside until they are nearly full grown, when they leave the fruit to pass through a pupal or resting stage. The complete absence, for seven months each year, of host fruits on which such breeding could take place means that it would be very difficult for flies which might reach the area to establish a permanent infestation there. Those which emerge from the pupal or resting stage in the spring after the fruit-free period had begun would be exposed to all the chances of injury by weather conditions, starvation, and other vicissitudes before eggs could be laid in the fruit of the next crop season the following fall.

The volume of work involved in removing the green fruit from the noncitrus summer-fruiting trees and shrubs such as peaches, pears, and guavas showed that such measures would be impracticable as a recurring annual method of permanent protection of the region. It became clear that the only feasible plan of carrying out such a method of prevention of future outbreaks would be the elimination of all fruit trees and shrubs which normally bear fruit during the spring and summer months.

The total number of summer-fruiting trees found in the valley in connection with this undertaking has exceeded 40,000. Many of these were destroyed by the owners at the beginning of the work and are therefore unrecorded. Since that time 38,761 have been taken out, all of them voluntarily by, or with the consent of, the owners. On July 1, 1930, only 187 such trees and shrubs could be discovered in the entire area. Thus far the owners of this small remaining number are in all cases removing the green fruit from the trees before it ripens, and fulfilling the host-free period requirements in that manner.

High Degree of Community Cooperation

The entire program is an instance of almost unequaled community coöperation and, in some instances, extraordinary self-sacrifice on the part of citizens of the district. For its success the citrus fruit industry is greatly indebted to many citizens whose incomes are not dependent on fruit-growing and whose action has been wholly altruistic. By this remarkable instance of united effort throughout an area with a population of over 160,000 persons it has become possible for citrus production to continue its expansion there on a sound basis of freedom from any serious hazard of Mexican fruit fly establishment. Combined with a plant-quarantine policy which enables the valley fruit to reach the Nation's markets under Federal inspection and certification, the citrus industry of the section has continued to grow and prosper.

Plant Ouarantine and Control Administration.

MILK-BOTTLE Losses Partly Traceable to Consumers' Negligence Nearly $15,000,000 is spent annually by the milk dealers of the United States for the purchase of between 300,000,000 and 400,000,000 milk and cream bottles, most of which are used to replace bottles that are lost or broken. Carelessness in handling the bottles in the home is responsible for a large part of this loss. In a survey of the records kept by 76 milk dealers in various cities of the country, the Bureau of Dairy Industry found that the life of a milk bottle varied from 6 to 91 trips; the average was 37.32 trips, while the most common figures given ranged between 20 and 30 trips. About one-third of this loss is due to breakage in the bottling plants, much of which is unavoidable. About two-thirds of the loss, however, is due to the fact that the bottles never

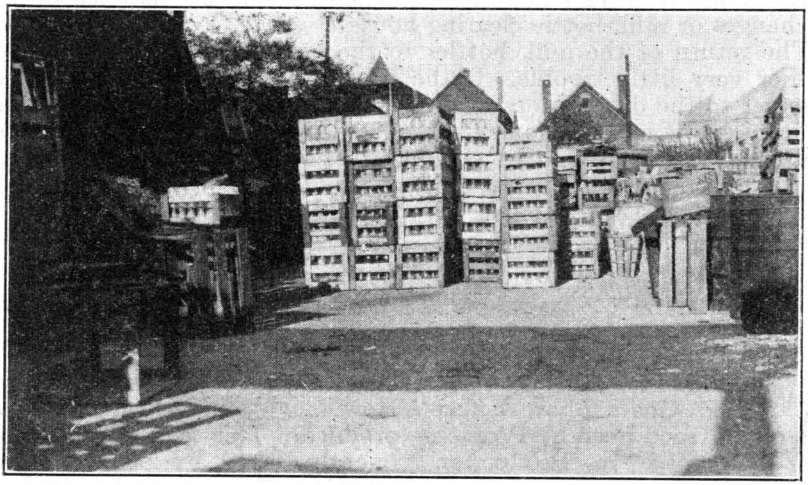

FIGURE 114.—The storage yard of a milk-bottle collector. These bottles were misplaced by household consumers. They will be transferred to the milk-bottle exchange, where they will be washed, sorted, and returned to the distributor who owns them

get back to the dealer who delivered them, and the consumer, usually unintentionally, is responsible for a large part of this loss.

Many housewives buy milk from the store. Instead of returning the empty bottles to the store where the milk was bought, they often set them out for the milkman to collect, who, in many instances, does not represent the owner of the bottles. Although these bottles may eventually get back to the dealer who owns them, oftentimes the process is a roundabout one and involves unnecessary expense. Some housewives, especially those living in flats and apartment houses, may set the bottles out for the janitor, who may or may not deliver them to a milkman; or they may even throw the bottles into the refuse can, in which case they may be picked up by a junk man or may find their way to the city dump.

Milk Bottle Exchanges

In many cities the milk dealers have established what are known as milk-bottle exchanges. These exchanges are clearing houses for lost and misplaced bottles. Many of these exchanges receive bottles from milkmen who have picked up bottles which belong to other milkmen;

from junk men who have picked them up from alleys, refuse cans, etc; and from city dumps.

In one large city the exchange receives and returns to the owners more than 1,000,000 bottles a week. About two-thirds of these bottles are received from milkmen who have picked up bottles that were set out for them by the housewife but which belonged to others. The other third comes from collectors, junk men, and the city dumps. Thus, more than one-third of 1,000,000 bottles come into the hands of one exchange each week because of the carelessness of householders in not returning them to the concerns which own them. Many bottles, however, are never received by the exchange but are lost.

Consumers have to pay for the bottles that are destroyed. They also have to stand the cost of collecting, washing, treating to kill bacteria, sorting, and returning the millions of bottles that are handled by the exchanges or milk-bottle clearing houses.

The return of the milk bottles to the owner need give the householder very little trouble. If the bottles were returned in a direct manner to the distributors who own them, the cost of milk distribution might be reduced somewhat. If milk is received from a regular milkman, the empty bottles should be set out for him every morning. If the milk is bought from a store, the bottles should be returned to the store if possible. If not, they should be set out for the regular milkman.

Associate Market-Milk Specialist,
Bureau of Dairy Industry.

MILK Goats Show Effect of Good Feed by Prompt Increase in Production

How much milk will a milk goat produce? This is a question frequently asked by persons interested in these animals. It is a pertinent question, since goats vary greatly in the quantity of milk produced daily and also in the length of their lactation periods, which is an important factor in annual production. A doe producing 6 pounds of milk a day during a lactation period of from 8 to 10 months is considered an excellent milker.

Feed has a great influence on the milk flow, notwithstanding the general belief that goats can be fed almost any kind with success. Maximum production can be expected only when proper feeding methods and good-quality feeds are used.

Experiments conducted with the milk-goat herd at the United States Animal Husbandry Experiment Farm, Beltsville, Md., indicate that does respond readily to good feeding and that satisfactory production can be maintained by supplying good-quality grains and roughages throughout the lactation period. Purebred and high-grade does of the Saanen and Toggenburg (fig. 115) breeds were used to test the comparative feeding value of alfalfa and clover hays of low and high quality. In order to be of high quality, legume hays such as these must be cut at a stage of growth when they are high in nutritive value and cured so that they will be bright and leafy.

The experiment was of two years' duration. The first year, when low-quality hay was fed, 18 does produced 12,300 pounds of milk, or an average of 683 pounds per doe. The following year, when high-from junk men who have picked them up from alleys, refuse cans, etc; and from city dumps.

In one large city the exchange receives and returns to the owners more than 1,000,000 bottles a week. About two-thirds of these bottles are received from milkmen who have picked up bottles that were set out for them by the housewife but which belonged to others. The other third comes from collectors, junk men, and the city dumps. Thus, more than one-third of 1,000,000 bottles come into the hands of one exchange each week because of the carelessness of householders in not returning them to the concerns which own them. Many bottles, however, are never received by the exchange but are lost.

Consumers have to pay for the bottles that are destroyed. They also have to stand the cost of collecting, washing, treating to kill bacteria, sorting, and returning the millions of bottles that are handled by the exchanges or milk-bottle clearing houses.

The return of the milk bottles to the owner need give the householder very little trouble. If the bottles were returned in a direct manner to the distributors who own them, the cost of milk distribution might be reduced somewhat. If milk is received from a regular milkman, the empty bottles should be set out for him every morning. If the milk is bought from a store, the bottles should be returned to the store if possible. If not, they should be set out for the regular milkman.

MILK Goats Show Effect of Good Feed by Prompt Increase in Production

How much milk will a milk goat produce? This is a question frequently asked by persons interested in these animals. It is a pertinent question, since goats vary greatly in the quantity of milk produced daily and also in the length of their lactation periods, which is an important factor in annual production. A doe producing 6 pounds of milk a day during a lactation period of from 8 to 10 months is considered an excellent milker.

Feed has a great influence on the milk flow, notwithstanding the general belief that goats can be fed almost any kind with success. Maximum production can be expected only when proper feeding methods and good-quality feeds are used.

Experiments conducted with the milk-goat herd at the United States Animal Husbandry Experiment Farm, Beltsville, Md., indicate that does respond readily to good feeding and that satisfactory production can be maintained by supplying good-quality grains and roughages throughout the lactation period. Purebred and high-grade does of the Saanen and Toggenburg (fig. 115) breeds were used to test the comparative feeding value of alfalfa and clover hays of low and high quality. In order to be of high quality, legume hays such as these must be cut at a stage of growth when they are high in nutritive value and cured so that they will be bright and leafy.

The experiment was of two years' duration. The first year, when low-quality hay was fed, 18 does produced 12,300 pounds of milk, or an average of 683 pounds per doe. The following year, when high-quality hay was fed, the same does produced 18,150 pounds of milk, or an average of 1,008 pounds. This was an increase of 5,850 pounds of milk, or approximately 47 per cent. The length of the lactation periods was approximately nine months, each of the two years. All other factors and conditions except the hay were likewise the same. The grain ration remained constant and consisted of the following mixture: 8 parts corn, 4 parts oats, 2 parts bran, and 1 part linseed meal, by weight. The does received 1.5 pounds of this mixture, per head, daily throughout each year.

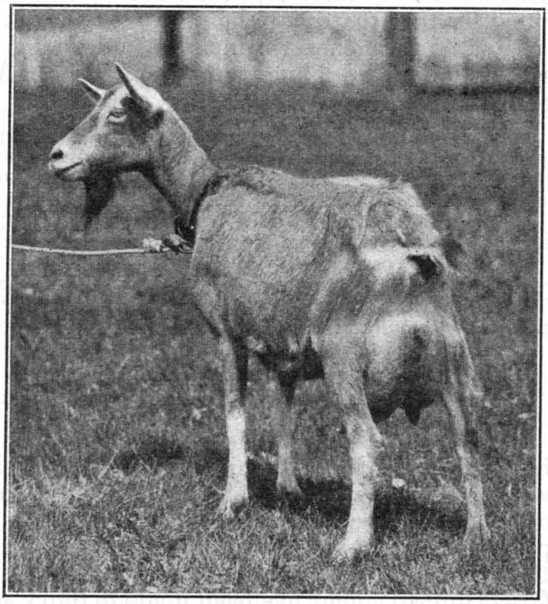

FIGURE 115.—Toggenburg doe of the type used in the feeding tests with good and poor hay

Similar studies were made by feeding a good-quality hay one month and a poor quality the next. In March of one year alfalfa hay of good quality was fed to 10 milking does and their total production for the month was 1,727 pounds. The following month a very poor quality of clover hay was fed in place of the alfalfa hay. The clover hay was coarse, improperly cured, and stemmy. The total production for the month dropped to 1,439 pounds, a decrease of 16.7 per cent, in spite of the fact that in April of preceding years milk production had increased over that in March.

As roughage usually constitutes at least 50 per cent of the feeding value of the ration for milk goats, it is evident that the very best quality should be provided.

V. L. SIMMONS,
Junior Animal Husbandman, Bureau of Animal Industry.

MILK Improvement on Nation-Wide Basis Is Dairy Extension Aim

Amid almost revolutionary changes in methods of marketing, one basic factor remains important—quality. There has seldom been a time when a superior product failed to gain or hold a better market than an inferior article. As trade competition increases, and when supply exceeds demand, the low-grade commodity usually is the first to suffer.

Dairy products are no exception. More and more market channels are being filled with milk, butter, cheese, and other products of higher grades, while low-grade products sell at lower prices or go without a market. Demand for foodstuffs depends largely upon the quality hay was fed, the same does produced 18,150 pounds of milk, or an average of 1,008 pounds. This was an increase of 5,850 pounds of milk, or approximately 47 per cent. The length of the lactation periods was approximately nine months, each of the two years. All other factors and conditions except the hay were likewise the same. The grain ration remained constant and consisted of the following mixture: 8 parts corn, 4 parts oats, 2 parts bran, and 1 part linseed meal, by weight. MILK Improvement on Nation-Wide Basis Is Dairy Extension Aim

Amid almost revolutionary changes in methods of marketing, one basic factor remains important—quality. There has seldom been a time when a superior product failed to gain or hold a better market than an inferior article. As trade competition increases, and when supply exceeds demand, the low-grade commodity usually is the first to suffer.

Dairy products are no exception. More and more market channels are being filled with milk, butter, cheese, and other products of higher grades, while low-grade products sell at lower prices or go without a market. Demand for foodstuffs depends largely upon the following factors: (1) Familiarity of the consumer with the product; (2) price, in relation to other foods and to purchasing power; (3) necessity in the diet; (4) palatability; and (5) quality.

No attempt is made here to list these factors in the order of their importance. The last two are of special value, and the Department of Agriculture is making a vigorous campaign to bring about improvement. Quality and palatability in milk are almost wholly decided by the treatment the product receives in the dairy industry.

Most of the general principles underlying the production of clean, safe milk have been known for a long time. As long ago as 1794 James Stele wrote:

> For the industrious farmer would be able to produce considerably larger quantities of these now very valuable, as well as useful commodities (butter and cheese) from his farm into the market without almost any additional expense whatever. At the same time he would derive a larger share of gain from the mere increase of weight, he would beside receive a proportionable advancefromthe superior quality of the articles, and a quicker market. * * * in order to have butter and cheese cleanly prepared, much caution and attention, no doubt, is requisite; yet a little more pains will be found to make all the difference, and, in fact, is all that is necessary for obtaining this notable and honorable end; in general, we would have people more careful to study cleanliness, in every respect, in the management of milk and its produce.

Wider Improvement Desirable

Of course the development of bacteriology and sanitary science has been almost entirely within the past generation; but even when Stele wrote, 136 years ago, the effect of cleanliness and cooling on the quality of milk was recognized. Although many leading dairymen have practiced approved methods, there has been a lamentable lack of thorough application of such principles throughout the industry. Great improvement has been made in dairy sanitation in this country, which on the whole has the safest milk supply in the world. But much of this improvement has taken place in fairly restricted localities, such as city milk sheds, and among patrons of individual plants. It has become increasingly evident to leaders in the industry that the time has arrived when an extensive country-wide program of quality improvement should be inaugurated. Such a program of information and demonstration should be available to every dairyman in the United States and, being an agricultural problem, it should be brought to him through agencies properly trained and equipped to handle agricultural questions. Fortunately the Congress, by the Smith-Lever Act, has established machinery for such purposes. This act provides funds for cooperative agricultural extension work by the State agricultural colleges and the United States Department of Agriculture. By over 2,700 county agents and 100 dairy extension specialists in the various States the latest information from the State agricultural colleges and the department is carried direct to farmers and their families.

The Office of Cooperative Extension Work and the Bureau of Dairy Industry of the Department of Agriculture have worked out two complete programs as suggestions for milk quality improvement work in the various States. The first of these is a project capable of being applied on the area plan in milk-producing sections. It provides for a preliminary survey of market requirements and present production methods and conditions. This is followed by a meeting of dairy specialists, county agents, representatives of dairy organizations, and milk-control officials, at which results of the survey are presented and methods of improvement discussed. A permanent committee is formed and a series of farmers' meetings and demonstrations follow. In this way, cooperators are secured who have special problems to deal with. The program also includes follow-up work and the measurement of results obtained during the year.

Project for Boys and Girls

For farm boys and girls, a somewhat different form of project has been devised. This is adapted for incorporation in whole or in part into the programs of the 4-H dairy clubs. The subject matter is divided into 12 lessons which deal with the fundamental principles of quality milk production. Each step calls for the production of milk samples by different methods. Simple tests for milk quality are applied to these samples at the club meeting. In this way every boy and girl has a vivid visual demonstration of quality improvement through the use of improved methods. At the end of the year there is a field day at which a demonstration team performs the tests for milk quality, a visit is made to an especially fine dairy, a picnic dinner is enjoyed by club members and parents, and awards for proficiency are made.

Although these projects have only recently been definitely formulated, several States have already begun work on both the adult and 4-H club programs. As dairymen see more clearly the tremendous economic advantage of this line of work and give it their wholehearted support, progress will be even more rapid. The time is not far off when dairymen will unite to jealously guard their markets against the influx of any inferior products. Theirs is the gain, and upon their shoulders rests the responsibility.

ERNEST KELLY,
Chief of the Division of Market-Milk Investigations,
Bureau of Dairy Industry.

MILK Plants of Small Size Must Be Carefully Planned and Operated Many farmers or groups of farmers have gone into the milk-distributing business, either as a side line or as their main occupation. For the most part their plants are small, supplying the fluid milk for the local community. Although the volume of the individual plant is not large, the plants are so numerous that in the aggregate they handle a considerable proportion of the bottled milk of the country.

For the most part these small plants are not prominently located. They are usually situated at the rear of the owner's home site, or on a small side street, or back from the main road on a farm. In the case of the town plant the location is usually picked with a view to economy in the cost of the site, and for convenience in the case of the farm plants. As to the town plant, although the use of the cheaper land for the site might seem to be a proper saving, it seems reasonable to suppose that the higher land value of a well-located site would often be more than offset by the advertising value and the counter sales that might be made if the plant were in a prominent location.

The Bureau of Dairy Industry is constantly receiving requests for information on the construction, arrangement, equipment, and man-milk-control officials, at which results of the survey are presented and methods of improvement discussed. A permanent committee is formed and a series of farmers' meetings and demonstrations follow. In this way, cooperators are secured who have special problems to deal with. The program also includes follow-up work and the measurement of results obtained during the year.

MILK Plants of Small Size Must Be Carefully Planned and Operated Many farmers or groups of farmers have gone into the milk-distributing business, either as a side line or as their main occupation. For the most part their plants are small, supplying the fluid milk for the local community. Although the volume of the individual plant is not large, the plants are so numerous that in the aggregate they handle a considerable proportion of the bottled milk of the country.

For the most part these small plants are not prominently located. They are usually situated at the rear of the owner's home site, or on a small side street, or back from the main road on a farm. In the case of the town plant the location is usually picked with a view to economy in the cost of the site, and for convenience in the case of the farm plants. As to the town plant, although the use of the cheaper land for the site might seem to be a proper saving, it seems reasonable to suppose that the higher land value of a well-located site would often be more than offset by the advertising value and the counter sales that might be made if the plant were in a prominent location.

The Bureau of Dairy Industry is constantly receiving requests for information on the construction, arrangement, equipment, and management of these small plants. In all processing plants, the best arrangement permits the product to enter at one end of the plant, then go from one process to another in a straight line, the finished product leaving the plant at the other end. In a milk-pasteurizing plant this means that the raw milk and empty bottles enter at one end; the bottles go to the washer and the milk to the pasteurizer; then the pasteurized and cooled milk, and the clean bottles, meet at the filler; the filled bottles move on to the cold-storage room and from there out of the plant to the delivery equipment. This system eliminates all back-tracking, interference, and confusion. Although it is not always practicable to have exactly this arrangement, the principle is correct and should be followed as closely as possible.

Sanitary Standards

The sanitary standard of the small plant depends upon two things—the intelligence of the owner, and the efficiency of the inspector. Generally the owners of these plants take a great personal pride not only in keeping their plants clean and sanitary but also in delivering pure and wholesome milk to the consumer. To maintain a high sanitary standard and a high quality of flavor and odor of the bottled milk, it is necessary to separate the plant into rooms. The pasteurizing and bottling room should be separate from all other rooms. The bottle washing and milk-receiving may be done in the same room if there is enough space to allow for a reasonable separation of the two operations. The boiler and toilet must be separate from the other rooms with, preferably, no direct opening into the rest of the plant; there may be, however, a door opening from the boiler room into the bottle-washing room if it is kept closed when not in use.

Data gathered in three Eastern States on the construction, equipment, and arrangement of 120 small pasteurizing plants, show that the small plants of to-day are advancing very rapidly as to equipment and management. It was found that 97 per cent of the plants covered by the survey were using electricity for their operating power. Of the plants which handled less than 300 gallons of milk a day, 68 per cent were using mechanical refrigeration. The milk pasteurizing, cooling, and bottling equipment was usually of modern design and construction and the motor truck had almost entirely superseded the horse for delivery purposes. In general the owners were using modern labor-saving devices and equipment and were constantly trying to improve their operations and management.

Assistant Market-milk Specialist,
Bureau of Dairy Industry.

MILK Secretion Shown by Experiments to be a Continuous Process

The firm, distended condition of the cow's udder just before milking, and the looser and more mellow condition immediately after the milk is drawn, are common observations. Sometimes the distention before milking is so great that streams of milk leak from the teats, and the cow appears to be in pain. In spite of these common observations, however, the belief has persisted rather generally among teachers and other professional men in dairy-cattle and veterinary work, that the capacity of agement of these small plants. In all processing plants, the best arrangement permits the product to enter at one end of the plant, then go from one process to another in a straight line, the finished product leaving the plant at the other end. In a milk-pasteurizing plant this means that the raw milk and empty bottles enter at one end; the bottles go to the washer and the milk to the pasteurizer; then the pasteurized and cooled milk, and the clean bottles, meet at the filler; the filled bottles move on to the cold-storage room and from there out of the plant to the delivery equipment. This system eliminates all back-tracking, interference, and confusion. MILK Secretion Shown by Experiments to be a Continuous Process

The firm, distended condition of the cow's udder just before milking, and the looser and more mellow condition immediately after the milk is drawn, are common observations. Sometimes the distention before milking is so great that streams of milk leak from the teats, and the cow appears to be in pain. In spite of these common observations, however, the belief has persisted rather generally among teachers and other professional men in dairy-cattle and veterinary work, that the capacity of the udder for the storage of milk was not more than about one-half pint to each quarter, and that nearly all of the milk obtained at a milking was secreted during the milking process. Supposedly, the manipulation of the udder and teats in milking stimulated, in some way, the rapid secretion of milk during this brief period. Even as recently as 1924 a textbook appeared with a discussion of milk secretion which contained the following statements:

> The udder contains only a small amount of milk, usually between a pint and a quart, when one starts milking. This is found in the four milk cisterns. The enlargement of the udder which occurs before milking is doubtless due to the storing up of the ingredients out of which milk is to be made. For the most part—milk is really made during the milking process. A cow killed just before milking time will be found to have no milk in the udder except that present in the milk cisterns.

In order to test this theory, which seemed illogical, 11 cows have been included in an experiment in which each was first kept for several days on a carefully controlled program of feeding and watering, and milked at uniform intervals until her level of production could be determined. With a single exception this preliminary period extended over 10 days. Milking always took place at a definite hour in the morning. In the case of one or two heavy milkers an intermediate milking was performed. The plan was to have the udder well distended at the morning milking, and whether the interval between this milking and the last previous one was 12 hours or 24 hours, the quantity of milk obtained at the morning milking was averaged for the 10 days to determine the lactating level of the cow at that milking. On the eleventh morning, at exactly the same hour, she was killed, either by a blow on the head or by shooting through the brain and suspended for bleeding, after which, in rapid succession, her udder was amputated, suspended in a natural position by its surrounding skin and median septum from an iron frame, and milked out in the usual manner by hand.

Two Post-Mortem Milkings

It is taken for granted that when the circulatory and nervous systems and all other body connections have been severed and the blood supply removed, milk secretion can not continue. That being true, any milk drawn from the amputated udder must have been present in the udder at the time of death. Two post-mortem milkings were performed on each udder—one immediately after its amputation and suspension and one four hours later. The second post-mortem milking was performed for the purpose of obtaining any milk which had drained into the cisterns and larger ducts. The total milk obtained in both post-mortem milkings was then compared with the lactating level of the cow during the previous 10-day period to show the percentage of the ante-mortem yield obtained by milking the amputated udder post-mortem. For brevity this is referred to as the "per cent post-mortem recovery."

The first four cows were felled by a blow on the head. In two of these cases the first blow was not entirely effective and the cows struggled vigorously, became almost violent and died with tensely contracted muscles. The milk from these two udders was released more slowly and the per cent post-mortem recovery was lower than for the others. The next seven cows were killed by shooting into the brain. Death in almost every case was nearly instantaneous and very little struggling or tenseness of muscles was observed. In each case the milk was released quite rapidly and the per cent of post-mortem recovery was relatively high. Table 12 shows that the first four cows (Group 1) were producing at an average level of 16.41 pounds at a milking before death and that an average of 9.22 pounds of milk, or 61.10 per cent of the quantity obtained at corresponding milkings before death, was obtained from their amputated udders. In the second group of seven cows conditions were more carefully controlled. The average ante-mortem milking level was 19.88 pounds at a milking and an average of 14.83 pounds of milk or 75.32 per cent of the ante-mortem production was obtained from these udders after amputation. In one instance the ante-mortem production was 18.51 pounds and 18.70 pounds was obtained post-mortem. When both groups were combined the ante-mortem level of production was 18.62 pounds at a milking, and the post-mortem recovery of milk was 12.79 pounds or 70.15 per cent of the ante-mortem level. Of the total quantity of milk obtained from amputated udders 81.9 per cent was obtained at the first and 18.1 per cent was obtained at the second post-mortem milking.

TABLE 12.—*Quantity of milk obtained before and after death of cow and amputation of the udder*

Cow No.	Average production for 10 days, ante mortem	Total milk, post-mortem	Proportion of ante-mortem production obtained post-mortem
	Pounds	*Pounds*	*Per cent*
459	[1] 12.07	10.27	85.09
292	21.38	10.60	49.58
123	10.37	7.20	69.43
272	21.83	8.80	40.31
Average of Group 1	16.41	9.22	61.10

Average of Groups 1 and 2	18.62	12.79	70.15

[1] 3-day average.

Samples Chemically Analysed

Samples of the milk from each udder on the last two days before slaughter and at both post-mortem milkings, were taken for chemical analysis. In the first four cases no attempt was made to maintain body temperature in the udder from the time of amputation until after completion of the second post-mortem milking, and the udders undoubtedly became chilled throughout. In the first post-mortem milking the average butterfat test was only 57.29 per cent as high as in the ante-mortem and in the second post-mortem milking it was only 27.45 per cent as high as in the ante-mortem milk. In other words the butterfat test was only about half as high in the first post-mortem as in the ante-mortem milk and only half as high in the second post-mortem as in the first post-mortem milk. Changes less extreme were noted in some of the other constitutents. It seemed probable that the low butterfat test in the post-mortem milk may have been at least partly due to the chilling of the udder and the consequent solidification and adhesion of the butterfat to the lining of the ducts within the udder.

The next seven udders were kept as nearly as possible at body temperature until after the second post-mortem milking was finished. The average butterfat test of the first post-mortem milking from these cows was only 51.80 per cent but that of the second post-mortem milking was 58.68 per cent of the ante-mortem. Controlling the temperature, therefore, did not prevent the lowering of the butterfat test from the ante-mortem to the first post-mortem milking, but appeared to be responsible for maintaining the butterfat test of the second post-mortem milking at an equal or slightly higher level than that of the first post-mortem milking. The reason for the 50 per cent decline in butterfat test in the first post-mortem as compared with the ante-mortem milk has not been definitely determined.

The post-mortem milk differed from that obtained before the death of the cow in several other respects. The total solids declined steadily and markedly from ante-mortem to second post-mortem, the solids not fat were nearly normal in the first post-mortem but low in the second post-mortem, the ash content increased steadily from ante-mortem to second post-mortem, the total protein varied very little from the ante-mortem in either post-mortem, and the lactose was about normal in the first post-mortem but distinctly low in the second post-mortem milk.

Milk Secretion Apparently Continuous

The results obtained with the 11 cows studied offer almost conclusive evidence that milk secretion is to a great extent a continuous process and that a very large proportion, in fact nearly all, of the milk obtained at any milking is present in the udder before the milking process is commenced. The low butterfat test, as well as abnormalities in other constituents of the milk obtained from amputated udders has been noted as a matter of interest.

But what is the significance of this work and the information obtained by it? In the first place it will provide a scientific rather than an unsound theoretical basis for teaching this particular phase of the subject of milk secretion. The fact that nearly all of the milk is stored within the udder before the milking process is commenced also raises the question of the importance of the frequent milking of cows which produce heavily. The importance of size of udder is immediately suggested and the necessity for more frequent milking for high producing cows is indicated. On the other hand, the quantity of fluid which can be forced through the teats into the secretory system of an amputated udder is much greater than it has been supposed the udder was capable of holding. The 11 udders on which the post-mortem milking tests were conducted showed an average capacity for holding fluid equivalent in volume to slightly more than 50 pounds of milk. This would appear to indicate ample space for storing within the secretory system of the udder all of the milk obtained at a milking. In all probability, however, the living udder is not able to hold a quantity of milk as great as the capacity indicated because at the time of measuring the capacity the blood had been removed and the pressure employed in filling was undoubtedly greater than that of the milk within the living udder.

A theory which has been advanced and which seems reasonable, is that as the milk accumulates, the pressure within the udder increases and that the rate of secretion is inversely proportional to the pressure. The most rapid secretion should, therefore, take place soon after milking and the greatest total secretion should be obtained from udders that are milked sufficiently often to keep their internal pressure below the point at which the activitiy of the secreting cells commences to be inhibited. This is in accord with the common practice of milking heavy producing cows more than twice daily whereas two milkings daily is probably sufficient for cows of moderate production.

MORTGAGE Planning as Important to Farmers as Planning of Crops

The large annual volume of farm-mortgage loans and the large number of farm foreclosures in recent years suggest the importance of giving careful consideration to what can be done to obtain favorable long-term loans when needed and how to avoid being distressed by them later. That past practice can be improved is suggested by the fact that most farmers give better attention to planning their cropping program of a single season than they do to their finances, yet the value of the crop may be but a fraction of the mortgage, and the one is an annual event while the mortgage debt may continue for a generation.

Studies of long-term farm financing in the United States indicate that more loans have been made at high rates than at low rates and that most loans are made for an average of 5 years although the debt continues for an average of 30 years. The great part of the annual billion-and-one-half mortgage business represents refinancing which takes place not at a selected time but whenever the previous mortgage expires or when credit stringency prompts local creditors to demand payment.

Careful management of a farm-mortgage debt generally requires that it should be placed or renewed when the supply and cost of money are favorable, that the term of the mortgage should be related to the length of time the farm is likely to carry the debt, that the ratio of debt to value of the farm should not exceed the ratio of net income to the annual interest charge and that the method of repayment should accord with the receipt of income.

Study of Money Markets Necessary

Selection of a favorable loan-cost period requires close observation of central money markets. Reference to the accompanying chart of rates on short-term commercial loans and mortgage loans to farmers from 1917 to 1930 indicates that changes in mortgage rates have followed changes in short-term rates and bond yields by at least six months or a year, both on the rise and on the fall. High yields on bonds, however, may cut off the supply of mortgage funds from that source and hence may affect the supply of credit more promptly than its retail rate. This occurred in 1921 and 1929. Although a farmer may have a prepayment privilege clause included with loans incurred at high cost, the process of transferring the loan causes both expense and trouble. It is apparent from Figure 116 that the farmer with

A theory which has been advanced and which seems reasonable, is that as the milk accumulates, the pressure within the udder increases and that the rate of secretion is inversely proportional to the pressure. The most rapid secretion should, therefore, take place soon after milking and the greatest total secretion should be obtained from udders that are milked sufficiently often to keep their internal pressure below the point at which the activitiy of the secreting cells commences to be inhibited. This is in accord with the common practice of milking heavy producing cows more than twice daily whereas two milkings daily is probably sufficient for cows of moderate production.

MORTGAGE Planning as Important to Farmers as Planning of Crops The large annual volume of farm-mortgage loans and the large number of farm foreclosures in recent years suggest the importance of giving careful consideration to what can be done to obtain favorable long-term loans when needed and how to avoid being distressed by them later. That past practice can be improved is suggested by the fact that most farmers give better attention to planning their cropping program of a single season than they do to their finances, yet the value of the crop may be but a fraction of the mortgage, and the one is an annual event while the mortgage debt may continue for a generation.

Studies of long-term farm financing in the United States indicate that more loans have been made at high rates than at low rates and that most loans are made for an average of 5 years although the debt continues for an average of 30 years. The great part of the annual billion-and-one-half mortgage business represents refinancing which takes place not at a selected time but whenever the previous mortgage expires or when credit stringency prompts local creditors to demand payment.

Careful management of a farm-mortgage debt generally requires that it should be placed or renewed when the supply and cost of money are favorable, that the term of the mortgage should be related to the length of time the farm is likely to carry the debt, that the ratio of debt to value of the farm should not exceed the ratio of net income to the annual interest charge and that the method of repayment should accord with the receipt of income.

Study of Money Markets Necessary

Selection of a favorable loan-cost period requires close observation of central money markets. Reference to the accompanying chart of rates on short-term commercial loans and mortgage loans to farmers from 1917 to 1930 indicates that changes in mortgage rates have followed changes in short-term rates and bond yields by at least six months or a year, both on the rise and on the fall. High yields on bonds, however, may cut off the supply of mortgage funds from that source and hence may affect the supply of credit more promptly than its retail rate. This occurred in 1921 and 1929. Although a farmer may have a prepayment privilege clause included with loans incurred at high cost, the process of transferring the loan causes both expense and trouble. It is apparent from Figure 116 that the farmer with mortgage financing to do will do well to keep the same watch on the course of the money market that he is accustomed to give to the crop and livestock markets.

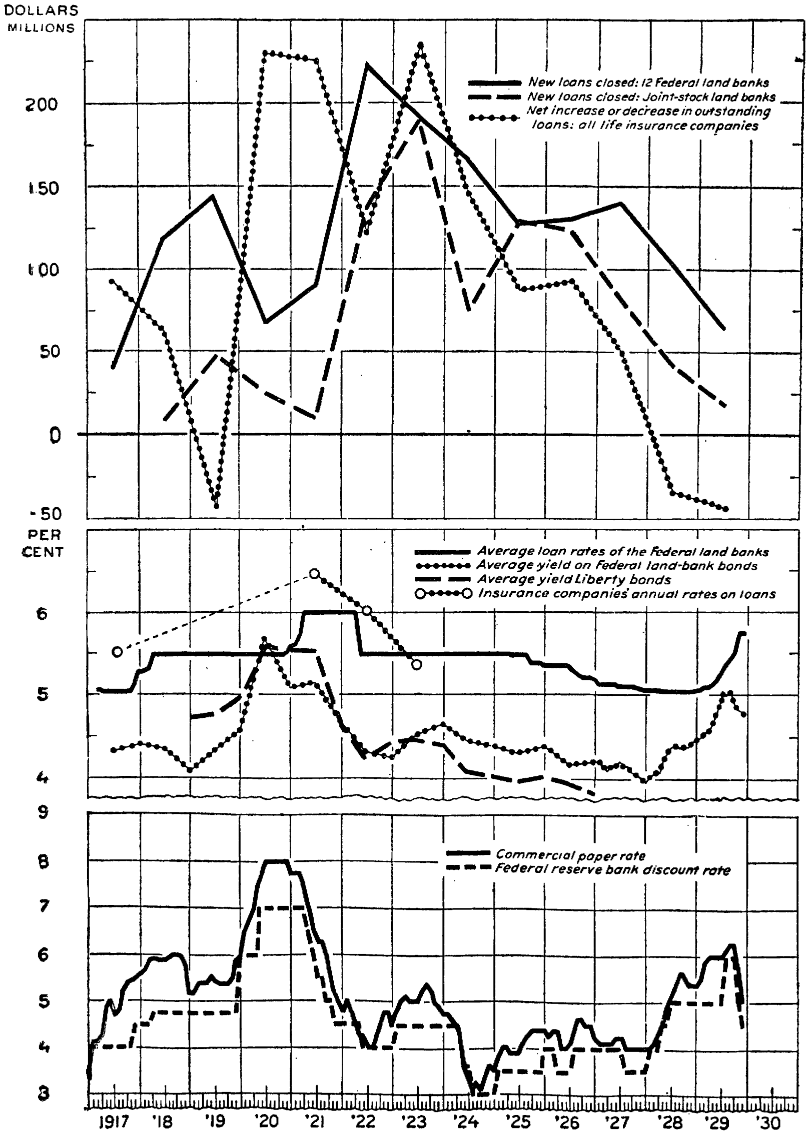

FIGURE 116.—The lower section of the chart shows the course of commercial paper rates and Federal reserve discount rates in New York from 1917 to 1930. The middle section shows the yields on Federal land-bank bonds and liberty bonds and the rates on farm-mortgage loans by the Federal land banks and insurance companies. While the bond market follows closely the course of short-term rates, the quoted rates lag behind. The upper section, showing annual loans by the land banks and insurance companies, reflects the influence which major changes in money rates had on the amount of funds available for farm mortgages at that time. (During most of 1920 and 1921 the Federal land banks and joint-stock land banks were not making loans because of litigation)

A further problem arises out of the fact that the average mortgage debt, either in the same or in a renewed form, remains on the land for at least 30 years. Since an average of only about 3 per cent of mortgaged farms are cleared of debt each year the farmer must have due regard for possible changes in soil fertility, foreign competition, and price level during that time. The question of loan term becomes of prime importance. The usual term of five years may be suitable for some cases, but the farmer who depends largely on his farm for his income usually has to renew the loan five or six times with the expense, uncertainty, and inconvenience which that involves.

This difficulty of renewal is avoided by the amortization loan which provides for gradual retirement of the principal by means of small regular payments over a long period of 20 to 35 years. Furthermore, it has the advantage of repaying a part of the principal with income reflecting the same price level. Before the war, farmers generally believed that the lapse of years would bring only increases in land value. The steady decline of land values and other prices since 1920 have shown that a debt incurred at one price level may have to be paid with sale of products at much lower prices.

A third vital question is the size of the loan and its relation to the value and income of the farm. Although most lending agencies limit loans to about half of the land values, second mortgages or purchase money mortgages given to the seller may be used to obtain an amount of credit equal to most of the farm's current value. In this situation the farmer will usually do better to gauge the amount of the loan by the amount which the average land income can carry rather than by the current sale value of the farm. A loan with a rate of interest higher than the net rental rate for the farm carries a danger of making trouble if the ratio of debt to value is very high. Debt-carrying cost in excess of the farm-rental rate tends to accumulate unpaid balances which gradually consume the remaining equity in the farm; the sale price may keep ahead of the debt during periods of rising land values, but with stationary or declining prices the encroachment on equity means eventual foreclosure.

Means of Paying Principal

The means and facility of paying the principal of the loan constitute a further problem which can best be considered at the time the loan is negotiated. Since most loans are too large to be paid off by the amount of savings possible during the few years of the loan term, such savings rarely prove adequate for the purpose and the average farmer can care for them only by means of a new loan or an extension of the old one. Moreover, most people do not save systematically unless they have previously budgeted their income carefully. The long-term amortization loan provides for annual or semiannual payments whereby a fraction added to the regular interest makes renewals unnecessary.

Although straight loans for short terms may save the farmer some temporary inconvenience and sacrifice in paying regular installments on the principal, the ultimate gain from this course is questionable. If land values continue low at the end of the short term of years the lender may require a reduction of the principal as a condition of renewal. Many farmers encountered this difficulty in 1928 and 1929. An abrupt reduction is likely to cause more inconvenience than a small amortization payment which could be provided for in advance. Moreover, a system of small annual payments steadily increases the safety margin also, so that lenders are less likely to foreclose.

Agricultural Economist, Bureau of Agricultural Economics.

MOUNTAIN Pine Beetle, Epidemic in Northwest, Fought by Two Methods In the last few years the losses of white pine throughout the forests of northern Idaho and western Montana, resulting from the attacks of the mountain pine beetle, have increased from an endemic, or so-called normal infestation, to an epidemic condition. Although white pine is the most valuable of all commercial tree species within our western forests, it is an expensive forest type to maintain, as it is grown under extremely hazardous fire conditions and requires from 100 to 120 years to reach maturity, resulting in high protective charges and long-time investments. The infestation within certain areas of this region was very heavy, the loss varying from 6 to 10 per cent of the total white-pine volume. In other areas the outbreak was not so severe, the loss of pine being confined to a small part of the stand. An exceedingly alarming situation exists within the white-pine forests of Idaho and Montana, and it is apparent that unless the rapidly increasing outbreak can be reduced through the use of artificial control measures a large proportion of the total pine volume will be destroyed. In addition to the economic loss of timber, thousands of inflammable snags will be scattered throughout the region, creating a more serious fire hazard than that which already exists. Such snags, standing for 20 years or more, will always be the fire fighter's mortal enemy, increasing the severity of the task and the danger of the operation.

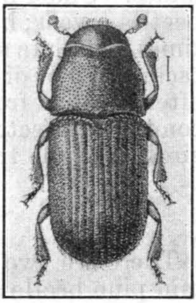

FIGURE 117.—Mountain pine beetle (*Dendroctonus monticolae*). About four times natural size.

FIGURE 118.—Inner surface of white-pine bark showing egg galleries and larval mines of the mountain pine beetle. About three-eighths natural size

The Mountain Pine Beetle

The mountain pine beetle (fig. 117) is a small, black, cylindrical bark beetle, about one-third of an inch in length, which attacks and kills healthy, mature white-pine, sugar pine, yellow pine, lodgepole pine, white-bark pine, and sometimes Engelmann spruce when occurring in association with white-pine infestations. The attack is made by the adult beetles boring through the bark and constructing perpendicular galleries, varying from 18 to 24 inches in length, between the bark and the wood, along which eggs are deposited. (Fig. 118.) These eggs hatch into small, white, legless grubs that in turn construct, while feeding, short larval mines at right angles to the egg galleries, also between the bark and the wood. When mature the grubs, or larvae, transform to new adults within small cells constructed at the end of the larval mines. Under normal conditions there is but one generation of these beetles a year; however, during long, dry seasons a partial and sometimes complete second generation occurs. The number of insects attacking a foot of bark surface ranges from 14 to 20, and the infestation often extends from the base of the tree to a height of 130 feet. The combined effect of the egg galleries and larval mines results in the girdling of the tree, causing its death.

Methods of Control Practiced

There are two methods of control used in the suppression of mountain pine beetle outbreaks in white pine. In thinking of bark-beetle control one must remember that after a tree has been successfully attacked it can not be saved; so control measures are directed toward the destruction of the insect broods within the infested trees to prevent their emergence and subsequent attack of other trees. To destroy the broods the trees are felled, cut into logs, piled, and burned, or else the bark is peeled from the infested portion of the bole. The effectiveness of the first method is, of course, self-evident, but concerning the second a word of explanation is necessary. As the complete development of these beetles takes place beneath the bark, its removal exposes the immature insects to the attacks of predacious insects, birds, and small mammals, as well as unfavorable climatic conditions, which together completely destroy the insect broods exposed by removing the bark. (Fig. 119.) Both these methods have their special advantages, being adapted to certain types of infestations or conditions of terrain. With the burning method there is, of course, the danger of fire, which prevents its being used when the forests are dry. Wherever the infestation is heavy, horses are used to skid the logs into large decks. Where infested trees are scattered throughout a large area, the infested bole can be cut into short lengths and hand-logged into decks for burning. When trees are peeled, for which a heavy peeling spud is used, the bole is cut only sufficiently to permit its being rolled so that the bark can be removed from the underside.

Organization of Control Projects

The first and most important task in connection with a bark-beetle control project is the locating of the infested trees for treatment. This is accomplished by a spotting crew, consisting of three or five men, making a 100 per cent survey of all the infested areas. These spotting crews are organized with a chief spotter who runs the compass, paces the distance traveled, constructs a map of the region showing the location of the trees marked for treatment, and is responsible for the proper marking of all insect-killed trees located by the spotters, who cover strips of a certain width on each side of the compass man. The completed maps are turned over to the treating crew foreman to be used in relocating the trees marked for treatment.

Control Projects Under Way

During 1930 control operations directed against mountain pine beetle outbreaks in white pine were conducted on the Coeur d'Alene, Clearwater, and Kootenai National Forests, and Glacier National Park. In 1929 control measures had been applied on the Coeur d' Alene Forest on a very small scale, insufficient to affect the general infestation, but showing very good results within the area covered. On the Kootenai Forest control operations had been conducted in 1928 and 1929 on a fairly adequate scale, showing a very satisfactory reduction in the general infestation of white pine. On the Clearwater Forest and Glacier National Park control operations were instituted for the

FIGURE 119.—Treating infested white pine by removing the bark

first time in 1930. The most serious situation existed on the Coeur d'Alene National Forest where the infestation was found to be established throughout the entire white-pine type. On the four areas mentioned some 29,000 trees were treated during May and June, 1930, at an average cost of $5.10 per tree. The majority of these trees (22,841) were on the Coeur d'Alene National Forest. The actual results obtained from the intensive control operations of 1930 are, of course, not available at this time, but, knowing the potential danger of an infested tree, it is safe to assume that there could have been sufficient insects emerging during July, 1930, from the 29,000 trees treated during May and June, to have attacked and killed at least 100,000 trees, which would have required $500,000 for treatment in 1931.

Entomologist, Bureau of Entomology.

MUSHROOM Disease Known as "Bubbles" Controlled by Exclusion and Eradication

Most commercial growers are familiar with the symptoms of the destructive disease of cultivated mushrooms known in the United States as bubbles or mycogone and in France as la môle. It is caused by a fungus called *Mycogone perniciosa*, which grows into the mushroom and transforms it to a distorted putrid mass. Soon after the parasite attacks a mushroom it produces a layer of white or brown spores over the surface of the diseased mushroom. These spores are spread about by currents of air, by insects, workmen, etc. They may be lifted or deposited by convection currents and blown about through the air like dust particles too small to be seen unless floating through a beam of light in a dark room. Like many other fungous spores, they are able to germinate and grow immediately if conditions are favorable, or to live through a long rest period under unfavorable conditions. They may infect healthy mushrooms, grow in soil or compost, or remain in a resting stage for several months or even years.

The recurrence or accumulation of the disease from one crop to another indicates that the Mycogone fungus either is remaining alive inside the house from one crop to another or is being carried into the house during one of the cultural operations. There are several possible methods of introducing the fungus into the house: (1) By air or on insects entering through doors or ventilators, (2) in water, (3) spawn, (4) compost, (5) soil, and (6) by workmen.

Burning sulphur and fumigating with formaldehyde between crops are practical methods of eradicating Mycogone from the house. Experiments have shown that the burning of one-fourth pound of sulphur per 1,000 cubic feet of air space in a closed container will kill Mycogone spores. When it is used as a combination insecticide and fungicide, sulphur should be burned at the rate of 5 pounds per thousand cubic feet of air space. Formaldehyde is used at the rate of 1 pound of the commercial preparation per 1,000 cubic feet of air space. Detailed methods of using formaldehyde are given in United States Department of Agriculture Circular 27. If either of these methods of disinfection is used there will be little or no disease due to inoculum persisting within the house from one crop to another.

The danger of infection due to spores carried into the house in the air or by insects can be materially reduced by removing spent mushroom manure and all mushroom refuse from the immediate vicinity of the house and occasionally disinfecting the soil around the house. Various solutions are suitable, such as lysol, 2 per cent; formalin, 2 per cent; or bichloride of mercury, 1 pound to 60 gallons.

Infection from contaminated water or spawn can be largely avoided by using water direct from deep wells and by using bottle spawn. To prevent the growth of green mold and other contamination in spawn bottles, spawn makers transfer bottle spawn under as nearly aseptic conditions as possible. Because of this there is little chance for Mycogone to be distributed in bottle spawn. Furthermore, if clear-cut cases of the distribution of disease in spawn should arise it would be a comparatively simple matter for the spawn maker to trace the source of infection and start again with clean cultures.

Mycogone Eradicated by Heat

A good "heat" in the mushroom house during the final fermentation is the most effective method known of eradicating Mycogone from mushroom compost. All of the evidence at hand indicates than an air temperature of 120° F. for 48 hours in a mushroom house will eradicate the fungus from the air, compost, and soil. Obviously, this temperature must be obtained in all parts of the house to eradicate the fungus completely. Therefore it is advisable to use some means to circulate the air to prevent temperature layering. Some growers accomplish this by opening the ventilators very slightly, others set large electric fans tilted up at an angle of 45° in the center aisle. It is also advisable to raise the lower beds off the floor to allow a circulation of air under them. Even when these precautions are taken it often happens that the manure is too wet or overcomposted to heat the air in the house to 120°. To insure against this condition some growers are providing themselves with auxiliary steam-heating systems to obtain artificially the desired temperature in the house during the "heat." This practice has given satisfactory results in the United States Department of Agriculture experimental mushroom house since it was first used in 1928 and seems to be a logical step in the right direction.

Outbreaks From Infested Casing Soil

Circumstantial evidence indicates that most of the severe outbreaks of "bubbles" in commercial houses in the United States are due to infested casing soil. Losses from this source can be eliminated by avoiding the use of contaminated casing soil, which usually is soil from fields that have been fertilized with spent mushroom manure or that have been subject to the drainage overflow from such fields. To determine whether soil is contaminated, small test beds may be cased with soil samples out of fields from which soil will be taken for subsequent crops. If soil infestation becomes general and there is no Mycogone-free soil available, the fungus can be eradicated from the soil by placing it inside the mushroom house during the "heat." Soil to be treated in this way should be placed near the top of the house, where the temperature is highest, and a temperature of at least 120° F. must be maintained in the soil for 48 hours or more.

The spread of the disease by workmen can be largely prevented by a few common-sense rules. For example, men who have been working with contaminated casing soil should not be allowed to cut mushrooms without first washing their hands; likewise, the removal of the occasional diseased mushroom often occurring on beds that are otherwise clean should be made a separate job and not done by men who are cutting mushrooms for market.

After infection has become widespread in a house a moderate amount of loss is inevitable, but the disease can be somewhat reduced by growing the crop at a low temperature, 50° to 55° F.

From the foregoing discussion it is apparent that a complete program of control is necessary to combat the disease effectively. So far as possible the spores and mycelium of Mycogone must be eradicated from the house and all avenues of entrance must be closed. Since the causal organism is capable of rapid reproduction, the neglect of one source of inoculum may render useless the measures taken to control others. Because of the various conditions under which mushrooms are cultivated, each grower must plan a control program to suit best his individual needs. The measures outlined above apply particularly to the prevention of the disease in standard mushroom houses. In heavily infested areas they will not assure a 100 per cent control, but if carefully followed they will prevent serious outbreaks and control the disease sufficiently for practical purposes.

MUSHROOM Growing Risky Without Control Action for Insects and Mites

The growers of the cultivated mushroom *Agaricus campestris* have long been troubled with insect pests and mites, the infestations of which have gradually increased with the localization and growth of the industry to the point where they have made mushroom culture rather hazardous unless measures of prevention and control are constantly practiced.

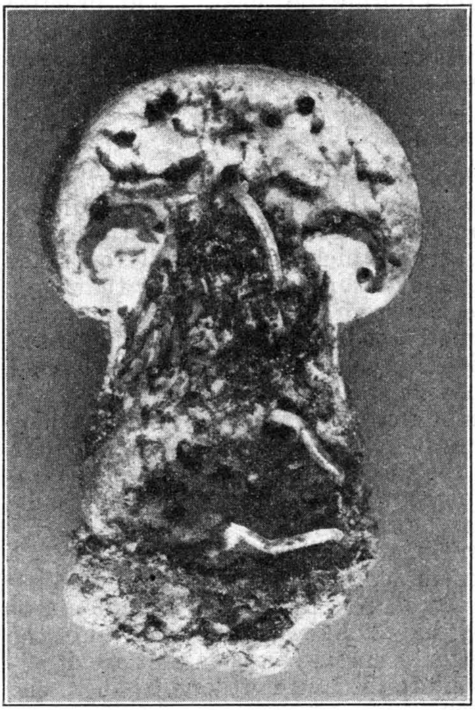

FIGURE 120.—Mushroom button showing maggots of fungus gnats and damage done chiefly by them

The chief pests causing commercial damage to mushrooms are the fungus gnats, mites, and springtails.

In general, the fungus gnats, of the genus Sciara, are productive of the most injury to the mushroom industry. They are prevalent in almost every type of mushroom house or cave, since they enter, as a rule, in the compost when it is taken into the houses. The larvae or maggots of these flies cause injury both by destroying the mycelium in the beds and by feeding on the small mushrooms, which they completely devour in many instances. These maggots are also capable of rendering the large sporophores unfit for market by tunneling upward through the stem and cap. (Fig. 120.) The adult flies often transport injurious mites, which attach themselves to the bodies of the flies, from one mushroom house to another and they also aid in the dissemination of some diseases of mushrooms.

The mites, while not so prevalent in general as the fungous gnats, are capable, nevertheless, of causing serious losses, once they become established in a range of mushroom houses. The mushroom mite proper, *Tyroglyphus lintneri* Osb., feeds on the mushroom, producing dark pits which result in decay, destroy the mycelium in the beds, and cut off the feeder "root system" (fig. 121) so that the sporophores do not mature, resulting in decreased yields. A severe infestation of this mite was experienced by an Ohio grower during the past season, resulting in a crop damage of approximately $25,000.

infested areas they will not assure a 100 per cent control, but if carefully followed they will prevent serious outbreaks and control the disease sufficiently for practical purposes.

The larvae or maggots of these flies cause injury both by destroying the mycelium in the beds and by feeding on the small mushrooms, which they completely devour in many instances. These maggots are also capable of rendering the large sporophores unfit for market by tunneling upward through the stem and cap. (Fig. 120.) The adult flies often transport injurious mites, which attach themselves to the bodies of the flies, from one mushroom house to another and they also aid in the dissemination of some diseases of mushrooms.

The mites, while not so prevalent in general as the fungous gnats, are capable, nevertheless, of causing serious losses, once they become established in a range of mushroom houses. The mushroom mite proper, *Tyroglyphus lintneri* Osb., feeds on the mushroom, producing dark pits which result in decay, destroy the mycelium in the beds, and cut off the feeder "root system" (fig. 121) so that the sporophores do not mature, resulting in decreased yields. A severe infestation of this mite was experienced by an Ohio grower during the past season, resulting in a crop damage of approximately $25,000.

It is much more widely distributed, apparently, than the mite *Linopodes antennaepes* Banks, which was recently found causing commercial damage to mushrooms in several plants and which resulted in a loss of approximately $50,000 to one grower.

Springtails cause very little damage to mushrooms in the East, but are one of the most serious pests with which the growers operating in the sandstone caves of the Northwest have to contend. While the species found in the sandstone caves has never been described in this country and apparently is not present in the East, it is doubtful whether it would cause a great amount of damage in the modern eastern houses on account of unfavorable atmospheric conditions for rapid development and reproduction.

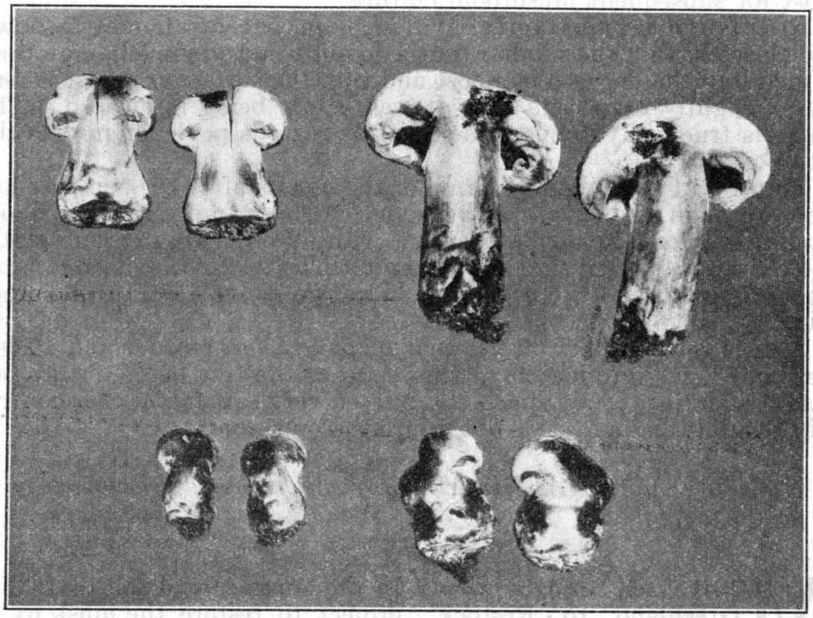

FIGURE 121.—Mushrooms showing damage caused by the mushroom mite, *Tyroglyphus lintneri*

Measures of Prevention and Control

In view of the extreme sensitivity of the mushroom mycelium as well as the mushroom itself to most fumigants, it is necessary to take certain precautionary measures prior to placing the spawn in the beds in order to prevent heavy infestations of these pests and subsequent damage to the crop.

Experiments have shown that the manure, if properly composted before it is put into the beds in the house, will undergo a secondary decomposition process and heat up sufficiently (if aided by forced circulation) to either kill the pests in the compost or drive them to the surface where fumigants can be effectively used. Forced circulation is obtained by the use of electric fans of the oscillating type while the compost is undergoing its secondary decomposition process in the beds. By means of two 16-inch fans it is possible to equalize the air temperature all over the house and to get the temperature in the compost fairly even in all the beds, making it possible to kill off the various pests by fumigation while the temperatures are at the peak.

Calcium cyanide, at the rate of 1 pound per 1,000 cubic feet of air space, scattered on the floor in the alleyways, has been most widely used to date, but the burning of sulphur, in view of its cheapness and its double rôle as a fungicide and insecticide, is gradually replacing cyanide for this purpose. The practice of burning sulphur at the rate of 2 pounds per 1,000 cubic feet of air space while the compost is at its peak heat in the beds and leaving the house closed for five hours after all the sulphur has burned has proved to be very effective against any pests which may inhabit the house at this time, and, judging from results of yield tests, it has not injured the compost for subsequent mushroom culture.

Results of determinations of hydrogen-ion concentration have shown conclusively that the sulphur fumes do not penetrate much more than 1 inch into the uncased compost and that the surface compost is rendered slightly more acid than it was before being fumigated. The same is true of hydrocyanic-acid gas as regards penetration into the compost.

To prevent possible infestation of the houses after the compost has gone through its heat in the beds and has been fumigated, the doors and ventilators should be screened with 30-mesh copper-wire cloth. To prevent rapid development and multiplication of insects and mites the temperature of the house should not go above 55° F. while cropping.

A dust consisting of 60 per cent of pyrethrum powder and 40 per cent of a finely ground clay, when used at the rate of 2½ ounces per 1,000 cubic feet of air space, has proved very satisfactory for control of the adult flies and does not injure the mushrooms.

MUSK Oxen Brought from Greenland to Restock Alaska's Tundra Lands

In the summer and fall of 1930 a project to restore the musk ox to Alaska, where formerly it lived in small numbers, resulted in the transportation from northeastern Greenland of a herd of 34 young animals. These were captured by a Norwegian collector, and after transshipment in Norway traveled on an ocean liner to New York. Following a 30-day quarantine period, the animals were taken by rail to Seattle, thence by ship to Seward, Alaska, and again by rail to the reindeer experiment station maintained by the Bureau of Biological Survey near Fairbanks. Here they are being held for feeding and breeding studies with a view to the eventual liberation of stock in suitable parts of the Territory to add another large animal to Alaska's wild-life resources.

When the liner tied up at a Brooklyn wharf about the middle of one of September's warmest days, these hardy animals must have wondered, in their silent, stolid way, what next adventure was in store for them. Taken from their associates, and in most cases from their mothers (for half the individuals were only about 4 months old), put into strong crates barely large enough to allow for turning around, shipped to the various pests by fumigation while the temperatures are at the peak.

MUSK Oxen Brought from Greenland to Restock Alaska's Tundra Lands

In the summer and fall of 1930 a project to restore the musk ox to Alaska, where formerly it lived in small numbers, resulted in the transportation from northeastern Greenland of a herd of 34 young animals. These were captured by a Norwegian collector, and after transshipment in Norway traveled on an ocean liner to New York. Following a 30-day quarantine period, the animals were taken by rail to Seattle, thence by ship to Seward, Alaska, and again by rail to the reindeer experiment station maintained by the Bureau of Biological Survey near Fairbanks. Here they are being held for feeding and breeding studies with a view to the eventual liberation of stock in suitable parts of the Territory to add another large animal to Alaska's wild-life resources.

When the liner tied up at a Brooklyn wharf about the middle of one of September's warmest days, these hardy animals must have wondered, in their silent, stolid way, what next adventure was in store for them. Taken from their associates, and in most cases from their mothers (for half the individuals were only about 4 months old), put into strong crates barely large enough to allow for turning around, shipped to

Norway, transshipped to the upper deck of this great ocean liner, and finally, after rolling for several days on the cool, breezy waters of the North Atlantic, slipped into this strange medley of metropolitan noises, queer sights, and unaccustomed odors, in a climate that to musk oxen must have seemed well-nigh intolerable—theirs was certainly an experience new in the history of the race. But whatever may have been their thoughts they gave no sign of surprise or alarm. Apparently unconcerned, they munched the wild hay brought along with them, and drank from a long-handled dipper as if they had never known any other life. Toward their keeper, who had tended them through the long voyage, they were gentle, but a stranger attempting to stroke their furry faces would draw back with celerity when greeted by a sharp coughing grunt and a stamping start. Though evidently unafraid they did not court familiarity.

Long Ancestry Shown in Fossils

What kind of creatures are these, thus snatched from the icy wastes of arctic Greenland and taken on this far journey through scenes so strange and by ways so devious? They are the most truly arctic of our large American mammals, and they have a long and interesting ancestry. The presence in North America of fossilized remains of animals that appear to be remotely ancestral to our modern musk ox, and the absence of any such types in Eurasia, where, however, musk oxen closely resembling our own species had a wide distribution in Pleistocene times, point to an origin in the New World. Several genera of extinct bovines, more or less distantly related though not directly ancestral to the musk ox of to-day, are represented by fossils that have been unearthed as far south as Ohio, Kentucky, Arkansas, and New Mexico, and remains more distinctly referable to our recent animal, in Pennsylvania, Iowa, Indiana, Kansas, and southern British Columbia. In the Old World, remains of musk oxen not widely different from our own North American species have been found in northern Siberia, European Russia, Germany, Austria, France, and England. Over all the Old World range, however, there seems to be no record of the animal's presence within historic times.

Living musk oxen were first discovered in North America by the fur traders of the Hudson's Bay Co., who, during the closing years of the seventeenth century, built several trading posts on the shores of Hudson Bay. None of these early posts were actually in musk-ox country. It was a long time, therefore, before any of the traders came into personal contact with the living animals, and much later when the first specimen reached Europe. This happened about the year 1772, through the efforts of Samuel Hearne, who was the first white man to observe musk oxen in numbers and to study them in their haunts. Not long after this the Hudson Bay species was given its first scientific name, *Bos moschatus*. The later generic name, Ovibos, translates the erroneous notion that the animal has characters intermediate those of sheep and cattle. Anatomical studies, however, show that the supposed affinities with the sheep are nonexistent, but that the musk ox, as its vernacular name indicates, has its closest affinities with wild and domestic cattle. At about the same time that the first American specimen reached Europe, fossil skeletons came to light from the River Ob, in northern Siberia, and these were later described as *Ovibos pallantis*, a name that is now generally applied to the animals that in Pleistocene times were widely distributed in Eurasia.

Greenland Animals a Separate Race

For more than a hundred years all the musk oxen of North America were supposed to belong to one form, but lately the species has been studied rather intensively by systematists, with the result that the animals from Greenland and the neighboring islands have been found to constitute a race separable from the mainland animal, being smaller, lighter in color, and having a white patch about the base of the horns. The animals now being taken to Alaska, therefore, probably differ slightly in characters from the former inhabitants of its barrens, which we must presume were essentially like those of the Mackenzie River and Hudson Bay regions. From the practical standpoint, however, the differences are so slight as to be negligible.

Musk oxen are considerably smaller than domestic cattle. Adult males commonly reach a weight of 700 pounds, and as a very old and large one that was weighed piecemeal by Seton aggregated 850 pounds; allowing for loss of blood, it might well have reached 900 pounds when alive. It was 8 feet long from the point of its muzzle to the end of its diminutive tail, and the height at shoulder was 59 inches. The cows are considerably smaller than the bulls.

The areas north of the limit of tree growth, where alone musk oxen are content, is a pleasant land in summer. By May most of the snow is gone, and the well-watered and rich-soiled tundra quickly bursts into life. Grasses and sedges spring up, the prostrate shrubs put forth their young leaves and bright blossoms, and the lowly life is aroused from its winter sleep. Myriads of birds come from the south, some even from far-off Argentina, to rear their young in this plenteous feeding ground. Amid these pleasant pastures the mother musk ox leads about her single young one, which usually is born on the last of the snow in April. By late summer the young are strong and active, though for another year or two they will be dependent upon the older ones for protection.

In the musk-ox country winter succeeds summer with a suddenness that leaves but little of autumn, and with its arrival the scene changes. Snow, though it is not excessively deep, usually comes in September, and covers the ground for the next seven months, and during this period blizzards are frequent. The migrant birds have raised their young, and all have left. The pleasant land of summer days is changed to a waste whose depths of desolation are incomprehensible to the inhabitants of temperate lands. Most of the caribou, the only other herbivore that shares with the musk ox its habitat, have migrated south to find better pastures. But the musk ox remains on its chosen ground, moving only from one valley to another as necessary, and saving its energy for defense against its enemies. The animals keep in small herds, and when beset by wolves gather in a circle, with their young either in the center or between the adults. (Fig. 122.) The enemy is thus confronted with an impenetrable wall of sharp horns and is forced to give up the attack.

Winter Food Supply

The winter food of musk oxen, which the animals can reach only by pawing away the snow with their broad hoofs, consists principally of dwarf willows, though other depauperate shrubs, saxifrage, and various herbaceous plants and grasses also are eaten. The summer food is similar, though naturally the animals' preference at that season seems to be for the fresh grasses.

Until musk oxen encountered man they prospered, though their native land was one of the bleakest regions of the earth. Against primitive tribes they long held their ground, or retreated only slowly. But before the weapons of modern man they have declined rapidly, and unless he stays his hand they must soon join the ranks of those wild creatures that have been destroyed forever through human greed and thoughtlessness. It is significant that the hunter is usually accompanied by dogs, and these easily hold the musk oxen at bay, perhaps being mistaken for wolves. But the tactics that have so well served these courageous creatures through the centuries fail them when the supposed wolves are backed by men with modern rifles. The confidence and courage that impel them to stand by their helpless young make them as easy to kill as cattle in a barnyard, and in consequence many a herd has been wiped out within a few minutes. Men have journeyed to the Arctic with no other purpose in mind than to obtain a few musk-ox heads under these conditions.

FIGURE 122.—Group of musk oxen on Devon Island, Northwest Territories, Canada, August, 1928

Ever since the use of improved firearms became widespread in the north, man's pursuit of the musk ox has been relentless. In its mainland range and on the Arctic islands eastward of the Mackenzie, its gradual diminution began about 1860. In the relatively small area that was inhabited by the animal in northern Alaska, it had almost certainly disappeared before that date, as there seems to be no authentic record of its observation there by Europeans, though some of the natives say that their grandfathers killed the animals. Up to about 1870 a few were still found not far east of the lower Mackenzie, but the activities of the fur trade in that section soon led to the extermination of these small herds.

Slaughter By Whalers

A little later, with the more intensive operations of whalers, large vessels wintered in the harbors about Franklin Bay and elsewhere, and most of the herds of musk oxen in the region tributary to these bases were soon destroyed. At about this same period, 1890–1900, a rather brisk trade in skins, carried on by the Mackenzie River traders, together with some pursuit by visiting sportsmen, resulted in the extirpation of the musk ox all about the southwestern and western borders of its range, and this persecution was supplemented by vigorous pursuit in all the region bordering northwestern Hudson Bay by the crews and native associates of the whalers of that section. To make this sad story of commercial exploitation a short one, it may be said that the only herds of musk oxen now known to be living on the mainland of North America are a few animals, estimated to aggregate not more than 250 head, that remain in the Thelon River region in the Northwest Territories of Canada, in an area that fortunately has lately been set aside as a game sanctuary.

And so we will leave our little herd of 34 hardy, courageous, arctic cattle, taken from their bleak habitat on the ice-bound plains of Greenland and transplanted to the scarcely less rigorous setting of northern Alaska. For a time their lot will be relatively easy. They will be given surroundings approximating as closely as practicable those of their native land, and still compatible with the requirements of the feeding and breeding studies to be pursued by the Biological Survey. It is the purpose to build up a herd that will allow the stocking of various parts of the treeless Arctic, to the end that the vast tundras lying north of the Arctic Circle may yield another resource in meat and leather to supplement those now available to persons who choose our northern territory as their permanent homes.

Edward A. Preble,
Senior Biologist, Bureau of Biological Survey.

NATIONAL-FOREST Range Management Assisted by Livestock Associations

Organized cooperation between the stockmen and the United States Forest Service in the Pacific Northwest region, which embraces the States of Oregon and Washington, is resulting in distinct benefits to both the stock and the range. On the 22 national forests included in this region approximately 110,000 head of cattle and horses owned by 1,500 individuals, are now grazed under permit. Most of these owners are active members of small neighborhood associations organized to include all owners who run stock on a particular range. In the Pacific Northwest region the Forest Service now recognizes 104 of these small associations and encourages and fosters them to the fullest extent possible. Once a year the local forest supervisor, or a member of his staff, meets with each association on his forest and at these meetings all matters relating to the use and management of the range are informally discussed. In this way a Federal bureau is brought into intimate contact with each individual with whom it does business, and an opportunity is afforded for direct interchange of ideas between Forest officers and the stockmen.

Among the accomplishments of lasting benefit to both the stock and the range, brought about through these associations, are:

A more economical control of the stock on the forest range through construction of drift and division fences.

Development of watering holes and seeps to furnish an ample supply of water for the grazing stock. (Fig. 123.)

most of the herds of musk oxen in the region tributary to these bases were soon destroyed. At about this same period, 1890–1900, a rather brisk trade in skins, carried on by the Mackenzie River traders, together with some pursuit by visiting sportsmen, resulted in the extirpation of the musk ox all about the southwestern and western borders of its range, and this persecution was supplemented by vigorous pursuit in all the region bordering northwestern Hudson Bay by the crews and native associates of the whalers of that section. Among the accomplishments of lasting benefit to both the stock and the range, brought about through these associations, are:

A more economical control of the stock on the forest range through construction of drift and division fences.

Development of watering holes and seeps to furnish an ample supply of water for the grazing stock. (Fig. 123.)

Salting and distributing cattle in accordance with systematic plans which at the same time produce fatter stock and protect the range from overgrazing.

Building up a better type of beef animal through breeding only to purebred bulls of some recognized beef breed.

Elimination of complaints through working out of all differences of opinion on the ground.

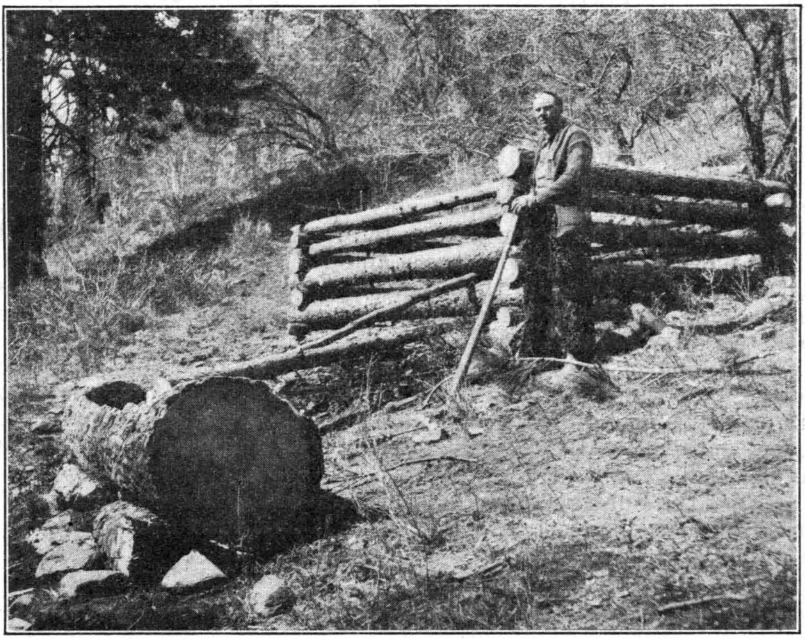

FIGURE 123.—Development of watering holes and seeps on national-forest range provides the stock with an ample supply of clean water

Furnishing a medium through which the stockman may voice his opinions and be heard on all matters of policy affecting the use of the range on which his cattle are permitted.

Development of a stronger social and community cohesion in the neighborhood represented.

W. L. DUTTON,
Regional Forest Inspector, Forest Service.

NATIONAL Forests Have Municipal Recreation Camps in California Fifteen recreation camps on the national forests in California are operated by municipalities to provide opportunities to their taxpayers for summer outings at cost. The plan was first put into effect by Los Angeles, followed by Oakland, Berkeley, San Francisco, Stockton, Sacramento, and Riverside, and by Los Angeles County. The demand for the use of these camps, which are located from 25 to 300 miles from the municipality that maintains them, has been so great as to call for the establishment of two camps by several of the cities; Los Angeles has four.

NATIONAL Forests Have Municipal Recreation Camps in California Fifteen recreation camps on the national forests in California are operated by municipalities to provide opportunities to their taxpayers for summer outings at cost. The plan was first put into effect by Los Angeles, followed by Oakland, Berkeley, San Francisco, Stockton, Sacramento, and Riverside, and by Los Angeles County. The demand for the use of these camps, which are located from 25 to 300 miles from the municipality that maintains them, has been so great as to call for the establishment of two camps by several of the cities; Los Angeles has four.

The 15 camps represent an investment of over $500,000. The land they occupy is furnished by the Forest Service free of rental charges. At some camps the guests participate in the maintenance of the camps and thus help to keep down the cost. It is possible for a person to get a 2-week outing for about $1.50 a day, excluding transportation. Guests are housed in attractive, well-ventilated cabins, or tent houses and are furnished with individual iron cots and mattresses. Every camp provides plenty of wholesome food. Stores and libraries are maintained, and interesting pack-train or hiking trips are conducted for the benefit of the guests. Nearly all camps have natural or developed swimming pools as well as athletic fields with an instructor in charge. Every camp is in charge of a trained camp director.

Guests at the camps come from all walks in life. Generally taxpayers of the municipality are the only persons eligible to make reservations. Some of the camps provide for family parties; some for organizations like Boy Scouts and Camp Fire Girls. Other camps provide for all classes of residents by designating certain periods for family parties and others for boys' and girls' organizations, so arranging the summer schedule that there is no conflict. Where there is a heavy demand for camp accommodations it is the policy to limit guests to a stay of two weeks.

Plain living in a fine natural environment is the fundamental objective, and though these camps provide all forms of diversion, the camp spirit finds best expression about the open fire, around which the guests gather nightly for song and story, impromptu stunts, and discussion.

All that the Forest Service asks of the guests of these camps is to be careful of fire in the woods and to see to it that the rules of camp sanitation and cleanliness are strictly observed.

L. A. Barrett,
Assistant Regional Forester, Forest Service.

NATIONAL Forests in California Increase Revenues of Counties Federal ownership of land and property means a loss of taxes to the community, as the Federal Government pays no taxes. Federal buildings, military reservations, Indian reservations, national parks, and national forests are forms of Government ownership. In most cases the benefits received are obvious and the area is comparatively small. But the national forests of California embrace about 19,000,000 acres and withdraw from private ownership and taxation nearly one-fifth of the land area of the State. Therefore the question arises as to their effect on the State and counties because of the withholding of potentially taxable lands in Government ownership with a consequent loss of revenue.

As long ago as 1906 Congress recognized that the withdrawal of public lands for national-forest purposes meant a reduction in future tax returns. Beginning that year the Forest Service was authorized to turn over to the State 10 per cent of all receipts derived from the sale and use of national-forest resources, for distribution to the counties in which national forests are located, the money to be used for road and school purposes. Two years later, in 1908, this return was increased to 25 per cent of the total receipts. In 1912, Congress

The 15 camps represent an investment of over $500,000. The land they occupy is furnished by the Forest Service free of rental charges. At some camps the guests participate in the maintenance of the camps and thus help to keep down the cost. It is possible for a person to get a 2-week outing for about $1.50 a day, excluding transportation. Guests are housed in attractive, well-ventilated cabins, or tent houses and are furnished with individual iron cots and mattresses. Every camp provides plenty of wholesome food. Stores and libraries are maintained, and interesting pack-train or hiking trips are conducted for the benefit of the guests. Nearly all camps have natural or developed swimming pools as well as athletic fields with an instructor in charge. Every camp is in charge of a trained camp director.

Guests at the camps come from all walks in life. Generally taxpayers of the municipality are the only persons eligible to make reservations. Some of the camps provide for family parties; some for organizations like Boy Scouts and Camp Fire Girls. Other camps provide for all classes of residents by designating certain periods for family parties and others for boys' and girls' organizations, so arranging the summer schedule that there is no conflict. Where there is a heavy demand for camp accommodations it is the policy to limit guests to a stay of two weeks.

Plain living in a fine natural environment is the fundamental objective, and though these camps provide all forms of diversion, the camp spirit finds best expression about the open fire, around which the guests gather nightly for song and story, impromptu stunts, and discussion.

All that the Forest Service asks of the guests of these camps is to be careful of fire in the woods and to see to it that the rules of camp sanitation and cleanliness are strictly observed.

L. A. Barrett,
Assistant Regional Forester, Forest Service.

NATIONAL Forests in California Increase Revenues of Counties Federal ownership of land and property means a loss of taxes to the community, as the Federal Government pays no taxes. Federal buildings, military reservations, Indian reservations, national parks, and national forests are forms of Government ownership. In most cases the benefits received are obvious and the area is comparatively small. But the national forests of California embrace about 19,000,000 acres and withdraw from private ownership and taxation nearly one-fifth of the land area of the State. Therefore the question arises as to their effect on the State and counties because of the withholding of potentially taxable lands in Government ownership with a consequent loss of revenue.

As long ago as 1906 Congress recognized that the withdrawal of public lands for national-forest purposes meant a reduction in future tax returns. Beginning that year the Forest Service was authorized to turn over to the State 10 per cent of all receipts derived from the sale and use of national-forest resources, for distribution to the counties in which national forests are located, the money to be used for road and school purposes. Two years later, in 1908, this return was increased to 25 per cent of the total receipts. In 1912, Congress authorized the Forest Service to spend an additional 10 per cent of all receipts on cooperation with the State and counties for minor road and trail construction within the national forests.

Contribute to Road Development

Following the acceleration of the national road-building program since 1916, Congress has passed several acts appropriating money for major roads that form part of the State, interstate, and county highway systems, both within and adjoining the national forests. This enabled the Forest Service to fulfill its obligation as a landowner by contributing its share toward the development of the country where national forests are located.

The Forest Service is therefore contributing directly to the counties by giving income in the form of payment of 25 per cent of all receipts and in giving assistance in the way of cooperation in road and trail construction, both from the 10 per cent fund for trails and minor roads and by special appropriation for State and county highways.

Indirect Contributions to Counties

In order to determine accurately the effect of national forests on county revenues, the Forest Service in 1927–28 made a special study covering all of the national forests of the United States. It was found that in addition to income and assistance to schools and roads the Forest Service was also making indirect contributions to the counties by developing free camp grounds and recreational resources, granting free timber for the use of settlers and prospectors for home use, making sales of timber at cost to farmers and settlers for farm improvements, issuing free grazing permits for work and milk stock owned by ranchers residing in the national forests, and by cooperating with the State authorities in enforcing fish and game laws and in planting fish fry in the streams and lakes—all this in addition to administering and protecting forest resources.

Data for this tax study covered a 5-year period and the figures given are the average for the years 1923 to 1927, inclusive. A recapitulation of the results of this study for the national forests within the State of California follows:

Direct returns and benefits	Annual average 1923–1927
25 per cent fund	$297, 554
Road and trail expenditures	1, 205, 564
Indirect contributions	12, 065
Total	1, 515, 183

This is equivalent to a tax of 8 cents per acre, per year, for all national-forest lands, including rocky and barren areas or other lands of no value for grazing or timber production and from which no revenue can be derived by the Forest Service, although considerable money must be spent each year for their protection and development. (Fig. 124.)

Forest Benefits Exceed Potential Taxes

The next step was to draw a comparison between this figure and what the counties would probably receive in tax revenue if the potentially taxable land were in private ownership. The tax study classified the 18,971,409 acres of Government land within the national forests of California by comparing them to similar land in private ownership and it was found that only 4,179,148 acres were in the taxable category. The remaining 14,792,261 acres consist of inaccessible timber stands, nonmerchantable stands of young growth and inferior timber, brush lands and considerable areas of barren lava or granite along the summits of the mountain ranges. The potentially taxable timber and grazing lands were then assessed exactly at the tax rates and by the same system in effect in the county in which they were located. The results follow:

Probable annual tax returns on 4,179,148 acres of national-forest land if in private ownership, based on the assessment rates applying to similar private land in county concerned, $1,168,770.

Difference between $1,515,183, which represents the income, assistance, and benefits received from the Forest Service, and $1,168,770, or the amount the counties would receive in taxes, $346,413.

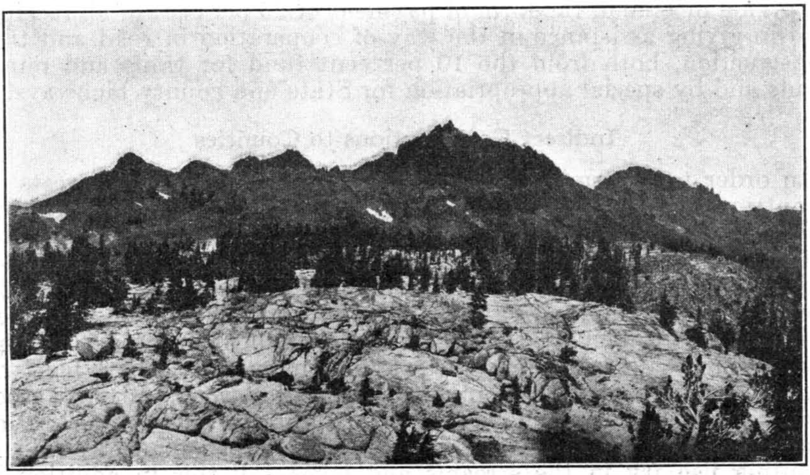

FIGURE 124.—There are a million and a half acres of land in the national forests of California of no value for grazing or timber that are now helping to contribute 8 cents per acre annually to the State and counties

The actual situation is, therefore, that the national forests, under the administration of the Forest Service, are not only paying their full share of taxes, but are actually contributing $346,413 more to the State and counties than would be received if the same lands were taxable under private ownership. These figures are for present conditions. Conservative estimates, made on the basis of present stumpage prices, grazing fees, and rentals of Government land show that the annual returns from the national forests to the State and counties will, when the national forests are fully developed, be double the present return.

R. W. AYRES,
Logging Engineer, Forest Service.

NATIONAL Forests Policy Is to Perpetuate While Using Their Resources The 151 national forests of the United States are administered by the Forest Service of the United States Department of Agriculture under a policy which provides that all national-forest land is to be devoted to its most productive use for the permanent good of the whole people.

and it was found that only 4,179,148 acres were in the taxable category. Logging Engineer, Forest Service.

NATIONAL Forests Policy Is to Perpetuate While Using Their Resources The 151 national forests of the United States are administered by the Forest Service of the United States Department of Agriculture under a policy which provides that all national-forest land is to be devoted to its most productive use for the permanent good of the whole people.

Conservation through the protection and wise use of the forest resources of water, wood, forage, recreation, and wild life not only is of great importance to the Nation as a whole, but it is particularly vital to the communities adjacent to the national forests whose welfare is directly dependent upon these resources. To illustrate this, a brief description is given of one of the western national forests and the manner in which it functions. (Fig. 125.)

This national forest has a net area of 1, 354,986 acres of timbered mountainous territory adjacent to a region in which farming, livestock production, lumbering, and mining are the principal industries. On the arable land outside the forest, water for irrigation, which is an absolute necessity for the production of agricultural crops, is obtained from streams originating within the forest. The forest cover aids in regulating stream flow. The forage crops from irrigated fields are used locally in the winter feeding of sheep and cattle, and the national

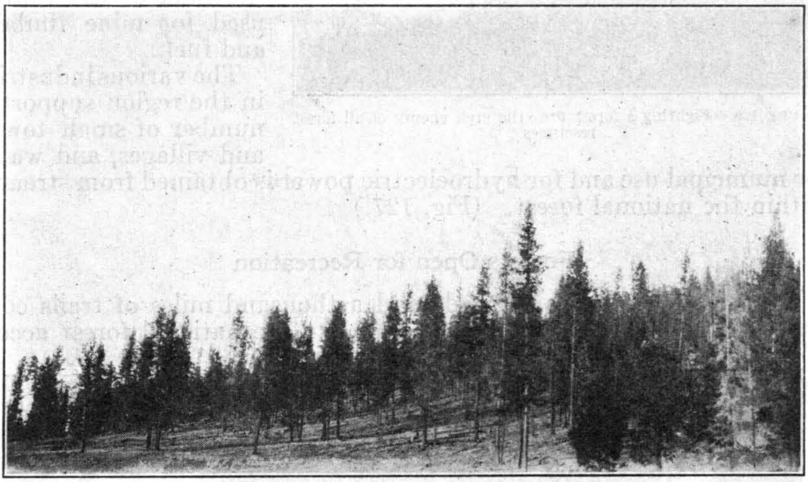

FIGURE 125.—The mature and overmature trees on this area have been cut and sold; a second crop is already growing

forest furnishes summer grazing for most of this stock, 15,000 cattle and 127,000 sheep. The owners of the stock pay the Government moderate annual fees for grazing permits.

The ranchers secure wood for their own use from the national forest—dead material free of charge and live trees at a rate which merely compensates the Government for the cost of handling the sale.

Timber Handled as Crop

A dozen small sawmills in and adjacent to the national forest furnish lumber for local use, and three large mills cut lumber for distant markets. Between 20 and 30 per cent of the lumber is cut from national-forest land, and the purchaser pays the full commercial value for this timber except for material used on the local ranches. (Fig. 126.)

In the near future the supply of privately owned timber will be greatly depleted and the lumber industry, which provides 30 per cent of the local pay roll, will become more and more dependent upon the national forest for its existence. As the need for Government timber increases, the annual cut from the national forest can be increased until a sustained annual cut of approximately 50,000,000 board feet is reached. It is estimated that under sound forest management this amount of timber can be cut each year perpetually. On the national forest, only mature or decadent trees are cut, and unnecessary damage to young trees and seedlings is prohibited so that a new crop of trees will replace the timber cut.

FIGURE 126.—Fighting a forest fire—the arch enemy of all forest resources

The national forest is open for prospecting and mineral development, and it furnishes the bulk of the timber used for mine timbers and fuel.

The various industries in the region support a number of small towns and villages, and water for municipal use and for hydroelectric power is obtained from streams within the national forest. (Fig. 127.)

Forests Open for Recreation

Three hundred miles of roads and a thousand miles of trails constructed by the Forest Service help make the national forest acces-

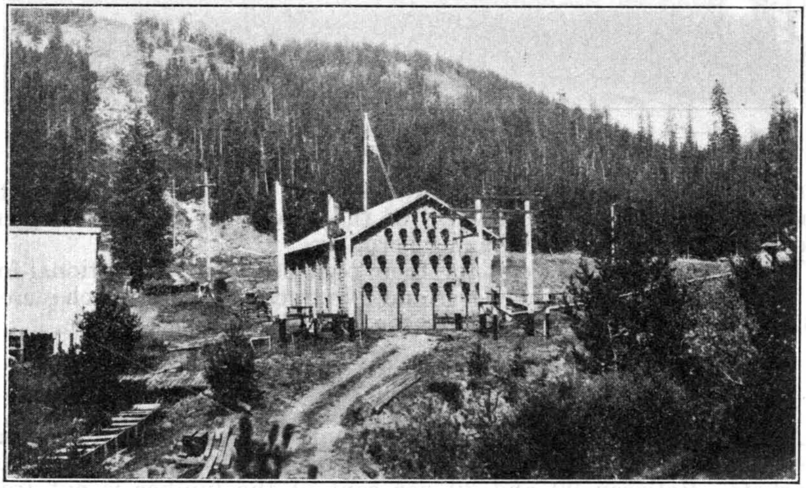

FIGURE 127.—A hydroelectric power plant on a national forest

sible to those who seek outdoor recreation. The scenic beauty of the mountains, well-stocked streams and lakes, and good hunting attracted 17,000 visitors to this forest in 1929. The more popular camping places have been improved for the free use of the public. For those who wish to rough it, over 200,000 acres have been set aside as a "primitive area" which will be kept in its original wilderness condition.

Aside from a very few very reasonable and necessary requirements as to care with fire, the public have free and unrestricted use of the national forests for recreational purposes. A charge is made only where exclusive use of a tract of land is granted.

Although service rather than revenue is the objective of national-forest administration, this forest has turned into the United States Treasury an average income of over $100,000 annually during the past decade, of which 25 per cent has been paid to the counties in which the forest is located for roads and schools.

In order to handle all business efficiently and facilitate the work of preventing and suppressing forest fires, the arch-enemy of all forest resources, it has been necessary for the local forest organization to construct and maintain roads, trails, bridges, lookout houses, cabins, horse pastures, drift fences, stock-watering places, and also simple fire-prevention and sanitation improvements on recreation areas.

The yearlong forest organization consists of a supervisor, assistant supervisor, eight district rangers, and a small staff of clerical and technical assistants and specialists. These forest officers live in and are a part of the communities adjacent to the national forest and are familiar with the interests and problems of the forest users. During the summer months a temporary force of 60 fire guards and laborers in construction crews also is employed.

Local officers are responsible for comprehensive plans for the administration of each resource and for the efficient utilization of each forest officer's time, and to the fullest extent possible all national-forest business is handled by the local organization.

The national forests are located in many parts of the United States and present such a wide diversity of conditions that the volume and character of business entailed in handling the different resources varies greatly. All national forests, however, are administered with the same objective in view, that is, to perpetuate the forest resources through wise use.

JOHN C. KUHNS,
Supervisor, Forest Service.

NITRATE Bacteria, Main Source of Soil Nitrates, Depend on Farm Practice

This is the story of the nitrate. The farmer already has met it for it comes in the bag of fertilizer and costs more to the pound than any other kind. But it is necessary since the crop plants must have nitrates in abundance, especially when they begin to grow in the spring and again when they produce their fruits or seed. What we spread out of the bag is ordinarily only a negligible contribution, a kind of appetizer. Our chief source of nitrates is the activity of the nitrate bacteria in the soil itself. Whether he knows it or not, therefore, the farmer is quite dependent upon these nitrate bacteria; success or failure in crop production is involved in supplying these organisms with favorable conditions for their activity.

To adjust his practice then so as to make the most of nitrate production in the soil he must first consider the conditions under which it occurs. To begin with, there is the factor of temperature. Nitrate bacteria, just as our crop plants, are inactive in the winter; they begin aside as a "primitive area" which will be kept in its original wilderness condition.

Aside from a very few very reasonable and necessary requirements as to care with fire, the public have free and unrestricted use of the national forests for recreational purposes. A charge is made only where exclusive use of a tract of land is granted.

Although service rather than revenue is the objective of national-forest administration, this forest has turned into the United States Treasury an average income of over $100,000 annually during the past decade, of which 25 per cent has been paid to the counties in which the forest is located for roads and schools.

Supervisor, Forest Service.

NITRATE Bacteria, Main Source of Soil Nitrates, Depend on Farm Practice

This is the story of the nitrate. The farmer already has met it for it comes in the bag of fertilizer and costs more to the pound than any other kind. But it is necessary since the crop plants must have nitrates in abundance, especially when they begin to grow in the spring and again when they produce their fruits or seed. What we spread out of the bag is ordinarily only a negligible contribution, a kind of appetizer. Our chief source of nitrates is the activity of the nitrate bacteria in the soil itself. Whether he knows it or not, therefore, the farmer is quite dependent upon these nitrate bacteria; success or failure in crop production is involved in supplying these organisms with favorable conditions for their activity.

To adjust his practice then so as to make the most of nitrate production in the soil he must first consider the conditions under which it occurs. To begin with, there is the factor of temperature. Nitrate bacteria, just as our crop plants, are inactive in the winter; they begin to grow about the time our crops do, and reach a peak of activity about the time our grains and vegetables are growing most rapidly, enlarging their root systems and bearing their fruit, and hence most dependent upon constant supplies of nitrates. They slow down again in the fall, and finally reach the inactive condition characteristic of winter. But temperature is not alone in controlling nitrate formation; moisture is essential. In sections where moisture is abundant in spring and fall, and dryness prevails in midsummer, nitrate production reaches a peak in the spring, falls to a low point in summer, and rises again during the moist period of the fall. In other sections, where rainy weather prevails in midsummer, and drier periods in spring and fall, maximum nitrate production seems to follow the rainfall by being highest in midsummer. Again, these bacteria seem to work best in the presence of air. Plowing and harrowing aerate the soil and favor nitrate production. Good cultivation is then favorable to this process.

Nitrates are produced from nitrites which are derived from ammonia. They are end products of the decay of organic matter. Farm manure, vegetable stuffs like cornstalks, straw, stubble, roots, weeds, and brush, and waste animal substances are not used by crop plants directly but must go through the rotting process in which they are attacked by a hungry horde, consisting of such organisms as bugs, worms, bacteria, yeasts, molds, etc. All contribute to reduce waste matter to earthy forms. Only toward the end of this reducing process do we find ammonia, later nitrites, then finally the nitrates for which the competition is so keen that those plants unable to obtain their share are often starved out.

Rate of Nitrate Production

The organic matter used up in this process may be that stored in the soil and thus destroyed for current crop production, or material added from year to year and from crop to crop. In land already rich in organic matter, the rate of nitrate formation is often great enough to show an excess throughout the growing season. In land low in organic matter, crop plants remove nitrates often so rapidly that no excess can be found during the actively growing season. The crop residues, such as dead root systems, stubble, cornstalks and weeds, all contribute their part. Many of these substances themselves contain so little nitrogen that they scarcely supply the bacteria necessary to rot them, leaving no nitrogen over for the crop plants during the period of active rotting. Their contribution to the nitrate supply is often very tardily delivered. Aside from resorting to the fertilizer bag, other sources and intermediate products are to be sought.

Since ammonia formation in the soil precedes nitrate formation, sources of ammonia in the soil become important. The easiest way to get it is to add ammonium salts directly to the soil, care being taken that the residue after the removal of the ammonia does not create an acid condition of the soil. This method is used frequently where quick results are wanted. Rotted barnyard manure formerly was the chief source of ammonia and is still preferred where it is easily obtainable. This has an advantage over the ammonium salt in supplying organic matter to the soil which besides serving as food for bacteria and other forms of microscopic life improves the physical condition of the soil and spreads its effects over a longer period.

Plowing under green manures, especially legumes, provides a source of ammonia as the material rots. Obviously some time is necessary for such rotting to take place. Bacteria in the presence of food require moisture and a warm or at least a mild temperature for activity. The physical condition of the soil when plowing under a green manure, therefore, will greatly affect the process of rotting. Green manure or other organic matter plowed into dry soil will decay much more slowly than if the soil is moist, due to the slower activity of the microorganisms under these conditions. The same holds true as to temperature, cool weather being less favorable to the process than warm weather. Under greenhouse conditions of optimum moisture and temperature green manures have been found to decay in seven days to such an extent that only faint traces of them could be found. In two weeks, the nitrates were increasing rapidly. A crop planted 10 days after green manuring made good growth. Such conditions are not generally found in the field. Under field conditions green manure plowed under in cool and very dry weather disappeared so slowly that the more resistant stems of the rye and vetch could be taken from the soil two months after plowing. Under these conditions ammonia was formed slowly from the decaying mass and consequently nitrates were low and rose slowly. Planting a crop under such conditions places a handicap on it. Undoubtedly this may be one of the reasons for certain crop failures after green manuring. Practices must be adjusted to climate, soil, and often to the particular crop grown.

Nitrate Formation Begins in Spring

Nitrate formation begins in the spring about the time our young crop plants begin to need nitrates. The demand differs with the kind of crop and with climatic conditions. Naturally, nitrates are taken up by the crop plants most rapidly during the most actively growing period. At such times, they are often absorbed as rapidly as they are formed. A test for nitrates if made at this stage may show none remaining in the soil. But as the crop matures and the call for nitrates is less there may be an accumulation of nitrates in the soil. Fall rains leach out such soluble nitrates, and by winter none are found under usual conditions. Saving these nitrates and holding the soil against washing seem to be major problems confronting the farmer. This is especially true in sections where the season is long and where conditions are favorable for the formation of nitrates for some time after the removal of the crop.

Planting a cover crop under these conditions has long been recommended. The choice of the crop to be used will vary with the soil and the locality. A legume is to be preferred. By the aid of bacteria growing in the nodules on their roots, these plants are able to use the nitrogen of the air, thus adding to the store of soil nitrogen if they are plowed in. On the other hand, if a nonlegume such as rye is grown and turned under nothing is added to the soil which was not there before the rye was grown. However, any cover crop is preferable to leaving the ground bare. It will absorb the nitrates produced in the fall, keep soil from washing, and maintains a better physical condition.

The nitrate bacteria are, therefore, an important factor in crop production. Fortunately, their association with crop plants is so close that conditions which favor one usually favor the other during the growing season. But the bacteria remain in the soil whether it is covered by a crop or not. Losses of nitrogen occur when nitrates are formed without crop plants to use them. Crop failures sometimes occur when crops are planted without remembering their dependence upon nitrate formation. Difficult as these adjustments may sometimes be, it is often easier to alter the farm practice than to change the habits of the nitrate organisms.

NITROGEN Fixation by Legumes Essentially a Cooperative Process

A large number of species of common agricultural plants, known as legumes, possess the ability of growing independent of the supply of nitrogen in the soil, provided the proper bacteria are present. Their ability to use the free nitrogen of the air has been known for a long time; hence the common practice of inoculating the seeds of alfalfa, clover, soybeans, and other legumes at the time of planting if the bacteria are not already known to be present.

How do these inoculated plants obtain their nitrogen? This question has been under consideration by this department for a number of years but the complete answer has not yet been obtained. We know that the leguminous plants when grown free of the bacteria are unable to use gaseous nitrogen. Under such conditions they make a stunted growth on the nitrogen stored up in the seed and die prematurely unless available nitrogenous compounds are supplied. The nodule-producing bacteria are, therefore, essential for the nitrogen fixation to take place.

Extensive studies of the relation of the nodule bacteria to free nitrogen, recently completed in the Bureau of Chemistry and Soils, gave no indication that the bacteria growing apart from the legume plants could ever use free nitrogen. On artificial culture media the organisms made little or no growth in the absence of combined nitrogen. Where nitrates, ammonium salts, and various types of organic nitrogenous compounds were supplied the growths obtained were excellent in most cases, but no increase in the nitrogen content of the media occurred. Various attempts to duplicate conditions in the nodule in an artificial way also gave negative results.

Cooperative Principle Demonstrated

These findings show beyond a reasonable degree of doubt that nitrogen fixation by legumes is a strictly cooperative process between the higher plants and the bacteria which live in the nodules on the roots. Until recently it has usually been assumed that the bacteria were the agents responsible for the nitrogen fixation and that the higher plant played a secondary rôle. According to this theory the bacteria obtain their energy for growth and fixation in the form of sugars which the legume furnishes. The legume, in turn, constantly removes the products of the bacteria, including the nitrogenous compounds being formed. Our present information indicates that this theory is essentially correct with the exception of the assumption that the bacteria growing season. But the bacteria remain in the soil whether it is covered by a crop or not. Losses of nitrogen occur when nitrates are formed without crop plants to use them. Crop failures sometimes occur when crops are planted without remembering their dependence upon nitrate formation. Difficult as these adjustments may sometimes be, it is often easier to alter the farm practice than to change the habits of the nitrate organisms.

NITROGEN Fixation by Legumes Essentially a Cooperative Process

A large number of species of common agricultural plants, known as legumes, possess the ability of growing independent of the supply of nitrogen in the soil, provided the proper bacteria are present. Their ability to use the free nitrogen of the air has been known for a long time; hence the common practice of inoculating the seeds of alfalfa, clover, soybeans, and other legumes at the time of planting if the bacteria are not already known to be present.

How do these inoculated plants obtain their nitrogen? This question has been under consideration by this department for a number of years but the complete answer has not yet been obtained. We know that the leguminous plants when grown free of the bacteria are unable to use gaseous nitrogen. Under such conditions they make a stunted growth on the nitrogen stored up in the seed and die prematurely unless available nitrogenous compounds are supplied. The nodule-producing bacteria are, therefore, essential for the nitrogen fixation to take place.

Extensive studies of the relation of the nodule bacteria to free nitrogen, recently completed in the Bureau of Chemistry and Soils, gave no indication that the bacteria growing apart from the legume plants could ever use free nitrogen. On artificial culture media the organisms made little or no growth in the absence of combined nitrogen. Where nitrates, ammonium salts, and various types of organic nitrogenous compounds were supplied the growths obtained were excellent in most cases, but no increase in the nitrogen content of the media occurred. Various attempts to duplicate conditions in the nodule in an artificial way also gave negative results.

Cooperative Principle Demonstrated

These findings show beyond a reasonable degree of doubt that nitrogen fixation by legumes is a strictly cooperative process between the higher plants and the bacteria which live in the nodules on the roots. Until recently it has usually been assumed that the bacteria were the agents responsible for the nitrogen fixation and that the higher plant played a secondary rôle. According to this theory the bacteria obtain their energy for growth and fixation in the form of sugars which the legume furnishes. The legume, in turn, constantly removes the products of the bacteria, including the nitrogenous compounds being formed. Our present information indicates that this theory is essentially correct with the exception of the assumption that the bacteria fix the nitrogen. It is possible, of course, that the bacteria do fix nitrogen in the nodule even though they do not do so on the outside, but it is difficult to obtain direct evidence on this point.

A study of nodule growth in relation to plant growth further emphasizes the interdependence of the bacteria and the higher plant. Unusually favorable conditions for the growth of the legume are usually followed by a corresponding increase in the mass of nodules formed and apparently greater activity on the part of the bacteria. Conversely, if there is a marked slowing down in the growth rate of the host plant because of unfavorable conditions or approaching maturity the nodules may show evidence of decomposition.

The effect of leguminous crops on other crops which follow in the rotation is almost always beneficial. This fact is well known and is one of the many reasons for including legumes in the rotation. Investigations have shown that a marked residual effect may occur even though the legume crop is harvested and the tops removed. Among the many reasons advanced for this effect is the fact that the growing of the crop leaves the soil heavily inoculated with the nodule bacteria, which are supposed to fix nitrogen in the soil independently of the host.

Organic Matter Added to Soil

The recent investigations in this bureau fail to substantiate this idea. More likely the residual effect of the leguminous crop is due more to the addition of organic matter in the heavy root growths and in some cases to the deepening of the soil by penetration of these roots to lower depths. There are also many reasons for believing that the soils are in many instances left with more nitrogen than before cropping even though the tops are removed. This is especially true on soils very deficient in available nitrogen, but even on rich soils legumes fix considerable quantities of nitrogen. These plants seem to possess the ability of using free nitrogen gas nearly as readily as nitrogenous compounds, provided conditions are favorable for vigorous plant growth.

Even though the recent investigations have failed to show that the legume nodule bacteria, living apart from the host plant, can fix nitrogen this does not detract in the least from their great economic importance. The results, on the contrary, emphasize the necessity for inoculating legume seed at the time of planting unless the soil is known to contain the proper bacteria.

Senior Chemist, Bureau of Chemistry and Soils.

NURSERY Stock Rid of Japanese Beetles by Hot-Water Treatment

The immersion of the roots of certain dormant or semidormant nursery plants in hot water has been found to be a simple, quick, and effective method for destroying infestations of the Japanese beetle in the soil about the roots of these plants. In preparing the plants for treatment, loose soil is removed, the roots are pruned, and the large clumps are divided as much as possible without causing injury to the plants. Small plants, bulbs, and root stocks may be treated in mass in wire baskets but the large plants should be handled individually.

The roots are immersed completely in water held at a constant temperature of 112° F. After the soil about the roots of the plants is heated fix the nitrogen. It is possible, of course, that the bacteria do fix nitrogen in the nodule even though they do not do so on the outside, but it is difficult to obtain direct evidence on this point.

A study of nodule growth in relation to plant growth further emphasizes the interdependence of the bacteria and the higher plant. Unusually favorable conditions for the growth of the legume are usually followed by a corresponding increase in the mass of nodules formed and apparently greater activity on the part of the bacteria. Conversely, if there is a marked slowing down in the growth rate of the host plant because of unfavorable conditions or approaching maturity the nodules may show evidence of decomposition.

The effect of leguminous crops on other crops which follow in the rotation is almost always beneficial. This fact is well known and is one of the many reasons for including legumes in the rotation. Investigations have shown that a marked residual effect may occur even though the legume crop is harvested and the tops removed. Among the many reasons advanced for this effect is the fact that the growing of the crop leaves the soil heavily inoculated with the nodule bacteria, which are supposed to fix nitrogen in the soil independently of the host.

Organic Matter Added to Soil

The recent investigations in this bureau fail to substantiate this idea. More likely the residual effect of the leguminous crop is due more to the addition of organic matter in the heavy root growths and in some cases to the deepening of the soil by penetration of these roots to lower depths. There are also many reasons for believing that the soils are in many instances left with more nitrogen than before cropping even though the tops are removed. This is especially true on soils very deficient in available nitrogen, but even on rich soils legumes fix considerable quantities of nitrogen. These plants seem to possess the ability of using free nitrogen gas nearly as readily as nitrogenous compounds, provided conditions are favorable for vigorous plant growth.

Even though the recent investigations have failed to show that the legume nodule bacteria, living apart from the host plant, can fix nitrogen this does not detract in the least from their great economic importance. The results, on the contrary, emphasize the necessity for inoculating legume seed at the time of planting unless the soil is known to contain the proper bacteria.

NURSERY Stock Rid of Japanese Beetles by Hot-Water Treatment The immersion of the roots of certain dormant or semidormant nursery plants in hot water has been found to be a simple, quick, and effective method for destroying infestations of the Japanese beetle in the soil about the roots of these plants. In preparing the plants for treatment, loose soil is removed, the roots are pruned, and the large clumps are divided as much as possible without causing injury to the plants. Small plants, bulbs, and root stocks may be treated in mass in wire baskets but the large plants should be handled individually.

The roots are immersed completely in water held at a constant temperature of 112° F. After the soil about the roots of the plants is heated throughout to the temperature of the bath, the plants are kept in the water for an additional period of 70 minutes. The water must be maintained at a temperature of 112° for the entire period of treatment. If the temperature falls below 111.5° the insect may not be destroyed; if it rises above 112.5° the plants may be injured. The insecticidal action is practically complete when the plants are removed from the hot water. The plants should be cooled slowly to room temperature and, in some cases, dried before being packed for storage or shipment.

The treatment has been applied successfully to the roots of many dormant or semidormant plants in the commercial nurseries. Among these plants were *Allium* sp., *Amsonia* sp., *Astilbe* sp., *Baptisia* sp., *Clematis* sp., *Convallaria* sp., *Coreopsis* spp., *Dahlia* spp., *Forsythia* sp., *Franklinia* sp., *Hemerocallis* spp., *Humulus* sp., *Iris* spp., *Liatris* sp., *Limonium* sp., *Lychnis* spp., *Lythrum* sp., *Paeonia* spp., *Phlox* spp., *Polygonum* sp., *Spiraea* spp., *Symphoricarpos* sp., *Syringa* sp., *Vaccinium* sp., and *Weigela* sp. The treatment killed or seriously retarded the subsequent growth of some plants among which were *Azalea* spp., *Canna* sp., *Chrysanthemum* spp., *Cibotium* sp., *Hydrangea* spp., *Lonicera* spp., *Picea* sp., and *Thuja* sp. Many of the species of plants which were severely injured under commercial conditions have been treated successfully experimentally. Consequently, it is probable that many of these doubtful varieties could be treated commercially if the methods of handling the stock after treatment were changed in the commercial nurseries.

OATS of Hardier Strains Needed for Fall Sowing in the Southern States

Fall-sown oats are grown in two widely separated sections of the United States—in the Southern States and in the Pacific Coast States. Although of considerable economic importance in both areas, the crop is more important in the South.

The growing of oats from fall seeding in the South is attended always with uncertainty owing to probable losses from winterkilling. In abnormally cold seasons there may be an almost complete loss of the crop from winterkilling. There is usually a reduction in the acreage of fall-sown oats following years of severe losses from winterkilling, and this acreage is partly replaced by spring oats. Spring-sown oats, however, usually are decidedly less productive, and the ratio between the acreages of spring-sown and fall-sown oats soon is restored. The wide annual fluctuation in the acreages of fall-sown oats in the South emphasizes the need for hardier varieties. The methods of meeting this need are by breeding and by exploration for new varieties.

The 16 Southern States, including Delaware, Maryland, West Virginia, Kentucky, Arkansas, Oklahoma, and those southward, grow approximately 5,000,000 acres of oats annually. Available information indicates that approximately half the total annual oat acreage in this region is fall-sown, and that in the area including the Carolinas, Georgia, Florida, Alabama, Mississippi, and Louisiana, fall-sown oats occupy a proportion varying from 50 to 75 per cent of the total oat acreage. The estimated fall-sown acreage for Texas varies from about 30 to over 50 per cent. In the more northern States of the southern group the spring-sown area always exceeds the fall-sown acreage.

OATS of Hardier Strains Needed for Fall Sowing in the Southern States

Fall-sown oats are grown in two widely separated sections of the United States—in the Southern States and in the Pacific Coast States. Although of considerable economic importance in both areas, the crop is more important in the South.

The growing of oats from fall seeding in the South is attended always with uncertainty owing to probable losses from winterkilling. In abnormally cold seasons there may be an almost complete loss of the crop from winterkilling. There is usually a reduction in the acreage of fall-sown oats following years of severe losses from winterkilling, and this acreage is partly replaced by spring oats. Spring-sown oats, however, usually are decidedly less productive, and the ratio between the acreages of spring-sown and fall-sown oats soon is restored. The wide annual fluctuation in the acreages of fall-sown oats in the South emphasizes the need for hardier varieties. The methods of meeting this need are by breeding and by exploration for new varieties.

The 16 Southern States, including Delaware, Maryland, West Virginia, Kentucky, Arkansas, Oklahoma, and those southward, grow approximately 5,000,000 acres of oats annually. Available information indicates that approximately half the total annual oat acreage in this region is fall-sown, and that in the area including the Carolinas, Georgia, Florida, Alabama, Mississippi, and Louisiana, fall-sown oats occupy a proportion varying from 50 to 75 per cent of the total oat acreage. The estimated fall-sown acreage for Texas varies from about 30 to over 50 per cent. In the more northern States of the southern group the spring-sown area always exceeds the fall-sown acreage.

Advantages of Fall Seeding

Where oats survive the winter, higher acre yields usually result from fall than from spring seeding. Results of varietal experiments in the South indicate that higher average yields usually are obtained from fall-sown than from spring-sown oats, even when no allowance is made for those years in which yields are reduced by winterkilling. Winter oats mature earlier and more uniformly, which often contributes to increased yield and quality. They are removed from the land earlier, permitting earlier seeding of the succeeding crop. Fall-sown oats make an excellent winter cover crop, and are useful for winter pasturage. They are especially satisfactory as pasturage for dairy cows. Fall-sown oats also contribute to a better distribution of farm labor. In some sections of the South cotton picking may interfere with seeding operations, but fall seeding allows more time and labor for other farm operations in the spring.

Fall-sown oats are less winter hardy than winter wheat or rye, and even in the South loss from winter injury is relatively frequent. In years when the oat production in the South is highest, winterkilling usually is not serious. Statistics on abandonment of fall-sown oats because of winterkilling are meager, but estimates on acreages of fall-sown oats harvested in nine States for the nine years from 1922 to 1930, inclusive, show that in three of these years (1925, 1928, and 1930) harvested acreages of fall-sown oats were below average, owing to winterkilling. This 9-year period is fairly typical, indicating clearly the relative uncertainty of the crop and the need for hardier varieties than are now grown.

New Varieties Needed

Two distinct types of cold-resistant oats are needed. The southern part of the winter-oat area, which is the most important, conforms closely to the Cotton Belt proper. Strains of the Red Rustproof and Fulghum varieties are now grown almost exclusively in this section. They are the only sorts at all adapted to it, being early maturing and somewhat resistant to heat during the flowering and ripening stages. On the other hand, they lack resistance to severe cold. Winter forms of Fulghum, considerably hardier than the parent variety, have been selected, but their susceptibility to crown rust limits their value. Resistance to crown rust should be combined with the cold resistance of these selections by breeding, and this is now under way.

Common varieties of true winter oats such as Winter Turf are best adapted to the northern part of the southern oat area in Virginia, Tennessee, and Arkansas. The discovery or development of earlier-maturing varieties still more winter-hardy than Winter Turf would make the crop much more certain throughout this region and also would make possible the advancement of the fall-sown oat area northward.

For a number of years the United States Department of Agriculture has conducted experiments to develop improved oat varieties for fall seeding. Several hundred strains have been introduced from foreign countries and tested under fall-sown conditions. So far, none has proved significantly superior to varieties previously grown. Thousands of selections have been made from the leading fall-sown varieties. As yet none of these has shown exceptional value, although several are somewhat better than parent varieties in yield and quality. More recently, numerous crosses between the more winter-resistant sorts have been made, and while tests have not been continued long enough to be entirely conclusive, the results are promising.

Two Promising New Varieties

The Lee and the Custis are two promising new varieties produced by crossbreeding. In these varieties the cold resistance of Winter Turf has been combined with the earliness and excellent kernel characters of Aurora. The new combinations seem particularly adapted to the northern part of the winter-oat area, and, so far as tested, are most promising. Further improvement should be possible through continued hybridization and selection.

Since a degree of winter hardiness not now available is highly desirable, a search for more hardy material from foreign sources must be continued. If found, such varieties, even though not adapted to the region in question, or though lacking agronomic value, can be used in breeding operations through combinations with adapted sorts.

The development of hardier winter-oat varieties can be accomplished only through careful, patient effort. It may not be possible to extend winter-oat culture northward to any extent with present material, but it should be possible to effect decided improvements for the southern part of the area. A winter oat 20 per cent more resistant to cold than any now available and resistant to crown rust and other diseases would go far toward increasing the certainty of oats in the Cotton Belt. This seems possible with material now available, although it must be recognized as a difficult and exacting undertaking requiring time and labor.

ORANGES Impaired in Vitamin C Content by Arsenical Spray

The theory that the chemical composition of a growing plant can not be modified to a marked extent by environment because the character of a plant is determined primarily by heredity is being broken down as new facts are accumulated. An insufficient quantity of water or of any of the necessary elements in the soil will result in retardation of growth rate. There is a fairly constant ratio between the mineral elements in any one of our cereal grains, and it differs from that in the other grains. Also a fairly constant ratio exists between protein, starch, and fat or oil in any of these species.

There are many exceptions to the rule that the influence of environment is negligible. A well known example is the difference in chemical composition between wheat grown in the north-central part of the United States and that grown in the southeastern part. The hard wheat of the Dakotas is uniformly higher in protein than the soft wheat of southern Indiana. A more striking example of the rôle of external influences in modifying the composition of plant tissue has been brought about inadvertently in an attempt to control insect pests. An arsenical spray, containing a small amount of molasses as a bait, was found to be very effective in combating insect infestations. There is nothing in the development or appearance of the fruit from orange trees treated with this spray which would lead one to believe that they have been made, and while tests have not been continued long enough to be entirely conclusive, the results are promising.

Also a fairly constant ratio exists between protein, starch, and fat or oil in any of these species.

There are many exceptions to the rule that the influence of environment is negligible. A well known example is the difference in chemical composition between wheat grown in the north-central part of the United States and that grown in the southeastern part. The hard wheat of the Dakotas is uniformly higher in protein than the soft wheat of southern Indiana. A more striking example of the rôle of external influences in modifying the composition of plant tissue has been brought about inadvertently in an attempt to control insect pests. An arsenical spray, containing a small amount of molasses as a bait, was found to be very effective in combating insect infestations. There is nothing in the development or appearance of the fruit from orange trees treated with this spray which would lead one to believe that they are abnormal. However, the juice from these oranges is unusually sweet, and the refreshing acid flavor is noticeably absent.

The Protein and Nutrition Division and Food Research Division of the Bureau of Chemistry and Soils cooperated with the Bureau of Plant Industry in a study to determine the nature of the modification in chemical composition and possible change in nutritive value of oranges from trees sprayed with lead arsenate. Oranges were obtained from trees that had been sprayed at least 10 times during the growing season, and compared with oranges of unsprayed trees from the same section.

Citric Acid Content Reduced

Chemical examination of the sprayed fruits showed that the amount of citric acid in the juice had been very markedly reduced and, although the amount of sugar in the juice was about normal, it was different from that of the ordinary orange. The term sugars is here used in the chemical sense, that is, to designate a group of compounds that are similar in composition and character. Cane or beet sugar ordinarily used in the household is only one of this group of compounds. The chemical composition of the fruit from sprayed trees accounts very well for the taste of the juice. The lower citric acid content would make the juice rather insipid, and the change in the character of the sugars would make it sweeter.

The juice from two lots of oranges was also fed to guinea pigs to determine whether any difference in vitamin C content could be detected. Briefly, the method consists in putting young guinea pigs on a diet free from vitamin C and determining what level of the material to be tested must be fed to prevent vitamin C deficiency. It was found that whereas a given daily dose of orange juice from normal fruit would produce a certain response in the experimental animals the dose had to be increased by more than 50 per cent to produce the same response when the juice of oranges from oversprayed trees was fed.

The changes in the oversprayed oranges determined by chemical studies are not significant from the standpoint of nutrition. All sugars that are utilized by the body are changed to the same compound and serve as a source of energy. Citric acid is not essential as a food, but its presence in the juice is very desirable, in that it imparts a flavor which is relished. However, oranges have become recognized as an important source of vitamin C, and a practice or condition which is shown to modify the amount of that vitamin is bound to receive serious consideration. Doctor Eddy, of Columbia University, has interpreted his recent work to indicate that we can benefit by increasing the vitamin C content of our diet. Because of its vitamin C content feeding of orange juice to infants is generally recommended by the medical profession.

No Danger of Arsenical Poisoning

From a scientific standpoint, the observation that a chemical element can modify the character of plant material is very interesting. How it acts has not been established, but it suggests new possibilities of determining some of the chemical changes taking place within the plant which have been difficult to unravel. In the control of insect pests there are other sprays which are effective and which do not change the appearance or taste of oranges. They will perhaps be used in preference to arsenates unless further studies similar to those described show them to be undesirable. The consumer, however, need not be apprehensive of danger of arsenic poisoning when eating oranges from sprayed trees, as chemical examination has shown that the juice and pulp are not contaminated with that element even in the most extreme cases of over spraying with arsenates.

Senior Chemist, Bureau of Chemistry and Soils.

OVEN Canning Tests Show Factors Governing Heat-Penetration Rates

With the development of stoves equipped with heat-regulating devices recommendations have been made by manufacturers that ovens may be used for home canning. The advantages of oven canning are that no extra equipment need be brought into the kitchen, and that the jars of food can be placed in the oven and given no further attention until the processing time is up. A brief study has been made in the Bureau of Home Economics on the rates of heat penetration in jars of different foods processed in an oven.

It has been found in these tests that the rates of heat penetration into jars of food in an oven vary with the consistency and initial temperature of the food and the temperature of the oven. Size of the jar is also a factor. The temperature inside of the jars rises most slowly in foods which are thick in consistency, and in which liquid can not circulate easily. This is illustrated by the rates of heat penetration into 40 jars of eight different kinds of food.

In these experiments the oven temperatures, 250° and 275° F., generally recommended for oven canning were used. Quart glass jars were used in all tests. Temperatures were registered by thermometers from the centers of the jars. In the following temperatures corrections have been made for the heat of the oven, which in these instances was 275°. Cubed squash, with an initial temperature of 108°, reached 175° in 70 minutes and 212° in 2 hours. Crushed squash with a higher initial temperature, 147°, required 95 minutes to reach 175°, and 2 hours to reach the boiling temperature. Sliced carrots with initial temperatures of 158° to 162° required 53 to 55 minutes to reach 212°; while similar jars with initial temperatures of 140° to 147° reached 212° in 65 to 75 minutes. Green beans cut into 1-inch lengths with initial temperatures of 180° to 183° reached 212° in 30 minutes and others with initial temperatures of 167° to 169° required 60 to 75 minutes to reach 212°. Spinach, with an initial temperature of 171° reached 212° in 78 minutes, whereas another jar with an initial temperature of 165° reached 212° in 95 minutes. Plums with an initial temperature of 163° reached 213° in 55 minutes, but a similar jar with an initial temperature of 133° required 86 minutes to reach 213°. Applesauce, with an initial temperature of 156°, reached boiling in 60 minutes, while with an initial temperature of 86° another jar required 95 minutes to reach the boiling point.

Preheating Effective

These figures show that heating the food before placing in the jars is very effective in reducing the period before temperatures near 212° F. are reached. If food is heated to boiling and placed in jars at once, the initial temperature is generally around 180°. Heat penetration was scribed show them to be undesirable. The consumer, however, need not be apprehensive of danger of arsenic poisoning when eating oranges from sprayed trees, as chemical examination has shown that the juice and pulp are not contaminated with that element even in the most extreme cases of over spraying with arsenates.

Crushed squash with a higher initial temperature, 147°, required 95 minutes to reach 175°, and 2 hours to reach the boiling temperature. Sliced carrots with initial temperatures of 158° to 162° required 53 to 55 minutes to reach 212°; while similar jars with initial temperatures of 140° to 147° reached 212° in 65 to 75 minutes. Green beans cut into 1-inch lengths with initial temperatures of 180° to 183° reached 212° in 30 minutes and others with initial temperatures of 167° to 169° required 60 to 75 minutes to reach 212°. Spinach, with an initial temperature of 171° reached 212° in 78 minutes, whereas another jar with an initial temperature of 165° reached 212° in 95 minutes. Plums with an initial temperature of 163° reached 213° in 55 minutes, but a similar jar with an initial temperature of 133° required 86 minutes to reach 213°. Applesauce, with an initial temperature of 156°, reached boiling in 60 minutes, while with an initial temperature of 86° another jar required 95 minutes to reach the boiling point.

Preheating Effective

These figures show that heating the food before placing in the jars is very effective in reducing the period before temperatures near 212° F. are reached. If food is heated to boiling and placed in jars at once, the initial temperature is generally around 180°. Heat penetration was more rapid in an oven at 275° than at 250°. The use of pans beneath jars in an oven retards heat penetration. Jars were found to heat as well in an oven filled to capacity as when only one jar was present. In filling an oven to capacity about 2 inches of space for air circulation were left on all sides of the jars.

The maximum temperature reached in these experiments was 212° F. in all jars of food except some fruits containing a considerable quantity of sugar, and in them the temperatures were only slightly higher. Since jars in an oven are not fully sealed, the steam escapes as formed, and the temperature of the food can not rise above 212° unless a considerable quantity of sugar or some other material is present to increase the boiling point of the liquid. Sealing the jars to hold the steam and force up the temperature would result in broken jars.

Repeated research has shown that some of the bacteria causing spoilage in canned foods of low acidity are likely to survive the temperature of boiling water unless the heating period is very prolonged, and that some may survive indefinitely. The spores of *Clostridium botulinum*, which have been the cause of serious cases of food poisoning, are not destroyed by canning at 212° F. As the temperature reached in jars of nonacid foods in an oven does not go above 212°, this method of canning, like the water-bath method, is not recommended for the nonacid vegetables, meats, and shellfish, and may be questionable for low-acid fruits, such as pears, although it may be used safely for tomatoes and the more acid fruits. The use of higher temperatures, 240° to 250°, is recommended for adequate sterilization of foods low in acidity. These temperatures can be obtained in the interiors of the jars and cans only in steam-pressure cookers.

PAPER Industry Concerns Farmer as Raw-Material Producer and Consumer

The farmer's interest in paper is not limited to his daily newspaper. As in so many other products of industry, he has an interest in paper which is more comprehensive than that of any other class of citizens. The raw materials—wood, cotton, flax, hemp, and other plants—from which paper is made are all products of the farm or forests; all are grown, harvested, and marketed by the farmer, a term which here includes the forest-land owner. Finally, being the largest single group of citizens, the farmer as a class is among the larger users of paper. He is interested in newspapers, in books and in magazines, in the wrapping paper in which he gets his supplies, in the building paper and insulating board with which his house is sheathed, and finally in the paper on which his contracts, deeds, wills, and other legal documents are recorded for his and for posterity's protection. The papers used in the records preserved in the county courthouse, their durability, of what they are made, are all of vital importance to him.

Paper and board making afford a large market for certain classes of farm and forest products. Wood is by far the most generally used paper-making material. The farms and forests of this country supply annually more than 5,500,000 cords of wood for paper making, and in addition the farms supply 350,000 tons of straw for making box board, more rapid in an oven at 275° than at 250°. The use of pans beneath jars in an oven retards heat penetration. Jars were found to heat as well in an oven filled to capacity as when only one jar was present. In filling an oven to capacity about 2 inches of space for air circulation were left on all sides of the jars.

The maximum temperature reached in these experiments was 212° F. in all jars of food except some fruits containing a considerable quantity of sugar, and in them the temperatures were only slightly higher. The farms and forests of this country supply annually more than 5,500,000 cords of wood for paper making, and in addition the farms supply 350,000 tons of straw for making box board, thousands of tons of sugarcane bagasse for making building and insulating board. More than 100,000 tons of jute and manila for making strong wrapping paper and paper for wrapping electric cables are imported annually. The total quantity of paper and board (exclusive of building and insulating board on which no exact figures are available) made annually in this country is about 15,000,000 tons, or an average of approximately 250 pounds for each man, woman, and child.

The public usually thinks of the farmer as the producer of the world's food and clothing, but he is much more than that. The world has other important needs that are filled by some of the vegetable growth that to such a large extent has no use as food or as clothing. In the production of these two primary products, food and fiber, fully an equal weight of by-products, such as stalks of corn, sorghum, and sugarcane, straws of wheat, rye, oats, barley, cotton, flax, and hemp, and the limbs and tops of trees, must of necessity be grown, for which some profit-yielding outlet is desirable.

Cellulose in Farm Wastes

Cellulose, a chemical compound, usually of a fibrous nature, which forms the supporting structure of plants and which is made from starch and sugars in the wonderful laboratory of nature, by methods that man has not yet been able to imitate and about which he knows but little, is one of the most important constituents of waste straws, stalks, cotton, flax, and wood, both from the point of view of the composition of these wastes and of industrial use.

Cellulose constitutes from 35 to 55 per cent of the weight of all vegetable matter. It is very resistant to chemicals and to the action of air, light, and living organisms, and when freed from other plant constituents by the proper means or when produced in nature as a practically pure product, such as the fiber of cotton, flax, and hemp, it is capable of being made into a flexible, durable sheet, such as paper, or into a strong durable board such as building and insulating boards.

The farmer needs an outlet for the by-products of his primary industry of producing food, clothing, and fuel, and the paper and board industries afford this outlet, although it must be borne in mind that these industries can at present use but a small fraction of the raw materials that the farm produces and has available in the form of wood, straws, and stalks. The development of more efficient and cheaper processes for pulping farm products, and the cutting out of the principal commercial forests in certain parts of the country, may bring about a better demand for such by-products as straws and stalks, and for farm timber for paper and board making. To what extent or how rapidly this may develop can not be foretold, but it seems probable that the demand for paper and pulp boards of all kinds will steadily increase. If board manufacturing plants are established in the farming districts to supply the local demand for such products, there is promise that the farmer will profit through the disposal of a large part of what has long been waste.

Farmer's Interest in Paper Materials

The interest of the farmer in supplying the raw material for paper is direct and clearly evident. His interest in paper as a user, as a citizen, is quite as evident but perhaps indirect. For every dollar he receives for paper-making raw materials he must on the average pay out $3, or more, for the finished paper, made therefrom, and while he does not use more than his proportionate share of paper, the cost of that share in the form of insulating boards, building boards, fiber containers, newspapers, legal documents, magazines, farm journals, Government and State publications, school books, experiment-station publications, and the thousand and one other uses of paper runs into millions of dollars. He is directly concerned with the suitability of the paper for the purpose for which he uses it. In newspapers he has but to-day's interest except that in common with other citizens he is interested in the preservation of the historical record unfolding day by day in the papers. In wrapping paper he is interested only so far as it serves its purpose satisfactorily.

In books, Government and State reports and bulletins the paper should not be needlessly heavy and bulky, the surface of the paper and the printing should not be injurious to the eyes and, since some of them at least are worth keeping, they should be reasonably durable and of good appearance. It is, however, in the papers used for record purposes, wills, deeds, and other documents of historic, financial, and legal importance, that in common with other citizens the farmer is peculiarly interested. These papers must be of the utmost durability, permanent if such a thing is possible; they must be of a quality that will withstand the frequent handling to which such documents are subjected during hundreds of years; they must not discolor, but must remain clear and legible. And since with the passing time such documents accumulate, they should be as light as is consistent with durability under the conditions of use and storage to which they are subjected. The literature and the history of civilization would have been lost if the earliest written records had been committed to paper of the quality of newspapers of to-day instead of to papers of great durability.

Thus we see that the farmer has an interest as the producer of the raw materials for making paper, and as a user of the finished product. It is because of this preponderant interest of the farmer in paper that the Department of Agriculture for more than 40 years has given attention to paper-making raw materials, to paper making, and to the rational use of paper, and has conducted research work and supplied technical and economic information on these subjects.

PASTURE Improvement the First Need in Strengthening South's Livestock Industry If we grant, as most agricultural authorities do, that an expansion in livestock production throughout the Southeastern States is warranted, then the first consideration is, What are the additional animals going to eat? If there were at present, in this particular section of the United States, an oversupply of forage and other animal feeds agitation for an increase in the number of livestock unqualified and unassociated with related agricultural programs, might be warranted. Such is not the case. The natural pastures are unproductive, and the people long accustomed to growing cotton are not educated in the methods of efficient feed production.

PASTURE Improvement the First Need in Strengthening South's Livestock Industry

If we grant, as most agricultural authorities do, that an expansion in livestock production throughout the Southeastern States is warranted, then the first consideration is, What are the additional animals going to eat? If there were at present, in this particular section of the United States, an oversupply of forage and other animal feeds agitation for an increase in the number of livestock unqualified and unassociated with related agricultural programs, might be warranted. Such is not the case. The natural pastures are unproductive, and the people long accustomed to growing cotton are not educated in the methods of efficient feed production.

There are no natural grasslands in this part of the country. It was originally an almost completely forested area, and from Texas eastward to the Atlantic Ocean, below the southern boundary of Tennessee, there is hardly one native grass or legume that ranks high as a pasture plant. All of the productive pastures are a result of the introduction of plant immigrants such as Lespedeza and Bermuda, carpet, and Dallis grasses. (Figs. 128 and 129.) The coarse forage also comes from other introduced plants such as Japanese cane, sorghum, and Napier grass.

It is recognized that the forage and livestock programs are interdependent. Increase in forage production would be futile without a corresponding increase in livestock. A surplus of forage, however, would be less disastrous than a forage deficiency caused by an ill-considered increase in the number of animals to be fed. An abundant supply of

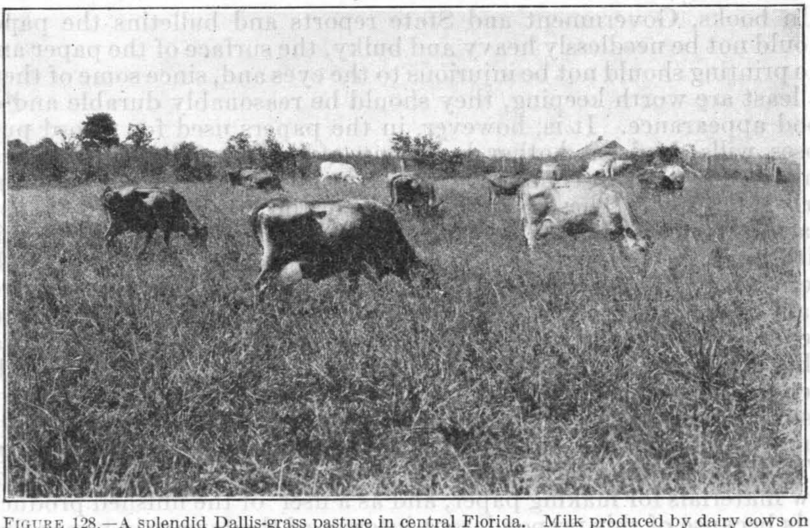

FIGURE 128.—A splendid Dallis-grass pasture in central Florida. Milk produced by dairy cows on such pasture can be sold at a profit

cheap raw material is one of the prerequisites of success in any manufacturing industry. The bovine animal is manufacturing either meat or milk from the feed available. If that feed is expensive, the cost of the product is often so high as to prevent marketing it at a profit. The first thing to do in the South, therefore, is to make sure of an abundance of cheap feed. Pasture supplies such a feed. It costs less than harvested feed because of the low labor cost in connection with pastures. In Pennsylvania[8] the labor cost of a ton of digestible nutrients in the form of silage was $21.21; as pasture the labor cost was only 66 cents. One ton of digestible nutrients supplied by a grain rotation on cultivated land, involved a labor cost of $15.94 as against the labor cost of 66 cents for the same quantity of feed from pasture. These results are from a farm-cost survey made in 1921 in Lancaster County, Pa.

Southern Pastures Must Be Improved

To be productive, southern pastures must be improved by the introduction of carpet grass, Bermuda grass, Dallis grass, Bahia grass,

[8] WHITE, J. W. and HOLBEN, F. J. DEVELOPMENT AND VALUE OF KENTUCKY BLUE-GRASS PASTURES. Penn. Agri. Expt. Sta. Bul. 195., p. 15, 1925.

Lespedeza, white clover, black medic, etc. Unimproved or natural pastures will support cattle only at the rate of 1 animal unit for each 10 acres of pasture, and the gains made on such pastures are small. Improved pastures, on the other hand, will support cattle at the rate of 1 animal for each 2 acres, and the gains are almost double those on the natural pastures. The census of 1920 reported only 20 per cent of the southern pastures as improved. Until this situation is remedied there can be no extensive development of the livestock industry in these States.

The total pasture acreage in the eight States of Alabama, Arkansas, Florida, Georgia, Louisiana, Mississippi, North Carolina, and South Carolina according to the agricultural census of 1925 was 22,411,162 acres. If 20 per cent of this were improved pasture there would be

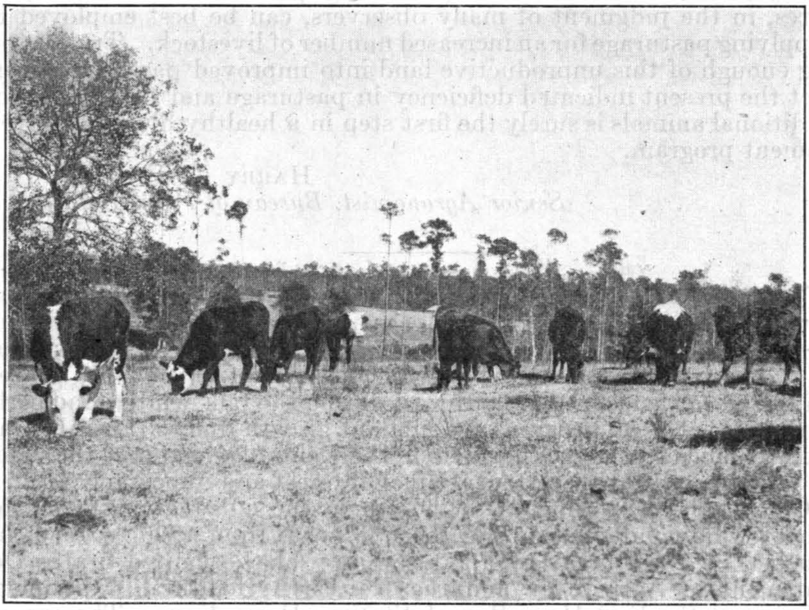

FIGURE 129.—Beef cattle grazing an improved pasture on typical flat-woods land in the coastal plain of Mississippi. Good pasture was obtained here on cut-over land by the introduction of carpet grass and Lespedeza

4,482,232 acres of such pasture, capable of supporting 2,241,116 animal units for the grazing season of approximately nine months. The remaining 17,928,930 acres of unimproved pasture would graze 1,792,893 animal units at the rate of 10 acres for each cow or the equivalent thereof. There was, therefore, according to the census in 1925, pasturage in these States sufficient for a total of 4,034,009 mature cattle or their equivalent.

Animal Surplus in Relation to Pasture

Disregarding the question of whether there is normally sufficient harvested feed to care for these 4,000,000 animal units during the remaining three months of the year, what is the relation of the actual supply of livestock of these States to the available pasture? Referring again to the 1925 census and considering only grazing animals (cattle, horses, sheep, and goats), we find a total of 5,604,003 animal units[9] reported in these eight States. It would appear that there is already a surplus of over 1,500,000 animal units in these States from the standpoint of available pasturage. Can anything be more obvious than the necessity of correcting this situation before we encourage an increase in the number of livestock in this region?

Potential pasture land in this part of the United States is indicated by the area of cut-over and burned-over land. It is estimated that there are over 110,000,000 acres of this class of land in the States under consideration.

The unproductive condition of this immense body of land constitutes a serious handicap to the prosperity of these States. Some of this land should undoubtedly be reforested, and a very small part might be profitably devoted to cultivated crops. A large portion of this 110,000,000 acres, in the judgment of many observers, can be best employed in supplying pasturage for an increased number of livestock. Transforming enough of this unproductive land into improved pastures to correct the present indicated deficiency in pasturage and to provide for additional animals is surely the first step in a healthy livestock development program.

PASTURING Winter Wheat In Central Plains Pays If Properly Managed

The utilization of winter wheat as a pasture is a common practice in the central Great Plains area. Thousands of cattle were grazed on the wheat fields of the Southwest during the fall, winter, and early spring of 1929–30 because of abundant growth due to favorable fall rains. The effect of pasturing upon the yields of wheat and the value of wheat pasture are matters of much interest and importance.

Cooperative experiments to determine the effect of pasturing on wheat were conducted during the five years from 1926 to 1930, inclusive, by the Bureau of Plant Industry of the United States Department of Agriculture and the Kansas Agricultural Experiment Station at the Fort Hays Branch Station, Hays, Kans. The experiments involved (1) the reduction of excessive growth and tillering by pasturing, (2) the effect of grazing on yields of wheat, and (3) the carrying capacity of wheat pasture. Two series of plots were used, one on land where wheat followed fallow, and the other on cropped land where wheat followed wheat. The crop usually makes a heavy growth after fallow, but less growth is expected on wheat-stubble land, on which most of the wheat in western Kansas is sown. The plots were sown the last week in September, the optimum time to seed wheat in the Hays section for grain yields.

The wheat sown on fallow land usually made an excessive growth, particularly in the spring. Pasturing such wheat judiciously for a period of 45 days in the fall resulted in an average gain of 2.9 bushels per acre. When the wheat was pastured moderately for 105 days and not later than April 15, there was an average gain in yield of 2.3 bushels. When it was grazed to the ground for 120 days during fall

[9] The number of animals was reduced to equivalent units by the process customarily used. See Department of Agriculture Yearbook for 1923, p. 321.

horses, sheep, and goats), we find a total of 5,604,003 animal units[9] reported in these eight States. It would appear that there is already a surplus of over 1,500,000 animal units in these States from the standpoint of available pasturage. PASTURING Winter Wheat In Central Plains Pays If Properly Managed The utilization of winter wheat as a pasture is a common practice in the central Great Plains area. Thousands of cattle were grazed on the wheat fields of the Southwest during the fall, winter, and early spring of 1929–30 because of abundant growth due to favorable fall rains. The effect of pasturing upon the yields of wheat and the value of wheat pasture are matters of much interest and importance.

Cooperative experiments to determine the effect of pasturing on wheat were conducted during the five years from 1926 to 1930, inclusive, by the Bureau of Plant Industry of the United States Department of Agriculture and the Kansas Agricultural Experiment Station at the Fort Hays Branch Station, Hays, Kans. The experiments involved (1) the reduction of excessive growth and tillering by pasturing, (2) the effect of grazing on yields of wheat, and (3) the carrying capacity of wheat pasture. Two series of plots were used, one on land where wheat followed fallow, and the other on cropped land where wheat followed wheat. The crop usually makes a heavy growth after fallow, but less growth is expected on wheat-stubble land, on which most of the wheat in western Kansas is sown. The plots were sown the last week in September, the optimum time to seed wheat in the Hays section for grain yields.

The wheat sown on fallow land usually made an excessive growth, particularly in the spring. Pasturing such wheat judiciously for a period of 45 days in the fall resulted in an average gain of 2.9 bushels per acre. When the wheat was pastured moderately for 105 days and not later than April 15, there was an average gain in yield of 2.3 bushels. When it was grazed to the ground for 120 days during fall

[9] The number of animals was reduced to equivalent units by the process customarily used. See Department of Agriculture Yearbook for 1923, p. 321.

and spring and as late as April 20, the average loss in acre yield was 3.2 bushels. When the wheat was grazed to the ground from the time it started growth in the spring until April 15, there was a loss in average yield of 1.7 bushels. On fallowed land, pasturing begun after April 15 caused an average reduction in acre yield of 6.3 bushels. (Fig. 130.)

Effects of Grazing on Cropped Land

On cropped land, where there was less stored moisture than in the fallowed land, there was an average loss in yield of from 1.2 to 5.3 bushels per acre, depending on the severity and time of pasturing. In two of the five years moderate pasturing in fall and spring gave an increase in yield on cropped land. These were both seasons of plentiful moisture, and conditions were similar to those for the fallow land in ordinary years.

The experiments, verified by observations, lead to the conclusion that wheat sown in a well-prepared seed bed with a plentiful supply of subsoil moisture and making excessive growth may be benefited by moderate pasturing. When the season is dry and growth is limited, grazing reduces the yields of wheat.

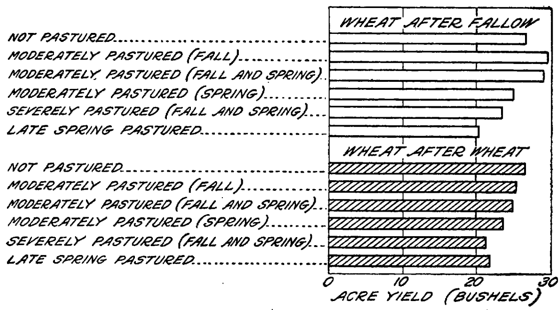

FIGURE 130.—Average acre yield of winter wheat after different intensities of pasturing, grown on fallow and on fall-plowed wheat land at Hays, Kans.

The grazing capacity of winter wheat varies from year to year, depending on the growth of the crop. Wheat may or may not make sufficient growth for pasturing in the fall, but usually some pasture can be expected in the spring. The carrying capacity is always lowest in the fall, when as many as 5 to 7 acres may be needed to feed one horse or cow. In a season of abundant moisture, wheat sown early in September may make enough fall growth so that half of the above acreage will be sufficient for one animal unit. In the early spring from 2 to 3 acres will carry one cow while in the late spring after April 15 from one-half to 1 acre is enough if the wheat has not been pastured previously.

Wheat sown in late September in a well-prepared seed bed with plenty of reserve moisture usually makes a good top growth. The crop may be grazed moderately during November and part of December, the livestock then being withdrawn until the wheat makes new growth in the early spring. From the beginning of spring growth the wheat may be pastured moderately until about April 15, the exact date depending on the crop development and varying somewhat with season. The greatest injury from pasturing occurs after April 15, because by this time the wheat stems have jointed and the animals destroy the young heads.

Early Grazing Desirable

Grazing should be started in the early spring when the wheat begins to grow. Livestock will then graze more evenly than when turned into the fields after the wheat has attained some height. In the latter case the animals tend to graze in spots, which causes unevenness of growth and maturity. In general, grazing delays maturity from one to five days, depending on the severity and length of the pasturing period.

Limited observations show that grazing reduces the number of tillers in wheat. When wheat tillers too profusely early in a season of abundant moisture, a reduction in number of tillers appears to be beneficial. When the stand is thin and growth limited, a reduction in number of tillers is decidedly harmful. During a dry season, soil blowing also may be induced by overpasturing.

Pasturing sometimes reduces the yields of wheat but the feed value of the pasture may compensate wholly or in part for grain losses. Chemical analyses made at the Kansas experiment station show that green wheat is high in its content of protein and mineral nutrients. The greatest value of wheat pasture is as a supplement to other feeds, rather than as the only source of feed, although it is largely used for the latter purpose before other pastures are available.

Green wheat may cause occasional bloating in cattle. The danger seems to be greatest when the green wheat is pastured while wet with dew or rain.

Associate Agronomist, Bureau of Plant Industry.

PEANUT Seed May be Kept for Several Years Under Proper Conditions

The effect of age on the vitality of peanut seed, and its storage under conditions that do not impair its quality, are factors of prime importance, because it is often desirable to keep peanut seed for extended periods.

Recent experimental work carried on in cooperation with the South Carolina Agricultural Experiment Station has yielded facts showing the effect of age and storage under different conditions on the vitality of peanut seed. The results of this work are of considerable practical importance to growers of peanuts, as they indicate that peanut seed if stored under proper conditions may be kept for several years without serious impairment of its vitality. Heretofore there has been hesitancy about using peanut seed more than 1 or 2 years old.

Stock of known character was used for growing a supply of seed of the Improved Spanish and Valencia varieties at the Pee Dee Experiment Station, Florence, S. C., in 1921, and each year thereafter through 1926. The peanuts were well cured in the stack before picking, but they were not otherwise dried. The seed was stored in the shells in muslin bags placed in large galvanized cans in a storeroom in Washington, D. C. The temperature conditions were normal for an office building, with winter temperatures of about 70° to 72° F., and summer temperatures as determined by weather conditions. These cans were covered with rather loose-fitting hinged lids and had no special equipment for ventilation.

All lots of seed were fumigated every spring and autumn with carbon bisulphide for the control of insects.

PEANUT Seed May be Kept for Several Years Under Proper Conditions

The effect of age on the vitality of peanut seed, and its storage under conditions that do not impair its quality, are factors of prime importance, because it is often desirable to keep peanut seed for extended periods.

Recent experimental work carried on in cooperation with the South Carolina Agricultural Experiment Station has yielded facts showing the effect of age and storage under different conditions on the vitality of peanut seed. The results of this work are of considerable practical importance to growers of peanuts, as they indicate that peanut seed if stored under proper conditions may be kept for several years without serious impairment of its vitality. Heretofore there has been hesitancy about using peanut seed more than 1 or 2 years old.

Stock of known character was used for growing a supply of seed of the Improved Spanish and Valencia varieties at the Pee Dee Experiment Station, Florence, S. C., in 1921, and each year thereafter through 1926. The peanuts were well cured in the stack before picking, but they were not otherwise dried. The seed was stored in the shells in muslin bags placed in large galvanized cans in a storeroom in Washington, D. C. The temperature conditions were normal for an office building, with winter temperatures of about 70° to 72° F., and summer temperatures as determined by weather conditions. These cans were covered with rather loose-fitting hinged lids and had no special equipment for ventilation.

All lots of seed were fumigated every spring and autumn with carbon bisulphide for the control of insects.

Germination Counts Made

In the spring of 1922 a portion of seed of each variety was removed from storage and shelled by hand just prior to planting. Germination counts of these were made for the purpose of determining the original vitality of the seed. The germination of the 1921-grown Valencia seed at the beginning of the experiment in 1922 was 52.5 per cent. In 1927 the same stock gave a germination of 47.2 per cent.

Beginning with the crop season of 1924, lots of seed of the two varieties from each year's crop were removed from storage in the spring, shelled by hand, and two 90-foot rows of each were planted at the Pee Dee Experiment Station. Germination counts and yields were recorded. This test was repeated each year through 1927, after which time the work was discontinued.

There was but little difference in the yield of peanuts and hay from the old and new seed. With the Improved Spanish variety there was a drop in germination from 84.5 per cent in 1922 to 56.4 per cent in 1927, but this decline was slow until after the seed had reached the age of 3 years. Yield records for this variety showed less variation than the germination tests, but varied rather widely from year to year, probably on account of different weather conditions. The work would seem to justify the conclusion that peanut seed may be kept under favorable conditions for from three to four years without serious loss of vitality. There is apparently no reason why good lots of peanut seed can not be kept in storage to guard against seed shortage during any particular season.

The Cold Storage of Peanut Seed

The cold storage of peanuts is an important commercial practice, and the effect, if any, of this kind of storage on peanuts to be used for seed purposes is one of some moment to the industry. The work upon which these conclusions are based was a cooperative enterprise with the Clemson Agricultural College at the Pee Dee Experiment Station, Florence, S. C.

Beginning with crop material of 1921, including the African, Improved Spanish, Jumbo, Spanish, and Valencia varieties, lots of each, in both the shelled and unshelled states, were placed in cold storage at 32° and 40° F. and in common storage at about 70° F. The seed was removed from storage during the spring of 1922 and planted at the Pee Dee station, and germination records were taken. Similar work was carried on with seed grown during the years 1922 to 1926, inclusive.

The average germination, over a period of four years, of the five varieties where the seed was stored shelled at 32°, 40°, and 70° F. was practically the same. That of the unshelled seed was a little higher, but also about the same for all storage temperatures. The yields over a period of three years for the different storage temperatures were practically alike, but the seed stored unshelled gave a slightly higher yield. This is probably due to the protection of the shell during storage.

It would seem that the cold storage of peanut seed is not injurious and that the seed keeps somewhat better when stored unshelled.

Associate Horticulturist, Bureau of Plant Industry.

PINE-BEETLE Control Costs Reduced Through Logging and Salvage The western pine beetle has been considered for many years as the most destructive insect enemy of mature western yellow-pine timber in the virgin forests of California and Oregon. During the last decade its destructive activities have been particularly severe in southern Oregon and northern California, where, on an area of 1,600,000 acres, over two and a half billion board feet of merchantable timber has been destroyed—a loss conservatively estimated as amounting to $10,000,000.

The Federal timber-managing agencies, such as the Forest Service and Indian Service, in cooperation with the private timber owners of the region, have carried on a determined campaign since 1921 to control this pest, using the methods which have been devised by the Bureau of Entomology.

These control methods consist of running strip surveys through the affected forests during the fall, winter, and spring and locating the infested trees. At these seasons the beetles are all to be found within the bark of trees attacked during the preceding summer. Then treating crews go through the woods, fell the designated trees, and peel or burn the bark containing the injurious beetle larvae and new adults. The timber of the felled trees is, for the most part, only slightly damaged by the treatment and, except for some lowering in grade by blue stain, is still merchantable. However, the trees cut in this work are so widely scattered through the forest as to make their salvage difficult and uneconomical. So they are usually left in the woods to rot. The cost of the treating work has averaged about $4.50 per tree containing a thousand board feet of lumber (M b. m.).

Control Work Should Pay Its Way

The control work has had the effect of reducing the losses but has not permanently stopped the inroads of the beetles, and the work has to be repeated to secure more lasting benefits. In any case it is doubtful whether more than temporary relief can be secured from such work until growth conditions are improved in the forests or the old mature trees removed through cutting operations. It is therefore essential that the control work should currently pay its way.

It will be readily seen that the control methods used in the past have been cumbersome and expensive. The timber cut in the work has usually been a total loss and the timber owner received no returns except in a reduction of subsequent killing. In view of the results secured, it is thought that if the timber to be cut is valued at less than the cost of the treating work, control can not be profitably undertaken.

For some years the Bureau of Entomology has advocated logging the beetle-killed timber, burning the insect-infested bark at the mill, and salvaging the lumber as a means of reducing the net cost of the control operation. But only a few serious attempts have been made to put this method into practice.

In 1923 the Weyerhaeuser Timber Co. sold the logs left in the woods, after the completion of a beetle-control job, to a contractor who removed many of the best logs to a mill some 5 miles distant and paid $1 per M b. m. for the logs taken. But the undertaking was not profitable to the contractor, and further salvage work of this character was abandoned.

Later this same company purchased a small portable sawmill and tried salvaging the logs felled in beetle-control work by sawing them into lumber in the woods and hauling the lumber to the nearest market. Because the felled trees were scattered over a very large area, necessitating frequent moves of the portable mill, this operation also proved unprofitable.

In the fall of 1928 the Pickering Lumber Co., having contracted to carry on beetle control on a unit of 15,000 acres in Modoc County, Calif., comprising both the company's and national forest lands, decided to salvage this timber and burn the infested bark at the mill. A small mill was constructed near the center of the area. The infested trees were located by a survey crew in the usual manner. The trees were felled and then, with tractors and fair-lead arches equipped with

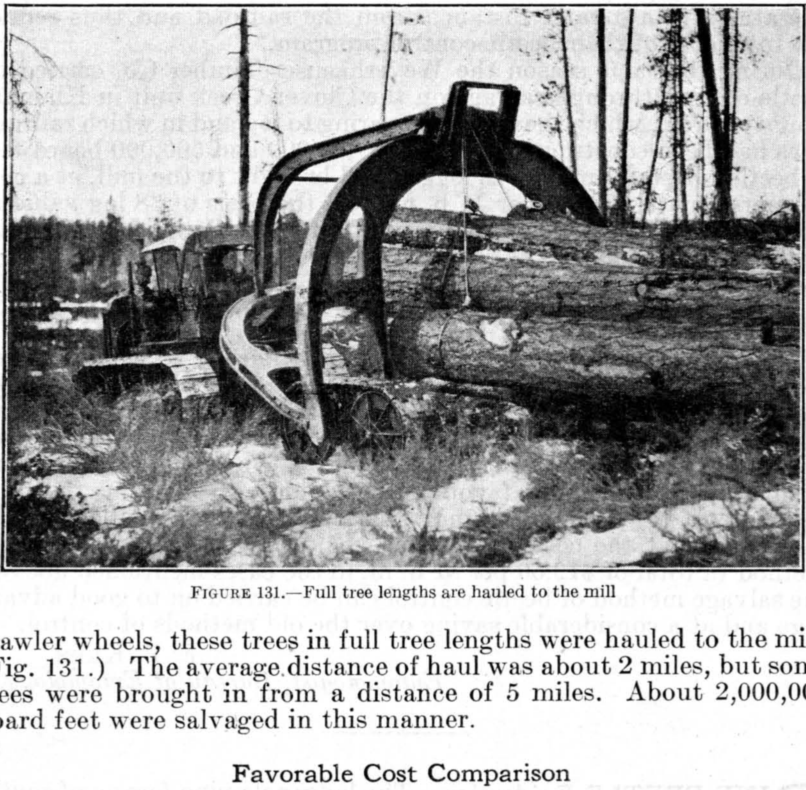

FIGURE 131.—Full tree lengths are hauled to the mill

crawler wheels, these trees in full tree lengths were hauled to the mill. (Fig. 131.) The average distance of haul was about 2 miles, but some trees were brought in from a distance of 5 miles. About 2,000,000 board feet were salvaged in this manner.

Favorable Cost Comparison

The costs of this operation compared very favorably with the cost of the old burning method and the treatment was every bit as satisfactory from the standpoint of disposing of the bark beetles. Where the old method would have involved a direct outlay of $4.50 per M b. m. of timber treated, with no return from salvage, the method used cost $6.58 per M b. m. to bring the trees to the mill, with an estimated value at the mill of $8 per M b. m., or a net profit on the operation of $1.42 per M b. m. This cost does not include any charge for the investment in the mill, which in this case was to be used for other purposes later, and which in any case would be a charge against the milling costs.

40442°—31——28

In the spring of 1929 the McCloud River Lumber Co., having extended their logging railroad into a unit of their holdings in Modoc County, in preparation for logging, decided to log out the beetle-infested trees within easy reach of their lines as a beetle-control measure. Tractors were again used, and for a distance of 2 miles on either side of the tracks the beetle-killed trees were skidded to decking points along the railroad and about 1,000,000 board feet of salvaged timber sent to the mill. On the remainder of the area the usual method of peeling and burning was resorted to, and 2,000,000 board feet were treated and left in the woods. The cost of the burning method was $4.45 per M b. m., while the felling and skidding operation cost $5.20 per M b. m., with a return of at least $8 per M b. m. for the timber so salvaged, leaving a net profit of $2.80 per M b. m. It is probable that this company could well have afforded to extend the salvage operations to a greater distance from the railroad and thus reduce the total cost of their beetle-control program.

During the same season the Weyerhaeuser Timber Co. carried on beetle control through salvage on the Clover Creek unit in Klamath County, Oreg., which they were preparing to log and in which railroad lines had been constructed. Between 400,000 and 500,000 board feet of beetle-infested timber was logged and brought to the mill, at a cost of approximately $5.06 per M b. m. On the basis of $8 log value at the mill, this operation yielded a profit of $2.94 per M b. m. for the timber treated.

Value of Salvaging Timber Demonstrated

The results of this work show very plainly that where beetle-infested trees can be salvaged and brought to a mill to be cut into lumber, the cost of the control work can be greatly reduced. It has been demonstrated that under certain conditions it is feasible to send tractors out for 4 and 5 miles to bring in the infested logs. In fact, this radius may even be extended under favorable conditions. So long as the total logging cost to the mill does not exceed the value of the logs at the mill plus what the cost of treating would have been under the old method (a total of $12.50 per M b. m. in the cases mentioned above), the salvage method of beetle control can be carried on to good advantage and at a considerable saving over the old methods of control.

F. P. Keen,
Entomologist, Bureau of Entomology.

PINE-BEETLE Epidemics Are Now Controlled by Burning Standing Trees

The lodgepole pine forests of southeastern Idaho, western Wyoming, and northern Utah are experiencing a mountain-pine-beetle infestation which has threatened to develop into a serious epidemic within the region and to spread into the valuable timber stands of the Yellowstone National Park. This infestation was first discovered in 1927 on a few mature trees of the national forests in southeastern Idaho and western Wyoming. Realizing the seriousness of such epidemics the Forest Service and the Bureau of Entomology immediately began to plan artificial control measures.

In the spring of 1929 the McCloud River Lumber Co., having extended their logging railroad into a unit of their holdings in Modoc County, in preparation for logging, decided to log out the beetle-infested trees within easy reach of their lines as a beetle-control measure. Tractors were again used, and for a distance of 2 miles on either side of the tracks the beetle-killed trees were skidded to decking points along the railroad and about 1,000,000 board feet of salvaged timber sent to the mill. On the remainder of the area the usual method of peeling and burning was resorted to, and 2,000,000 board feet were treated and left in the woods. The cost of the burning method was $4.45 per M b. m., while the felling and skidding operation cost $5.20 per M b. m., with a return of at least $8 per M b. m. for the timber so salvaged, leaving a net profit of $2.80 per M b. m. It is probable that this company could well have afforded to extend the salvage operations to a greater distance from the railroad and thus reduce the total cost of their beetle-control program.

During the same season the Weyerhaeuser Timber Co. carried on beetle control through salvage on the Clover Creek unit in Klamath County, Oreg., which they were preparing to log and in which railroad lines had been constructed. Between 400,000 and 500,000 board feet of beetle-infested timber was logged and brought to the mill, at a cost of approximately $5.06 per M b. m. On the basis of $8 log value at the mill, this operation yielded a profit of $2.94 per M b. m. for the timber treated.

Entomologist, Bureau of Entomology.

PINE-BEETLE Epidemics Are Now Controlled by Burning Standing Trees The lodgepole pine forests of southeastern Idaho, western Wyoming, and northern Utah are experiencing a mountain-pine-beetle infestation which has threatened to develop into a serious epidemic within the region and to spread into the valuable timber stands of the Yellowstone National Park. This infestation was first discovered in 1927 on a few mature trees of the national forests in southeastern Idaho and western Wyoming. Realizing the seriousness of such epidemics the Forest Service and the Bureau of Entomology immediately began to plan artificial control measures.

Timber Values Requiring Protection

Lodgepole pine in the national forests of this region has a large commercial value for railroad ties, mine and farm timbers, poles, etc. There is an even greater intangible value in the scenic forests of Yellowstone Park, Jackson's Hole, and summer resorts in the region. In addition to the actual destruction of scenic and commercial timber stands by the pine beetles, fire hazards are created through the vast accumulation of dead timber on the forest floor. Fires inevitably follow beetle epidemics—fires that are practically impossible to check while burning in such areas. Artificial control measures were necessary, therefore, to prevent the destruction of timber and the creation of fire hazards which might result in a complete devastation of the forests following the epidemic.

FIGURE 132.—Showing mountain-pine-beetle work on inside of bark

Practicability of Spraying Demonstrated

At first an attempt was made to control this outbreak by removing the infested timber for ties and farm timbers. As little progress was made in this manner, forest officers were detached from their regular duties in 1928 and assigned to actual control work. The methods of control in common use at that time were to fell the trees and either to peel the bark from the infested portion of the bole, exposing the immature insects to predatory insects and mammals, or to cut the trees into logs which were piled and burned. As both of these methods were laborious and expensive, a more economical procedure was sought. Representatives of the Forest Service and the Bureau of Entomology in Montana had previously found that if a light fuel oil were sprayed upon thin-barked lodgepole pine and then fired the temperature would be raised sufficiently to destroy the insects beneath the bark. (Fig. 133.)

FIGURE 133.—Burner spraying oil on infested trees

Forest officers working on the present infestation set about developing a field application of the method, believing it offered the economical procedure desired.

Though in 1928 the spraying equipment used was not satisfactory, it demonstrated the effectiveness and practicability of the method. Marked improvements have been made in this equipment, and in 1930 very satisfactory results were secured. An air-pressure hand pump, commonly used for spraying small fruit trees, was adopted. With a tank pressure of 25 or 30 pounds, a 9-foot light, steel-tubing extension, and a specially developed nozzle, trees could be sprayed to a height of 32 feet. The fire carries considerably above the actual height of the oil and it was possible to destroy the beetles in practically all of the infested trees. A light fuel oil, commonly called gas oil, was used. Its most important specification, besides being clean, of low viscosity, and with a flash point not exceeding 160° (PM), is that it burns freely in the open. Control projects in this region are instituted very early in the spring, while the snow is still on the ground, or at least the forest is very wet, to avoid all possible danger of fire spreading. In the spring of 1930 approximately 70,000 trees were treated by this method, at a cost of considerably less than $1 per tree, including regular forest officers' time.

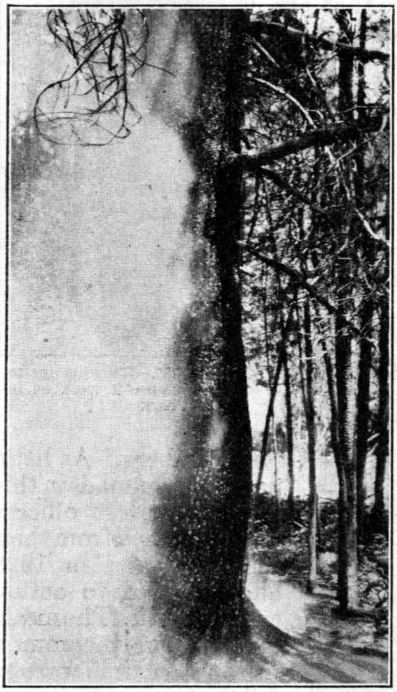

FIGURE 134.—Burned infested tree. White specks on black bark shows effective burn

Unless unknown areas of infestation are discovered, it is thought that the worst of the epidemic in the five national forests affected has been broken. It is necessary to treat some trees in the spring of 1931 within the areas previously covered by control, but the task will not be so great as that just completed. The potential danger of infested trees is large; sufficient beetles often emerge from one tree to attack and kill from three to five additional ones. It is therefore safe to assume that as a result of the 1930 operation, from 200,000 to 350,000 trees were saved from insect attack by the beetles which would have emerged from the trees treated and that a practically uncontrollable epidemic has been averted.

C. B. Morse,
Assistant Regional Forester, Forest Service.

PISTACHE Nuts Are a Promising Crop for Some Sections of U. S. During the last six years imports of the pistache nut into the United States have averaged 1,134,627 pounds of shelled nuts a year with an average yearly value of $501,564. In view of the fact that this is one of the most expensive nuts on our market, selling at times as high as $1 a pound wholesale, Forest officers working on the present infestation set about developing a field application of the method, believing it offered the economical procedure desired.

C. B. MORSE,
Assistant Regional Forester, Forest Service.

PISTACHE Nuts Are a Promising Crop for Some Sections of U. S. During the last six years imports of the pistache nut into the United States have averaged 1,134,627 pounds of shelled nuts a year with an average yearly value of $501,564. In view of the fact that this is one of the most expensive nuts on our market, selling at times as high as $1 a pound wholesale, an increase in importations from 547,673 pounds in 1924 to 1,491,339 pounds in 1929 suggests that the American people are rapidly acquiring a taste for this nut. Syria, Italy, India, and Persia, in the order named, are the four countries from which we get most of our supply, this nut being grown in the Mediterranean region and Asia Minor. In the United States it is used mainly in confections and ice cream, and should it become as popular with us as it is with the people in those countries where it is now grown, our importations would continue to increase.

Botanists mention some 17 species of the genus Pistacia, but the edible nuts of commerce are produced by *Pistacia vera*. This species grows wild in scattered areas through the foothills of the mountains which border southern and eastern Russian Turkestan. Although the

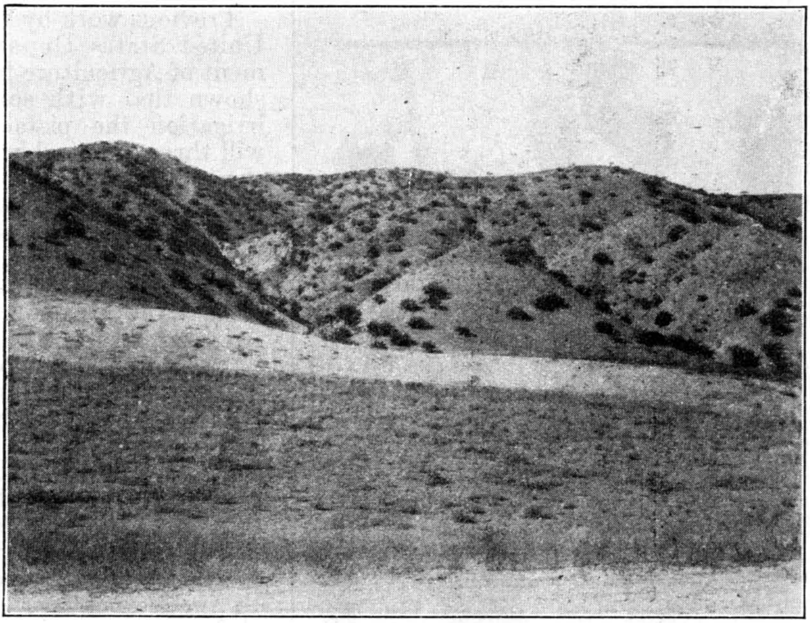

FIGURE 135.—Pistache trees (*Pistacia vera*) growing wild in the foothills near Djalalabad, Turkestan, U. S. S. R.

nuts from these wild trees are much smaller than from those of the cultivated forms, they are highly prized by the nomadic Kirghiz who live in these hills, who gather the nutritious nuts as they ripen and use them as part of their diet during the winter when food is scarce. The trees also supply firewood for these people, who cut them frequently, with the result that the trees are kept low and bushlike in appearance. Although the fruits of these wild trees are small, they are of interest in the United States for testing as stocks and for use in breeding for better varieties. (Fig. 135.)

The pistache nut is such an old fruit, dating back some 3,500 years, that the historians vary in opinion as to the area in which it was first native. The cultivated varieties of *Pistacia vera* probably originated in Syria, Asia Minor, and Palestine, and later were disseminated throughout the hot, dry region of the Mediterranean. The cultivated pistache is widely grown in Sicily. Although the trees have been known and cultivated for centuries, few varieties have been produced, compared with the almond or walnut, both of which have numerous easily recognized varieties. Botanists suggest that the long-continued practice of grafting the best varieties of *P. vera* on the wild *P. teribinthus* may explain the relatively few varieties in Sicily. The writer found that with few exceptions the pistache orchards of Persia were composed of *P. vera* seedlings and that there was considerable variability in the size and shape of the nuts borne on the different seedlings. Although many of them were producing nuts inferior in size to those already introduced into the United States from other countries, some were as good or better in size. Buds of these better types were brought back to this country. (Fig. 136.)

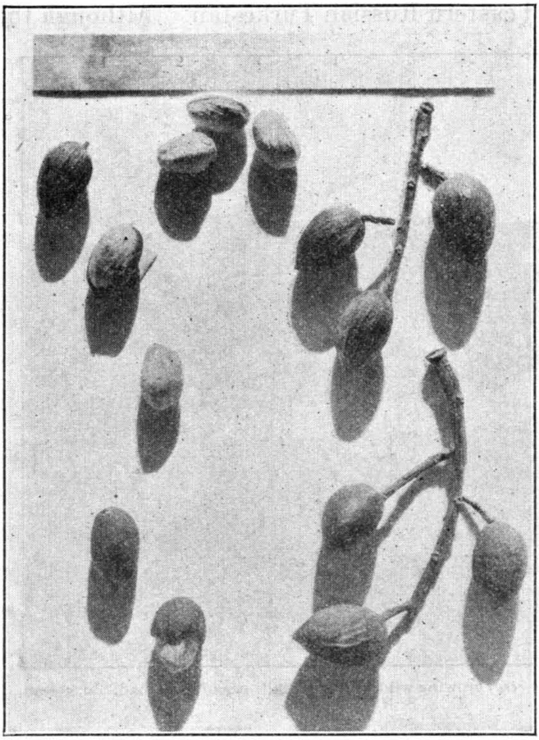

FIGURE 136.—Large, well-developed pistache nuts from Persia. Bud wood of this tree was successfully introduced into the United States last year

Previous work by the United States Department of Agriculture has shown that with some irrigation the pistache will thrive admirably in the early peach belt of the Sierra Nevada foothills in California; also that it promises to be successful in parts of Texas, New Mexico, and Arizona.

The American people, however, are abundantly supplied with other kinds of nuts, and to be successful the campaign to educate the public to eat the pistache nut must be backed by a product that will appeal to the consumer. In their native country the pistache nuts are roasted and salted. A large part of the crop is consumed in this manner. There is a limited sale of salted pistache nuts in the United States, but the small size of the nuts, added to the fact that many of them have closed shells that are difficult to open has discouraged the consumer. The American orchardist must be supplied with varieties that are large, and his crop, when harvested, must contain a high percentage of split nuts.

Splitting of the shell is apparently not a hereditary character; but according to many Persian growers, this tendency is associated with growth. When conditions are favorable for rapid growth of the seed or kernel, a greater percentage of splitting is noticed.

No final explanation has been reached, but various points may be noted. The pistache is dioecious; that is, the male, or staminate flowers, and the female, or pistillate flowers, are born on different trees. In Sicily it has been observed that drupes of *Pistacia vera* on trees planted nearest to the male, or staminate *P. terebinthus* trees had a tendency to open their valves at the top, owing to the large size of the seed within, suggesting the influence of pollination. When not pollinated, the shells develop and to all appearance are normal except that they are empty, no seed or kernel developing within. Investigations in the United States have shown that developing apple seeds favors the development of the fruit, the largest apples containing the greater number of well-developed seeds. The question of the right kind of pollenizer is apparently important. In Persia, where the fruit has been grown for centuries, there is still a great deal of confusion on this point, and in some orchards many of the trees bear a heavy crop of seedless shells.

Although during his studies in Persia the writer heard many conflicting opinions as to the best methods of orchard culture for pistache, it was interesting to note that in one or two cases, where the grower

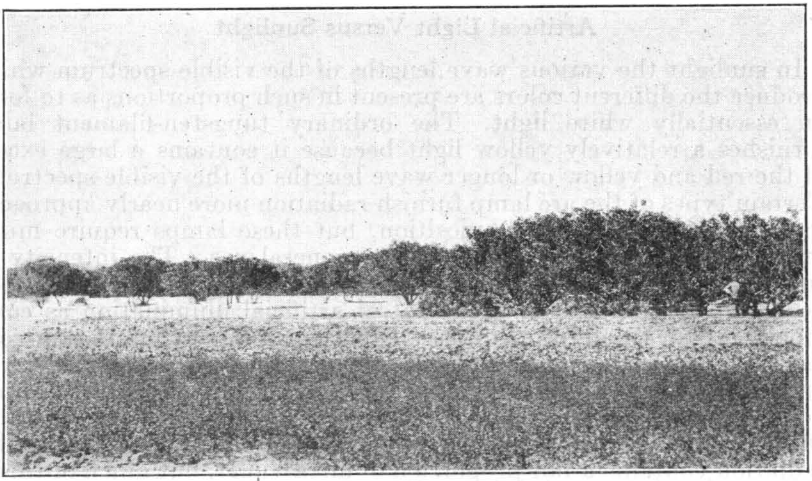

FIGURE 137.—Well-cared-for pistache orchard at Ardekan, Persia. Trees in the old orchard on the right are over 100 years old

was fertilizing, cultivating, and irrigating, the terminal growth was approximately five or six times as great, the percentage of split nuts was considerably higher, the crop was much larger, and the trees much healthier looking than in near-by orchards that received only average care. (Fig. 137.) Observations in Persia suggest that although the pistache will survive in some sections when given a minimum of care, it responds readily to good orchard management and that there is a correlation between tree growth and fruitfulness, just as there is in many other fruits.

Trials to date indicate that pistache trees will thrive in some sections of the United States, and when, after introduction and trial, it has been shown that with the better types of these nuts and good orchard management a product can be grown which appeals to the American consumer, there will be an opportunity for good fruit growers in these sections to develop the pistache industry.

Horticulturist, Bureau of Plant Industry.

PLANT Growth by Artificial Light Has Possibilities Green plants owe their characteristic color to the presence in their tissues of the complex pigment known as chlorophyll. With the aid of this pigment the leaves and other green parts of the plant, by utilizing a portion of the energy received from sunlight, are able to abstract the minute quantities of carbon dioxide present in the air and from it build up starch, sugar, and other organic substances. It is hardly possible to overestimate the importance of this process of photosynthesis, for without it all forms of life would cease to exist. Likewise, formation of flower and fruit, including of course the seed, is not only of the greatest importance to the plant itself in assuring its perpetuation but also may furnish highly valuable elements of nutrition for other forms of life. In these reproduction processes of the plant, light again plays an important rôle. The kind and the amount of illumination also affect plant growth in various other ways.

Artificial Light Versus Sunlight

In sunlight the various wave lengths of the visible spectrum which produce the different colors are present in such proportions as to form an essentially white light. The ordinary tungsten-filament lamp furnishes a relatively yellow light because it contains a large excess of the red and yellow or longer wave lengths of the visible spectrum. Certain types of the arc lamp furnish radiation more nearly approaching that of sunlight in composition, but these lamps require much attention and are hardly suitable for general use. The intensity of sunlight is quite variable, of course, but as a rule the daily average is very high in comparison with that of artificial illumination as commonly used. In addition to the visible portion, solar radiation contains a large component of longer wave lengths, the so-called infra-red or heat rays. The radiant energy from the tungsten-filament lamp, however, contains less than 15 per cent of the visible wave lengths, the remainder being mostly infra-red radiation. At high altitudes solar radiation contains a fair proportion of ultra-violet, but much of this is lost in the atmosphere before the sunlight reaches sea level. The tungsten-filament lamp supplies only a small component of the ultra-violet wave lengths lying immediately above the upper end of the visible spectrum. The quartz mercury-vapor lamp radiation is rich in ultra-violet and in certain bands in the violet and blue-green regions, but is deficient in the red wave lengths. The use of this lamp is attended with some danger. A type of lamp combining the essential features of the tungsten-filament and the mercury-vapor lamps has recently come on the market.

Although it appears that no single portion of the visible spectrum is essential for the growth of plants, differences in composition of the light may considerably affect the character of the growth. The longer red and yellow wave lengths promote photosynthesis, but if present in excess, as in the tungsten lamp, they tend to cause undue elongation of the stem, at least in some plants. The shorter wave lengths of the blue and violet region favor a more stocky type of growth. In many plants, however, the color or spectral composition of the light does not seem to have very striking effects on flowering and fruiting if other conditions are favorable. Ultra-violet radiation seems not to be essential for normal plant growth and so far as now known appears to be harmful when used in sufficient dosage to produce pronounced effects.

Effect of Relative Length of Day and Night

It has recently come to be recognized that change in length of day with season and with latitude may have profound effects on the seasonal behavior of plants and on their natural distribution. The effects of day length on flowering and fruiting are particularly striking. In some plants flowering and fruiting are induced by exposure to relatively long days, but in another large group of plants this form of development is favored by short days, while a third group is able to flower and fruit under a wide range in day length. In general, plants that normally flower in late spring or in summer respond best to long days and are known as long-day plants. (Fig. 138.) Conversely, plants normally flowering in the fall or winter respond to short days and are spoken of as short-day plants. With conditions otherwise favorable, short-day plants may be forced out of season by artificially shortening the daylight period. Thus poinsettia will readily flower in midsummer if the early morning or late afternoon light is excluded so that the plant receives only about 10 hours of illumination daily. Similarly, by using electric light to prolong the daily light period to 15 hours or longer, coneflower may be made to flower in midwinter in the greenhouse. (Fig. 139.) Many long-day plants may be thus forced during the short days of winter with artificial light of low intensity if the plants also receive the benefit of good natural illumination.

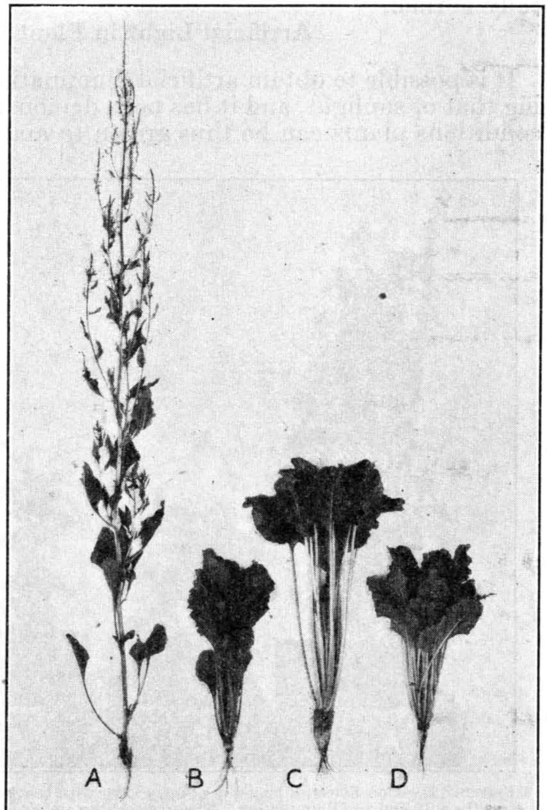

FIGURE 138.—Sugar beet, a long-day plant, grown in greenhouse. The treatments were: (A) Day artificially lengthened to 16 hours with electric light and cool temperature; (B) natural winter day and cool temperature; (C) artificially lengthened day and warm temperature; (D) natural winter day and warm temperature. The beet, usually biennial in habit, behaves as an annual when exposed to a very long day combined with a cool temperature

It is an interesting fact that reducing the daily illumination by darkening the plants for several hours in the middle of the day fails to induce flowering in short-day plants, and usually it also fails to retard flowering in the long-day type of plants. Moreover, by means of artificial light it has been found that short alternating periods of light and darkness ranging in length from six hours down to five seconds all affect long-day and short-day plants about the same as the midday darkening so far as concerns flowering and fruiting. However, as the alternations of light and darkness are progressively shortened the growth and general nutrition of the plant suffer to an increasing and surprising degree until the alternations have been reduced to about one minute. Curiously enough, as the alternations are further shortened the vigor and growth of the plant rapidly increase and with alternating periods of light and darkness of five seconds again become practically normal.

Artificial Light in Plant Culture

It is possible to obtain artificial illumination of intensities approaching that of sunlight, and it has been demonstrated that under suitable conditions plants can be thus grown to maturity with artificial light.

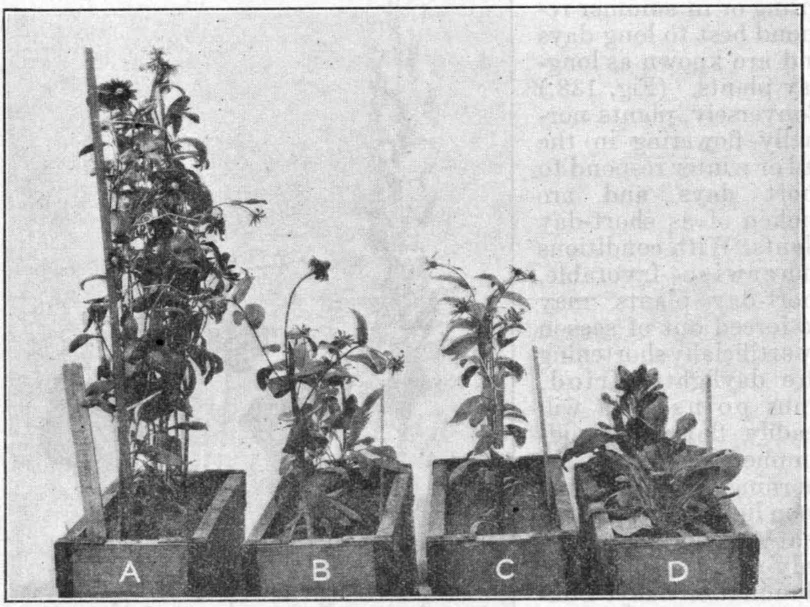

FIGURE 139.—Coneflower, a long-day plant, grown with continuous and intermittent electric light as the only source of illumination. The treatments were: (A) Continuous light; (B) 1-hour alternations of light and darkness; (C) 15-minute alternations; (D) 12-hour alternations. With 15 hours or more of uninterrupted light daily both the growth and flowering are normal; 12 hours of unbroken light give a stocky growth but delay flowering; while the very short light periods result in normal flowering but weak growth and symptoms of malnutrition

However, for reasons previously pointed out, such plants are not likely to be entirely normal in appearance, and from a practical standpoint the cost involved would be prohibitive. With further improvement in the efficiency of the electric light and in its composition, together with decreased cost of electric current, there may come a time when artificial light can be used to advantage in special cases for growing plants of relatively high value. There is at present special need of a type of lamp that will furnish illumination approximating sunlight in composition. By taking full advantage of sunlight there would seem to be possibilities in the practical use of artificial light to prolong the daily light period during the winter months for the purpose of forcing plants of the long-day type in the greenhouse. It is necessary, however, to give proper consideration to the specific requirements of the particular plant involved with respect to light, temperature, and other environmental factors.

Principal Physiologist, Bureau of Plant Industry.

POISONOUS-PLANT Study on Livestock Ranges Involves Many Problems

The early explorers found immense droves of bison grazing the Great Plains and the Rocky Mountains. Deer, elk, and antelope were countless over the entire western ranges. Forage was abundant when cattle, horses, and sheep began to utilize the range. Stock raising proved so profitable, however, that the range was soon overstocked. It was so overgrazed in places that much of the natural forage was destroyed. Vigorous native or introduced plants of little or no forage value, and also poisonous plants, multiplied in great numbers on trails and ranges. Sometimes range land was put under the plow and later abandoned. As a result, poisonous plants, such as whorled milkweek and other native weeds, as well as foreign weeds, increased greatly. Animals were trailed, bedded, or grazed on such ranges, and often ate the harmful plants. Study of the poisonous plants by the botanist, the chemist, and the animal experimenter became necessary.

Many discoveries about poisonous plants are made by stockmen. The botanist first consults stockmen who are known to give constant attention to the animals on their ranges and who know the plants eaten and the results. The botanist with a general knowledge of plants, and a particular knowledge of poisonous plants, should be able to judge most situations quickly. However, knowledge of poisonous plants is not yet so extensive that he does not need all the help obtainable.

Difficulties in Poison-Plant Study

Moreover, the botanist can not often be present where animals are sick and dying from poisonous plants. Often he receives word from the range after the animals are dead and the evidence of what they have been eating is destroyed. Usually, when plans are made to observe animals on a suspected area, none of the animals are sick. Cattlemen and horsemen are more apt to find cattle or horses dead than sick on the range, since they have much territory to cover. Sheep, from the nature of their handling on the range in bands under the constant care of their herders, are more easily found and the conditions accompanying the poisoning studied. It is of importance to both stockman and student that the symptoms of plant poisoning be known, since distinct species of poisonous plants may and often do produce different results. Knowing the symptoms, one can often detect the plant causing them, and suggest the remedy.

Most of the exact knowledge of the action of poisonous plants on animals is gained at the experiment stations. An examination of the stomach contents of a poisoned animal may reveal the harmful plant. More frequently it does not, because digestion has destroyed the identity of the plant. The chemist usually sends stomach specimens to the botanist for identification before making his analysis.

The far Western States have numberless mountains, valleys, plains, and plateaus with a diversified flora. The botanist sometimes finds give proper consideration to the specific requirements of the particular plant involved with respect to light, temperature, and other environmental factors.

W. W. GARNER,
Principal Physiologist, Bureau of Plant Industry.

POISONOUS-PLANT Study on Livestock Ranges Involves Many Problems

Knowing the symptoms, one can often detect the plant causing them, and suggest the remedy.

Most of the exact knowledge of the action of poisonous plants on animals is gained at the experiment stations. An examination of the stomach contents of a poisoned animal may reveal the harmful plant. More frequently it does not, because digestion has destroyed the identity of the plant. The chemist usually sends stomach specimens to the botanist for identification before making his analysis.

The far Western States have numberless mountains, valleys, plains, and plateaus with a diversified flora. The botanist sometimes finds areas having plants radically different from those seen elsewhere. Occasionally the plants are nearly all new to the botanist. Although this adds interest to the work, it increases its difficulty. Until recently the West has not been well supplied with local botanies and floras. This has often obliged the botanist to make a more general botanical study of a region. To identify properly a single species, sometimes the entire group of many species has to be studied and described.

More than 100 Poisonous Plants Studied

Yet the knowledge of poisonous plants as related to livestock is increasing. For more than 25 years the Department of Agriculture has maintained field experiment stations in the West for studying the action of poisonous plants on livestock. Chemists in the department have worked on poisonous-plant problems for a longer period. The State experiment stations also study these problems. Department botanists have inspected the mountains of 13 of the far Western States. This inspection extends eastward to the Black Hills of South Dakota and the mountains of western Texas. It includes nearly 80 national forests and hundreds of stock ranches.

More than 100 poisonous plants have been investigated in the United States west of the Mississippi River. Many plants that were suspected of being poisonous have been tested and found harmless. Among these poisonous plants are 5 species of death camas, 13 larkspurs, 28 of the pea family, 3 parsnips, 6 laurels (heaths), 11 of the true milkweeds, 2 tobaccos, and perhaps a score of the composite family. The pea family, which contains so many valuable forage plants, also produces a large proportion of the poisonous plants. It is the locos, belonging to the pea family, that have been studied the longest. The locos cover more territory and cause more damage to livestock than any other group of plants. The larkspurs are the main source of poisoning to cattle in the mountain areas. Species of death camas poison more sheep in the foothills of the mountain ranges than any other closely related group of plants. The death of many sheep is due to the lupines. The milkweeds also cause heavy losses.

The inspection of a "poison range" is a very different matter now from what it was 20 years ago. In 1911 a botanist was sent to inspect poisonous ranges in the Lassen and Plumas National Forests in northern California. Both larkspur and waterhemlock (known locally as "poison parsnip" or "wild parsnip") were believed to be causing the trouble. Neither of these plants, however, was found in the numerous areas inspected. No knowledge was gained of the plants actually causing the trouble on these forest ranges.

Fourteen years later another inspection of the Lassen and Plumas Forests was made. A certain large fenced pasture in the Plumas Forest where cattle are ranged during June and July contained great patches of *Lupinus caudatus*. Cattle began to die here early in July when the lupine was making seed. The manager suspected the lupine, removed his cattle from the pasture, and placed them on a range free from lupine. The deaths ceased. Pods of this species and also of *L. laxiflorus* variety *silvicola* were collected and sent to the Salina Experiment Station of the Bureau of Animal Industry, where both were found to be poisonous to cattle. The sick animals developed symptoms somewhat similar to those of larkspur poisoning. On "poison parsnip" areas, Mexican whorled milkweed was plentiful. This plant was without much doubt responsible for the deaths which the stockmen had thought were caused by "wild parsnip."

Up to 1925, much feeding of other lupine species had been done without positive results, except in the case of the northwestern species, *Lupinus leucophyllus*, which had been proved to be poisonous to sheep. Evidence is accumulating that other lupine species of California, Oregon, and Washington are poisonous. Many such problems still need solution.

Assistant Botanist, Bureau of Plant Industry.

POP CORN Selecting for Added Popping Expansion Would Pay Large Growers

The value of pop corn as human food depends to a very large extent on its quality. One of the important factors in determining quality is popping expansion. This is measured commercially as the ratio of volume of the popped corn to that of the unpopped corn. For example, a sample with 20 volumes popping expansion is one in which 1 cupful of corn will pop out to 20 cupfuls. The satisfaction of the home consumer of pop corn and the profits of the vendor depend to a considerable extent on this popping expansion.

It has long been recognized that bulk samples of different varieties from different localities, and even from different individual growers in the same locality, will vary considerably in popping expansion. It is not so generally known, however, that within a variety grown under uniform conditions some ears will give markedly greater expansion on popping than will other ears of very similar external appearance. Repeated trials have shown that if a large number of ears from a uniform field are popped individually, by far the greater proportion will have a popping expansion similar to the average of the field, while a few will pop very poorly and a few will pop extremely well.

Some of the excellence of the few outstanding ears may be due to environmental advantages of the parent plants, but some undoubtedly is due also to inherited differences which can be passed along to future crops. Heritable variation is the basis of improvement by selection in plants and animals. The Bureau of Plant Industry of the United States Department of Agriculture, cooperating with the Kansas Agricultural Experiment Station, has demonstrated during the past seven years the feasibility of improving the popping expansion of a strain of pop corn by continuous selection of seed ears on the basis of individual popping tests. As a result of this investigation, an improved strain of yellow pearl pop corn, christened Sunburst, has been produced.

Figure 140 shows a comparison of the popping expansion of Sunburst and unselected Queen Golden, representative of the material from which Sunburst was selected, grown in the same field. The average popping expansion was raised considerably by selection, being 26.1 volumes for Sunburst and 19.3 volumes for Queen Golden. The ears of Sunburst also were less variable in popping expansion than Queen Golden. The occasional very poor ear frequently found in unselected sorts has been practically eliminated from Sunburst.

The average popping expansion was raised considerably by selection, being 26.1 volumes for Sunburst and 19.3 volumes for Queen Golden. The ears of Sunburst also were less variable in popping expansion than Queen Golden. The occasional very poor ear frequently found in unselected sorts has been practically eliminated from Sunburst.

Testing Individual Ears

The method used to make the individual ear tests is simple. Certain details, however, must be strictly followed to obtain comparable results. The ears must all be of the same moisture content when popped. Uniformity may be attained by storing in a cool protected place and by not bringing the unpopped ears into a heated room until immediately before popping. In the northern portions of the country where corn does not reach good popping condition until spring, some artificial drying may be necessary to make satisfactory popping tests before planting time. The source of heat for popping must be constant, and distance from the heat source must be arranged so that all samples may be popped under uniform conditions. Two glass graduates, one small and one large, both calibrated in cubic centimeters, make convenient measures for determining expansion. (Fig. 140.) One man can test from 60 to 75 ears per day.

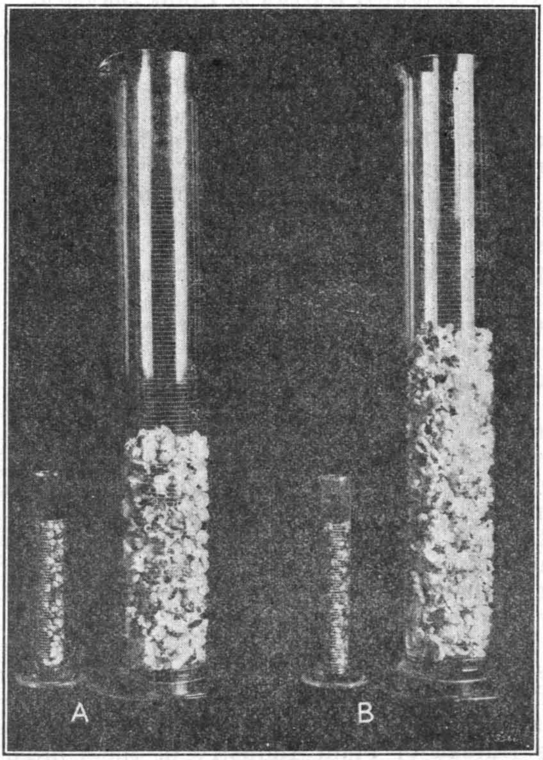

FIGURE 140.—The equipment used in measuring expansion. The two graduates (A) show the relative expansion of Queen Golden and the other two (B) of Sunburst pop corn

Both mass selection and ear-to-row methods have been used in selecting pop corn with almost equally favorable results. Mass selection is preferred because of its simplicity. In this method the remnants of all selected ears are bulked together for seed. The following fall, ears of the new crop are picked for testing from any portion of the field which is well isolated from other corn. As an indication of the amount of labor involved, something over 1,000 ears have been popped individually each winter in the mass-selection experiment previously noted, the best 5 to 10 per cent of these being saved for seed. Since less than half of each ear is needed for the popping test, a generous seed remnant is available for planting.

Ears vary not only in popping expansion but also in tenderness and flavor. Fortunately, there is a high correlation between tenderness and high popping expansion, so that in selecting for expansion one is likely to obtain ears of better than average tenderness. The best insurance is to taste each popped sample after measuring so that the occasional ear having a tough hull or woody texture may be discarded. Almost equally important with texture is flavor. Most people prefer a slightly sweetish corn with a pronounced, characteristic pop-corn taste. The product from some ears is woody and tasteless and from other ears is actually bitter. If there has been recent opportunity for crossing with dent corn, it is likely that some ears having a distinct field-corn flavor will be found. All ears with undesirable texture or flavor should be discarded, irrespective of popping volume.

This method of improvement can be utilized by the grower to improve his pop corn. The small grower who has no permanent demand for a quality product probably can not afford the time and effort, but the large grower can well afford to spend the necessary time during the winter to select some good ears for a seed plot. To an even greater extent, seed houses and companies that contract for large acreages of pop corn each year would find pop-corn improvement a paying investment. As the public becomes more discriminating the premium for high quality in pop corn should increase.

Agronomist, Bureau of Plant Industry.

POTASH Extraction from Domestic Sources Has Great Possibilities For years the potash situation in the United States has been highly unsatisfactory owing to our dependence on foreign sources and an ever increasing use of concentrated fertilizers, which require large quantities of high-grade potassium salts. In spite of the encouraging growth of the American potash industry, the yearly importation of potash still requires an expenditure of more than $23,000,000. Research on the further utilization of domestic sources of potash is being carried on by the Bureau of Chemistry and Soils and substantial progress has been made this last year. Particular stress is being laid on the leucitic rock of Wyoming, the alunite of Utah, the potash shales of Georgia, and the greensand of New Jersey.

Leucite

In Wyoming are found enormous deposits of leucite (Wyomingite), constituting potash reserves of immense size. In the same region are found plentiful supplies of high-grade phosphate rock, cheap fuels, and other raw materials representing an unusual combination of resources for fertilizer manufacture. This situation is of great interest and based on these conditions notable progress has been made in the development of chemical processes yielding products susceptible of widest distribution. With the idea of utilizing possible by-products the extraction of potash from leucite by oxides of nitrogen and various industrial acids is being studied. Another method of particular interest due to its simplicity is the volatilization of potash from leucite by smelting with special reagents and subsequent recovery of the potash in a concentrated form. Preliminary results show this method is feasible especially when carried out simultaneously with the volatilization of phosphoric acid. These materials can then be combined to form a highly concentrated fertilizer salt, potassium phosphate, which will greatly reduce distribution costs, thus opening up a much wider occasional ear having a tough hull or woody texture may be discarded. Almost equally important with texture is flavor. Most people prefer a slightly sweetish corn with a pronounced, characteristic pop-corn taste. The product from some ears is woody and tasteless and from other ears is actually bitter. If there has been recent opportunity for crossing with dent corn, it is likely that some ears having a distinct field-corn flavor will be found. All ears with undesirable texture or flavor should be discarded, irrespective of popping volume.

This method of improvement can be utilized by the grower to improve his pop corn. In spite of the encouraging growth of the American potash industry, the yearly importation of potash still requires an expenditure of more than $23,000,000. Research on the further utilization of domestic sources of potash is being carried on by the Bureau of Chemistry and Soils and substantial progress has been made this last year. Particular stress is being laid on the leucitic rock of Wyoming, the alunite of Utah, the potash shales of Georgia, and the greensand of New Jersey.

Leucite

In Wyoming are found enormous deposits of leucite (Wyomingite), constituting potash reserves of immense size. In the same region are found plentiful supplies of high-grade phosphate rock, cheap fuels, and other raw materials representing an unusual combination of resources for fertilizer manufacture. This situation is of great interest and based on these conditions notable progress has been made in the development of chemical processes yielding products susceptible of widest distribution. With the idea of utilizing possible by-products the extraction of potash from leucite by oxides of nitrogen and various industrial acids is being studied. Another method of particular interest due to its simplicity is the volatilization of potash from leucite by smelting with special reagents and subsequent recovery of the potash in a concentrated form. Preliminary results show this method is feasible especially when carried out simultaneously with the volatilization of phosphoric acid. These materials can then be combined to form a highly concentrated fertilizer salt, potassium phosphate, which will greatly reduce distribution costs, thus opening up a much wider market for fertilizers manufactured in this section. With these new advantages and, in addition, an abundant supply of cheap fuel an industrial chemical development is very probable in which the Middle West would be supplied with a totally adequate and accessible supply of fertilizer ingredients.

Alunite

The Middle West is well supplied with another mineral, alunite, which has a promising future as a raw material for potash and alumina manufacture. Up to the present the processes employed have not been economical because of the inadequacy of the alumina recovery and because the portion recovered has been in too impure a form to enable it to enter the select market. To eliminate silica, one of the most objectionable impurities, a process is proposed in which alunite is heated with hydrofluoric acid, whereby the silica is volatilized. Further work is in progress on the elimination of iron as well as the improvement of methods with a view of simplifying plant equipment and reducing losses. Such improvements will make possible the use of lower grade alunite than has been used in past operations with a view to increasing the latent potash resources of this raw material.

Polyhalite

At the request of the Bureau of Mines work has been carried out and completed on the ammonium carbonate—ammonia extraction of polyhalite, a Texas saline mineral. The results clearly indicate the commercial possibility of such a procedure with the almost complete separation of the potash, as sulphate, from both the associated calcium and magnesium compounds. At the same time a further economy is obtained through the formation of ammonium sulphate from the sulphuric acid of the polyhalite and the ammonia in the leaching solution. The formation of these two concentrated fertilizer salts greatly reduces the cost of shipping the finished product to the remote fertilizer markets.

Greensand and Georgia Shales

In addition to these raw materials great interest is attached to both the potash-bearing greensands of New Jersey and the shales of Georgia because of their proximity to the great fertilizer markets of the East and Southeast. Being comparable to the Wyoming leucites these materials are being studied along analogous lines. However, from an economical view each raw material is an individual problem and must be studied as such. In the case of greensand, which may be considered a low-grade iron ore, smelting processes lend themselves advantageously to the volatilization of the potash and the recovery of pig iron as a by-product. Perfection of such a procedure will be applicable to the recovery of the potash which is now volatilized and lost in the iron industry. Other commercial chemicals are recovered as by-products in the manufacture of potash by acid-extraction methods, especially glaucosil, an active silica, for which there is a great number of uses.

Associate Chemist, Bureau of Chemistry and Soils.

POULTRY in Commercial Flocks Increasing in Relative Importance

Poultry keeping is an ancient calling, the beginnings of which antedate history. The imagination pictures children and tender-hearted women of primitive races keeping young or wounded birds for pets, and men with less unselfish concern keeping captured live birds as a reserve food supply. The Romans raised geese and the Greeks captured wild ducks to establish duckeries in the early history of those peoples. The poultry industry in China is very old, tradition pointing to beginnings as early as 1400 B. C. References to the lordly sport of cockfighting are incorporated in the code of the great Indian lawgiver, Manu, dating back probably a thousand years before the Christian Era. The early Hebrews had doves, which were used in sacrifice, and the Egyptians raised geese abundantly. In America the Maya Indians of Mexico and Central America were keeping large numbers of turkeys when Europeans reached this hemisphere.

The domestic breeds of chickens seem to be closely related to certain wild types of jungle birds in southeastern Asia. Chickens were introduced a few centuries before the Christian Era into western Asia and Europe from the farther east. According to Caesar they had already been introduced into Britain in 55 B. C.

The great diversity of types of chickens in different countries suggests the probability both of a varied origin and that man has from remote times tried to produce better types by mating superior birds. Practically no record remains of the efforts of the early breeders, even within comparatively recent historic times, but we have the results of their labors.

Chickens were brought to this country by the early colonists and became a feature of American country and small-town life. The abundance of game and of other meats, and the seasonal character of egg laying, interfered with the maximum usefulness of eggs as food. At the time of heavy spring layings, eggs were eaten very freely, with a relish induced by enforced abstinence during the period of scanty layings in the late fall and early winter. Attempts were made to preserve the surplus eggs by cold, or by dipping them in preparations designed to furnish a protective coating. These methods were only partially successful. Many eggs were lost and a large proportion of the preserved surplus had to be used in cooking and baking where their lack of freshness was not so evident, or else disposed of for other purposes, such as tanning.

Cold Storage Opens New Era

The development of cold storage opened the modern era for poultry. When it became possible to keep eggs from the spring surplus to the time of shortage in the fall and early winter and supply them to the market then comparatively fresh, consumption enormously increased.

The actual numbers of poultry in this country prior to 1880 are unknown. Beginning in that year the decennial census furnished reports of numbers. After adjustments for the differences in the time of year when the census was taken and for variations in the forms of questions used, the reports show for the most important class, chickens, approximately the following numbers:

Year	Number of chickens	Year	Number of chickens
Jan. 1, 1880	141, 000, 000	Jan. 1, 1910	322, 000, 000
Jan. 1, 1890	195, 000, 000	Jan. 1, 1920	360, 000, 000
Jan. 1, 1900	260, 000, 000	Jan. 1, 1925	409, 000, 000

Beginning with 1920, the United States Department of Agriculture has estimated comparative numbers of chickens on farms as of January 1, as follows:

Year	Number	Year	Number
1920	359, 537, 000	1926	424, 227, 000
1921	356, 168, 000	1927	448, 665, 000
1922	396, 507, 000	1928	463, 364, 000
1923	411, 469, 000	1929	444, 481, 000
1924	449, 188, 000	1930	469, 457, 000
1925 [a]	417, 755, 000		

The poultry industry has developed largely as a side line to farming and such it continues to be, in the main. With some protection and relatively little care, given mostly by women, poultry on farms are largely self-sustaining during a considerable part of the year. The birds gain much of their living by gleaning grain and seeds that would otherwise be lost, and from insects. But with the constantly growing demand for eggs, their production on a commercial scale has become increasingly important.

What proportion of the total number of chickens in the country is held in commercial flocks is unknown. But in 1925 flocks of 450 birds or over in two counties in California contained 36 per cent of the total number of chickens in the State. Somewhat similar conditions exist in sections of Washington, New York, New Jersey, and a number of other States. In the north-central group of States, however, which has about half of the chickens in the country, the proportion in commercial flocks has been insignificant. But during the last few years the increase in commercial flocks in these States seems to have been very rapid. The proportion of birds in commercial flocks, of from 400 to 999 birds, to the number in farm flocks of less than 400, as reported by about 20,000 crop correspondents, has been as follows: 1925, 9.86 per cent; 1926, 11.08 per cent; 1927, 12.78 per cent; 1928, 13.39 per cent; 1929, 14.7 per cent; 1930, 16.36 per cent.

The apparent increase has been to some extent due to the tendency of commercial producers to report to the department for their flocks in order that they may obtain the department's monthly reports in return. This has tended to increase the proportion of returns from large flocks; but even allowing for this, the figures indicate a marked increase in the relative importance of commercial flocks in egg production.

Estimates Based on Census Reports

Figures on the production of chickens were not collected by the Bureau of the Census until 1909 and the numbers reported to the enumerators for 1919 and 1924 are probably short of the true number. The numbers raised and the net production, after allowing for replacement of birds lost on the farm, have been estimated by this department for the last six years. The census figures and this department's estimates are given in Table 13.

[a] Including a conservative allowance for census omissions.

TABLE 13.—*Chickens raised in 1909, 1919, and 1924–1929 and net production 1924–1929*

Year	Report of Census	Estimates of Department of Agriculture	
	Number raised	Number raised	Number raised, less mature birds lost, or net production
1909	460,611,000		
1919	473,201,000		
1924 [1]	545,848,000	600,768,000	546,869,000
1925		622,321,000	572,193,000
1926		657,788,000	606,885,000
1927		691,680,000	637,837,000
1928		634,260,000	578,656,000
1929		697,548,000	644,210,000

[1] Estimate allows for understatements to enumerators.

Mortality of Chickens

The annual mortality from disease, vermin, accidents, exposure, etc., is, according to the judgment of crop correspondents for their localities, about 10 per cent of the grown chickens on hand January 1, and about 26 per cent of the chickens hatched during the current season. The mortality in different sections seems to be quite uniform, the percentages for the different geographic grand divisions being as follows, for mature and young birds, respectively: North Atlantic, 8.8 and 21.3; North Central, 9.7 and 26.7; South Atlantic, 9.6 and 25.5; South Central, 9.8 and 28.2; Western, 9.8 and 19.2; United States, 9.7 and 25.8.

Judging from the records available for commercial flocks, the mortality in these, in spite of the better care received, seems to be fully as great as among farm flocks. This fact is probably due to the greater liability of chickens to disease when large numbers are kept in restricted quarters; and sometimes to the breakdown of layers from intensive feeding for heavy egg production.

Cycle in Poultry Numbers

For the different classes of livestock there are fairly definite cycles of years of increase and decrease in numbers varying with the time required for the animal to mature and with the time required for producers to adjust their plans and operations to an increase or decrease in production. The length of the cycle of increase and decrease in numbers of poultry seems to be similar to the cycle for swine; in both cases numbers can be rapidly increased by heavy breeding or decreased by early and heavy marketing, within a single season. Beginning with 1920 the department's estimates show a peak in numbers of chickens held on farms on January 1 in 1924 and again in 1928. On January 1, 1929 and 1930, numbers showed renewed increase, and heavy early hatchings in 1930 pointed to further increase on January 1, 1931. The exceptional conditions and low prices of 1930 however led to a rapid disappearance of chickens by sale and by farm consumption, and resulted in a small decrease in numbers for January 1, 1931. The high points of the cycle evidently tend to recur every three or four years, with a more or less sharp recession in numbers the following year and a renewed trend of increase continued through two or three years to the next peak. While it is possible greatly to increase or decrease the number of chickens in a single year, the decision of the producers as to extent of change is usually the outgrowth of the experience of the preceding two or three years, so that actual changes for the industry as a whole are less rapid than would be the case if all producers were inclined and able to readjust radically their plans each year.

The adjusted census figures on numbers per person, of chickens on hand and of eggs produced on farms in the United States, are as follows for the different census years: 1880, 2.82 chickens and 9.14 dozens of eggs; 1890, 3.10 and 13.02; 1900, 3.42 and 17.03; 1910, 3.50 and 18; 1920, 3.50 and 18.28; 1925, 3.56 and 19.63. These figures show the per capita supply of poultry products to have been increasing quite markedly up to 1900. Since that period increase in chickens per person has been rather slight and increase in the supply of eggs per person much less marked than previously, though still material.

The marked decrease observed over a period of years in the average quantity of meat consumed per person in the United States seems not to have taken place with chickens or eggs, particularly not with the latter. Possibly the loss, if any, by people turning from poultry products to vegetables may be offset by gains from those turning from meats to poultry and eggs.

Relative Numbers of Different Breeding

The heavy dual purpose types of chickens, such as the Plymouth Rock and Rhode Island Red, both of which were developed in this country, have been favored for farm flocks in most sections, while the commercial egg producers have used the small-bodied, heavy-laying types—mainly Leghorns. No definite figures on the proportion of the different kinds have been available until recently. In 1929 an inquiry to the crop correspondents of the Department of Agriculture developed the following information concerning the proportions of the leading types: 42 per cent of the birds of the country are of lightweight breeding; Leghorns alone are 35 per cent; approximately 42 per cent also are of heavyweight breeding, 17 per cent each being Plymouth Rocks and Rhode Island Reds, and 8 per cent of other heavyweight breeding; 16 per cent are of mixed breeding. The Pacific Coast States have the highest proportion of Leghorn breeding, 68 per cent; the Middle Atlantic States have 52 per cent. The lowest proportion of Leghorns, 26 per cent, is shown by the Southeastern States. Of the heavy breeds, the East North Central States show 22 per cent of Plymouth Rocks and the Southeastern States 21 per cent. The lowest proportion of Plymouth Rocks is in the Pacific Coast States which show only 7 per cent. The Rhode Island Reds constitute 50 per cent of the chickens of New England, 20 per cent in the Southeastern and Rocky Mountain States, and about 18 per cent in the West North Central and the South Central States. The Southern States show the highest proportion of mixed breeding, 22 per cent, other groups showing 15 per cent or less.

Commercial Hatching

Along with the increase in commercial production of eggs has been an even more rapid increase in commercial hatching of chicks. An inquiry to crop correspondents in 1929 showed the proportion of chickens hatched by different means as follows: Under hens, 42.9 per cent; in incubators on farm where raised, 24.2 per cent; custom hatched (for a fee, from eggs supplied by the grower), 9.6 per cent; bought as baby chicks, 23.4 per cent. The practice is quite different in the different geographical sections. In the South about two-thirds of the chicks are still hatched under hens, but in the Northeast only 26 per cent. In farm incubators, 31 per cent are hatched in the North Central States, and down to 13 per cent in the Southeast. Eleven per cent are custom hatched in the Northeast and North Central States and about 7 per cent elsewhere. Purchased baby chicks comprise 45 per cent in the Northeast, 41 per cent in the West, 25 per cent in the North Central group, 12 per cent in the Southeast and only 9 per cent in the South Central States.

Production of Eggs

The production of eggs in the United States as reported in the successive census returns since 1879 and as estimated by the Department of Agriculture since 1925 is shown below. The census figures for the last three census enumerations are adjusted by a judgment allowance to care for the evident understatement by producers due to changes in the time of the year when the enumerations were made.

TABLE 14.—*Production of eggs in stated years*

Year	United States census	Estimates, United States Department of Agriculture	Year	United States census	Estimates, United States Department of Agriculture
	Number	*Number*		*Number*	*Number*
1879	4,845,000,000		1925		28,504,000,000
1889	9,840,000,000		1926		30,555,000,000
1899	15,528,000,000		1927		32,000,000,000
1909	[1] 19,872,000,000		1928		32,120,000,000
1919	[1] 23,256,000,000		1929		31,741,000,000
1924	[1] 27,096,000,000				

[1] Adjusted.

Poultry and egg production on a commercial scale, with flocks of a thousand or more birds, requires a man's entire attention. Most of these poultrymen buy their feeds. The extent to which efficient management of large flocks compensates the poultryman for buying rather than raising feed, is one measure of the success of a commercial poultry producer. The financial success of egg production under efficient management on a commercial scale is demonstrated by the very evident, though as yet unmeasured, increase in this branch of the industry. Whether the exceptionally favorable conditions of certain localities for commercial egg production will lead to a still greater proportion of the eggs being produced in such sections is still to be seen. The very rapid increase during the last year or two of commercial poultry flocks in the North Central States and in portions of the South, as well as in some Rocky Mountain States, may, if continued, result in holding present proportions in the different geographic sections reasonably constant.

Bureau of Agricultural Economics.*

POULTRY Profits Are Largely Dependent on High Egg Production Variable factors affect the returns from a poultry enterprise. Among these are prices of feeds and poultry products, the size of the project, efficiency of management, diversification of the business, and productiveness of the stock. As the major portion of income is derived from eggs, with meat as a supplementary source of revenue, the importance of high egg yield is obvious. About 60 per cent of the total income from poultry products on the average farm is obtained from eggs, while 40 per cent comes from poultry meat. Farms in Missouri and Ohio, carrying general-purpose fowls, show 70 per cent of the receipts coming from the egg crop. Commercial poultry farms in New Jersey and California obtain an even larger percentage of income from eggs, totaling from 85 to 90 per cent.

Information from various sources on factors influencing poultry profits indicates that high average egg production is most important.

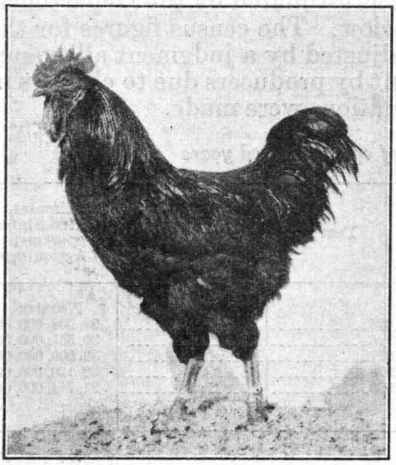

FIGURE 141.—A Rhode Island Red cockerel with high-class "relatives." His dam laid 248 eggs in one year. The average production of his 10 sisters ranged from 210 to 301 eggs, with an average of 244

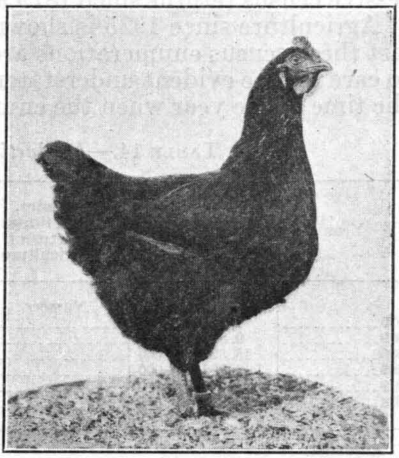

FIGURE 142.—This Rhode Island Red ranks high in both numbers of eggs and size of eggs. In one year she laid 274 eggs, averaging 27 ounces to the dozen

Studies at the Massachusetts Experiment Station showed that each additional dozen eggs per bird increased the labor income by 35 cents in 1926 and 1927. One dollar more per bird was made with flocks averaging 154 eggs than with flocks laying 120 eggs; also average egg production per bird was the most important factor influencing profits per bird. Figures from Ohio (1926) show that owners of flocks producing 180 or more eggs per year incurred expenses of $2.51 per bird more than owners of flocks of less than 100-egg production. But the high-producing group returned $4.83 more in cash receipts than the low-producing group. Statistical studies at the University of California indicated an increase of 153 per cent in net profits between two groups of layers, one producing 122 eggs per annum and the other 163 eggs. Such an increase is much greater in proportion than the 33.6 per cent in average number of eggs produced per hen. In other words, as production increases income over feed cost rises more rapidly.

Importance of Breeding Demonstrated

The average egg production of the flock can be increased by proper feeding, rigid culling, and good breeding. Direct evidence as to the importance of breeding is supplied from Cornell University in a comparison of results from their high and low line White Leghorns. The high-producing family averaged about 180 eggs, while the other averaged 120 eggs. A 5-year average value of eggs produced by the high line was 60 per cent greater than the low line and resulted in a much greater percentage of return over feed costs, approximating $2 per hen. The cost of feeding the high line was somewhat greater, but the difference was so slight that the increased production was obtained at relatively less cost per dozen. More recent results have made even a more favorable comparison.

Lateness of maturity seems to be characteristic of poor producers. Late-maturing birds are generally inferior to early-maturing birds. At the United States Animal Husbandry Experiment Farm, Beltsville, Md., in 1927–28, the average production of Leghorn pullets in early maturing families totaled 224 eggs for those beginning in September and 226 eggs for October pullets, compared with an average production of 86 eggs for pullets beginning to lay in January. Rhode Island Red pullets, beginning to lay in October and November, averaged 205 and 201 eggs, respectively, while the January pullets averaged 133 eggs. In 1928–29 Leghorn pullets starting to lay in September and October averaged 211 and 196 eggs, respectively, while the January pullets averaged 131 eggs. In 1928–29 the Rhode Island Reds beginning to lay in September and October averaged 212 and 209 eggs, respectively, while the January birds averaged 161 eggs.

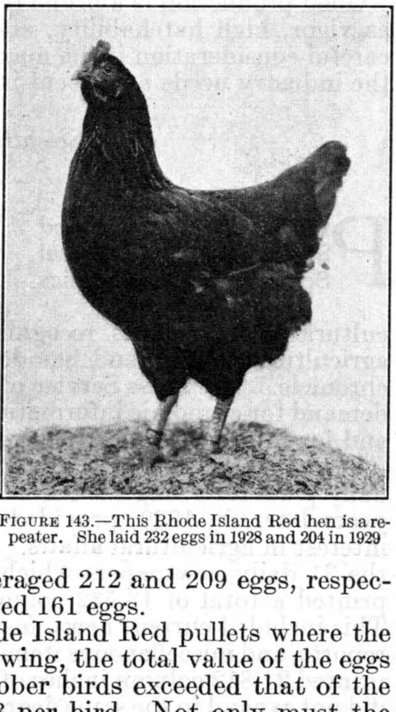

FIGURE 143.—This Rhode Island Red hen is a repeater. She laid 232 eggs in 1928 and 204 in 1929

Taking the last two groups of Rhode Island Red pullets where the January birds have made the best showing, the total value of the eggs produced by the early maturing October birds exceeded that of the later maturing group by about $2.28 per bird. Not only must the higher-producing group be given credit for greater value of their total production but also for greater value per dozen, as 22 per cent of the eggs were laid in October, November, and December. New York prices of "average extra near-by" eggs were 57 cents per dozen during these months as against 41 cents for the January-September period. Feed cost for the October pullets was only about 18 cents more per bird.

Method for Improving Production

Since increased production is the most practical way to greater profits the fundamental importance of improving egg-laying ability can readily be seen. The job of improving production quality can not be accomplished by hit-or-miss methods. Methodical year-round trap nesting and progeny testing are essential steps in breeding work. Study of trap-nest records discloses five essential factors in breeding for increased efficiency:

1. Early maturity.
2. Steady winter laying.
3. High rate or intensity of production.
4. Elimination of broodiness.
5. Persistency of production.

Only the larger producers of market eggs or those engaged in the production and sale of breeding stock may be in a position to trap nest. The average farmer or poultryman may find it more expedient and economical to purchase stock or eggs from reliable breeders. The important point is that bred-to-lay stock, whether purchased or produced at home, is essential for greatest opportunity for profit.

Good production is a prime requisite. Other desirable factors, such as vigor, high hatchability, and large egg size, should also receive careful consideration if the maximum profit is to be obtained. What the industry needs at present is not more poultry but better poultry.

PRESS Giving Increased Space to Agricultural Science and Economics Daily newspapers recently have devoted far more attention to news of agriculture than they formerly did. The press, confronted with an urgent agricultural problem, has recognized its responsibility in interpreting agricultural affairs, and has devoted more space to the agricultural chronicle. The Press Service of the department has had an increasing demand for economic information, for news of scientific developments, and for information on better methods of farming.

The Press Service, in comparing a representative sample of the daily press for a single week in 1919 and the corresponding period 10 years later, in 1929, provided statistical evidence of this increased interest in agricultural affairs. In the last seven days of June, 1919, the 31 daily newspapers which formed the basis for the comparison printed a total of 13,532 column inches of agricultural information. This included current news, feature articles, editorial opinion, market reports, and miscellaneous items. In the week in 1929 the same papers printed 21,812 column inches of similar material. The market reports did not expand to the same degree as other classifications, but increased 39 per cent in space occupied. The total of the other classifications increased 85 per cent, and the current news of agriculture in these dailies increased nearly 90 per cent.

One metropolitan newspaper in an eastern city—a paper which is generally regarded by newspapermen as one of the leaders in its field—showed a greater increase in its agricultural matter than any other paper surveyed. In 1919 the paper printed 231 column inches of agricultural matter, of which 147 inches were market reports. This was one of the smallest totals in the list. In 1929 the same daily printed 1,079 column inches or more than 4.5 times as much as in 1919 and stood near the head of the list. In the 1919 week it printed 84 inches of agricultural news. In the 1929 week this classification for the week be accomplished by hit-or-miss methods. Methodical year-round trap nesting and progeny testing are essential steps in breeding work. Study of trap-nest records discloses five essential factors in breeding for increased efficiency:

1. Early maturity.
2. Steady winter laying.
3. High rate or intensity of production.
4. Elimination of broodiness.
5. Persistency of production.

RANGE Surveys Help Livestock Industry and Conserve Forage Growth When the administration of the western national forests was undertaken by the Forest Service great numbers of cattle, sheep, and horses grazed unrestricted on these areas. In many cases the more desirable and accessible ranges had been seriously damaged and the forage depleted through overgrazing. The more inaccessible range on the other hand remained unused.

In order to manage these grazing lands properly, some method had to be devised to determine how much forage was available on the various areas, what plants furnished the most and best feed, how much forage a cow or a sheep required in a given time, and what forms of management were necessary to maintain the forage crop so that the greatest amount of beef or mutton could be turned off. To meet these needs the present method of conducting range surveys has gradually been developed by the Forest Service.

Large numbers of stockmen and ranchers are affected by the results of good or poor management of the ranges. Depleted areas not only fail to provide good feed for large numbers of stock, but the lack of sheltering, soil-binding plants allows the soil to wash away. The danger of floods is increased, and during the dry season springs and streams may dry up because the water runs off rapidly and is not stored in the ground. The object of a range survey is to collect the information needed to formulate plans for the best correlated use of grazing, watershed, and other resources.

Making a Range Survey

The work is usually done by crews of specially trained men. The range is mapped to show the location and acreages of the various types of forage, and the location of high ridges, canyons, watering places, and similar features of the range which influence grazing. The amount and kind of forage on all portions of the range are recorded. Each stockman operating on the area may then be allotted feed in proportion to the number of animals which he grazes and the stock can be distributed according to the amount of forage found on various parts of the range. (Fig. 144.)

Through pasture tests, as well as experiments on portions of the range itself, the amount of forage required for cattle or sheep is determined.

RANGE Surveys Help Livestock Industry and Conserve Forage Growth When the administration of the western national forests was undertaken by the Forest Service great numbers of cattle, sheep, and horses grazed unrestricted on these areas. In many cases the more desirable and accessible ranges had been seriously damaged and the forage depleted through overgrazing. The more inaccessible range on the other hand remained unused.

In order to manage these grazing lands properly, some method had to be devised to determine how much forage was available on the various areas, what plants furnished the most and best feed, how much forage a cow or a sheep required in a given time, and what forms of management were necessary to maintain the forage crop so that the greatest amount of beef or mutton could be turned off. To meet these needs the present method of conducting range surveys has gradually been developed by the Forest Service.

Large numbers of stockmen and ranchers are affected by the results of good or poor management of the ranges. Depleted areas not only fail to provide good feed for large numbers of stock, but the lack of sheltering, soil-binding plants allows the soil to wash away. The danger of floods is increased, and during the dry season springs and streams may dry up because the water runs off rapidly and is not stored in the ground. The object of a range survey is to collect the information needed to formulate plans for the best correlated use of grazing, watershed, and other resources.

Making a Range Survey

The work is usually done by crews of specially trained men. The range is mapped to show the location and acreages of the various types of forage, and the location of high ridges, canyons, watering places, and similar features of the range which influence grazing. The amount and kind of forage on all portions of the range are recorded. Each stockman operating on the area may then be allotted feed in proportion to the number of animals which he grazes and the stock can be distributed according to the amount of forage found on various parts of the range. (Fig. 144.)

Through pasture tests, as well as experiments on portions of the range itself, the amount of forage required for cattle or sheep is determined.

The results may be applied to any similar range on which the amount of available feed is known. The numbers of stock or length of season may then be adjusted so that the range is used fully and properly.

Turning out stock too soon after growth first begins is responsible for much range deterioration. During the early spring plants are easily damaged by grazing, and if this practice is continued the valuable forage is eventually thinned out or destroyed. Range-survey methods are used to determine the dates when each portion of the range is ready for use during an average season, and the stock may then be placed on each unit when it is ready to be grazed. Frequently stock may be turned on one portion of the range early and other parts may be allowed to rest. The following year another area may be used first, so that each part of the range will have a complete rest during the principal growing period at least every few years.

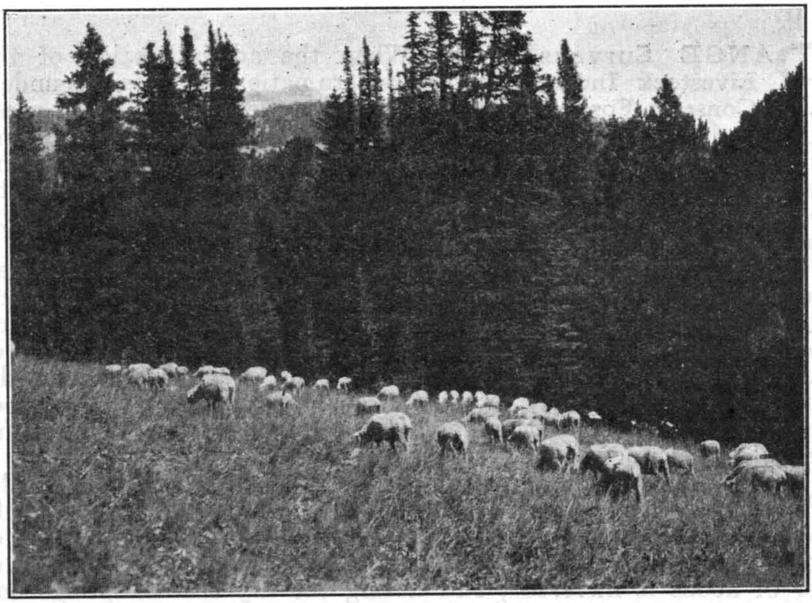

FIGURE 144.—Sheep grazing on the Jefferson National Forest, Mont.

Salting Aids Proper Distribution

After the various natural divisions of each range are determined and the amount of feed within each is known, it is possible to work out a plan of distribution so that all parts of the range may be grazed to the same degree. Such a plan is greatly aided by refinements in actual practices of handling stock. Well distributed salt will do much toward keeping cattle scattered over the area and also toward drawing them to those portions of the range where use is ordinarily light. The salt grounds are usually located on ridges and in parks away from water so that cattle will feed off these areas as well as graze the range between water and salt. Range damage due to stock congregating along creeks and springs is largely eliminated and frequently, with proper salting, the range is capable of carrying larger numbers of stock with less accompanying damage. By knowing the amount of available forage which each portion of the range supports, a definite plan can be drawn up showing how many cattle are to be located in each drainage or pocket and the needed amount and location of salt. (Fig. 145.)

On sheep range, the old method of trailing the band back to a central bed ground each night is detrimental to the sheep and very destructive to the range. The tepee system, as used on the national forests, provides for quiet open herding during the daytime, allowing the sheep to graze slowly outward and bed down where night overtakes them. The herder has a cook and supply camp centrally located on each range unit, but he moves his tepee and bed to the place where the sheep will be bedded for the night. This system of herding allows the sheep to graze progressively over the range, so that they are on fresh feed continuously. A range survey is necessary because the amount of forage in each area used from a central camp must be known in order that the

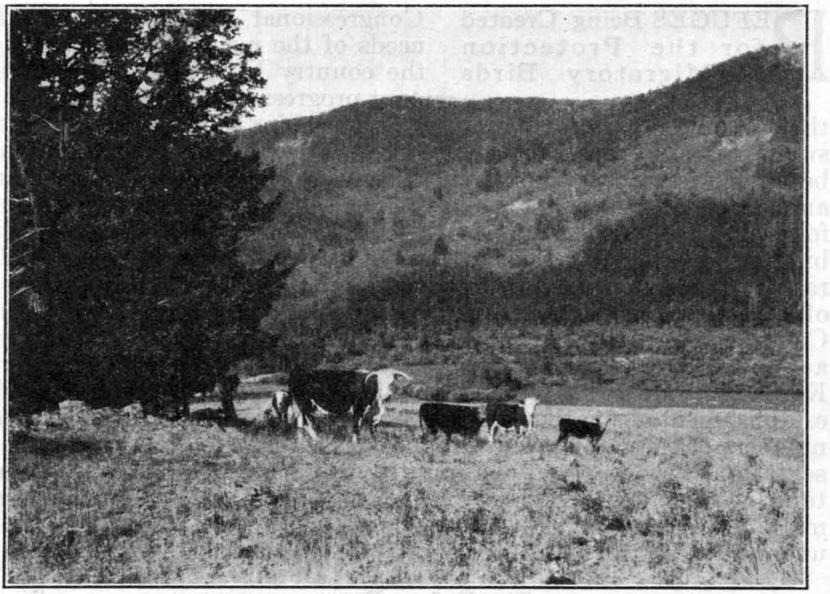

FIGURE 145.—Cattle using feed on ridges. Well distributed salt will do much toward drawing cattle to those portions of the range where use is ordinarily light

range can be evenly grazed. Otherwise, as frequently happens where the forage resources have not been estimated, some areas will be overgrazed and others not grazed at all or only lightly, because the herder has no guide to indicate how rapidly each area should be gone over.

Opening Areas Difficult of Access

Often through the construction of a few range improvements it is possible to open up inaccessible areas, to prevent too early use of the higher range, and to aid in the even distribution of stock so as to prevent local overgrazing. During the progress of a range survey a record is also kept of all needed improvements, such as development of springs, construction of stock trails and driveways, handling corrals, drift fences, and similar features that are necessary to good management. The boundaries of dangerous patches of poisonous plants are noted so that, where possible, eradication may be undertaken, or serious losses may be prevented by modifying the management plan of the range.

While much progress in range management has been made, many additional refinements are desirable. Overgrazed and damaged ranges must be allowed to recuperate so that they may contribute their full share toward meat production and watershed protection. The lightly grazed areas should be made accessible in order that the forage can be used. When all of the information obtained in range surveys is fully applied in the management of the ranges, they should yield their maximum benefits to the users and the surrounding communities.

H. E. Schwan,
Junior Range Examiner, Forest Service.

REFUGES Being Created for the Protection of Migratory Birds Congressional recognition of the needs of the migratory wild fowl of the country has resulted in important progress during the past year in the creation of a national system of refuges for the wild ducks, geese, swans, and other migrants that twice each year, spring and fall, pass between this country and Canada. Two refuges—one in Montana and the other in Oklahoma—have been set aside by Executive order, following investigations as to their suitability under the migratory bird conservation act of February 18, 1929; two others—one in Colorado and the other in South Carolina—are being acquired by purchase of necessary lands as authorized by the Migratory Bird Conservation Commission created by this act; and in the Seventy-first Congress authorization was granted for the acquisition of 20,000 acres in central Kansas for migratory-bird refuge purposes. These beginnings in the establishment of a nation-wide system of sanctuaries for the threatened numbers of migratory birds are most gratifying to the wild-life conservationists throughout the country, who have been active for years to bring this about. The placing of these areas under administration marks a further step in this country's efforts to carry out its obligations under the migratory bird treaty of 1916.

The Refuge Programs

The new conservation measure authorizes appropriations over a period of 10 years, aggregating about $8,000,000, for the establishment of migratory game bird refuges. The initial allotment, made available on July 1, 1929, set up $75,000, and this was used to explore and study regions recommended as suitable for reservation purposes. Two lines of investigation were at once instituted:

(1) Migratory-bird resources, existing and potential, were studied in 48 States, covering 189 units, with an aggregate area of about 3,700,000 acres. Of these 66 thus far have been found suitable as nesting, resting, and feeding grounds. (2) Within the acceptable units detailed examinations were made to determine accurately the types of land, ownership, the uses made of land and cover, and the character, extent, and value of existing improvements. At the end of the fiscal year 1930 valuation investigations had been completed on areas aggregating 1,225,000 acres in 24 States, and statistical data and maps compiled on 40 of the units under consideration.

so that, where possible, eradication may be undertaken, or serious losses may be prevented by modifying the management plan of the range.

While much progress in range management has been made, many additional refinements are desirable. Overgrazed and damaged ranges must be allowed to recuperate so that they may contribute their full share toward meat production and watershed protection. The lightly grazed areas should be made accessible in order that the forage can be used. When all of the information obtained in range surveys is fully applied in the management of the ranges, they should yield their maximum benefits to the users and the surrounding communities.

H. E. SCHWAN,
Junior Range Examiner, Forest Service.

REFUGES Being Created for the Protection of Migratory Birds Congressional recognition of the needs of the migratory wild fowl of the country has resulted in important progress during the past year in the creation of a national system of refuges for the wild ducks, geese, swans, and other migrants that twice each year, spring and fall, pass between this country and Canada. The placing of these areas under administration marks a further step in this country's efforts to carry out its obligations under the migratory bird treaty of 1916.

The Refuge Programs

The new conservation measure authorizes appropriations over a period of 10 years, aggregating about $8,000,000, for the establishment of migratory game bird refuges. The initial allotment, made available on July 1, 1929, set up $75,000, and this was used to explore and study regions recommended as suitable for reservation purposes. Two lines of investigation were at once instituted:

(1) Migratory-bird resources, existing and potential, were studied in 48 States, covering 189 units, with an aggregate area of about 3,700,000 acres. Of these 66 thus far have been found suitable as nesting, resting, and feeding grounds. (2) Within the acceptable units detailed examinations were made to determine accurately the types of land, ownership, the uses made of land and cover, and the character, extent, and value of existing improvements. At the end of the fiscal year 1930 valuation investigations had been completed on areas aggregating 1,225,000 acres in 24 States, and statistical data and maps compiled on 40 of the units under consideration.

Information collected by the Bureau of Biological Survey during the past 45 years on the distribution and migration of waterfowl was available as a foundation on which to prosecute intensive field studies. At hand also was a vast store of data gathered by specialists who had visited a large number of areas known as favorite haunts of migratory birds. In addition, many recommendations regarding places deemed suitable by reason of waterfowl concentrations during migration were received by the Biological Survey from persons interested in wild-life conservation. Most of the information at hand regarding the numerous proposed refuge sites, however, was only general in character. It was necessary, therefore, to make more comprehensive studies of the places that seemed to meet sanctuary standards.

At the beginning of the fiscal year 1931, $200,000 became available under the act of February 18, 1929, for the further prosecution of refuge-land survey and acquisition work. Next year Congress is authorized by the same act to appropriate $600,000, and during the succeeding seven years $1,000,000 each year. Such a program will permit orderly progress in the acquisition of refuge areas and will facilitate the wise and economical expenditure of the funds provided.

Though the stage of actual purchase of areas recommended, examined, and approved has been reached, the work of examination of proposed refuge sites has not been completed. Field parties of the Biological Survey will investigate additional tracts of extensive lowlands of marsh and neighboring woodland that were formerly well suited as feeding and resting grounds for migratory birds but are now useless for the purpose by reason of drainage or evaporation, to determine whether they can be restored to their natural condition. It is planned to have the primary network of refuges consist of units of approximately 20,000 acres each, though areas suitable for the purpose up to 50,000 acres will be considered.

The Migratory Bird Conservation Commission, upon recommendation of the Secretary of Agriculture, and in conjunction with the appraisal and valuation data previously assembled, will pass upon the purchase of lands at prices quoted in options obtained from the owners by the Biological Survey.

Refuges Established by Executive Order

The first of the refuges established by Executive order as a result of investigations under the new act was the Benton Lake Bird Refuge, situated in Chouteau and Cascade Counties, Mont., which will contain in its entirety 26,669 acres, of which 12,389 acres are public lands. The President, by order of November 21, 1929, set aside these public lands and immediately thereafter they came under the jurisdiction of the Bureau of Biological Survey for administration. Large numbers of migratory game birds congregate at Benton Lake during their nesting and migration seasons, including many species of ducks and geese. Other migratory species that will find sanctuary on the area include some of the diving birds and several kinds of shore birds.

By Executive order of March 26, 1930, an area of 18,683 acres of public lands in Alfalfa County, Okla., was withdrawn for creating the Salt Plains Wild Life Refuge. The total area designated as suitable for the purpose contains 19,985 acres and comprises extensive flatlands that have been repeatedly submerged by flood waters from the Arkansas River. Many migratory birds common to the region, chiefly ducks and coots, will frequent the Salt Plains Refuge and nest there when it is fully developed. Shore birds, rails, bitterns, herons, gulls, and terns also appear on the marsh and water areas in the vicinity of the refuge.

Refuges To Be Acquired by Purchase

The Migratory Bird Conservation Commission in May, 1930, approved plans presented by the Biological Survey for the purchase of lands for two refuges under the migratory-bird conservation act. One is a 5,500-acre area in Alamosa County, Colo., embracing San Luis and Head Lakes, as well as numerous shallow sloughs, ponds, and lesser lakes. By reason of its situation in an otherwise arid region, this refuge will be of outstanding importance in the nation-wide network. Some of the migratory birds that are frequent or common breeders there are ducks, geese, coots, herons, grebes, soras, and several species of shore birds.

Negotiations were also concluded for the purchase of a 32,000-acre unit at Cape Romain, on the Atlantic seaboard in Charleston County, S. C. The State of South Carolina cooperated in the establishment of the refuge by enacting a law ceding to the United States jurisdiction over certain tidal lands falling within its boundaries. The Cape Romain unit is attractive to several species of ducks and is used as a nesting ground by various kinds of shore birds. Other birds seek this region in their migrations, while skimmers, terns, and herons are relatively abundant there.

Other Refuges for Migratory Birds

By an act of June 12, 1930, Congress authorized the Secretary of Agriculture to acquire 20,000 acres of land for a migratory-bird refuge in what is known as the Cheyenne Bottoms, in Barton County, Kans., the only extensive lake area in the State. The Biological Survey had previously made exhaustive investigations as to the suitability of the site for sanctuary purposes. Migratory waterfowl and shore birds in their semiannual flights frequent the Cheyenne Bottoms in immense numbers, and the area is the most suitable haven for them within hundreds of miles. Funds were made available to the Biological Survey in July, 1930, for initial steps toward the acquisition of the refuge.

For the Bear River Migratory-Bird Refuge in Utah, which was authorized by an act of April 23, 1928, 15,860 acres of land were purchased in the fiscal year 1930, and negotiations were concluded for the conveyance to the United States of 7,126 acres by exchange. The total land acres now under control within the Bear River Refuge is 56,486 acres.

Progress also continues in the acquisition of lands for the Upper Mississippi River Wild Life and Fish Refuge, created by an act of June 7, 1924, and at the close of the fiscal year 1930 the total area of land under control in the States of Iowa, Minnesota, Illinois, and Wisconsin amounted to 106,823 acres. The many sloughs, ponds, and lakes intermingled with the refuge lands contain an estimated area of 16,023 acres, making the total land and water area 122,846 acres, exclusive of approximately 70,000 acres in the main channel of the Mississippi River within the exterior limits of the refuge. About 20,000 acres of land are yet to be acquired.

The plan to establish refuges for our migratory birds calls for the active interest of lovers of wild life in all parts of the country and for their cooperation, individually or through their organizations, with the Bureau of Biological Survey.

RUDOLPH DIEFFENBACH,
Senior Land Valuation Engineer,
Bureau of Biological Survey.

REGIONAL Conferences Carry Outlook Facts Closer to Farm Needs

The development of the regional outlook conference in addition to the annual national conference held at Washington was the most significant progress made in 1930 in the work of bringing information on probable future markets to the attention of farmers.

Five such regional outlook conferences of groups of States were held during the year 1930 as follows: New England States, Boston, February 9–11; Appalachian States, Washington, D. C., September 18–28; Middle Western States, Ames, Iowa, September 25–27; Southern States, Atlanta, Ga., November 10–14; and Western States, Salt Lake City, Utah, December 15–17.

One of the problems in outlook work has been the difficulty of adapting the national outlook to local conditions in any given region. The practical use by an individual farmer of the facts supplied him is largely dependent upon the adjustments he can make in production. In many producing areas, natural, climatic, and geographic conditions are such that farmers have only a few, if any, optional lines of production. Statements regarding the best probable course for farmers of the country as a whole to follow in the production of a certain commodity may not be applicable to certain local areas because of the local conditions. In certain regions where climatic and rainfall conditions are such as to exclude the possibility of growing many crops except wheat, for example, the individual farmer is concerned with growing his wheat at the lowest possible cost and developing the most efficient possible unit of operation. In individual cases, this may mean an increase in acreage even in the face of probable low prices.

In the regional outlook conferences, States that have somewhat similar problems are grouped. Months previous to the conference, a program of procedure is formulated, and State and regional commodity committees are formed to assemble commodity facts from State sources. Committee members bring these data and facts to the regional conference. The national outlook is presented by the representatives of the Bureau of Agricultural Economics, and the national outlook is interpreted with the regional facts in mind.

Regional conferences usually last from three to four days, and emphasis is placed only upon the commodities which are of greatest importance in the region. The limited number of subjects considered allows time for a detailed discussion of each. Out of these discussions practical conclusions are drawn which are used as a basis of extension work.

Information is Localized

The principal benefit of the regional conferences is that they afford a means of localizing the reports by considering them at a time and

The plan to establish refuges for our migratory birds calls for the active interest of lovers of wild life in all parts of the country and for their cooperation, individually or through their organizations, with the Bureau of Biological Survey.

Senior Land Valuation Engineer,
Bureau of Biological Survey.

REGIONAL Conferences Carry Outlook Facts Closer to Farm Needs The development of the regional outlook conference in addition to the annual national conference held at Washington was the most significant progress made in 1930 in the work of bringing information on probable future markets to the attention of farmers.

Five such regional outlook conferences of groups of States were held during the year 1930 as follows: New England States, Boston, February 9–11; Appalachian States, Washington, D. C., September 18–28; Middle Western States, Ames, Iowa, September 25–27; Southern States, Atlanta, Ga., November 10–14; and Western States, Salt Lake City, Utah, December 15–17.

One of the problems in outlook work has been the difficulty of adapting the national outlook to local conditions in any given region. The practical use by an individual farmer of the facts supplied him is largely dependent upon the adjustments he can make in production. In many producing areas, natural, climatic, and geographic conditions are such that farmers have only a few, if any, optional lines of production. Statements regarding the best probable course for farmers of the country as a whole to follow in the production of a certain commodity may not be applicable to certain local areas because of the local conditions. In certain regions where climatic and rainfall conditions are such as to exclude the possibility of growing many crops except wheat, for example, the individual farmer is concerned with growing his wheat at the lowest possible cost and developing the most efficient possible unit of operation. In individual cases, this may mean an increase in acreage even in the face of probable low prices.

In the regional outlook conferences, States that have somewhat similar problems are grouped. Months previous to the conference, a program of procedure is formulated, and State and regional commodity committees are formed to assemble commodity facts from State sources. Committee members bring these data and facts to the regional conference. The national outlook is presented by the representatives of the Bureau of Agricultural Economics, and the national outlook is interpreted with the regional facts in mind.

Regional conferences usually last from three to four days, and emphasis is placed only upon the commodities which are of greatest importance in the region. The limited number of subjects considered allows time for a detailed discussion of each. Out of these discussions practical conclusions are drawn which are used as a basis of extension work.

Information is Localized

The principal benefit of the regional conferences is that they afford a means of localizing the reports by considering them at a time and place in the region which affords an opportunity for the maximum number of State workers to attend the meetings. They also encourage State workers to prepare local outlook information and use it in connection with the regional report. They enable the conference to devote more time to commodities of importance in the region and to omit discussions of unimportant subjects, thus conserving the time of all the workers.

The development of the regional conferences does not replace or restrict the annual national conference, since the latter is necessary to consider the world-wide and nation-wide aspects of the outlook. State workers wish to attend the national conference to make contacts with the sources of information in the Federal department; to meet workers from all other States; to inform themselves concerning many commodities which can not be considered at regional conferences, and to follow interregional adjustments more closely.

The development of regional outlook conferences is very timely in view of the readjustments that are becoming increasingly necessary in the farming systems of various regions as the result of nation-wide changes in economic conditions. The problem of the most profitable combinations of enterprises for farmers to follow is of major importance in many regions.

Outlook conferences in those regions supply facts and information that are of great benefit in attempting to solve these problems. A closer coordination of research and extension work is brought about. Research results are given the test of practicability, and an impetus is given to economic research along lines of greatest benefit to extension and experiment station workers and farmers.

A Guide in Planning Farm Work

Outlook reports are designed to furnish basic facts that will serve as a guide in farming operations. Greater success attends the management of a farm if such management is based upon probable future price conditions rather than upon current or past prices. Farmers always have expanded or contracted their farming operations in response to changing economic conditions, and they will continue to make such shifts. The primary purpose in outlook work is to furnish to farmers the facts, so that expansion or contraction can be effected at the right time.

One means of indicating the dollars-and-cents value of basing farm operations upon probable future market conditions is the setting up of a farm organization typical of a given area, showing probable receipts, expenses, and net income under each of several systems of management. Both the long-time and short-time outlook are considered in the set-up, and the relative advantages in probable income are shown. This method of presenting outlook material requires an intimate knowledge of local farming conditions; it brings to local farmers the local outlook adaptation in terms of actual farm operations which they can readily understand and use on their own farms.

THEW D. JOHNSON,
Agricultural Economist, Bureau of Agricultural Economics.

RETAIL Prices Follow Wholesale Prices But Change Later and Less Wholesale prices fell 15 per cent between July, 1929, and July, 1930. During the same period prices received by farmers fell more than 20 per cent. Farmers are wondering, therefore, whether retail prices for the commodities they buy can be expected to make similar declines. A study of the relationship of wholesale prices to prices paid by farmers for the goods they buy in other periods of rapidly changing prices should give some indication of how retail prices may be expected to react to the recent decline in wholesale prices.

Retail prices tend to follow changes in wholesale prices, but usually change later and to a somewhat smaller extent. The accompanying chart (fig. 146) of all commodity prices shows that, during the period of rapidly rising prices, 1915 to 1920, retail prices lagged behind wholesale prices and did not advance nearly so far. In the period of rapidly declining prices, 1920 to 1922, the same lag is noted in the decline of retail prices and the decline was not so great as in wholesale prices.

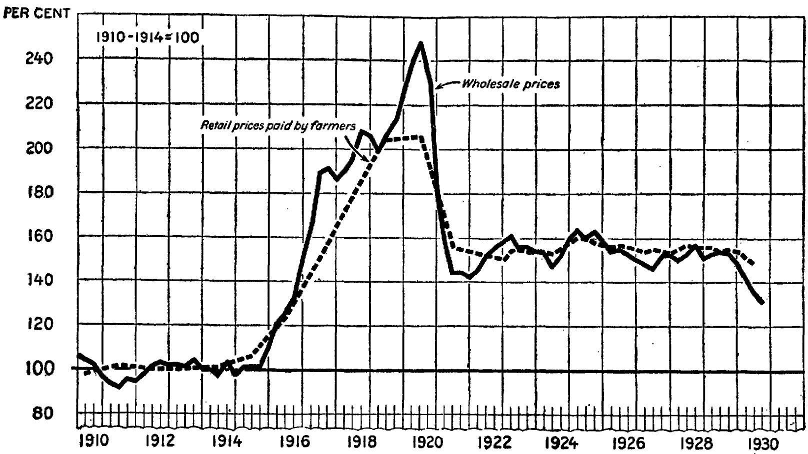

FIGURE 146.—Comparison of changes in wholesale and retail prices of all commodities, 1910–1929

During 1923 both series of prices reached a level about 56 per cent above pre-war and until last year tended to fluctuate near that level.

The general level of wholesale prices as shown in the accompanying chart is considerably influenced by prices of raw materials, such as steel, rubber, cotton, and wool. A decline in the prices of these raw materials frequently is not reflected in prices of the finished products until materials bought at the lower prices have been made into farm machinery, automobile tires, clothing, etc. Consequently, a part of the lag of retail prices behind wholesale prices is accounted for by the time consumed in converting raw materials into finished products. Since costs of manufacturing do not usually fluctuate so much as prices for raw products, prices for finished goods are more stable and cause less fluctuations in retail prices than in wholesale prices.

Wholesale Change Eventually Passed Along

Everyone hesitates to buy in a market where prices are continually changing. For this reason retailers like to keep their prices as steady as possible. In a period of rapidly changing prices they frequently

40442°—31——30

do not raise or lower their prices to customers until they are sure that the new level of prices will continue. To a certain extent retailers are justified in not lowering their prices when wholesale prices decline; if they did they would suffer a loss, as their stocks of goods on hand were often bought at the old price level. Costs for transportation, labor for assembling and distributing commodities, and rent for shop or storage space, which must be added to the wholesale prices, are all slowly adjusted to changes in the general price level. When the change in the level of wholesale prices is permanent, however, the retailer is soon forced to pass the change in wholesale prices on to the consumer. Therefore, if the lower level of wholesale prices continues, it is likely that a large part of the recent price decline will soon be reflected in prices farmers pay.

The time at which the lower levels of retail prices will be reached will vary considerably for different commodities. Retail prices for goods that require little or no processing and are held by the retailer a short time only may be expected to change very soon after a change

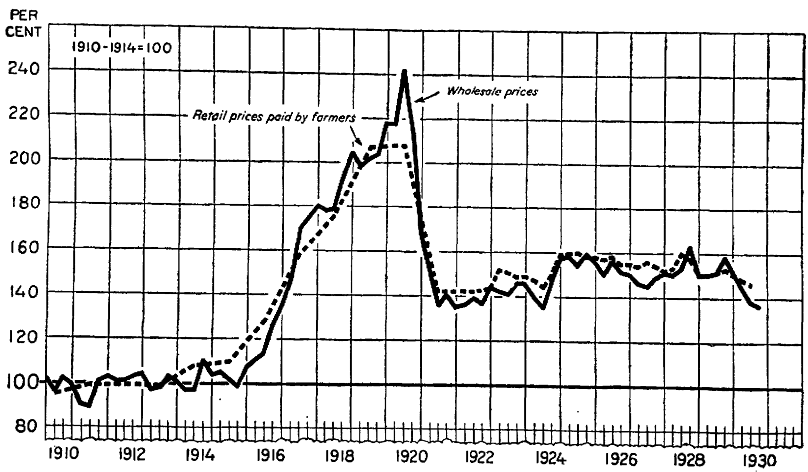

FIGURE 147.—Comparison of changes in wholesale and retail prices of food, 1910–1929

occurs in wholesale prices. Most foods, feeds, and fuels fall into this class of goods. Prices for commodities that farmers buy at only one time during the year, such as seeds and fertilizers, also respond quickly to changes in wholesale prices, as local dealers carry them for only a short period during the year. On the other hand, retail prices for commodities that require a great deal of processing and are held by dealers for some time respond very slowly to changes in wholesale prices and usually change less than wholesale prices because of the large amount of labor involved in manufacturing. A large part of farmers' purchases, such as farm machinery, building materials, clothing, and furniture, fall into this class and largely account for the lag of prices paid by farmers behind wholesale prices. The accompanying chart of food prices (fig. 147) shows how closely retail prices follow wholesale prices.

Different methods of retailing commodities also cause variations in the length of time between changes in retail prices and wholesale prices. Some commodities such as automobiles are sold to farmers at the factory or wholesale price plus the cost of freight and a fixed handling charge. For these commodities any change in the wholesale price is almost immediately reflected in the retail price. Other commodities such as lumber are bought in carload lots by the retailer and sold to the farmer in smaller lots over a period of time. Although wholesale prices may decline before the retailer has sold out his stock, he can not afford to lower prices until he receives a new order of goods at the lower price level.

Prices Fairly Stable from 1923 to 1929

From 1923 to 1929 there were no wide fluctuations in either wholesale or retail prices and there was little change in the important costs of distributing commodities. Therefore a comparison of retail and wholesale prices for the different groups of commodities during this period will show how much more closely the retail prices of some commodities tend to follow wholesale prices than others. The chart of food prices shows that from 1923 to 1929 every important change in the level of wholesale prices was almost immediately followed by a similar change in retail prices. Feed and fertilizer prices during this period also followed closely the changes in wholesale prices. The tendency of these commodities to respond to changes in wholesale prices can be shown by their price trends during the first part of the recent price decline. In June, 1930, the decline in prices was well under way and wholesale prices were 9 per cent below June, 1929. Retail food prices in June were 3.3 per cent lower than a year earlier, feed prices were 5.5 per cent lower and fertilizer prices were 4.5 per cent below the same time last year.

On the other hand, retail prices of several groups of commodities have shown little tendency to follow wholesale prices during the years 1923 to 1929. In 1929, wholesale prices of clothing were nearly 12 per cent lower than in 1923, while retail prices were the same as 1923. Building-material prices declined 11 per cent at wholesale markets, while retail prices advanced 2 per cent. Prices of farm machinery at wholesale markets in 1929 were 1 per cent higher than in 1923 and retail prices were 8 per cent higher. These comparisons show that the two series of prices for these commodities do not move closely together and that farmers have not received the benefits of declining wholesale prices. Up to June 15, 1930, clothing had made the greatest response to the recent decline in prices and prices were 4.5 per cent below a year earlier. Prices for building materials and machinery were about 2 per cent below a year before. The extent to which retail prices for these commodities will reflect the decline in the general price level is uncertain and unless the lower level of prices continues retail prices are not likely to decline so much as the general level of wholesale prices.

C. M. PURVES,
Agricultural Economist, Bureau of Agricultural Economics.

ROADSIDE Tree Planting Restores Beauty Impaired by Highway Construction With the increasing interest in the appearance of the roadsides, the laws governing the operations of the State highway departments are gradually being amended to authorize expenditures for roadside planting as well as road construction. The departments have always been cognizant of the economic as well as esthetic value of such plant-dling charge. For these commodities any change in the wholesale price is almost immediately reflected in the retail price. Other commodities such as lumber are bought in carload lots by the retailer and sold to the farmer in smaller lots over a period of time. Although wholesale prices may decline before the retailer has sold out his stock, he can not afford to lower prices until he receives a new order of goods at the lower price level.

Prices Fairly Stable from 1923 to 1929

From 1923 to 1929 there were no wide fluctuations in either wholesale or retail prices and there was little change in the important costs of distributing commodities. Therefore a comparison of retail and wholesale prices for the different groups of commodities during this period will show how much more closely the retail prices of some commodities tend to follow wholesale prices than others. The chart of food prices shows that from 1923 to 1929 every important change in the level of wholesale prices was almost immediately followed by a similar change in retail prices. Feed and fertilizer prices during this period also followed closely the changes in wholesale prices. The tendency of these commodities to respond to changes in wholesale prices can be shown by their price trends during the first part of the recent price decline. In June, 1930, the decline in prices was well under way and wholesale prices were 9 per cent below June, 1929. Retail food prices in June were 3.3 per cent lower than a year earlier, feed prices were 5.5 per cent lower and fertilizer prices were 4.5 per cent below the same time last year.

On the other hand, retail prices of several groups of commodities have shown little tendency to follow wholesale prices during the years 1923 to 1929. In 1929, wholesale prices of clothing were nearly 12 per cent lower than in 1923, while retail prices were the same as 1923. Building-material prices declined 11 per cent at wholesale markets, while retail prices advanced 2 per cent. Prices of farm machinery at wholesale markets in 1929 were 1 per cent higher than in 1923 and retail prices were 8 per cent higher. These comparisons show that the two series of prices for these commodities do not move closely together and that farmers have not received the benefits of declining wholesale prices. Up to June 15, 1930, clothing had made the greatest response to the recent decline in prices and prices were 4.5 per cent below a year earlier. Prices for building materials and machinery were about 2 per cent below a year before. The extent to which retail prices for these commodities will reflect the decline in the general price level is uncertain and unless the lower level of prices continues retail prices are not likely to decline so much as the general level of wholesale prices.

ROADSIDE Tree Planting Restores Beauty Impaired by Highway Construction With the increasing interest in the appearance of the roadsides, the laws governing the operations of the State highway departments are gradually being amended to authorize expenditures for roadside planting as well as road construction. The departments have always been cognizant of the economic as well as esthetic value of such planting, but the demand of automobile owners for highways of smooth, easy-riding, and dustless surfaces has engaged their whole attention and revenue. Improvement of highways has been the greatest need, and in most States the largest revenue it has been possible to collect has not been more than sufficient to satisfy the minimum requirements of the growing traffic.

With the completion of the most urgently needed roadway improvements, public attention is turning more and more toward the condition and appearance of the countryside. Motorists are demanding that the highways afford them recreation and beauty. State highway departments, so far as their laws permit, have cooperated with agencies interested in roadside restoration. For the lack of beauty along the highways is mainly the result of a failure to restore that which in the construction of the roads it has been necessary to destroy. Unquestionably, there has been some needless destruction of old trees which it will take many years to replace. But, a free use of the knife has been needed in the major operation which has been required to clear the way for the great and steadily mounting surge of motor vehicles that demanded freer passage over the main roads of the country. Widening, straightening, and reduction of the grades of the old roads have been necessary, and these operations have entailed much sacrifice of natural beauty and have left ragged scars upon the landscape. In carrying out the betterment of the road surfaces, the scars have not been obliterated.

Massachusetts Began in 1912

Massachusetts was perhaps the first State to realize the interdependence existing between roadside planting and road construction, when in 1921, it created an office in the State highway department and filled it with a man whose skill in landscape planting has made possible the accomplishment of large results at relatively small expenditure. The State had begun planting trees along its highways as early as 1912, but it was not until nine years later that the work was correlated with that of construction, and an office created for carrying it out.

Pennsylvania, another pioneer, authorized the planting of roadsides under the supervision of its State highway commissioner by amendments in 1921 and 1923 of its State highway act. This was followed in 1927 by the creation of a forestry unit as a branch of the department of highways to plant and care for roadside trees, shrubs, vines, and grasses. The department also cooperates with persons and organizations according to a definite policy.

Delaware has been planting trees and shrubs along its roads since 1920, with the result that probably 50 per cent of the entire State highway mileage is now improved with planting.

Connecticut organized a landscape division of its State highway department in 1927 and has since done some effective work. In the same year the highway commission of Michigan took over the task of beautifying the trunk-line roads of that State; and the Oklahoma Highway Department began similar work.

In 1928 Missouri employed a landscape architect to cooperate with interested organizations and individuals in roadside development; and California in the same year also employed a landscape planner and embarked on a limited program.

Wisconsin, the most recent addition to the group which has recognized the interdependence of planting with construction, authorized its State highway commission in 1929 to employ a director of regional planning, one of whose duties is to cooperate with and assist local planning agencies in roadside planting.

On the part of the Federal Government, Congress in 1928 recognized the planting of shade trees as a part of the improvement of the Federal-aid highway system and specifically authorized the expenditure of Federal funds for that purpose whenever such aid is requested by the State highway departments. The fact that no State has yet applied for aid is due to no lack of interest in roadside planting but rather to the fact that the States that are ready to start planting have no need to request financial assistance.

It was after the World War and following closely upon the signing of the armistice that the search of patriotic societies and local community organizations for a fitting means of commemorating the services of the men who fell in conflict led to the planting of bordering trees along short sections of roads in all parts of the country. Their efforts served as object lessons of what might be done at relatively small expense to relieve the prevalent barrenness of American roadsides.

Requires Careful Planning

Thus, tree planting became the means of roadside beautification upon which most of the aroused popular interest has been centered. It is also the activity that requires the most careful planning. In the absence of such planning, it is the activity which, more than all others needed for the restoration of the beauty of our roadsides, may be fraught with the greatest waste and futility.

Trees at full growth are among the most conspicuous objects in the landscape. When, therefore, as in every scheme of roadside development, the reason of their planting is the creation of beauty, there is need for care and thought to make sure that in kind and position they will harmonize with their surroundings.

Trees attain maturity slowly and while young require a good deal of care and protection, the amount depending upon their hardiness and adjustment to their surroundings. Their successful use in roadside development demands effective provision for their maintenance as well as for the planting, and calls for the selection of only the hardier varieties of indigenous growth.

As a full grown tree represents a considerable investment of care, money, and time, its destruction constitutes a distinct loss, which should be avoided whenever possible by forethought in planting beyond the limits of probable subsequent road widening and relocation.

Through failure to take account of some or all of these facts, much praiseworthy effort of patriotic and civic groups has been misdirected. Trees have been planted within existing narrow right of ways so close to the present roadways that they must certainly be uprooted to make way for necessary future surface widening. Exotic varieties and tender young indigenous trees have been set out and left to struggle through to a doubtful maturity without the least provision for their care and protection.

Row planting, which characterizes most of the voluntary effort of civic groups, is a form of treatment that should be used sparingly in rural surroundings. It may be employed with good effect on an occasional straight stretch of country highway traversing level or slightly rolling, cultivated and relatively treeless farm land, under which conditions the trimness of the regular alignment and spacing of the trees may add the final touch to an ordered countryside. But even in such surroundings, with overuse, it may easily become monotonous.

On a road that lies alternately in cut and fill, so that adjacent ground varies from levels well above to others well below the roadway, such mathematical precision of placement is almost impossible, and if it is somehow arranged, is extremely unnatural.

Approximation to Natural Conditions Desirable

While tree planting is of great importance in roadside development, the most successful scheme of beautification of a rural road is generally that which restores the roadside as nearly as possible to the undisturbed natural condition in which it existed before it was slashed and scarred by the hurried work of the road maker. While tree planting is necessary to repair much of the destruction that has been permitted in the past, of equal importance is the sodding of the road shoulders and the mantling of banks and side slopes with grasses, vines, and wild flowers to hide the scars of construction and to restore the natural beauty of the countryside. They are equally desirable as measures for the protection and maintenance of the road structure. Sodding of shoulders and planting of side slopes with vines or small shrubs prevent soil erosion. Judicious planting of hedges, shrubs, bushes, and other low growth lends additional charm to the roadside picture and is of value to song birds and other wild life. In northern latitudes, such planting must be properly placed to aid in the prevention of road-clogging snowdrifts, otherwise it will prove harmful.

The removal of trees and underbrush to afford distant views from mountainside roads and the opening of vistas toward rivers and lakes from roads paralleling their banks are desirable contributions to the pleasure of motoring. But they necessitate consideration of the probable halting of traffic and suitable provision for parking in the planning of the roadway.

In the construction of future roadways, it is highly important that there shall be a studied effort to preserve and enhance the natural beauty by intelligent clearing of the right of way, the preservation of desirable trees and natural growth, and the development of vistas of decorative value.

The interception and control of springs within the right of way are essential to the protection of the road. If their water is potable they may be developed at small expense into attractive drinking fountains for the comfort and convenience of travelers.

These are only a few examples of the interrelation of measures that may be adopted for the beautification and the planning and construction of the roads.

B. M. Joyce,
Assistant Editor, Bureau of Public Roads.

ROADS of Traffic-Bound Type Meet Needs of Some Sections at Low Cost

Traffic-bound and gravel roads which have been developed to meet the needs of the relatively light traffic on some of the main roads in sparsely settled sections of the West and on secondary roads in more densely populated sections are well adapted for use where it is desired to surface a farm road.

ROADS of Traffic-Bound Type Meet Needs of Some Sections at Low Cost

Traffic-bound and gravel roads which have been developed to meet the needs of the relatively light traffic on some of the main roads in sparsely settled sections of the West and on secondary roads in more densely populated sections are well adapted for use where it is desired to surface a farm road.

The first step in building such a road is to grade the roadway to the proper width and crown with side ditches and culverts as needed.[10] Crushed rock, gravel, cinders, slag, chats, and shell may be used for this type of surfacing. Crushed limestone is particularly desirable because of its binding qualities and the small sized material can often be obtained as waste product from lime plants. Slag, chats, and cinders may be obtained from industrial plants and in many localities along the seacoast it is possible to obtain shell suitable for road material. The material from any of these sources should preferably be

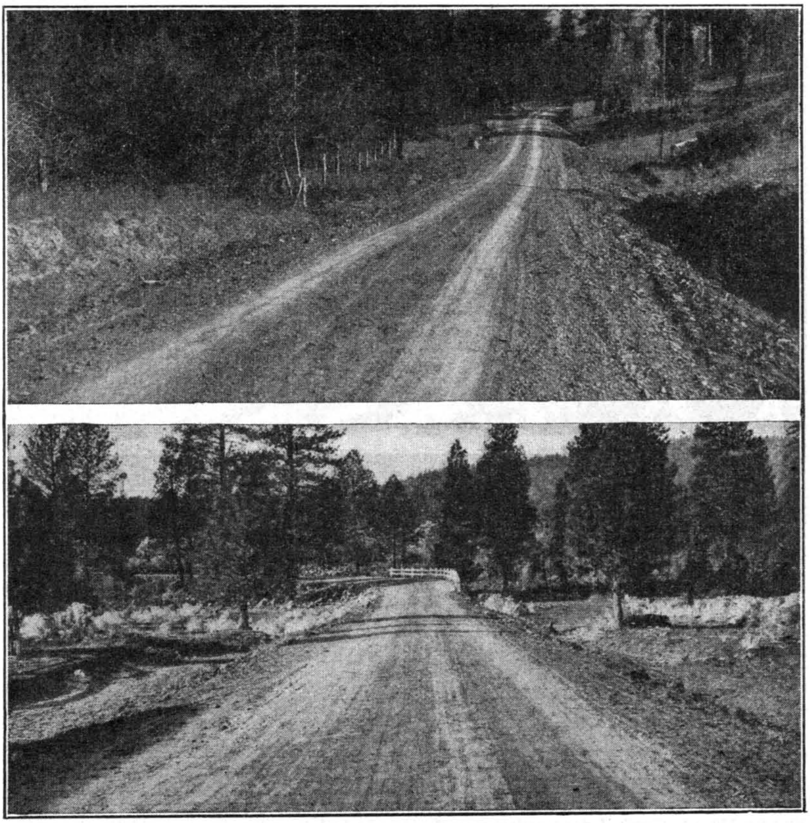

FIGURE 148.—Traffic-bound crushed stone roads showing the smooth surface which can be produced

of a size that will all pass a 1-inch ring and contain at least 80 per cent larger than ¼-inch size.

If gravel is used it will be best to be guided by local experience in selecting a material. Gravels varying greatly in composition have been successfully used. Unsatisfactory results are frequently due to use of material containing gravel particles of too large a size or an excess of clay in the mixture. For good construction the largest size of gravel should not exceed 1 inch. From 55 to 75 per cent of the

[10] Information on this subject will be found in the article Road Work on Farm Outlets Needs Skill and Right Equipment, on p. 528 of the Yearbook of Agriculture, 1928. This article has been reprinted as Yearbook Separate No. 1036, and can be supplied by the Bureau of Public Roads, U. S. Department of Agriculture, Washington, D. C.

material (by weight) should be larger than one-fourth of an inch in size. The greater the amount of small particles in the mixture the more clay will be required as a binder. Clay should not be in excess of 10 to 15 per cent of the mixture. Gravel from pits frequently has an excess of clay, while that from stream beds sometimes requires the addition of clay. (Fig. 148.)

In the traffic-bound macadam type of surfacing, the initial application of granular material is forced into the subgrade and acts as a subgrade stabilizer. For this reason it is sometimes economical to use inferior material for the first application and better material for the courses that will take the wear of traffic.

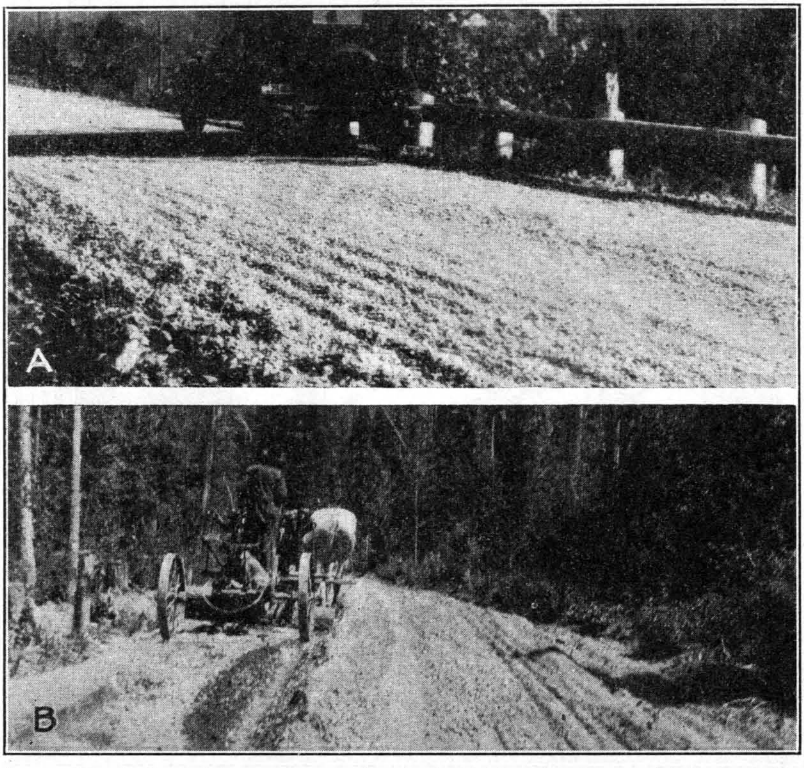

FIGURE 149.—A, Crushed stone surface recently placed which is undergoing consolidation by traffic Frequent dragging is required during this period. B, Spreading crushed stone

After the road has been graded and drained and somewhat compacted by traffic, the surfacing material is brought to the job and dumped in a windrow along one shoulder. Two windrows make passing of vehicles difficult and dangerous and also tend to hold water on the subgrade. Best results are obtained by blading light applications of the surfacing material over the subgrade but on farm roads where a blade grader is not available, the material may be spread by hand and the road drag used to even it up. The amount placed during this first application will depend on the condition of the subgrade. If the subgrade is moist it will be necessary to use considerably more than if it is dry. Ordinarily 1½ to 3 inches will be sufficient and it is important that too heavy an application be avoided because it will defeat the purpose intended, namely, compaction by traffic. If the material is placed in a thick course traffic will use the shoulder if it is possible, and even if traffic attempts to consolidate it, the material is scattered about and much of it is wasted. (Fig. 149.)

While the compacting process is going on, care should be taken that it is dragged often enough to keep the surface smooth and that the traffic is distributed over the surface so as to compact it uniformly. The small size of the particles permits this method to be used without serious inconvenience to traffic.

If the work is properly done the resulting surface will be quite smooth—decidedly more so than a rolled stone surface and can be kept in excellent condition by dragging.

Where a higher type of surface is desired it may be possible to arrange to have a surface treatment applied when such work is being done on public highways in the vicinity. There are a number of methods of applying surface treatment and a typical method will be briefly described.

The road surface must be properly shaped, well compacted, and cleaned of dust and loose material. From one-fourth to one-third gallon per square yard of priming material (tar or light asphaltic oil) is applied. Time is allowed for this material to penetrate the surface and then one-third to one-half gallon per square yard of binder (asphaltic oil or tar) is applied hot and immediately covered with crushed stone ranging in size from one-fourth to three-fourths of an inch and at a rate of 30 to 50 pounds per square yard. The surface is then rolled and is ready for traffic which completes the consolidation and smoothing of the surface. Rolling is sometimes omitted but this would not be desirable on a farm road with very light traffic unless the bituminous material is of the type mentioned below. It is necessary that the surface be worked and ironed out so as to form a mat within a few days after placing.

For farm roads where equipment for heating the asphalt and rolling is not available good results may be obtained by using cold tar or a cut-back asphalt instead of binder asphalt. If the cut-back asphalt is used a road drag should be operated while it is drying out.

In buying bituminous materials it will be best to obtain the advice of some one familiar with their use in road construction.

R. E. Royall, *Senior Highway Engineer*,
A. G. Bruce, *Senior Highway Engineer*,
Bureau of Public Roads.

SAWMILLS' Indirect Costs Often Ignored by Farmer Operators

Many farmers engaged in operating small sawmills in the hope of profitably employing, between crops, their teams, tractors, and trucks, often ignore some of the costs entering into the production of their product. Obvious direct costs, such as wages, supplies required each day, and even the costs of making roads and mill set-ups are usually considered. Less obvious costs, such as expenditures for depreciation, maintenance and repair of equipment, taxes, and interest on capital tied up in the business are usually ignored. Costs thus overlooked often run from around $2.40 to $3 a thousand feet, board measure, or between 10 and 20 per cent of the total production cost (stumpage included).

defeat the purpose intended, namely, compaction by traffic. If the material is placed in a thick course traffic will use the shoulder if it is possible, and even if traffic attempts to consolidate it, the material is scattered about and much of it is wasted. (Fig. 149.)

While the compacting process is going on, care should be taken that it is dragged often enough to keep the surface smooth and that the traffic is distributed over the surface so as to compact it uniformly. The small size of the particles permits this method to be used without serious inconvenience to traffic.

If the work is properly done the resulting surface will be quite smooth—decidedly more so than a rolled stone surface and can be kept in excellent condition by dragging.

Where a higher type of surface is desired it may be possible to arrange to have a surface treatment applied when such work is being done on public highways in the vicinity. There are a number of methods of applying surface treatment and a typical method will be briefly described.

The road surface must be properly shaped, well compacted, and cleaned of dust and loose material. From one-fourth to one-third gallon per square yard of priming material (tar or light asphaltic oil) is applied. Time is allowed for this material to penetrate the surface and then one-third to one-half gallon per square yard of binder (asphaltic oil or tar) is applied hot and immediately covered with crushed stone ranging in size from one-fourth to three-fourths of an inch and at a rate of 30 to 50 pounds per square yard. The surface is then rolled and is ready for traffic which completes the consolidation and smoothing of the surface. Rolling is sometimes omitted but this would not be desirable on a farm road with very light traffic unless the bituminous material is of the type mentioned below. It is necessary that the surface be worked and ironed out so as to form a mat within a few days after placing.

For farm roads where equipment for heating the asphalt and rolling is not available good results may be obtained by using cold tar or a cut-back asphalt instead of binder asphalt. If the cut-back asphalt is used a road drag should be operated while it is drying out.

In buying bituminous materials it will be best to obtain the advice of some one familiar with their use in road construction.

SAWMILLS' Indirect Costs Often Ignored by Farmer Operators

Many farmers engaged in operating small sawmills in the hope of profitably employing, between crops, their teams, tractors, and trucks, often ignore some of the costs entering into the production of their product. Obvious direct costs, such as wages, supplies required each day, and even the costs of making roads and mill set-ups are usually considered. Less obvious costs, such as expenditures for depreciation, maintenance and repair of equipment, taxes, and interest on capital tied up in the business are usually ignored. Costs thus overlooked often run from around $2.40 to $3 a thousand feet, board measure, or between 10 and 20 per cent of the total production cost (stumpage included).

Taxes and the cost of keeping equipment in working order are overlooked largely because they occur with an irregularity requiring a systematic accounting habit in order to include them. Depreciation and interest on the capital tied up in the business are overlooked because the average operator does not have the basic information by which they can be reckoned.

Depreciation Charges

Depreciation is a charge to compensate for the decrease in value of equipment as a result of use, time, or the development of more efficient machines. The accepted practice is to charge off as a cost each year a portion of the total value of the equipment so that when discarded this total equals the decreased value of the equipment. Timber-appraisal experts and other authorities commonly discount the following percentages of the original purchase price for each year of service: Teams, 15 per cent; harness, 25 per cent; small tools, 100 per cent; trucks, 25 per cent; tractors, 20 per cent; logging wagons, 50 per cent; lumber-hauling wagons, 20 per cent; sawmill, 15 per cent.

Interest on capital is obviously a cost when the operator is running on borrowed capital since he must pay such interest. If the operator provides the capital, he ties up money which otherwise could be placed in interest-producing investments. An interest return of 5 per cent is therefore properly allowed on capital. To determine the extent of this cost, estimate the average amount of capital tied up. This cost should include the cost of the average amount of stumpage carried during the year; the cost, properly discounted for previous service, of the equipment used; and the cost of producing the average amount of stock on hand. In operations that market their product green from the saw, the capital investment can be kept relatively low. Where seasoning is required, the capital investment is large, and the interest cost correspondingly high.

TABLE 15.—*Costs frequently ignored in operating small sawmills*

Item	Cost per year	Cost per thousand board feet
Interest on capital invested ($18,600 at 5 per cent)	$930	$0.93
Maintenance of equipment (saw teeth, belts, boiler repairs, grease, etc.)	280	.28
Depreciation (total investment in equipment $7,100; average life of equipment estimated at 6.57 years)	1,080	1.08
Taxes (equipment and lumber)	100	.10
Total of items usually ignored	2,390	2.39

NOTE.—The capital required comprised the following: Woods (4 teams, 4 sets of harness, and small tools), $1,300; mill (sawmill and boiler), $2,800; lumber haul (a 2-ton motor truck, and 4 teams, 4 wagons, and 4 sets of harness), $3,000; making a total gross of $7,100 of which $3,540 was charged off as depreciation against previous operations, leaving a total net equipment investment of $3,560; stock (an average stock of 5 months' cut) carried in the yard on which stumpage, logging, sawing, and hauling to yard amounted to $20.13 per thousand board feet or $11,730, in addition an average of 2 months' cut had been sold but the bills were still uncollected and the hauling to railroad, loading, and selling of this lot had, at $5.40 per thousand board feet, amounted to $890; margin of safety (for slow sales, collections, and similar variations) on the average total investment of $16,186 at 15 per cent was $2,427. Hence, the total capital required was $18,600.

Computing Costs on Board Foot Basis

Since sales and costs of lumber are computed on the basis of a thousand board feet, the final step in allocating the costs of taxes, maintenance, depreciation, and interest is to total them and divide the total by the number of thousand board feet cut annually.

In farmer-operated mills some of the equipment is used at intervals for nonsawmill jobs and a fair apportionment of depreciation and interest costs against the sawmill operation is to proportion them on the basis of the fraction of the year they are available to this operation.

The accompanying tabulation (Table 15) from an Appalachian hardwood operation cutting about 1,000,000 board feet per year shows the nature and extent of costs that are frequently ignored.

SAWMILLS Pay More for Logs That Are Correctly Bucked Sawmills large and small are depending increasingly upon logs from farmers and small timberland owners. A few facts on how to buck felled trees, or cut them into logs, so that they will bring the most money may therefore be helpful. Before making any cuts, the felled tree should be sized up and laid off tentatively to determine where the cuts should be made in order to get as much of the stem as possible into upper grades.

Trees should be bucked so that the clear lumber is kept within the same log as far as possible. Sixteen feet is the most desirable length from the milling standpoint. Oftentimes, however, a 16-foot butt log is clear for 14 feet and has 2 feet of knotty material on the end. It will be better to cut it to 14 feet and leave the knotty material in the next log.

Much waste also results if long logs are cut regardless of the crookedness of a tree. (Fig. 150, A.) Most grading rules allow a 4-inch deflection from a straight line in a 16-foot log. Sharp crooks should be cut out entirely. (Fig. 150, B.)

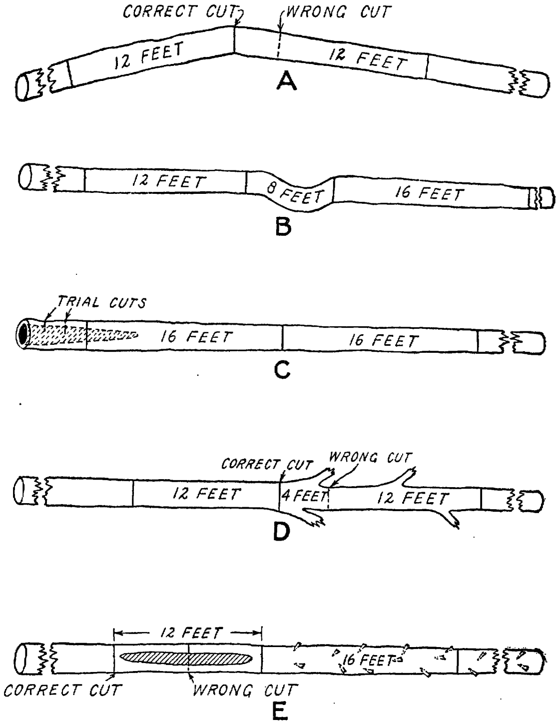

FIGURE 150.—A, Tree trunks with sweep should be cut where the sweep is greatest, even though some short logs may result; B, crooks should be eliminated; C, trial cuts should be made on rotten butts until enough sound material occurs to pay its way, the first log should be a long one; D, confine the clear material to the same log, in hardwoods the diameter below large branches is much larger than above them and the scale is consequently higher; E, rotten material, long cat faces, or other similar defects in softwoods should be confined to the same log

Making frequent trial cuts in defective butts or other sections where the extent of the defect is concealed, minimizes the chances of cutting out excessive sound material. (Fig. 150, C.) Most buyers, especially

Much waste also results if long logs are cut regardless of the crookedness of a tree. (Fig. 150, A.) Most grading rules allow a 4-inch deflection from a straight line in a 16-foot log. Sharp crooks should be cut out entirely. (Fig. 150, B.)

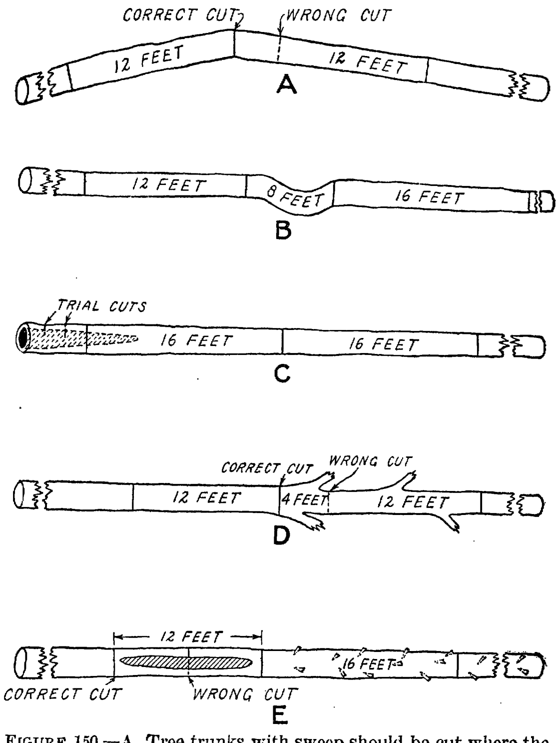

FIGURE 150.—A, Tree trunks with sweep should be cut where the sweep is greatest, even though some short logs may result; B, crooks should be eliminated; C, trial cuts should be made on rotten butts until enough sound material occurs to pay its way, the first log should be a long one; D, confine the clear material to the same log, in hardwoods the diameter below large branches is much larger than above them and the scale is consequently higher; E, rotten material, long cat faces, or other similar defects in softwoods should be confined to the same log

Making frequent trial cuts in defective butts or other sections where the extent of the defect is concealed, minimizes the chances of cutting out excessive sound material. (Fig. 150, C.) Most buyers, especially in the larger mills, encourage the butting of logs clear of all rot, which means better logs but more waste.

The value of the lumber from top, top knotty, and middle knotty logs is practically the same in logs 8 inches in diameter as in logs 20 inches in diameter. A large coarse-knotted log, however, costs considerably more to trim than one with small knots. Rotten material, long cat faces (fig. 150, D and E), or other similar defects in softwoods should be confined to the same log.

Freshly cut logs always bring a better price than weathered, stained, and dirty logs. Logs should be transported from the woods to the market as promptly as possible. When felling a tree, a low stump is important because high-quality material occurs in the lower part of the tree. Split logs, logs with splinters pulled from them, or logs with splinters hanging on the ends are never so desirable as logs without these defects.

SAWMILLS Profit by Closely Controlling Thickness of Boards

Farmer-operated sawmills often lose money by producing inaccurately cut lumber. The product brings less per thousand board feet and encounters stiffer sales resistance than that from the more accurate band mills. A less obvious loss is the excessive manufacturing waste that results from inaccurate cutting.

Recent studies by the Forest Products Laboratory indicate that the portable-mill operator, in sawing for thickness, cuts only about 20 per cent of the boards within one thirty-second of an inch of the thickness he sets for. The remaining 80 per cent vary in thickness from as much as eight thirty-seconds of an inch too thin to five thirty-seconds of an inch too thick. (Fig. 151, upper pile.) To counteract this tendency to cut too thin, the operator must set to cut most boards too thick. (Fig. 151, middle pile.) But in so doing each one thirty-second of an inch added reduces the possible total cut exactly as if the saw kerf were increased one thirty-second of an inch. A far better expedient is to minimize waste by keeping the equipment in good condition.

Causes of Inaccurate Cutting

The main causes for inaccurately cut lumber are: (1) Faulty condition of the saw, such as uneven filing of saw teeth, excessive or uneven swage, dull teeth on one side, unequal tension; (2) worn bearings in mandril, carriage wheels, and particularly in the setworks; (3) poor installation of carriage and saw, chips between log and headblock or on track; (4) careless setting, inadequate manipulation of dogs, miscalculation resulting in the last board cut from each log being either undersized or oversized; and (5) frozen timber, or other unusual stresses in wood.

After adjusting the saw, carriage, and track for the most accurate work possible, the output can be marketed as accurately cut lumber. In addition, waste in manufacture can now be reduced and yield increased by setting to cut all boards thinner. The number of thin rejects will not be increased thereby, because the effect of truing up in the larger mills, encourage the butting of logs clear of all rot, which means better logs but more waste.

The value of the lumber from top, top knotty, and middle knotty logs is practically the same in logs 8 inches in diameter as in logs 20 inches in diameter. A large coarse-knotted log, however, costs considerably more to trim than one with small knots. Rotten material, long cat faces (fig. 150, D and E), or other similar defects in softwoods should be confined to the same log.

Freshly cut logs always bring a better price than weathered, stained, and dirty logs. Logs should be transported from the woods to the market as promptly as possible. When felling a tree, a low stump is important because high-quality material occurs in the lower part of the tree. SAWMILLS Profit by Closely Controlling Thickness of Boards Farmer-operated sawmills often lose money by producing inaccurately cut lumber. The product brings less per thousand board feet and encounters stiffer sales resistance than that from the more accurate band mills. A less obvious loss is the excessive manufacturing waste that results from inaccurate cutting.

Recent studies by the Forest Products Laboratory indicate that the portable-mill operator, in sawing for thickness, cuts only about 20 per cent of the boards within one thirty-second of an inch of the thickness he sets for. The remaining 80 per cent vary in thickness from as much as eight thirty-seconds of an inch too thin to five thirty-seconds of an inch too thick. (Fig. 151, upper pile.) To counteract this tendency to cut too thin, the operator must set to cut most boards too thick. (Fig. 151, middle pile.) But in so doing each one thirty-second of an inch added reduces the possible total cut exactly as if the saw kerf were increased one thirty-second of an inch. A far better expedient is to minimize waste by keeping the equipment in good condition.

Causes of Inaccurate Cutting

The main causes for inaccurately cut lumber are: (1) Faulty condition of the saw, such as uneven filing of saw teeth, excessive or uneven swage, dull teeth on one side, unequal tension; (2) worn bearings in mandril, carriage wheels, and particularly in the setworks; (3) poor installation of carriage and saw, chips between log and headblock or on track; (4) careless setting, inadequate manipulation of dogs, miscalculation resulting in the last board cut from each log being either undersized or oversized; and (5) frozen timber, or other unusual stresses in wood.

After adjusting the saw, carriage, and track for the most accurate work possible, the output can be marketed as accurately cut lumber. In addition, waste in manufacture can now be reduced and yield increased by setting to cut all boards thinner. The number of thin rejects will not be increased thereby, because the effect of truing up equipment is to bunch boards closer to the intended one thirty-second of an inch group and thus to decrease the number of extremely thick and thin boards. (Fig. 151, middle pile.)

If twenty-eight thirty-seconds of an inch is taken as the thinnest dry lumber that qualifies, the set works can be moved either by one thirty-second of an inch intervals or, where the intervals are one sixteenth of an inch, by placing a one sixteenth of an inch leaf in the back stop, so that the entire cut is three thirty-seconds of an inch thinner. (Fig. 151, lower pile.) The consequent increase in yield is 4½ per cent. The ideal adjustment does not attempt to qualify every board but rather to set for thinner boards until a point is reached where the gain from increasing yields is balanced by the loss from thin rejects. This balance is reached when a 1½ per cent increase in rejects results from setting one thirty-second of an inch thinner. To determine this ideal adjustment for any mill, find what percentage of boards are too thin to qualify at the setting commonly used. Continue to set thinner by one thirty-second of an inch intervals until the number of thin boards increases by more than 1½ per cent over the previous setting. The ideal adjustment is one thirty-second of an inch thicker than this setting.

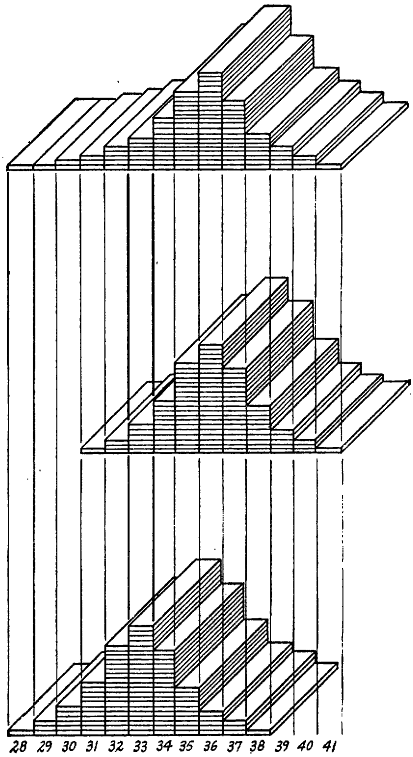

FIGURE 151.—Piles showing 100 boards sorted according to variations in cut. The top pile is typical of the farmer-operated mill. The middle pile shows the result of improved equipment; the cut is concentrated about the set of thirty-six thirty-seconds inches. The set can now be reduced to thirty-three thirty seconds, a far more economical cut, and still bring all boards within the original twenty-eight thirty-seconds inch qualification

Allowance Needed for Shrinkage

An allowance of one thirty-second of an inch must be made for shrinkage of inch softwood lumber from a green to a thoroughly air-dry condition. Moreover, most softwood grading rules admit 20 per cent twenty-eight thirty-seconds inch dry lumber; hence, the twenty-nine thirty-seconds inch green-lumber group is the thinnest to qualify. A mill cutting lumber as in the upper pile in Figure 151 should therefore set one thirty-second of an inch thinner, since the 1½ per cent increased yield is but partly offset by the 1 per cent increase in rejects. For a mill grouping its cut as in the lower pile in Figure 151, a one thirty-second of an inch thinner set, although gaining the 1½ per cent increased yield, results in an increase of 3 per cent in rejects.

The set-up for hardwood differs from this in that two thirty-seconds of an inch must be allowed for shrinkage (three thirty-seconds for beech and hickory), and the grading rule base is thirty-two thirty-seconds inch for rough dry lumber. Thus thirty-four thirty-seconds inches is the thinnest green board to qualify. A mill grouping its cut as in the upper pile in Figure 151 for hardwoods should set four places thicker, so that the 2 per cent shown in the thirty thirty-seconds inch group would be in the thirty-four thirty-seconds inches group.

Small-Mill Specialist, Forest Service.

SCALES May Be Balanced and Be Very Sensitive and Yet Be Inaccurate While thousands of tons of farm produce are weighed every day on farm scales, two mistaken ideas about scales are widely prevalent. As a consequence incorrect weights are sometimes accepted. One of those ideas is that if a scale balances, or is made to balance properly, with the scale platform empty and with the poises set to read zero, the scale is accurate. This idea may be erroneous.

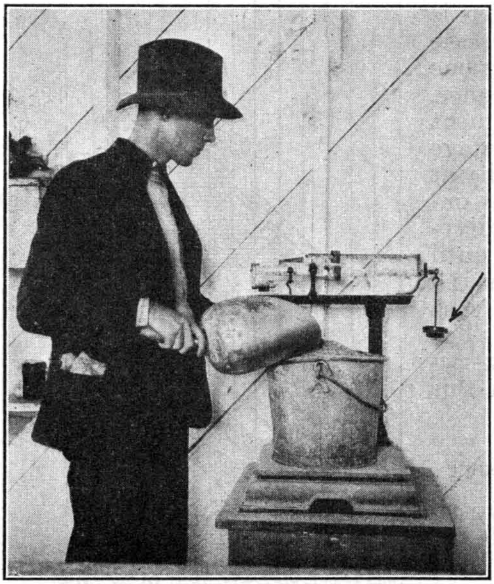

FIGURE 152.—A good scale that gave inaccurate weights. This bucket of feed normally weighing about 25 pounds registered 51 pounds. Investigation finally revealed that the ½-pound counterpoise weight (shown by arrow) had been borrowed from another scale having a different lever ratio

The fact that a scale balances correctly with the platform empty is no indication that the scale is accurate or that it does not possess serious defects. For instance, an accurate scale in good condition can be taken and the weight of both sliding and counterpoise weights can be reduced by half and the scale can be made to balance correctly with the platform empty. However, the weights obtained from the scale will be 100 per cent in error; a 100-pound load will be indicated as 200 pounds by the scale. Large errors of this character actually occur if counterpoise weights belonging to one scale are used on another scale designed for a different counterpoise ratio. (Fig. 152.)

Errors of similar character may arise from losing poise parts or from repairs made by persons who are not fully informed on scale construction and adjustment. For instance, if the set screw provided in some scales to clamp the poise to the beam in a desired position is removed through any cause, errors are produced in the weights obtained from the scale. The screw is a proper part of the weight of the poise in such a scale. In the foregoing case there will be nothing whatever in the action of the beam to indicate that incorrect weights are being obtained. Defects may exist also in the levers which may introduce errors in the weights and yet the beam can be balanced properly with no load on the scale.

seconds inch for rough dry lumber. Thus thirty-four thirty-seconds inches is the thinnest green board to qualify. A mill grouping its cut as in the upper pile in Figure 151 for hardwoods should set four places thicker, so that the 2 per cent shown in the thirty thirty-seconds inch group would be in the thirty-four thirty-seconds inches group.

C. J. TELFORD,
Small-Mill Specialist, Forest Service.

SCALES May Be Balanced and Be Very Sensitive and Yet Be Inaccurate

While thousands of tons of farm produce are weighed every day on farm scales, two mistaken ideas about scales are widely prevalent. As a consequence incorrect weights are sometimes accepted. One of those ideas is that if a scale balances, or is made to balance properly, with the scale platform empty and with the poises set to read zero, the scale is accurate. This idea may be erroneous.

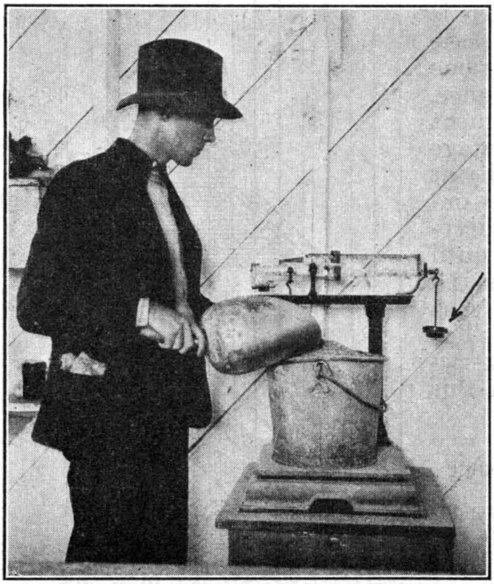

FIGURE 152.—A good scale that gave inaccurate weights. This bucket of feed normally weighing about 25 pounds registered 51 pounds. Investigation finally revealed that the ½-pound counterpoise weight (shown by arrow) had been borrowed from another scale having a different lever ratio

The fact that a scale balances correctly with the platform empty is no indication that the scale is accurate or that it does not possess serious defects. For instance, an accurate scale in good condition can be taken and the weight of both sliding and counterpoise weights can be reduced by half and the scale can be made to balance correctly with the platform empty. However, the weights obtained from the scale will be 100 per cent in error; a 100-pound load will be indicated as 200 pounds by the scale. Large errors of this character actually occur if counterpoise weights belonging to one scale are used on another scale designed for a different counterpoise ratio. (Fig. 152.)

Errors of similar character may arise from losing poise parts or from repairs made by persons who are not fully informed on scale construction and adjustment. For instance, if the set screw provided in some scales to clamp the poise to the beam in a desired position is removed through any cause, errors are produced in the weights obtained from the scale. The screw is a proper part of the weight of the poise in such a scale. In the foregoing case there will be nothing whatever in the action of the beam to indicate that incorrect weights are being obtained. Defects may exist also in the levers which may introduce errors in the weights and yet the beam can be balanced properly with no load on the scale.

If the scale does not balance properly with no load on the platform, the trouble may be serious or trivial. Sometimes shot may be lost from the shot cup or something may cause weight to be removed from or added to the scale platform and it may not be possible to bring the scale to balance with the balance ball provided for the purpose. In this case shot may be added or removed from the shot cup in the counterpoise hanger at the end of the beam until the scale can be balanced.

Generally, in adding or removing shot, it is best to place the balance ball in about the middle of its travel and bring the beam to balance with the platform empty, by the proper supply of shot. This gives the maximum leeway for moving the balance ball either way for taking care of the ordinary changes in the weight of the platform.

Sometimes, defects in a scale will be indicated by the balance of the empty scale. If, for no apparent reason, there is a rather sudden

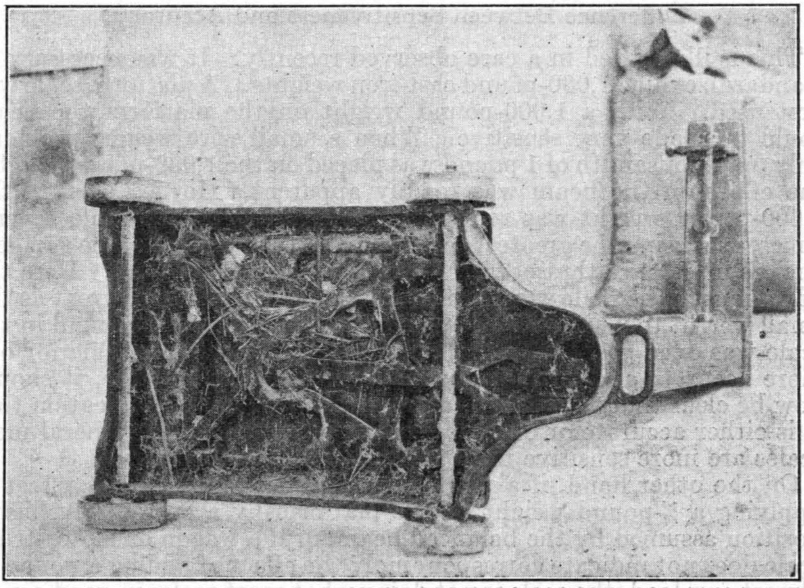

FIGURE 153.—One reason why scales go wrong. The accumulation of hay, straw, paper, string, and cob-webs, together with a mouse's nest between two levers of this scale, resulted in unreliable weights

change in the balance of the scale, investigate. Also be on the alert for slower changes. At the present time there are in scales probably thousands of nests of rats and mice which would have been discovered and cleaned out had each scale owner investigated why the scale had to have the balance adjusted or why the motion of the beam in weighing had changed from what it was at the previous weighing. (Fig. 153.)

Sensitiveness Unrelated to Accuracy

The second mistaken idea held by many scale users is that when a scale is very sensitive it is an accurate scale. Such is not necessarily the case. A scale may be very sensitive and readily show a pound applied on the scale platform and yet give weights in error by many pounds.

Consider the case previously used for illustration in which an accurate scale in good working order was used with another scale's counter-poises, of only half the proper weight. In such an instance the actual sensitiveness of the scale would not be changed. A pound weight on the scale platform would cause the same change in the balance position of the beam as before. Yet, the scale would give only half the proper weight.

It is easier to make a scale sensitive than it is to make it accurate and constant. To make a scale loaded with 10,000 pounds show the effects of adding a 1-pound weight to the 10,000 pounds already there is not difficult. But it is difficult, unusual, and expensive to get a scale which will weigh loads of about 10,000 pounds accurately to the nearest pound. Generally when a 10,000-pound load is removed and reapplied, even with the greatest care, differences of 2 or 3 pounds will appear in the indications for the weights obtained. The same relations substantially hold for smaller scales and smaller loads.

Difference Between Sensitiveness and Accuracy

This is illustrated in a case observed recently. It was necessary to standardize some 1,000-pound cast-iron weights. A platform scale was first used. With a 1,000-pound weight on the platform the beam could be made very sensitive. When a small wire weight weighing only one-thousandth of 1 pound was placed on the 1,000-pound weight, the effect on the beam was readily apparent. However, when the 1,000-pound weight was removed and replaced on the scale several times, exercising the greatest care not to disturb the scale, the smallest change in balance that occurred was a quarter of a pound. Here the variations in the scale were two hundred and fifty times as great as the small weight to which the scale was sensitive. The error found in the scale was even greater. It was necessary to reject this scale for one more accurate and constant but less sensitive. Therefore, it should now be clear that the fact a scale is sensitive is not an indication that it is either accurate or constant in its performance. In general most scales are more sensitive than they are accurate or constant.

On the other hand, if a platform scale does not show the effect of applying a ¼-pound weight on the platform by a perceptibly higher position assumed by the balanced beam, or if a wagon or motor-truck scale does not indicate correspondingly the effect of adding a pound to almost any load, the scale is not doing what most scales in good condition will do, and there is probably something wrong with it.

There is just one way to determine whether a scale is accurate and that is to test it thoroughly. This consists in using standard test weights and determining that the scale weighs correctly (1) at all loads it will be used to weigh and (2) in all positions of the weights on the scale platform in which the load is likely to be placed in the ordinary course of weighing.

Livestock Weight Supervisor, Bureau of Animal Industry.

SEED Treatment and Warm Soil Improve Stands of Sorghum

The securing of satisfactory and uniform stands is one of the chief difficulties in growing grain sorghums. The sorghums require relatively high temperatures for germination and early growth, and the seeds are easily rotted when planted in cold, wet soil. Varieties such as the feteritas, having soft poises, of only half the proper weight. In such an instance the actual sensitiveness of the scale would not be changed. A pound weight on the scale platform would cause the same change in the balance position of the beam as before. Yet, the scale would give only half the proper weight.

It is easier to make a scale sensitive than it is to make it accurate and constant. To make a scale loaded with 10,000 pounds show the effects of adding a 1-pound weight to the 10,000 pounds already there is not difficult. But it is difficult, unusual, and expensive to get a scale which will weigh loads of about 10,000 pounds accurately to the nearest pound. Generally when a 10,000-pound load is removed and reapplied, even with the greatest care, differences of 2 or 3 pounds will appear in the indications for the weights obtained. The same relations substantially hold for smaller scales and smaller loads.

Difference Between Sensitiveness and Accuracy

This is illustrated in a case observed recently. It was necessary to standardize some 1,000-pound cast-iron weights. A platform scale was first used. With a 1,000-pound weight on the platform the beam could be made very sensitive. When a small wire weight weighing only one-thousandth of 1 pound was placed on the 1,000-pound weight, the effect on the beam was readily apparent. However, when the 1,000-pound weight was removed and replaced on the scale several times, exercising the greatest care not to disturb the scale, the smallest change in balance that occurred was a quarter of a pound. Here the variations in the scale were two hundred and fifty times as great as the small weight to which the scale was sensitive. The error found in the scale was even greater. It was necessary to reject this scale for one more accurate and constant but less sensitive. Therefore, it should now be clear that the fact a scale is sensitive is not an indication that it is either accurate or constant in its performance. In general most scales are more sensitive than they are accurate or constant.

On the other hand, if a platform scale does not show the effect of applying a ¼-pound weight on the platform by a perceptibly higher position assumed by the balanced beam, or if a wagon or motor-truck scale does not indicate correspondingly the effect of adding a pound to almost any load, the scale is not doing what most scales in good condition will do, and there is probably something wrong with it.

There is just one way to determine whether a scale is accurate and that is to test it thoroughly. This consists in using standard test weights and determining that the scale weighs correctly (1) at all loads it will be used to weigh and (2) in all positions of the weights on the scale platform in which the load is likely to be placed in the ordinary course of weighing.

Livestock Weight Supervisor, Bureau of Animal Industry.

SEED Treatment and Warm Soil Improve Stands of Sorghum The securing of satisfactory and uniform stands is one of the chief difficulties in growing grain sorghums. The sorghums require relatively high temperatures for germination and early growth, and the seeds are easily rotted when planted in cold, wet soil. Varieties such as the feteritas, having soft starchy seed coats, are very susceptible to decay; milos and kafirs are somewhat less susceptible; while the sorgos (sweet sorghums) are the least likely to decay.

Seed treatment with copper carbonate or with one of several commercial organic mercury compounds often improves sorghum stands by largely preventing seed decay. Treatment is especially effective if the soil is cold or if soft-seeded varieties are planted. The stands of feterita obtained sometimes are more than doubled by seed treatment, although in warm soil the differences in stand are much less. These seed treatments also control kernel smut of sorghums. The varieties least susceptible to seed rotting often are most susceptible to smut, while some of the varieties that are most susceptible to rotting are rather resistant to smut. Consequently, it pays to treat all sorghum varieties as an insurance against losses from either seed rots or smut. The chemical dusts may be applied with a wheat-treating machine or by shaking the dust and seed together in a tight can or box. Three ounces of the dust per bushel of seed is sufficient. Since a bushel of grain-sorghum seed will plant from 10 to 40 acres, the cost and labor of treating enough seed for an acre are small items in comparison with the probable benefits.

Poor Germination Below 50° F.

Sorghums germinate very poorly, if at all, at temperatures lower than about 50° F. and usually germinate best at temperatures as high as 70° to 80°. During the spring the average temperature of the soil near the surface usually is slightly higher than the mean air temperature, but the soil at lower depths is cooler than the air. The soil will be sufficiently warm for sorghum planting if planting is delayed and proper preparation of the seed bed is practiced.

In an experiment at Hays, Kans., sorghums produced stands 50 to 100 per cent better when planted in May than when planted a month earlier. Several experiments in Oklahoma and Texas have shown similar increases in stand from delayed planting up until June, provided ample moisture was available at all plantings. Yields of grain sorghums usually are higher from planting after May 15 to June 1, if the soil is kept well tilled and free from weeds before planting, and where insects do not attack the late-planted crop.

Many farmers plant sorghums in the bottom of a lister furrow in cold soil which has not been worked previous to the planting operation, and poor stands frequently result. Experiments have shown that the stands obtained from lister planting usually are thinner than from surface planting unless the surface soil is too dry for germination. Better stands can be obtained by working the land well before planting. Additional tillage before planting also often reduces the number of cultivations necessary after planting. The land can be plowed and harrowed and the seed planted either with a surface planter or lister. The lister method of preparing the land and planting the seed is preferred by most farmers, largely because of the economy of labor and because it prevents soil blowing.

Lister Method of Planting

A lister method of planting grain sorghums, which nearly always results in excellent stands, has been developed in cooperative experiments at the Fort Hays (Kans.) Branch Experiment Station. The land is first listed in late fall or early spring. When weeds start to grow in the spring the lister furrows are "thrown in" with a "ridge buster." The seed is later planted in the old furrow with a lister planter or with a surface planter equipped with disk furrow openers. Only part of the loose soil is thrown out in the planting operation, and a layer of mellow, warm soil is left in the bottom of the furrow where the seeds are planted.

By proper attention to seed treatment, time of planting, and seedbed preparation, considerable loss from low yields due to poor stands or from the expense of replanting may be avoided. A loss of stand due to soil washing during heavy rains is difficult to prevent in lister-planted sorghums.

SHEEP Grow Better on Alfalfa Than Timothy Hay, Experiments Show Much has been said relative to the feeding value of timothy and alfalfa hays for sheep in New England, since timothy hay is abundant and cheap there, whereas alfalfa hay is rather expensive and not always available. That alfalfa can be grown successfully in the New England States and is not so uncertain a crop as it was once thought to be is accepted more fully each year.

To obtain information on the value of these hays for sheep, the Bureau of Animal Industry conducted a feeding trial at its experiment farm near Middlebury, Vt., during the winter of 1929–30. Twenty-eight grade ewe lambs were divided equally into two uniform lots, each lot consisting of six grade Southdowns and eight grade Shropshires. These lambs were the product of a grading-up experiment in which, at the beginning, crossbred Lincoln-Rambouillet ewes of the western type were bred to purebred Southdown and Shropshire rams. Their selected ewe offspring were mated with Southdown and Shropshire rams, respectively, for several generations. The ewe lambs used in the feeding trial here described were of the third and fourth top crosses.

Lot 1 received home-grown timothy hay, corn silage, and a grain mixture composed of 4 parts cracked corn, 4 parts oats, 2 parts bran, and 1 part linseed meal, by weight. Lot 2 received home-grown alfalfa hay and the same weight and quality of corn silage and grain mixture as were fed to lot 1. The only appreciable variation in the two rations was the kind of hay. The quantities of feed consumed by each lot were practically equal. Each sheep received daily 0.5 pound of the standard grain mixture, 1.5 pounds of corn silage, and 2 pounds of hay, lot 1 receiving timothy and lot 2 alfalfa. The timothy hay was typical of normal timothy hay—that is, it was made when rather mature—and the alfalfa hay was also typical for New England. (Table 16.)

Weekly weights were taken of individual sheep in each lot throughout the experiment. The trend of the average weights of the sheep, by breeds, is shown in Table 16.

From the figures in Table 16 it is apparent that gains were greater and more consistent in the alfalfa-fed lots. Average weights, however, may not be conclusive evidence of a larger body growth, so, after these ments at the Fort Hays (Kans.) Branch Experiment Station. The land is first listed in late fall or early spring. When weeds start to grow in the spring the lister furrows are "thrown in" with a "ridge buster." SHEEP Grow Better on Alfalfa Than Timothy Hay, Experiments Show

Much has been said relative to the feeding value of timothy and alfalfa hays for sheep in New England, since timothy hay is abundant and cheap there, whereas alfalfa hay is rather expensive and not always available. That alfalfa can be grown successfully in the New England States and is not so uncertain a crop as it was once thought to be is accepted more fully each year.

To obtain information on the value of these hays for sheep, the Bureau of Animal Industry conducted a feeding trial at its experiment farm near Middlebury, Vt., during the winter of 1929–30. Twenty-eight grade ewe lambs were divided equally into two uniform lots, each lot consisting of six grade Southdowns and eight grade Shropshires. These lambs were the product of a grading-up experiment in which, at the beginning, crossbred Lincoln-Rambouillet ewes of the western type were bred to purebred Southdown and Shropshire rams. Their selected ewe offspring were mated with Southdown and Shropshire rams, respectively, for several generations. The ewe lambs used in the feeding trial here described were of the third and fourth top crosses.

Lot 1 received home-grown timothy hay, corn silage, and a grain mixture composed of 4 parts cracked corn, 4 parts oats, 2 parts bran, and 1 part linseed meal, by weight. Lot 2 received home-grown alfalfa hay and the same weight and quality of corn silage and grain mixture as were fed to lot 1. The only appreciable variation in the two rations was the kind of hay. The quantities of feed consumed by each lot were practically equal. Each sheep received daily 0.5 pound of the standard grain mixture, 1.5 pounds of corn silage, and 2 pounds of hay, lot 1 receiving timothy and lot 2 alfalfa. The timothy hay was typical of normal timothy hay—that is, it was made when rather mature—and the alfalfa hay was also typical for New England. (Table 16.)

Weekly weights were taken of individual sheep in each lot throughout the experiment. The trend of the average weights of the sheep, by breeds, is shown in Table 16.

From the figures in Table 16 it is apparent that gains were greater and more consistent in the alfalfa-fed lots. Average weights, however, may not be conclusive evidence of a larger body growth, so, after these sheep were sheared on April 22, 1930, they were measured for width, depth, height, belly circumference, and length from nose to tail. That the alfalfa-fed sheep were larger than the timothy-fed sheep is evident from Table 17.

TABLE 16.—*Average weight of Southdown and Shropsnire sheep receiving timothy and alfalfa hay, respectively, in their rations*

Breed	Kind of hay (2 pounds daily)	Weight of sheep on —						
		Nov. 27	Dec. 25	Jan. 22	Feb. 19	Mar. 19	Apr. 16	May 7
		Pounds	*Pounds*	*Pounds*	*Pounds*	*Pounds*	*Pounds*	*Pounds*
Southdown	Timothy	71.0	70.8	75.5	75.6	74.8	78.8	[1] 74.0
	Alfalfa	70.5	71.5	75.8	78.5	79.5	83.8	[1] 80.5
Shropshire	Timothy	71.9	72.4	74.6	73.6	76.1	79.2	[1] 74.9
	Alfalfa	71.6	72.6	77.4	79.6	83.9	88.7	[1] 88.6

[1] Weights after shearing.

TABLE 17.—*Average body measurements after shearing of Southdown and Shropshire sheep receiving timothy and alfalfa hay, respectively, in their rations*

Breed	Kind of hay (2 pounds daily)	Body measurements				
		Width	Depth	Height	Belly circumference	Length from nose to tail
		Inches	*Inches*	*Inches*	*Inches*	*Inches*
Southdown	Timothy	7.8	9.4	20.7	32.2	41.9
	Alfalfa	8.0	9.7	21.4	34.7	41.5
Shropshire	Timothy	7.4	9.9	21.7	33.1	42.7
	Alfalfa	8.1	10.1	22.6	35.7	43.6

On the basis of average prices of these hays for the United States, at the time these sheep were fed, the alfalfa hay cost 48 cents per ewe more than the timothy hay for the 161-day winter-feeding period. The benefits of the increased thrift, size, and substance from the alfalfa hay in this experiment suggest the desirability of feeding good alfalfa hay as compared with normal, rather mature timothy hay for young breeding ewes.

SMALL-SCALE Farming Is Widespread in U. S., Census Figures Show Sixty per cent of the farm population of the United States were, in 1925, living on farms whose size was less than 100 acres. About 40 per cent were then living on farms of less than 50 acres. Fifteen per cent were living on farms of less than 20 acres. Broadly speaking, a farm in the United States of less than 20 acres is by common consent a small farm. Nor will many persons object to calling a farm of less than 50 acres a small farm. The people on such farms now number 10,000,000. These small farms are not all divided-up acreages of large cotton and tobacco holdings, as is occasionally hinted. In the region of the East North Central States, which includes Ohio, Indiana, Illinois, Michigan, and

Wisconsin, 24 per cent of the farms are under 50 acres; in Ohio, 30 per cent; in Illinois, 20 per cent. In the West North Central States—the Dakotas, Nebraska, Kansas, Minnesota, Iowa, Missouri—the States of supposedly large-sized farms, 15 per cent are small farms. Even in Iowa 16 per cent of all farms contain less than 50 acres each.

What is the situation of small-scale farmers? Who are they and why are they in small-scale farming? There are two quite legitimate uses, usually, of every farm in the United States—one is affording the opportunity to grow a product of value; the other is affording a good place to live. The most desirable farm from the production standpoint may not satisfy the ideal of a desirable place to live; and the most desirable land on which to live may not come up to the standard of a desirable farm for production. A small farm as a living place, however, may be on a par with a large farm. In fact, the small farm as a habitation is quite likely to overtop the small farm as an instrument of production (except where a small farm of good land is so intensively organized that it amounts to a highly capitalized business; and this type of farm is not being considered in this article), and one must be prepared to concede to the small farm preeminent value as a good place to live.

Three Groups of Small Farmers

Studies during the past year indicate that there are three main classes of persons living on small farms in the United States. The first class is made up of those who would rather own a small farm, if possible, than rent a larger farm.

The second class is composed of men who, whether they own or rent, feel at home with a small type of job, and are ill at ease with a large job.

The third class includes men who appreciate the small farm first of all as a place to live. These men reckon the small farm as equivalent for living purposes to a farm of large size. This type of farmer thinks first of his family, its security, space for restless, growing children, without large expense or great responsibility to produce.

Uniform neglect to establish a public policy for small farms and small farmers lends color to the idea that small farms are generally overlooked in public thought, or to the idea that small farms stand in the way of agricultural progress, and are being left to the fate of ruthless attrition, in the expectation of their eventual disappearance.

It is generally conceded that small farms can not be operated to advantage along the same lines of farm practice as large farms. Small operations in mercantile business are totally different from large operations in business. Yet there are thousands and thousands of legitimate small businesses. Small factories are run on a different system from large factories. Yet out of 200,000 factories in the United States, there are 80,000 factories employing between 6 and 50 operatives only and 90,000 employing less than 6 operatives.

Denmark's Small Farms

Why should we think that the small farm, just because it is not adapted to the mechanical technic of operations employed on a large farm, can not be operated advantageously on principles specially adapted to small-scale farming? In 1928, Denmark had 206,000 farms of which 109,000, or over 50 per cent, were in small holdings ranging from 1¼ to 25 acres; 69,000 holdings were farms with a range of from 25 to 75 acres. The Danes long ago set up and perfected a special production and marketing program for their small holders which has justified their existence alongside of the large farmers.

Let us suppose, however, that this special technic for the operation of small farms in the United States is not immediately forthcoming. Even then, the case against the small farm is feeble until it is shown that small-scale farming dooms the future personality and career of the children of the small farmer, or is incompatible with proper living standards. Europe has always owed a debt to its mountaineers. The highlands of Scotland, the mountains of Switzerland, the rugged slopes of Norway—all the abode of small farmers—have been and still are famous for their people. The 40 per cent of our farm population who live on small farms deserve, as a matter of fair play, serious investigation into ways of improving their production and their level of living.

Bureau of Agricultural Economics.

SOIL Erosion Is Often Caused by Burrowing Rodents A casual observer may wonder why a mountain stream, rushing and tumbling out of wooded hills, has such clear sparkling water, when the same stream, after winding its devious course through miles of lowlands, bordered with stock ranges or farms, becomes murky and muddy in appearance. The answer is to be found in conditions caused by erosion, the results of which may well alarm any one who will study them carefully. The headwaters of many streams, even though they flow at a rate that would quickly cut unprotected soil, carry only a light quantity of silt, because the upper watersheds are frequently well protected with a heavy vegetative cover, and, also, because the beds of the headwater channel ways are often stony and resistant to abrasion. Along the lower levels, cultivated fields, open to the effects of washing rains and cutting winds, supply ample eroded material to roil the waters as they flow through the wider valleys and eventually to the ocean.

The quantity of silt carried by the streams of the country is appalling. Bennett and Chapline[11] estimate that not less than 126,000,000,000 pounds of plant food material is removed by erosion from the fields and pastures of the United States every year. Not only are valuable plant foods thus removed, but much of the soil itself. This accounts for the yearly increasing silt deposits in the lower Mississippi Valley, with attendant difficulties in holding this treacherous stream within the bounds of man-made levees.

The removal of vegetative cover not only exposes the soil to the washing and eroding effects of rain, but is a large factor in the primary cause of the increased frequency and volume of floods. Trees, undergrowth, and grass form a surface matting of leaves and decaying vegetation that acts as a sponge in absorbing rain and as a screen to keep open the pores of the soil—the natural channel ways through which

ranging from $1\frac{1}{4}$ to 25 acres; 69,000 holdings were farms with a range of from 25 to 75 acres. The Danes long ago set up and perfected a special production and marketing program for their small holders which has justified their existence alongside of the large farmers.

Let us suppose, however, that this special technic for the operation of small farms in the United States is not immediately forthcoming. Even then, the case against the small farm is feeble until it is shown that small-scale farming dooms the future personality and career of the children of the small farmer, or is incompatible with proper living standards. percolating water passes. With the removal of such cover and the clogging of the soil openings with silt descending in muddied erosional water, the rain water rushes from the barren hillsides without check and results in serious floods in the valleys below.

Rodents on Western Ranges

Among the causes of erosion, the Bureau of Biological Survey finds that the part played by rodents is by no means inconsequential. Prairie dogs, ground squirrels, and pocket gophers infest western range and farming lands literally by the millions. W. P. Taylor,[12] in a recent rodent survey, found one rodent to each 1,088 square feet on the Santa Rita Range Reserve near Continental, Ariz. He estimates that there are 2,000,000 rodents on this 50,000-acre reserve.

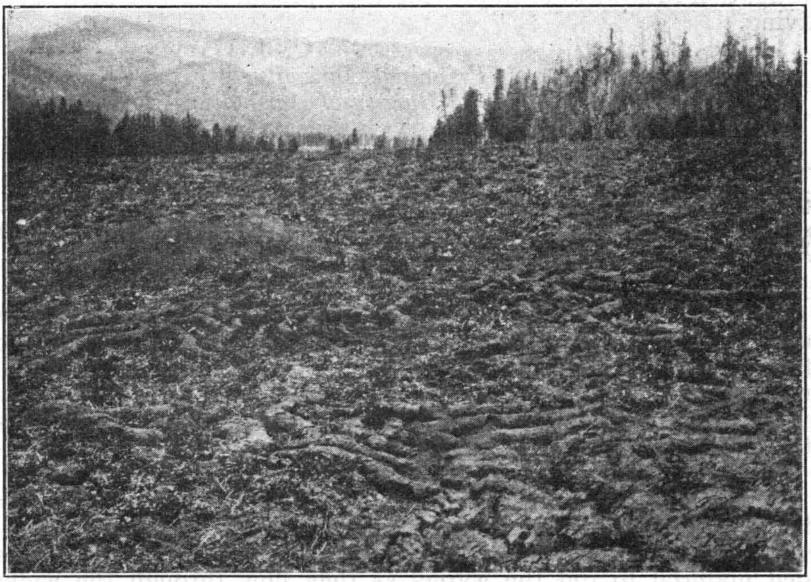

FIGURE 154.—Winter workings of pocket gophers in a mountain park of western Colorado. Such excavations, made under the snow, are definite means of starting erosion

Prairie dogs build their characteristic large mounds in inverted-funnel shape to prevent rain water draining into the underground burrows. As a means of protection against natural enemies, as well as for food, they keep all grass cropped close within a radius of 15 or more feet of the burrows. Not only is the grass cut short, but the roots are dug out. Thousands of acres of valuable western range land have thus been denuded by the ravages of this crop pest, and many cases of erosion, resulting directly from the removal of the grass cover and the building of mounds by prairie dogs, have been noted.

Perhaps the worst rodent pests, from the standpoint of causing erosion, are the pocket gophers, which are found in great numbers in all the Western States. These small, underground rodents burrow with apparently untiring efforts. In summer they throw the dirt re-

[12] TAYLOR, WALTER P. METHODS OF DETERMINING RODENT PRESSURE ON THE RANGE. Ecology 11 (3): 523-542, July, 1930.

moved by their burrowing activities to the surface of the ground, piling it up in mounds. When the snow comes in fall, and before it has melted away in spring, pocket gophers push the surplus dirt out of their underground workings in the form of long, chainlike ridges, or miniature dikes, as illustrated in Figure 154. With the melting of the snow, these earthworks form guide channels for water, and thus aid in starting definite erosion scars. Later, when sheep and cattle enter the mountain areas, the trampling stock break through into the shallow runways, creating more passageways to carry off the rains and melting snows. In many areas, following the destruction of forage and the removal of much of the surface soil in this combination of trampling by livestock and washing by rains, weeds and ofttimes poisonous plants gain a foothold. This creates a very serious range condition. (Fig.155.)

FIGURE 155.—An acre of alfalfa land, valued at $400, ruined by erosion resulting from pocket-gopher activities

Damage to Irrigation Works

In irrigation districts many instances of breaks in ditches and in reservoir dikes are directly traceable to burrowing by ground squirrels, pocket gophers, or prairie dogs. A small hole in the bank of an irrigation ditch carrying a heavy load of water soon plays havoc, in many places cutting great gullies. Not only is erosion damage great, but the loss in water, badly needed to produce crops, frequently amounts to thousands of dollars before the break can be repaired. Such a case occurred in Idaho, when a pocket gopher burrowed through an irrigation canal that carried 18,000 inches of water for the irrigation of 30,000 acres. Repairs to the break cost $5,000 and before the ditch could be put in serviceable condition the drought resulted in the loss of 25 per cent of the crops. Figure 156 illustrates the havoc a rodent burrow can cause in an irrigation district.

Prompt and effective measures of checking the destructive effects of erosion should be applied as soon as its beginnings become apparent, if wasteful loss of soil is to be prevented. A large part of the present erosion problem would be solved if effective rodent-control methods could be put into practice on many of the western mountain range areas and farming districts. The Bureau of Biological Survey is aiding in the organization of such control units in all the Western

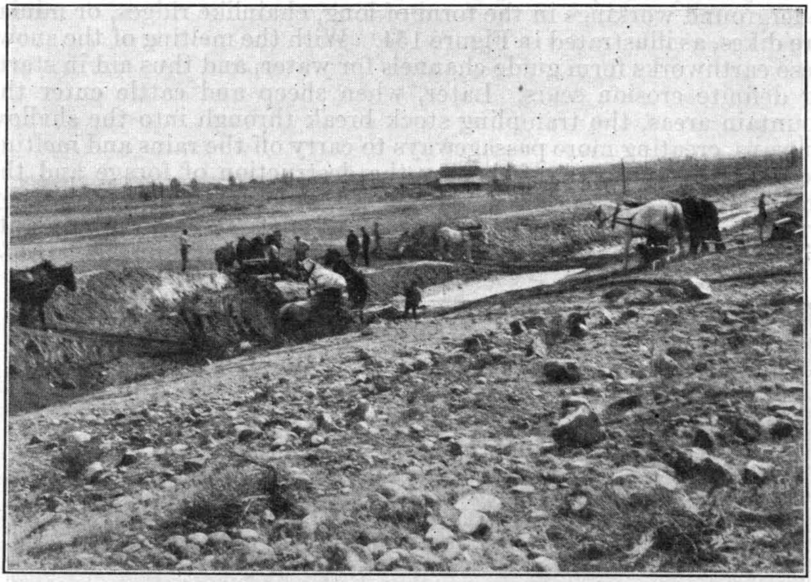

FIGURE 156.—Expensive break in irrigation ditch near Kennewick, Wash., caused by water finding its way through burrows made by pocket gophers

States, which will, in time, assist greatly in preventing further loss of soil through erosion caused by rodents.

Biologist, Bureau of Biological Survey.

SPRAY Residue Removal by Latest Methods Is an Economic Benefit The removal of arsenical spray residue from apples and pears is an almost universal practice in the Pacific Northwest. With more stringent regulatory measures being enforced, spray-residue removal has become necessary and is being adopted more and more in other sections of the country. Prolonged dry weather such as prevailed during 1930 over large areas of the Eastern States made it necessary for many growers to face this problem for the first time in areas where it had not been anticipated that the difficulty would be encountered.

Combination of lead arsenate with oil sprays generally makes fruit cleaning more difficult than when lead arsenate is applied alone. However, when these combination sprays are prepared with oils of a viscosity of 75 Saybolt or less, with relatively high volatility, and when properly applied, difficulty of cleaning is not materially increased.

Such combination sprays should be used immediately after mixing, in order to avoid separation and resulting heavy oil-covered blotches of residue on the fruit. Late applications of combined lead-arsenate oil sprays should be avoided.

The sooner fruit is cleaned after harvest the more easily the cleaning can be accomplished and with less risk of damage. If cleaning and areas and farming districts. The Bureau of Biological Survey is aiding in the organization of such control units in all the Western

States, which will, in time, assist greatly in preventing further loss of soil through erosion caused by rodents.

ALBERT M. DAY,
Biologist, Bureau of Biological Survey.

SPRAY Residue Removal by Latest Methods Is an Economic Benefit The removal of arsenical spray residue from apples and pears is an almost universal practice in the Pacific Northwest. With more stringent regulatory measures being enforced, spray-residue removal has become necessary and is being adopted more and more in other sections of the country. Prolonged dry weather such as prevailed during 1930 over large areas of the Eastern States made it necessary for many growers to face this problem for the first time in areas where it had not been anticipated that the difficulty would be encountered.

Combination of lead arsenate with oil sprays generally makes fruit cleaning more difficult than when lead arsenate is applied alone. However, when these combination sprays are prepared with oils of a viscosity of 75 Saybolt or less, with relatively high volatility, and when properly applied, difficulty of cleaning is not materially increased.

Such combination sprays should be used immediately after mixing, in order to avoid separation and resulting heavy oil-covered blotches of residue on the fruit. Late applications of combined lead-arsenate oil sprays should be avoided.

The sooner fruit is cleaned after harvest the more easily the cleaning can be accomplished and with less risk of damage. If cleaning and packing are unavoidably delayed the fruit should be held in the coolest storage available.

Dry cleaning is not generally satisfactory for removing excessive arsenical spray residue. Moreover, when the elements of cost, relative efficiency, safe handling of fruit, and capacity are considered, washing methods are invariably more economical and satisfactory.

To be commercially practicable, washing equipment should clean fruit satisfactorily without the necessity for frequent repairs and adjustment, and with a minimum of rough handling and mechanical or chemical damage to the fruit. Several types and sizes of satisfactory washing equipment are on the market, and it is also possible to construct satisfactory homemade devices. (Fig. 157.)

Washing methods employing hydrochloric acid are by far the most frequently used, although alkaline materials may also be employed. The latter are gelnerally efficient, but because of the solvent effect of alkalies upon the waxy coating of the fruit their use must be supervised rather closely, particularly the rinsing phase. Washing methods that require submersing the fruit more than a few inches below the surface of the liquid should be avoided, especially if the varieties to be washed have open calyx tubes, in order to avoid possible penetration of the washing solution into the core region with consequent injury and possible decay.

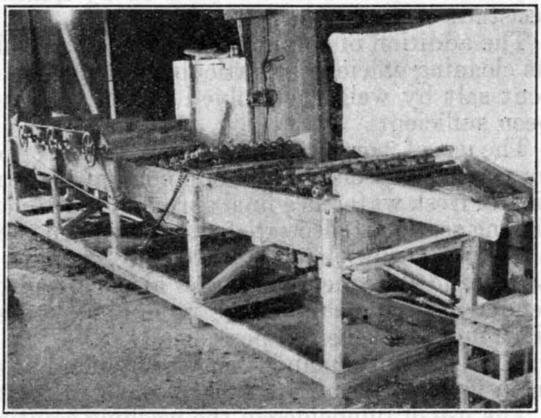

FIGURE 157.—Homemade washer of paddle type for removal of spray residue from apples and pears

Simple Dipping Relatively Inefficient

One of the primary requisites of any washer is that it shall move as large a quantity of fresh solvent over the fruit per unit of time as is mechanically economical. Simple dipping methods are therefore at a disadvantage in fruit cleaning unless the washing solution is agitated.

The satisfactory washing of apples and pears generally requires an acid concentration of at least 1 gallon to 100 gallons of water. The commercial grade of hydrochloric or muriatic acid is used.

Increasing the acid concentration to 4 gallons to 100 gallons of water gives significant increase in cleaning efficiency, but beyond this does not generally justify the added cost, and the higher concentrations put a greater burden on the rinsing section, as well as increase the danger of injury to the fruit from acid burning and from soluble arsenic, which may result on poorly rinsed fruit.

The acid concentration should be determined frequently. Simple and inexpensive apparatus is available for this purpose. Notes should be kept of the acid strength and temperature, of the chemical analyses made on the fruit, and of any other significant information, for reference in future operations.

The time required to remove spray residue depends upon a number of factors, such as the variety and maturity of the fruit, the amount of residue present, the strength and temperature of the acid solution, and the method of application. Generally, with flotation washers, an exposure of the fruit to the cleaning solution for 3 to 5 minutes is sufficient. When a dipping method is used, in which there is not much agitation of the solvent, an exposure of 5 minutes is generally required. Where the solution is pumped or thrown over the fruit an exposure of from 2 to 4 minutes is usually sufficient. With commercial washing machines 20 to 40 seconds generally suffice.

By raising the temperature of the cleaning solution to 80° F. and preferably to 95° or 100°, increased efficiency may be obtained. Warming the acid generally can be done best by some form of low-pressure steam coils placed in the tank or by heating directly in corrosion-resistant coils.

The addition of common salt to the acid solution will often enhance its cleaning efficiency, particularly if the solvent is warmed. One per cent salt by weight dissolved in the washing solution has generally been sufficient.

The use of 2 or 3 gallons of fresh water per bushel of fruit is desirable for rinsing. Recirculation of a portion of the rinse water and the addition of fresh water as a final spray or flood over the fruit as it leaves the rinsing section is also satisfactory. When there is a great shortage, all of the water may be circulated and 2 pounds of lime to 100 gallons of water added to neutralize the acid carried over on the fruit and to render insoluble the arsenic remaining. In such cases, however, the rinse must be renewed periodically.

The acid solution and rinse tanks should be emptied and flushed with fresh water after about 1,000 bushels of fruit have been cleaned.

The use of fungicides in the washing solution or rinse water has not given any practical benefit in reducing the danger of decay in the fruit. This danger is not great, however, if the washing is done with proper equipment and under reasonably sanitary conditions.

Injury From Faulty Washing

Faulty washing practices sometimes cause certain types of injury: (1) Arsenical injury, which occurs as depressed dark brown or black spots, sometimes extending into the flesh and usually found in the calyx end of the fruit; (2) hydrochloric acid injury, which is light brown or tan in color and may occur on any portion of the fruit; (3) chemical injury at the core, due to penetration of cleaning solution through open calyx tubes; and (4) mechanical injury due to defects in the equipment and rough handling. The remedies for these troubles have already been suggested in this discussion.

Reasonable drying of the fruit facilitates packing, but when it is well rinsed no storage troubles have resulted from the packing of wet fruit. Drying by air blasts, which sweep the water off the fruit, or by different types of cloth-drying apparatus are more satisfactory than by brush driers. The cloths on the rollers of wiping equipment, designed primarily for dry cleaning, will also serve the purpose, but must be frequently renewed if they are to function satisfactorily.

Commercial experience with properly washed fruit indicates that it keeps as well as unwashed fruit, that better grading and sorting result, that the final appearance of the fruit is much more attractive, and that it commands a higher price. Fruit cleaning, therefore, is a distinct benefit, particularly in sections where considerable spraying with arsenicals is necessary.

Physiologist, Bureau of Plant Industry.

STANDARD Specifications for Household Buying Are Being Developed

At the present time many farm products are graded for sale according to standards set up by the Bureau of Agricultural Economics. Manufacturers have for a long time been writing accurate descriptions for the raw materials and partly finished goods they buy. The Bureau of Standards of the Department of Commerce has worked with industrial and commercial agencies in setting up specifications that have limited the production of various articles to a given number of sizes and thereby cut down manufacturing costs. The Federal and State Governments have worked out specifications for purchases for various Government institutions. The housewife is beginning to ask why she can not buy in accordance with specifications that are guaranteed by the manufacturers.

The Bureau of Home Economics and the American Home Economics Association received so many requests for information on the subject of standard specifications for household goods that they cooperated during the past year in the compilation and publication of the booklet called "Household Purchasing: Suggestions for Club Programs." This booklet outlines the material available for club programs on difficulties the consumer meets in the present market, food standards and grades, food containers, weights and measures, quality standards and grades for foods, buying textiles and clothing, household equipment, and what the Government can do to help the consumer. The programs are now in use by a number of extension clubs.

In this attempt to bring together information as to the standard specifications which are now in definite, usable form for the housewife, several points came to light.

Some of the grades used in sorting agricultural products for the market can profitably be used by the housewife in her purchasing, provided definite information is furnished her as to what these grades mean. In some cities beef officially stamped with the official grade name can be bought in the retail shops. In some parts of the country poultry, eggs, and butter are now being sold to consumers labeled according to the Government grades. Large numbers of turkeys have been graded for the consumer, each bird being labeled with its Government grade mark. The standards for canned foods developed in the Bureau of Agricultural Economics under the warehouse act have been used in certain States as a basis for selling canned goods.

Definitions Under Food and Drugs Act

Under the food and drugs act, definitions and standards for a large number of food products have been promulgated by the department. These are designed (1) to fix the identity of the articles, and (2) to insure that they be of sound and merchantable quality. The specifications are of such a nature that any departure of an article above the maximum or below the minimum limits prescribed is evidence that the article is either impure or abnormal. Recently the food and drugs act has been amended to authorize the Secretary of Agriculture to promulit commands a higher price. Fruit cleaning, therefore, is a distinct benefit, particularly in sections where considerable spraying with arsenicals is necessary.

Large numbers of turkeys have been graded for the consumer, each bird being labeled with its Government grade mark. The standards for canned foods developed in the Bureau of Agricultural Economics under the warehouse act have been used in certain States as a basis for selling canned goods.

Definitions Under Food and Drugs Act

Under the food and drugs act, definitions and standards for a large number of food products have been promulgated by the department. These are designed (1) to fix the identity of the articles, and (2) to insure that they be of sound and merchantable quality. The specifications are of such a nature that any departure of an article above the maximum or below the minimum limits prescribed is evidence that the article is either impure or abnormal. Recently the food and drugs act has been amended to authorize the Secretary of Agriculture to promulgate standards of quality, condition, and fill of container for canned foods. The same amendment authorizes the Secretary to prescribe a statement which will appear in a plain and conspicuous manner on the labels of all canned foods which do not meet the standard and which will clearly indicate that they fall below such standard. This amendment in no sense authorizes the distribution of adulterated or misbranded canned foods. As heretofore, these are banned under the terms of the food and drugs act. It does, however, divide legal canned foods, into two classes: (1) A class of a quality which entitles it to be known as "standard," and (2) a class which is in some respects inferior and, therefore, must be labelled "substandard."

The imposition of the substandard labelling requirement is important from the housewife's standpoint because it is a precaution to save the pocketbook. The housewife with a limited budget who feels that she can not afford to purchase canned foods of standard quality but does desire to obtain canned articles of satisfactory nutritive value, can satisfy her desires by selecting those canned products which bear the substandard label, with full assurance that they are legal and wholesome, even if not so palatable or of such satisfactory appearance as the standard article. On the other hand, if it is her desire to avoid the lower grades of canned foods, she may assure herself of the character of the product she buys by refusing to accept an article bearing a substandard label.

Some of the specifications used by Government and State agencies for institutional purchases may also be used by the housewife. Most of these, however, need to be set up in terms which will help to indicate their use to her. This involves considerable study. A discussion of the development of standard specifications for textiles appears elsewhere in this Yearbook.

Specifications for Refrigerators

When she buys household equipment, the housewife frequently spends a considerable sum of money for a single article. In making such a purchase she wants the best possible information, and she frequently asks the Bureau of Home Economics for assistance in learning what she needs to know. A beginning has been made in the setting up of standard specifications for household refrigerators. The refrigerator, like many other pieces of household equipment, does not carry its value on its face. It has taken some three years of work by manufacturers, ice distributors, and refrigerator users to determine how ice-cooled refrigerators should be labelled so that the housewife will know what she is getting. There may be in one row refrigerators varying in price from $25 to $200 with little difference in outside appearance. It is important that in deciding what to purchase the housewife should have some other basis of judgment. The salesman may tell her much about insulation and probable length of life. She would be much more secure in her purchase if each manufacturer were to place on his ice box such a statement as the following with pounds and cubic feet definitely stated.

> Ice capacity ---------- pounds; ---------- cubic feet of usable space. Guaranteed temperatures. Milk compartment not over 45° F. Food compartment average temperature not over 50° (under standard test conditions, outside temperature not exceeding 80°, with daily ice consumption under standard test conditions of ---------- pounds).

Such information would enable the housewife to select the ice box best adapted to her needs. In conferences among manufacturers, distributors, and users of refrigerators agreement has been reached as to part, although not all, of this label. It is an indication of the type of specification which the housewife wants and which the best manufacturers are coming to see they must furnish in some form and stand behind if they are to protect their goods on the market.

As time goes on it will be possible to develop similar labels suitable for other pieces of household equipment which will be of material help in solving the purchasing problems of the housewife.

Senior Economist, Bureau of Home Economics.

STEM-RUST Hazard Is Reduced by Using the Proper Fertilizers The problem of building up soil fertility without increasing losses from stem rust of cereals must be considered from the standpoint of both soil type and climate. A few general rules, however, for the use of fertilizers may be noted.

Excessive amounts of nitrogen fertilizers should always be avoided in regions where epidemics of stem rust are likely to occur. It is a mistake to add nitrogenous fertilizers to the heavy loams of southeastern Minnesota in order to increase the yields of wheat. Most of the wheatlands of that area are fairly well supplied with nitrogen, and nitrogenous fertilizers are apt to be more harmful than beneficial, since excessive nitrogen is conducive to stem rust. With excess nitrogen the wheat grows luxuriantly and tillers profusely. The straw is weak and the plants lodge easily. Shading, incident to dense growth and lodging, checks evaporation, and the dew remains longer than on the normal plants. The rust spores require the presence of this moisture to germinate, and the longer the moisture remains on the surface of the wheat plant the greater the opportunity for the rust germ tubes to enter the wheat. If the rust organism does not enter before the plants dry, it shrivels and dies.

Nitrogenous fertilizers also delay maturity. Ripening may be delayed from four days to as much as two weeks. Stem rust does not infect wheat after it ripens. Prolonging the growing period of the wheat increases the length of time during which the stem rust may attack. Severe rust attacks also usually occur toward the end of the growing season, and a few days' delay in maturity may permit a severe attack, while earlier wheats may escape.

Phosphate and potash fertilizers are not so conducive to stem-rust development as are nitrogenous fertilizers. Wheat straw seldom lodges when phosphates or potash only are used. The wheat may grow vigorously but will not produce such a rank vegetation. Tillering is not so profuse, the number of culms is less, vegetation is more open, and aeration is better. Dews and rains evaporate more quickly than in more rank stands, and the rust has less time to accomplish infection.

Phosphate and Potash Hasten Ripening

Phosphate and potash fertilizers also tend to hasten ripening. At University Farm, St. Paul, Minn., in 1927, plants fertilized with phosphates ripened 3 or 4 days earlier than plants without fertilizers, Such information would enable the housewife to select the ice box best adapted to her needs. In conferences among manufacturers, distributors, and users of refrigerators agreement has been reached as to part, although not all, of this label. It is an indication of the type of specification which the housewife wants and which the best manufacturers are coming to see they must furnish in some form and stand behind if they are to protect their goods on the market.

As time goes on it will be possible to develop similar labels suitable for other pieces of household equipment which will be of material help in solving the purchasing problems of the housewife.

FAITH M. WILLIAMS,

STEM-RUST Hazard Is Reduced by Using the Proper Fertilizers

The problem of building up soil fertility without increasing losses from stem rust of cereals must be considered from the standpoint of both soil type and climate. A few general rules, however, for the use of fertilizers may be noted.

Excessive amounts of nitrogen fertilizers should always be avoided in regions where epidemics of stem rust are likely to occur. It is a mistake to add nitrogenous fertilizers to the heavy loams of southeastern Minnesota in order to increase the yields of wheat. Most of the wheatlands of that area are fairly well supplied with nitrogen, and nitrogenous fertilizers are apt to be more harmful than beneficial, since excessive nitrogen is conducive to stem rust. With excess nitrogen the wheat grows luxuriantly and tillers profusely. The straw is weak and the plants lodge easily. Shading, incident to dense growth and lodging, checks evaporation, and the dew remains longer than on the normal plants. The rust spores require the presence of this moisture to germinate, and the longer the moisture remains on the surface of the wheat plant the greater the opportunity for the rust germ tubes to enter the wheat. If the rust organism does not enter before the plants dry, it shrivels and dies.

Nitrogenous fertilizers also delay maturity. Ripening may be delayed from four days to as much as two weeks. Stem rust does not infect wheat after it ripens. Prolonging the growing period of the wheat increases the length of time during which the stem rust may attack. Severe rust attacks also usually occur toward the end of the growing season, and a few days' delay in maturity may permit a severe attack, while earlier wheats may escape.

Phosphate and potash fertilizers are not so conducive to stem-rust development as are nitrogenous fertilizers. Wheat straw seldom lodges when phosphates or potash only are used. The wheat may grow vigorously but will not produce such a rank vegetation. Tillering is not so profuse, the number of culms is less, vegetation is more open, and aeration is better. Dews and rains evaporate more quickly than in more rank stands, and the rust has less time to accomplish infection.

Phosphate and Potash Hasten Ripening

Phosphate and potash fertilizers also tend to hasten ripening. At University Farm, St. Paul, Minn., in 1927, plants fertilized with phosphates ripened 3 or 4 days earlier than plants without fertilizers, and about 8 to 10 days earlier than plants fertilized with nitrates. In years when stem rust is epidemic, early ripening plays an important part in avoiding loss. The use of fertilizers that hasten maturity may protect the crop and result in better yields than where no fertilizer is supplied or where nitrogen is used.

The real test of fertilizer value is crop yield and quality. Where stem-rust epidemics occur, a well-balanced fertilization will improve yield, and quality also in so far as it aids in avoiding rust. On light sandy soils nitrogen may be beneficial, but on heavy loams both yield and quality may be actually decreased if nitrogen fertilizers are applied. Under rust-epidemic conditions phosphate and potash fertilizers can well be used on all soils that are benefited by them.

Agent, Bureau of Plant Industry.

STRAWBERRY Weevil May Be Controlled by Using Sulphur and Arsenate The strawberry weevil, *Anthonomus signatus* Say, a native pest of cultivated strawberries, is an ever-present factor in the production of this crop in the eastern half of the United States. Serious outbreaks of this weevil have occurred periodically in the Eastern States during the last 50 years, particularly on the coastal plain from North Carolina northward.

The strawberry weevil is about one-tenth of an inch long and approximately half as wide, with a curved snout similar to that of the boll weevil. The color varies from almost black to a dull reddish brown, with a dark spot on each wing cover. The injury to the strawberry crop is caused by the weevil cutting the blossom stem during the process of egg laying. The female weevil deposits the egg in the bud and then cuts the bud stem a short distance below the bud. Oftentimes the buds are severed, from the stem, but usually the stem is cut so as to leave the bud attached to it by a tiny thread; however, it eventually falls to the ground. The egg hatches in the severed bud and the larva or grub feeds therein until it reaches maturity, finally emerging as a weevil.

The economic importance of this insect can not be judged wholly by the percentage of the crop it destroys, but must be based on the reduction in returns received for the crop. For instance, in the North Carolina area the early strawberries sell for more than three times the price of those marketed three weeks later in the season, and it so happens that the buds producing these early berries are the ones most heavily attacked by the weevil.

The presence of the weevil in the strawberry fields in early spring may be detected by the small circular feeding holes in the petals of the open flowers in the rows near the edges of the field, particularly those rows which are adjacent to accumulations of dead vegetation, as it is such locations that harbor the greatest number of weevils during the winter season. A few days later the presence of the weevil may be manifested by a scarcity of open blossoms and a close examination will show buds severed from the stems. The small size of the weevil together with its habit of dropping to the ground when disturbed prevents its general detection by the casual observer. Very often the and about 8 to 10 days earlier than plants fertilized with nitrates. In years when stem rust is epidemic, early ripening plays an important part in avoiding loss. The use of fertilizers that hasten maturity may protect the crop and result in better yields than where no fertilizer is supplied or where nitrogen is used.

The real test of fertilizer value is crop yield and quality. Where stem-rust epidemics occur, a well-balanced fertilization will improve yield, and quality also in so far as it aids in avoiding rust. On light sandy soils nitrogen may be beneficial, but on heavy loams both yield and quality may be actually decreased if nitrogen fertilizers are applied. Under rust-epidemic conditions phosphate and potash fertilizers can well be used on all soils that are benefited by them.

The female weevil deposits the egg in the bud and then cuts the bud stem a short distance below the bud. Oftentimes the buds are severed, from the stem, but usually the stem is cut so as to leave the bud attached to it by a tiny thread; however, it eventually falls to the ground. The egg hatches in the severed bud and the larva or grub feeds therein until it reaches maturity, finally emerging as a weevil.

The economic importance of this insect can not be judged wholly by the percentage of the crop it destroys, but must be based on the reduction in returns received for the crop. For instance, in the North Carolina area the early strawberries sell for more than three times the price of those marketed three weeks later in the season, and it so happens that the buds producing these early berries are the ones most heavily attacked by the weevil.

The presence of the weevil in the strawberry fields in early spring may be detected by the small circular feeding holes in the petals of the open flowers in the rows near the edges of the field, particularly those rows which are adjacent to accumulations of dead vegetation, as it is such locations that harbor the greatest number of weevils during the winter season. A few days later the presence of the weevil may be manifested by a scarcity of open blossoms and a close examination will show buds severed from the stems. The small size of the weevil together with its habit of dropping to the ground when disturbed prevents its general detection by the casual observer. Very often the destruction of buds escapes notice and at harvest time the shortage of the crop is attributed to some unknown cause.

In the North Carolina strawberry-growing area this weevil starts laying its eggs about the second week in March, continuing until the latter part of May, and reaching the peak of egg deposition about April 10. The weevils which develop from these eggs may be found active from early in May to the middle of June, feeding in the flowers of various kinds of wild shrubs. After a period of activity of about 10 days they become sluggish and inactive, seek coverage about the edges of the field in woodlands and uncultivated areas, and do not become active again until the following spring. Observations have shown that an average of over 90 per cent of the hibernating weevils pass the winter within 100 feet of the strawberry fields, particularly if suitable coverage is available.

Sulphur-Calcium Arsenate Mixture

The strawberry weevil may be effectively controlled by dusting with a sulphur-calcium arsenate mixture. This mixture is prepared by mixing 15 pounds of calcium arsenate with 85 pounds of sulphur. However, for the treatments to be effective they must be made early and be frequent enough to protect the buds as they develop. A close watch should be kept for the first sign of the presence of the weevils in the strawberry field. As soon as any evidence of the weevil is found, either from its feeding marks upon the petals of the strawberry blossoms, or cut buds, or by observation of the weevil itself, the first treatment should be applied. A thin coating of the dust should cover the developing fruit buds. The rate of application of the material per acre will depend somewhat upon the width of the rows of the growing plants, but should not exceed 35 to 40 pounds per acre for one application. Ordinarily two applications at 10-day intervals will be sufficient to protect the early fruit buds. The last application of the dust should be made not later than three weeks before the fruit begins to ripen. Any standard blower-type dust gun operated by hand or by horsepower may be used in making the dust applications.

Since the weevil hibernates about the edges of the field, usually in uncultivated or cut-over areas along the edges of the field, it is a good practice to clean up such areas during the dormant period.

W. A. Thomas,
Assistant Entomologist, Bureau of Entomology.

SUGAR-BEET Curly Top's Spread Aided by Vast Increase in Host Weeds With the coming of agriculture in the semiarid areas of western North America certain weeds were introduced from other countries, and the human activities favoring the increase and spread of these and some of the native plants are the principal factors in the bringing of the insect vector of sugar-beet curly top, the sugar-beet leaf hopper, *Eutettix tenellus* (Baker), up to its place of objectional prominence. The beet leaf hopper occurs mainly in the semiarid areas of western North America. It appears to be native to this continent and prior to the advent of civilized men on the western coast was probably a destruction of buds escapes notice and at harvest time the shortage of the crop is attributed to some unknown cause.

In the North Carolina strawberry-growing area this weevil starts laying its eggs about the second week in March, continuing until the latter part of May, and reaching the peak of egg deposition about April 10. Since the weevil hibernates about the edges of the field, usually in uncultivated or cut-over areas along the edges of the field, it is a good practice to clean up such areas during the dormant period.

W. A. Thomas,
Assistant Entomologist, Bureau of Entomology.

SUGAR-BEET Curly Top's Spread Aided by Vast Increase in Host Weeds

With the coming of agriculture in the semiarid areas of western North America certain weeds were introduced from other countries, and the human activities favoring the increase and spread of these and some of the native plants are the principal factors in the bringing of the insect vector of sugar-beet curly top, the sugar-beet leaf hopper, *Eutettix tenellus* (Baker), up to its place of objectional prominence. The beet leaf hopper occurs mainly in the semiarid areas of western North America. It appears to be native to this continent and prior to the advent of civilized men on the western coast was probably a relatively inconspicuous member of the fauna. The reason for this is that under the system of natural equilibrium which existed earlier the plants affording favorable food for the leaf hopper were so limited in quantity that the population of the insect was restricted. With the vast increase in weeds which are favorable host plants the population of the insect has increased enormously.

The great economic importance of this leaf hopper is due to the fact that it is the only agent known to transmit the virus disease of sugar beets known as curly top. This disease is a limiting factor in sugar-beet growing in infested areas and also causes serious damage to the tomato crop as well as some injury to beans and certain other crops.

The annual sequences of plants which serve to support and breed the leaf hopper are not the same in all infested areas. In Washington, Oregon, Idaho, and parts of Utah, for example, tumbling mustard (*Norta altissima*) and tansy mustard (*Sophia sophia* and *S. filipes*) are the more important hosts of early spring. Following these, Russian thistle (*Salsola pestifer*) plays an important rôle as a host plant for the remainder of the season. In the principal breeding areas of California, by contrast, the important range plant filaree (*Erodium cicutarium*), which appears after the first fall rains, harbors the insect over winter and into the spring. When the filaree dries up the leaf hoppers move to other annuals, of which probably the most important are bract scale (*Atriplex bracteosa*) and silver scale (*A. argentea expansa*).

Movement from Early Maturing Hosts

In all infested areas there occurs this extensive movement of the insects from the early maturing host plants to those which continue to live in a green and somewhat succulent state through the long summer drought period. At the time of this movement sugar beets as well as tomatoes and beans which are within the range of the movement are likely to become infested and epidemics of curly top initiated. These crops are not necessary, however, in the propagation of the insect, as is shown by the fact that it occurs in great numbers in areas where none of these crops are grown and only the weeds are available as favorable hosts plants.

That these weeds often occupy large areas of land and thereby cause such regions to serve as breeding grounds for the leaf hopper is due largely, as mentioned above, to disturbances by man of the natural equilibrium. Some typical activities which have had this result may be mentioned. Excessive grazing of ranges, for instance, has damaged or destroyed the native vegetation which had successfully occupied the land and resisted the intrusion of weeds. As a result of this mismanagement of the ranges, the weeds such as those mentioned as favorable host plants for the leaf hopper form one of the stages in the return to equilibrium. Moreover, continued overgrazing, a practice already condemned because of the resulting deterioration of both soil and range resources, prolongs the weed stage in the succession. Another unfortunate procedure which will eventually become less troublesome is the abandonment of land after a temporary period of tillage. The situation will be improved in this respect when the agriculture of more of the infested areas has passed through the pioneering stage. Abandoned lands resulting largely from unsuccessful attempts at dry farming or from an inadequate or unsatisfactory supply of irrigation water form vast areas which thus pass through the weed stage and as such function as breeding grounds for the leaf hopper. All lands cleared or lands where the native vegetation is damaged or destroyed are promptly occupied by weeds such as those mentioned as hosts of the leaf hopper. This is particularly true, in some sections, of roadsides or railroad right of ways which are repeatedly cleared or burned over. It is to be hoped that a better way of handling such areas as these will eventually be adopted. Also a better appreciation of the value of range lands will result in progress in the direction of a conserving management such as is now generally followed in the handling of forest lands.

The Search for Preventive Measures

The Department of Agriculture is studying the curly-top problem from various viewpoints in the hope of discovering preventive measures. As the factors influencing the size of the leaf-hopper population are important, study is being made of the conditions which control the objectionable weed stages in the succession, with the hope that methods may be discovered whereby the return to the native plant cover, which consists largely of nonhost plants, can be hastened. Attention is also being given to the prevention of burning the annual grass (*Bromus tectorum*), which now covers large areas where the original stand of sagebrush has been destroyed. Considerable tracts in these areas have stands of the grass dense enough to reduce greatly or almost eliminate the objectionable weed hosts. This plant also has some forage value in the early spring months and is worth maintaining on that account. Consideration is also being given to the possibility of introducing suitable grasses from other countries. These, if successful, would improve the value of the ranges and help to keep the objectionable weeds in check.

SUGAR-BEET Strains Resistant to Leaf Spot and Curly Top The development of the sugar beet of today from the types of beet which, more than a century ago, were being cultivated for feeding cattle is a fascinating story of the application of the scientific method to the benefit of agriculture. The percentage of sugar has been more than doubled, the purity with respect to sucrose greatly increased, and the yielding capacity increased.

The sugar beet is normally a cross-pollinated plant, and the set of seed from a completely isolated mother beet is small. Isolation is difficult because the sugar beet crosses readily with the garden beet, the mangel wurzel, and Swiss chard. The early experience of plant breeders led them to abandon almost entirely inbreeding methods and to concentrate attention upon mass selection.

The practices generally followed in commercial sugar-beet breeding consist of a selection test and then a recombination of the selected "families." Mother beets are selected on the basis of weight, richness in sugar, etc., and these are isolated more or less for the production of seed lots. The roots obtained as progenies from these seed lots are subjected to analysis, and the progenies that most nearly come up to the standard set are chosen as basic material. These roots, which function as breeding grounds for the leaf hopper. All lands cleared or lands where the native vegetation is damaged or destroyed are promptly occupied by weeds such as those mentioned as hosts of the leaf hopper. This is particularly true, in some sections, of roadsides or railroad right of ways which are repeatedly cleared or burned over. It is to be hoped that a better way of handling such areas as these will eventually be adopted. Also a better appreciation of the value of range lands will result in progress in the direction of a conserving management such as is now generally followed in the handling of forest lands.

The roots obtained as progenies from these seed lots are subjected to analysis, and the progenies that most nearly come up to the standard set are chosen as basic material. These roots, which

40442°—31——32

have thus given evidence of superiority over the general run, are commonly grouped with other roots from different mothers to form an elite stock. This elite stock is then increased for commercial use by two, three, or even more field increases, with occasionally some selection and with more or less testing of the yielding capacities. These mass-selection methods, patiently and painstakingly carried on, have been effective in providing seed stocks which have given satisfactory performance under normal conditions. The selections have been based largely upon the weight of the individual or weight per plot, the percentage of sucrose as revealed by the polariscope, and the apparent purity with respect to sucrose.

Research in Seed Improvement

The United States Department of Agriculture has sought to develop by scientific research a basis for sugar-beet seed improvement which would furnish varieties or strains of sugar beet adapted to definite local needs, and to produce strains resistant to diseases that are now threatening the very existence of the industry. This has involved investigation of the principles underlying the genetics of the sugar beet and the testing in strategically located areas of all commercial brands of sugar-beet seed to determine whether there are selections whose superiority would merit consideration as basic stock for seed increase. Tests of many years at Rocky Ford, Colo., where leaf spot is often present in epidemic form, and at State College, N. Mex., under severe curly-top conditions, have shown that, contrary to occasional claims made by overzealous agents, no commercial variety now available has such a degree of superiority over another in resistance to either leaf spot or curly top as to warrant its selection. Individual plants here and there in practically all of these commercial strains, however, have shown such resistance as to make them stand out from their diseased neighbors, and such resistant individuals have been selected and used as progenitors of inbred lines. Other selections have been used in group plantings to furnish seed for subsequent comparative tests against commercial lines of beets. Work with the progenies from inbred lines selected for disease resistance is as yet incomplete, and report on this phase must be deferred.

Results from the group plantings are significant. A number of individual sugar beets that were outstanding in size and in sugar percentage, as well as showing evidence of leaf-spot resistance, were selected in 1927 from a field where leaf spot was doing excessive damage. These beets were of satisfactory size and superior sugar content, and a group planting was made. The seed obtained has been outstanding in leaf-spot resistance and has produced a better yield of beets and a higher sugar percentage than the commercial lot from which it was isolated. By a single selection, results immediately detectable in the progeny were obtained.

Selection of Resistant Individuals

Similar selections of curly-top-resistant individuals have been made from fields where curly top was doing nearly its maximum damage. The progenies from such selections have produced more than three times the yield of the commercial variety under curly-top conditions, but are not as yet enough freed from the susceptible types to be commercially usable under severe conditions. At State College, N. Mex., in 1929, a selection was made for curly-top resistance from a commercial brand and compared with the original material with the results shown in Table 18. It seems certainly feasible to continue the sorting process to eliminate the susceptible types.

TABLE 18.—*Results of one season's rigid selection of sugar beets for curly-top resistance*

[Commercial brand Pioneer (check) contrasted with selections from it. State College, N. Mex., 1929. Results given as averages of three plantings]

				Pounds	*Pound*
Selection	2.9	103	87	12,037	0.91
Check	4.5	93	67	2,786	0.21

[1] Relative curly-top susceptibility obtained from individual plant readings on a scale based on relative damage by curly top, in which 0 and 1 indicate immunity and high resistance, respectively, and 5 and 6 indicate high susceptibility.

Recognizing the natural limitations presented by present-day sugar-beet material, which probably traces back to one or a few sources, attempt was made to widen the range of available characters by hybridizing the sugar beet with the wild sugar beet, *Beta maritima*, from which the sugar beet is believed to have been derived. Collections of wild beet seed were made in Europe, where *B. maritima* is indigenous, and these collections have been tested under leaf-spot and curly-top conditions. No wild beet immune to leaf spot was found, but certain collections have given individuals with a sugar percentage equal to that of the sugar beet and more resistant to leaf spot than any sugar beet yet found. The wild beet hybridizes readily with the sugar beet, and individuals have been obtained with high resistance and with marked improvement in top and root characters over the wild progenitor.

Highly Resistant Wild Beets

Similar tests under severe curly-top conditions have shown that there exist, among the numerous collections of wild beets, forms which, while maintaining the capacity for sugar production, are so nearly immune to curly top as to make even recognition of the presence of disease on these forms very difficult. These highly resistant individuals have been crossed with high-grade nonresistant commercial beets, and the hybrid material has been tested. The results of one such test are given in Table 19 and are shown graphically in Figure 158.

TABLE 19.—*Comparison of yields of a sugar beet and Beta maritima cross with those obtained from a standard commercial sugar beet*

[Average of two plantings. State College, N. Mex., 1929]

Stock used	Relative curly-top susceptibility [1]	Initial stand	Final stand	Yield computed on acre basis	Average weight of beet based on initial stand
				Pounds	*Pounds*
Wild cross	2.0	99	89	25,556	1.73
Commercial (check)	4.4	100	61	3,331	0.21

[1] Relative curly-top susceptibility obtained from individual plant readings on a scale based on relative damage by curly top in which 0 and 1 indicate immunity and high resistance, respectively, and 5 and 6 indicate high susceptibility.

The hybrid material contained a composite of true sugar beets, of true wild, and of hybrid material. The hybrid material was extremely promising in showing almost immediate response in two directions, namely, (1) in resistance to curly top due to factors obtained from the wild parent, and (2) improvement over the wild type, as a result of the genetic factors from the cultivated parent. In view of work carried on abroad where the wild forms have been crossed with cultivated beets, it is believed that beets of satisfactory type may be obtained from this cross, and it certainly seems that the highly desired resistance can be retained if the breeding work is continued with constant exposure to curly top.

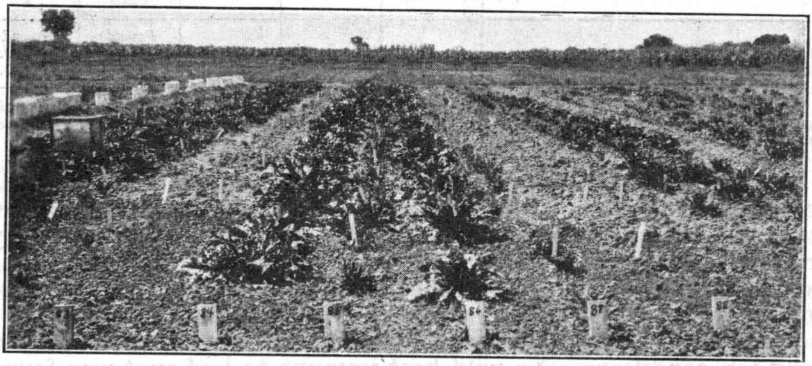

FIGURE 158.—Sugar beet tests under curly-top epidemic conditions at State College, N. Mex. Rows 84, 85, and 86 are hybrids of sugar beets and *Beta maritima*. Rows 81 and 87 are a commercial variety. (July 17, 1929)

The situation, therefore, with respect to improvement of the quality of sugar-beet seed for American use is very promising. By utilizing mass selection the advance in quality already made may be maintained while at the same time the desired resistance in seed stocks is developed. The recent demonstration of economical seed production in the United States from plants overwintered in the field in areas of mild climate will doubtless have important relation in this new development. Further, pure lines for amelioration of beet stocks by purposeful crossing are now being developed, and this basic breeding material gives promise of providing the ultimate solution for the serious beet diseases.

SWEETCLOVER, Though a Fertilizer Crop, May Itself Need Fertilizer

The use of fertilizer on a crop like sweetclover, which is grown primarily for improving the soil, seems at first very much like the proverbially useless task of carrying coals to Newcastle. Why, we ask, improve the soil for a crop that is supposed to be doing that of itself?

The answer lies in the fact that even a soil-improving crop makes a better growth if there is plenty of food material available for its use. Since the object of growing a soil-improving crop is to obtain the largest quantity of green material possible for plowing under, the use of a reasonable quantity of fertilizer often pays. However, discretion is needed in the choice of fertilizers, for some pay better than others.

The most expensive fertilizers are those that carry nitrogen. Since sweetclover, like all legumes, obtains most of its nitrogen from the air, there usually is no necessity of adding nitrogen to the soil in the form of fertilizer. However, there are times when a small quantity of a quick-acting nitrogenous fertilizer like nitrate of soda or ammonium sulphate is helpful. When seeding has been delayed until May 1 or later, 50 pounds per acre of one of these stimulating chemicals causes the young sweetclover to make rapid growth and helps it to overcome the handicap of late sowing. Such an application may well result in the production of an additional 2 tons per acre of green manure the following year. Similarly, when sweetclover is seeded in corn at the last cultivation, as is sometimes done, a small application of immediately available nitrogen gives the plant a quick start and may enable it to succeed in spite of dry weather. Nitrogenous fertilizers used on sweetclover at other times are likely to be wasted.

Phosphorus, the second most important element in commercial fertilizers, is sometimes, though by no means always, beneficial to sweetclover. One of the principal advantages of sweetclover as a green-manure crop is its ability to assimilate crude forms of soil phosphorus which plants like wheat and corn can not utilize. The sweetclover plant takes up these crude phosphorus compounds, changes them to a more usable form, and stores them in its tissues. When the sweetclover is plowed under these altered phosphorus compounds are returned to the soil, where they have the same effect on the succeeding crop as an application of a phosphorus fertilizer.

In some soils, however, even the crude forms of phosphorus are lacking. Then an application of 300 pounds of phosphate fertilizer per acre is necessary before sweetclover will grow. The exact locations of these phosphorus-deficient soils are not yet known, but if all other methods of obtaining a stand of sweetclover fail, phosphorus deficiency may be suspected and a generous trial application made of a phosphorus fertilizer.

Sweetclover seems unable to utilize soil phosphates of any kind if the soil is acid or "sour." Soil acidity may be corrected by applying lime. Possibly one of the principal reasons for the remarkable effect of lime on sweetclover is its influence in making the soil phosphates available. On soils which are only moderately acid, good sweetclover often may be grown by the use of a phosphate fertilizer having a strongly alkaline reaction. Such a fertilizer is basic slag. In tests in North Carolina and elsewhere, 500 pounds of basic slag per acre sometimes has produced as good sweetclover as a ton or more of limestone. The exact limitations of the basic slag method of growing sweetclover have not been determined, but the process is at least very interesting. Phosphates in the form of superphosphate (acid phosphate) are of little use on acid soils, but when combined with lime, especially on soils in which both the elements are lacking, frequently give excellent results. Most county agents and State agricultural experiment stations are prepared to test the lime and phosphorus content of soils.

Few instances have been noted in which sweetclover has suffered for lack of potassium in the soil. Possibly on sandy soils an application of potash fertilizer would be of benefit, but such instances, so far as known, are rare.

SWINE If Inbred Give Birth to Small Litters of Pigs Lacking Vigor Inbreeding never has met with widespread favor among swine breeders. The few who have been fortunate enough to succeed, when practicing it, naturally are enthusiastic; but the many who have failed are equally disappointed. The effect of inbreeding on swine has been, therefore, a debated question. Recently, however, experimental evidence has thrown considerable light upon the situation.

An experiment begun in 1923 by the Bureau of Animal Industry has furnished data showing that persistent close inbreeding of swine offers little likelihood of success to commercial pork producers. The plan of the experiment was to develop several distinct inbred strains in the Poland China, Tamworth, and Chester White breeds by brother-sister matings, generation after generation, as long as breeding animals were available. After several generations of such breeding the procedure involved crossing the inbred strains within breeds as well as among the three breeds.

More than 700 inbred pigs have been farrowed with widely varying results in type, color, size of litter, per cent raised to weaning, and growth. For example, the size of litter varied more in the Poland Chinas than in either the Tamworths or the Chester Whites, although this is not considered a breed characteristic. In general, the inbred stock of all the breeds, in all generations, had smaller litters than the noninbred stock. In per cent of pigs raised to weaning, at 70 days of age, great variation also was found. The lowest percentage was 26.6 in the second-generation Poland China inbreds; the highest was 81 per cent in the first-generation Chester Whites, which was considerably higher than for any of the noninbred groups used for comparison. In gains in weight to weaning age, the inbreds of all the breeds averaged less than the noninbreds, although this was not true of all individuals. Table 20 shows the results of inbreeding, in terms of number of pounds of pigs per sow raised to weaning age, for the three breeds.

TABLE 20.—*Number of pounds of pigs raised, per sow, to weaning age (70 days) in the different generations of inbreeding*

Generation of inbreeding	Poland China	Tamworth	Chester White
	Pounds	*Pounds*	*Pounds*
First	97.5	140.0	151.3
Second	32.7	84.7	120.7
Third	(1)	76.3	140.3
Fourth	(1)	76.3	(1)

[1] No progeny.

The combination of small litters, high mortality, and low gains in weight to weaning age exhausted the Poland China lines in the second generation. Only about one pig per sow was raised to weaning, thus making it impossible to obtain enough breeding stock for further study. The foundation stock apparently carried many hidden weaknesses which were brought to light by the close breeding. In the Tamworth and the Chester White breeds the results were somewhat similar. Of three separate strains of Tamworths and two of Chester Whites, only one in each breed survived more than one generation of brother-sister mating. The inbred Chester White pigs were superior to the inbred strains of the other two breeds in number of pounds of pigs raised per sow to weaning and showed less decrease as the number of generations of inbreeding increased. In pork production, this strain excelled all others used in the experiment. The present Chester White strain, which is in the third generation of inbreeding, is of a different type from that of the foundation animals. The bodies are longer and the hams are plumper although there is a tendency to lack depth of body. In the feed lot some of these pigs made very economical gains and produced very desirable carcasses.

Frequent Color Variations Found

Abnormal pigs have been rare among the inbred lots and the percentage of pigs born dead has been no higher than for the noninbred lots. Frequent color variations are found in the inbreds. One of these, a dilute black or sepia in the Poland Chinas, appears to be due to the segregation of a single recessive color factor. Among the Tamworths, the appearance of large black spots has been fairly common. Among the Chester White inbreds light reds, red with black and white, and black-spotted whites have appeared. Most of these color variations are in one line, which had to be discarded later because of high mortality and low fertility. All such variations are probably a result of the segregation of recessive factors which have been hidden by dominant characters until segregated and made manifest by a system of close breeding.

Persistent close breeding offers little chance of success to the commercial pork producer. Inbred pigs will make less average gain and show higher average mortality than noninbreds. It appears, however, that in some strains close breeding can be practiced without very serious consequences and, of course, in these strains inbreeding tends to conserve the good qualities of the stock. There is no means of determining which strains will succeed and which will degenerate when inbred except by trial. This has been shown, by the present experiment, to be an expensive and slow procedure.

In the hands of the experimentalist or research worker, swine inbreeding offers an almost unexplored field for study and much good probably will come from such studies continued over a long period of time. The isolation of pure strains by inbreeding should make possible a more thorough study than has heretofore been possible of inheritance in swine. But at the present stage of knowledge on this subject it seems inadvisable for the producer of pork to attempt the widespread use of inbreeding.

H. C. McPhee,
Senior Animal Husbandman, Bureau of Animal Industry.

SWINE Kidney Worm Causes Loss to Southern Producers from Condemned Carcasses The swine kidney worm, known to scientists as *Stephanurus dentatus*, causes a heavy loss to the meat industry and southern swine raisers. In some localities in the South the loss from this parasite averages about 27 cents per hog slaughtered, according to an investigation made by department veterinarians and investigators. This loss results from the trimming of infested carcasses and from condemnations of livers and other organs damaged by the parasite.

to the inbred strains of the other two breeds in number of pounds of pigs raised per sow to weaning and showed less decrease as the number of generations of inbreeding increased. In pork production, this strain excelled all others used in the experiment. The present Chester White strain, which is in the third generation of inbreeding, is of a different type from that of the foundation animals. The bodies are longer and the hams are plumper although there is a tendency to lack depth of body. In the feed lot some of these pigs made very economical gains and produced very desirable carcasses.

Frequent Color Variations Found

But at the present stage of knowledge on this subject it seems inadvisable for the producer of pork to attempt the widespread use of inbreeding.

H. C. McPhee,

Senior Animal Husbandman, Bureau of Animal Industry.

SWINE Kidney Worm Causes Loss to Southern Producers from Condemned Carcasses The swine kidney worm, known to scientists as *Stephanurus dentatus*, causes a heavy loss to the meat industry and southern swine raisers. In some localities in the South the loss from this parasite averages about 27 cents per hog slaughtered, according to an investigation made by department veterinarians and investigators. This loss results from the trimming of infested carcasses and from condemnations of livers and other organs damaged by the parasite.

The fact that about 10,000,000 hogs raised in the Southern States are slaughtered annually in Government-inspected abattoirs alone, is evidence that the losses in this section from the kidney worm can not be disregarded. The total slaughter of hogs affected by kidney worms is, of course, considerably more. By interfering with the orderly functions of the organs which it invades, this parasite causes further loss by arresting the normal growth and development of swine. Briefly, it is one of the most injurious pests confronting the swine grower in the South and one which he must combat in order to make swine raising profitable.

The first recorded discovery of the kidney worm was made in a Brazilian peccary, an animal resembling the pig. The worm is largely confined to tropical and subtropical countries. Until very recently it was not found in Europe, and its present known distribution on that continent is limited to southern Spain, where it is still a scientific curiosity rather than a parasite causing serious harm. In the United States it occurs chiefly in the South.

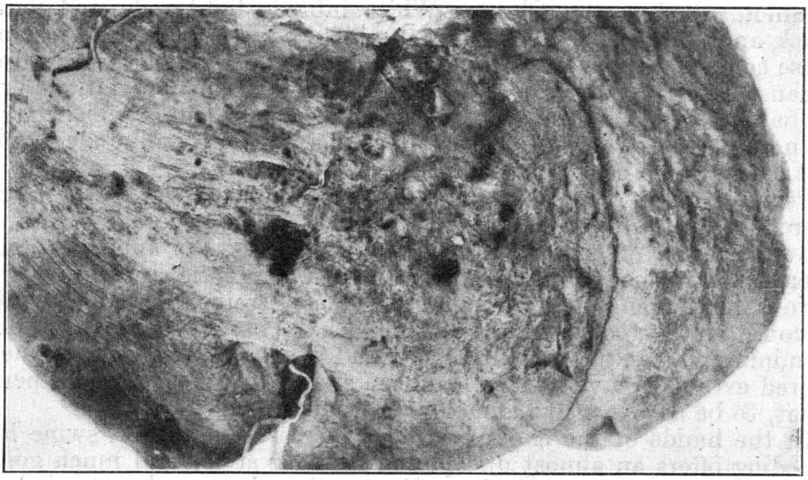

FIGURE 159.—One lobe of a pig's liver showing injuries produced by kidney worms. The dark areas are the lesions produced by the worms

Injures Organs and Retards Growth

A hog carcass and its organs which are heavily infested with kidney worms present anything but a pleasing appearance. The liver, if its injuries have healed, is badly scarred, the lesions appearing as hard, grayish areas of varying sizes and shapes. Unhealed or incompletely healed liver injuries are far more unsightly than are the healed lesions. The latter usually no longer contain worms, whereas the former (fig. 159) are soft and contain creamy pus and live, dead, or degenerated worms. In addition to containing lesions, the entire liver may be covered with a fibrinous deposit and may adhere rather firmly to the stomach and diaphragm. Similar lesions are not uncommonly found in the lungs. The lesions in and near the liver, in the fat around the kidneys, in the kidneys themselves, and in other abdominal organs usually contain an abundance of kidney worms, some loosely attached to the tissues with which they are in contact and others firmly embedded in tough cysts, or sacs. Even the body muscles are not safe from the attacks of kidney worms, for these parasites can and do penetrate the rather resistant muscle tissue in the region of the kidneys. Sometimes the worms even penetrate the spinal canal, in which case they may produce a partial paralysis.

Where meat is inspected, scarred or infested livers must be trimmed to remove the tough, fibrous substance of which the scar is composed, and if the scars or infested areas are excessive the entire liver is condemned. This applies also to the fat and muscle tissue.

Investigations have shown, moreover, that heavy infestations of pigs with kidney worms retard their growth, as shown in Figure 160. These pigs, all of the same litter, were about 2 months old when the photograph was taken and were still with the sow. Pigs A, C, and F were free from kidney-worm infestation, whereas pigs B, D, and E, when about 1 week old, were infected experimentally with kidney-worm larvae. The pigs were of strikingly uniform size when farrowed, with the exception of pig C, which was born a runt. This pig, however, was bigger and heavier when about 2 months old than were the three worm-infested pigs.

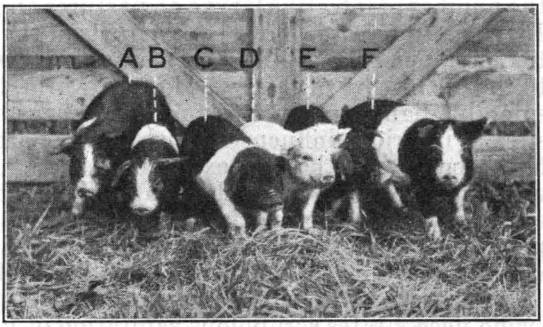

FIGURE 160.—Litter of pigs about 2 months old. Pigs B, D, and E were infected with kidney worms when about a week old; pigs A, C, and F remained uninfested. Pig C was born a runt. Note differences in size between infested and noninfested pigs

Passes Through Body of Animal

Unless the farmer knows something concerning the mode of life of the kidney worm, the manner of its propagation, and the ability of its eggs and free-living larvae to maintain themselves in hog lots and on hog pastures under various conditions, he can do comparatively little to overcome this parasite, since there is no known drug which will destroy it once it has invaded the body of the animal.

During warm weather and when moisture is abundant, the microscopic kidney-worm eggs, which are eliminated from infested hogs with the urine, develop on the ground in a day or so; the larvae which hatch from the eggs continue to develop on the soil and on pastures, and under favorable conditions they reach the infective stage in about four days. The infective larvae are about one-fiftieth of an inch long. Hog lots and pastures on which kidney-worm infested hogs are kept may be teeming with these larvae. Some are swallowed with the feed and water; others penetrate the broken skin through wounds and places on the body where the skin is merely rubbed off. Once they are inside the body of a pig they make their way to the liver, and in this organ they develop slowly, increase in size gradually, and at the same time work their way through the liver substance until they reach the capsule of the liver. Many of the worms remain in this organ and in its blood vessels until they die and degenerate; others break through the liver capsule, however, and thus get into the abdominal cavity where they wander freely for a time over the surfaces of the abdominal organs. Some of these worms may become inclosed in a cyst, or sac, in the tissues adjacent to the liver or other abdominal organs. Others penetrate the kidney fat, perforate the uterer, and discharge their eggs, which pass out with the urine. These are the ones which complete the cycle of development of the kidney worm in the body of a pig. The process is a slow one and may take six months or longer.

Control Measures Necessary

The most hopeful outlook for the control of these parasites is to keep the number of infective larvae on pastures and in lots as low as possible. Investigations carried out by scientists of the Bureau of Animal Industry have not only established many of the essential facts with regard to the life history of the swine kidney worm, but have also thrown considerable light on the reactions of the eggs and larvae of these parasites to injurious influences to which they are naturally subjected. It has been shown that on experimental pastures and plots which are well drained, exposed to the sun, and free from trash and litter, the eggs and larvae are relatively short-lived, whereas on poorly drained plots and pastures which are shaded and in which trash and litter abound, the larvae find more favorable conditions for existence.

It is evident, therefore, that control of kidney-worm infestation in swine necessitates scrupulous sanitation of hog lots and pastures, and for arrangements of a sort which will expose the eggs and larvae to the sun, prevent the accumulation of litter on pastures and on lots, and afford good drainage. The swine-sanitation system, which was developed by the bureau as a control measure for the large intestinal roundworm, also controls kidney-worm infestation to some extent, but not sufficiently, in most cases, to prevent some heavy losses. Other precautions are necessary, but what they are and how they can be practically applied still remain to be determined for the most part. The following recommendation is made, however, with the assurance that it will prove beneficial: Pigs should be weaned as early as possible and moved to a clean pasture in order to shorten, as much as possible, their period of exposure to infective kidney-worm larvae.

Since the kidney worm develops rather slowly in the body of pigs, infested swine are not likely to discharge kidney-worm eggs before they are at least 6 months old, and therfore will not contaminate their pastures with eggs before they reach that age. If pigs are raised under the swine-sanitation system and fed properly, most of them will be ready for market before they begin to discharge many kidney-worm eggs. The sources from which pigs acquire kidney worms are the larvae which develop from eggs discharged by infested sows. If the period of exposure to this source of infestation is reduced to the minimum consistent with good husbandry and if this precaution is coupled with scrupulous sanitary provisions as outlined above, considerable progress will be made in the control of this worm plague.

BENJAMIN SCHWARTZ,
Senior Zoologist, Bureau of Animal Industry

SWINE-SANITATION Plan Results in More and Better Pigs per Sow The continued losses sustained by swine raisers on account of various diseases and conditions, other than hog cholera, have developed a demand for information on effective control measures. The preventive serum treatment, as insurance against cholera, is widely known and used, but swine owners are not so familiar with means for reducing certain other sources of loss.

One of the diseases which stands out prominently is necrotic enteritis, characterized by inflammation of the intestines. This malady is definitely on the increase in many sections of the country. Parasites, both internal and external, also take a heavy toll, though not so much in actual death losses as in retarded growth and reduced vigor. Many pigs also are lost at farrowing time from a variety of causes.

Accepting the challenge of this array of losses, representatives of the Bureau of Animal Industry inaugurated and are now conducting a campaign against them in connection with hog-cholera-control work. The campaign centers chiefly in inducing farmers to keep their hog lots sanitary by following definite recommendations. In many instances these efforts have resulted in a decided increase in the number of pigs saved during the spring farrowing season, the production of a better quality of pigs, and more rapid growth, enabling farmers to market a 200-pound hog at about 6 months of age instead of at 8 or 9 months, as usually happened when no attention was given to sanitary precautions.

In localities where strict sanitary measures have been used necrotic enteritis and internal parasites have practically disappeared, and herds of strong, thrifty shotes, free of runts, may be seen on the farms where the sanitary program was carried out. The program consists essentially in washing sows thoroughly before farrowing, having them farrow in clean quarters, and keeping the young pigs on clean pastures until at least 4 months old. Details of the methods are described in department literature which is furnished on request. In an area where more than 7,000 pigs were grown under the swine-sanitation plan during the spring and summer of 1930, not a single call for assistance came to the bureau veterinarians; whereas in sections where no attention was given to sanitary precautions calls were continually coming for aid in combating necrotic enteritis, intestinal parasites, lung worms, and post-vaccination troubles, which are almost invariably due to some of these conditions.

Conditions that Prevent Normal Growth

It is inconceivable that an animal which is forced to exist under insanitary conditions and becomes diseased can thrive and grow normally. Neither can one expect normal growth from a pig heavily infested with parasites, either internal or external, that sap its strength and reduce its power to assimilate its food. When these simple facts are brought to the attention of a swine grower in language that he understands, and by post-mortem demonstrations (fig. 161), he is quick to realize that the adoption of reasonable sanitary precautions means the difference between health and disease and that that difference is the difference between profit and loss, success and failure. The measure of success achieved depends, to a large extent, on the effort put forth by the herd owner in following the swine-sanitation program. To follow the plan in any of its essential features produces

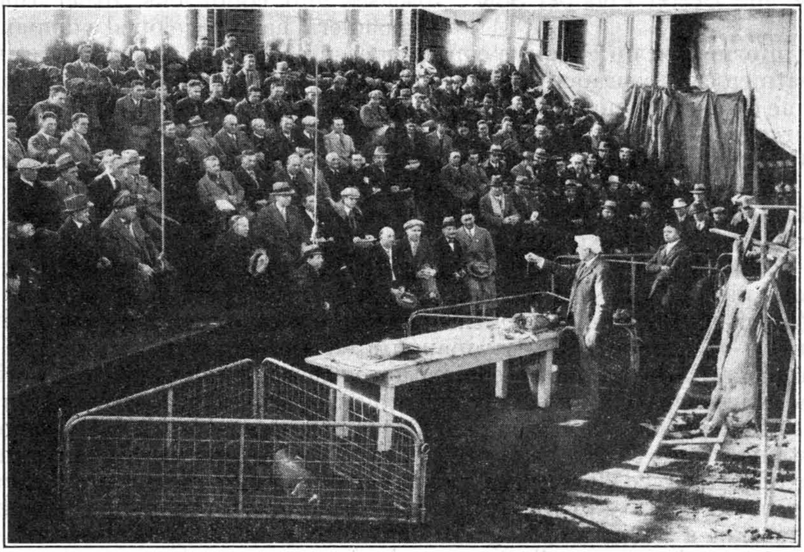

FIGURE 161.—Observing the results of a post-mortem examination at a swine-sanitation meeting

beneficial results, but one should not expect to obtain the best results through only half-hearted methods.

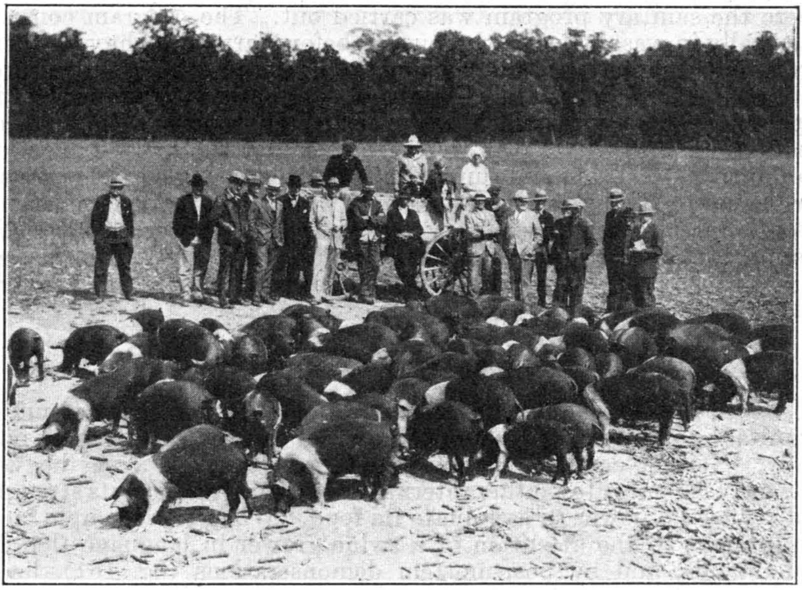

FIGURE 162.—Pigs raised under the sanitation system. Of 95 farrowed, 90 were raised to market weight

Under ordinary farm conditions, with pigs grown under insanitary surroundings, only about 50 in every 100 farrowed are marketed.

Swine sanitation increases the number of pigs reaching the market by about 50 per cent. About 75 in every 100 farrowed are raised successfully. Those lost fall victims to accident and other causes outside the saving influence of the system. By following swine sanitation a farmer can raise more pigs with a given number of sows or he can raise as many and also better pigs with fewer sows. In either case he can obtain a greater financial return for feed consumed.

The following typical experiences illustrate the kind of results obtained. In the fall of 1928 a swine owner in Indiana had 12 sows that farrowed 117 pigs in an old hog lot. Parasitic worms, necrotic enteritis, and other causes reduced the number until he had only 35 left for market the following spring. He also paid out about $200 for stock powders and tonics to save the pigs, but he lost them anyway. At a sanitation-campaign meeting he signed up as a demonstrator. He kept the same 12 sows and in the spring of 1929 they farrowed 95 pigs. Under sanitary handling and good feeding and housing, 90 of the 95 pigs were raised to market weights. "These pigs were not sick a minute," he said, "and I didn't spend a cent for anything but feed." A portion of his herd is shown in Figure 162.

Another swine grower who adopted the sanitation system because of the large proportion of runty pigs in his herd stated after using the new method two years, "My pigs are ready for market from six weeks to two months earlier."

One of the most interesting experiences was that of a 16-year-old 4-H club boy who entered a litter of 12 pigs in a ton-litter contest. The litter weighed 2,752 pounds when the pigs were 180 days old. They returned $199.25 over feed cost. When asked how he made his litter weigh so much at so low a cost, he said: "I merely followed instructions on swine sanitation to the letter."

Senior Veterinarian, Bureau of Animal Industry.

TAX Research Outlined to Discover Means of Reducing Farm Levies

Continued enlargement of the farmers' tax bill is creating a widespread movement not only for stemming the tide toward future increases, but also for actual reduction. Resolutions on the subject are being passed with renewed vigor by leading farm organizations and the issue will almost certainly absorb an important part of the time of a majority of State legislatures. Between 1924 and 1929 farm real estate taxes per acre for the United States as a whole increased 7 per cent, while farm real estate values per acre declined 11 per cent. The result is that the "true" tax rate—the ratio of taxes to full value as distinguished from assessed value—increased almost 20 per cent. Stated differently, farm real estate taxes per $100 of full value increased from $1.22 in 1924 to $1.46 in 1929. (Table 21.) Results of the department's research and of studies by experiment stations and other agencies support the conclusion that farm tax revision is desirable from the standpoint of reasonable public policy.[13]

[13] COOMBS, WHITNEY. TAXATION OF FARM PROPERTY. See especially U. S. Dept. Agr. Tech. Bul. 172, 75 p. 1930.

Swine sanitation increases the number of pigs reaching the market by about 50 per cent. About 75 in every 100 farrowed are raised successfully. Those lost fall victims to accident and other causes outside the saving influence of the system. By following swine sanitation a farmer can raise more pigs with a given number of sows or he can raise as many and also better pigs with fewer sows. In either case he can obtain a greater financial return for feed consumed.

The following typical experiences illustrate the kind of results obtained. In the fall of 1928 a swine owner in Indiana had 12 sows that farrowed 117 pigs in an old hog lot. Parasitic worms, necrotic enteritis, and other causes reduced the number until he had only 35 left for market the following spring. He also paid out about $200 for stock powders and tonics to save the pigs, but he lost them anyway. At a sanitation-campaign meeting he signed up as a demonstrator. He kept the same 12 sows and in the spring of 1929 they farrowed 95 pigs. Under sanitary handling and good feeding and housing, 90 of the 95 pigs were raised to market weights. "These pigs were not sick a minute," he said, "and I didn't spend a cent for anything but feed." A portion of his herd is shown in Figure 162.

[1] The term "true" tax rate as used here means the ratio of property taxes to true value, as distinguished from assessed value of farm real estate. The 1924 ratio is based on figures for farm taxes and farm real estate values as shown in the 1925 Census of Agriculture. Using this ratio as the base, those for other years were computed from trends of farm taxes reported regularly in the Agricultural Situation and trends of farm real estate values as reported in The Farm Real Estate Situation 1928–29, U. S. Dept. Agr. Cir. 101, by E. H. Wiecking.

Reasonable public tax policy is that policy which seeks to collect necessary public revenue with the least undesirable effects upon production, conservation, and land utilization, and with fairness to taxpayers. Hence the reasonableness of the present policy depends upon the answers to the following questions: Is the present high level of governmental expenditures necessary? What are the undesirable effects of the present tax system upon production, conservation, and land utilization? Is the apportionment of the cost of government among taxpayers fair?

Possibilities of Reduction

A proposal for farm-tax reduction might begin with the fundamental question of whether or not the level of all taxes—not merely farm taxes—is too high. This is simply another way of asking whether or not the general level of governmental expenditures is too high. It is evident that governmental expenditures can be reduced only by either reducing the services of government or getting the same services for less money. What are the possible economies that may result from consolidation and thorough modernization of the machinery of local government? This is an age of mergers and consolidations. Local governmental units and machinery, however, have remained relatively fixed, while the changes in production, marketing, and distribution have been revolutionary. Many of the forms, units, and methods of local rural government that served the purposes of our grandfathers may be antiquated now. Where the maintenance of unnecessary counties, townships, school districts, or other governmental units results in unnecessary tax burdens or impairs the services of government, every effort should be made to eliminate the unnecessary units. The opportunities for farm-tax reduction along this line will vary in different parts of the country and will depend upon local conditions, but they need to be called to public attention by thorough-going research. Such studies are contemplated in the research program of the Bureau of Agricultural Economics.

A prospective scarcity of timber supplies was the primary consideration that led the Congress to finance liberally an investigation now under way, one of the purposes of which is "to disclose the present methods and practices in the taxation of timber and forest-growing land and their actual effects upon the use of land for the growth of timber." An investigation no more difficult to make might attempt to disclose the present methods and practices in the taxation of farm property and their actual effects upon farm production, farm abandonment, and the value and utilization of farm land. Both types of studies relate to the economic effects of taxes as levied under the system in vogue in this country.

The issue in both cases is a question of the degree of conflict between the tax policy and other public policies. In both cases the questions are difficult to answer because of the difficulty of isolating the influence of taxes from other concurrent influences. And, after all, from the standpoint of an immediate program of action, the question is not only whether the tax was an influence, but also whether it was a limiting factor. Where farm prices, for example, have dropped to such low levels that the abolition of all taxes would have no appreciable effect upon land utilization and farm abandonment, taxes can not be considered the limiting factor. A tax that actually causes deficit or surplus output, or results in improper land use, is likely also to be an unfair tax. But a tax may be grossly unfair without having any of these effects. Unlike forest-tax investigations, farm-tax investigations have never been authorized because of any suspected causal relationship between methods of farm taxation and a prospective abundance or scarcity of food and fiber.

A Question of Fairness

The movement for farm-tax revision rests largely on considerations of fairness. Much has been written in recent years about the unfairness of the general property tax system. In practice there is no such tax system. What is called a "general" property tax is virtually a real-estate tax. The overwhelming predominance of real estate in the local tax base during a period of unparalleled increases in governmental expenditures is the starting point in any attempt to define the "unfairness" of the present system. The farmer's property is largely real estate and his taxes are largely local. But there is a trend toward the substitution of income, gasoline, and other taxes for the property levy for State purposes. Also, the States are gradually assuming an increasing share of financial responsibility for the support of certain functions, especially roads and schools, formerly regarded as strictly local in character. These developments will proceed further, and are undoubtedly elements of sound public policy. Are they proceeding rapidly enough?

The increasing share of the total tax burden assumed by nonfarming groups has generally not taken place at a sufficiently rapid rate actually to reduce farm taxes. It is often asserted that broadening the tax base for the support of schools and roads will simply mean more taxes for city people—not less for farmers. More frequently, it is contended that the adoption of an income tax will be "just another tax"—not farm-tax reduction. If the adoption of these measures is either preventing farm taxes from rising to otherwise higher levels, or making available to farmers desirable governmental services they otherwise would not have received, nonfarming groups are at least assuming an increasing share of the total tax burden, both absolutely and relatively. The advocates of a new tax are not fully answered by those who call the tax "just another tax." The real issue is whether the increased expenditure contemplated as a result of the new tax is wise or unwise.

New taxes are not easily adopted; and it is much easier to add a new tax than to substitute one for a portion of the property taxes. The gasoline tax was adopted only partially as a substitute for taxes real-estate owners would otherwise have paid. The people wanted expensive highways, and the real-estate owners would not and probably could not have supplied the needed funds. The gasoline tax is generally regarded as fair, but it grew partly out of the resistance of real-estate owners to higher property taxes for roads. Hence a conception of fairness without the power to make it effective is impotent.

Danger of Creating New Inequalities

Any effort at farm-tax revision should carefully avoid creating new inequalities more serious than those it seeks to eliminate. It should have due regard for the kinds of taxes already employed by the Federal Government as well as by the States. It should also take into account the inequality of tax payments as between various nonfarming groups. Many people believe that if real-estate taxes were levied on the basis of rental rather than selling value, a substantial portion of the taxes now paid by farmers would be paid by owners of urban real estate. Would such a change in the property tax actually lower farm taxes appreciably? Would it be fair to owners of urban real estate? What is European experience with this form of property taxation? Is the proposal fundamental or illusory? The bureau's projected research includes studies designed to throw light on these questions.

Excepting the possibility of far-reaching changes in governmental expenditures and in the revenue system, farmers will continue to pay relatively high taxes. The movement for retrenchment in the matter of public expenditures may be a factor favoring lower taxes; but the relatively high price level prevailing when the bulk of the public debt was contracted, the tendency of public expenditures to increase, and sheer inertia all point in the opposite direction. Furthermore, any significant farm-tax reduction will need to be accompanied by some provision to prevent the tax from rising quickly to its former level.

Agricultural Economist, Bureau of Agricultural Economics.

TERRACE Failures Often Result from Errors in Planning and Building

Properly planned, well-constructed, and carefully maintained terrace systems have demonstrated the merits of terracing and the benefits to be derived therefrom in practically all sections of the country where this method is practiced. It is not uncommon, however, to hear the practice of terracing severely condemned by men who have tried it on their farms. An examination of the terraces on these farms almost invariably reveals that the causes for the terrace failures were due to the terraces being poorly planned, improperly laid out, inadequately constructed, or carelessly maintained.

One of the outstanding causes for terrace failures (fig. 163) is the failure to prevent water from draining on to a terraced field from those who call the tax "just another tax." The real issue is whether the increased expenditure contemplated as a result of the new tax is wise or unwise.

New taxes are not easily adopted; and it is much easier to add a new tax than to substitute one for a portion of the property taxes. The gasoline tax was adopted only partially as a substitute for taxes real-estate owners would otherwise have paid. TERRACE Failures Often Result from Errors in Planning and Building

Properly planned, well-constructed, and carefully maintained terrace systems have demonstrated the merits of terracing and the benefits to be derived therefrom in practically all sections of the country where this method is practiced. It is not uncommon, however, to hear the practice of terracing severely condemned by men who have tried it on their farms. An examination of the terraces on these farms almost invariably reveals that the causes for the terrace failures were due to the terraces being poorly planned, improperly laid out, inadequately constructed, or carelessly maintained.

One of the outstanding causes for terrace failures (fig. 163) is the failure to prevent water from draining on to a terraced field from higher and adjoining unterraced land. This unterraced land may consist of timber, pasture, orchard, or other land on the same farm that is not regarded by the owner as needing terraces, or it may be an adjoining field owned by a neighbor who is not interested in terracing. If for some reason it is not possible to have this outside area terraced, then the water draining from it should be intercepted before it reaches the lower terraced field and diverted into a natural drainage course by means of a properly located drainage ditch of adequate capacity.

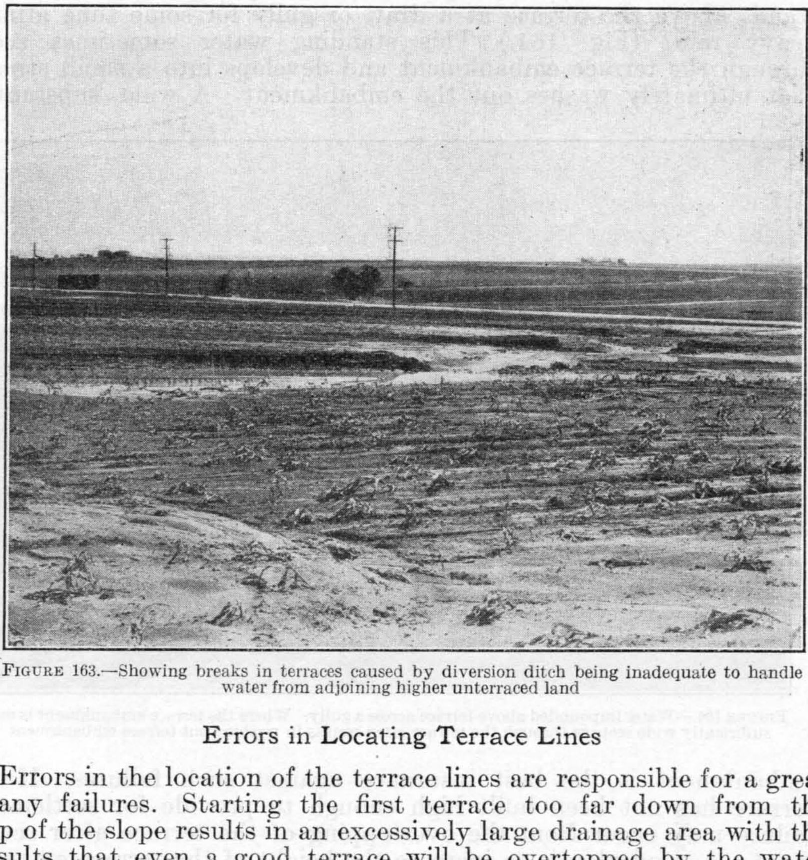

FIGURE 163.—Showing breaks in terraces caused by diversion ditch being inadequate to handle water from adjoining higher unterraced land

Errors in Locating Terrace Lines

Errors in the location of the terrace lines are responsible for a great many failures. Starting the first terrace too far down from the top of the slope results in an excessively large drainage area with the results that even a good terrace will be overtopped by the water draining from the large area above. Spacing terraces too far apart also has the same effect. Errors in laying out terraces may be due to carelessness or incompetency on the part of the instrument man or rodman. Points on the terrace line that are located too high may cause a damming of water and result in the accumulated water overtopping the terrace. If points are located too low on the terrace line the top of the terrace is usually built too low and washouts are of common occurrence at such points. The abrupt change from a steep to a flat grade along a terrace channel often causes an accumulation of water that overflows and breaks the terrace.

Even though a terrace is laid out properly this is no insurance against the possibility of its failure if it is not properly constructed. Faulty construction may consist of building the terrace to insufficient height, of building embankments too narrow, or of not making allowance for the settlement of the embankment across gullies. After a terrace is built the top should be checked with the leveling instrument to detect any low places and these low places should be built to the proper height with the scraper or other suitable implement. Terrace failures often occur at crossings of draws or gullies where the embankment is not built wide enough or sufficiently high. Water usually stands above the terrace at a draw or gully for some time after a heavy rain. (Fig. 164.) This standing water sometimes seeps through the terrace embankment and develops into a small stream that ultimately washes out the embankment. A wide, substantial

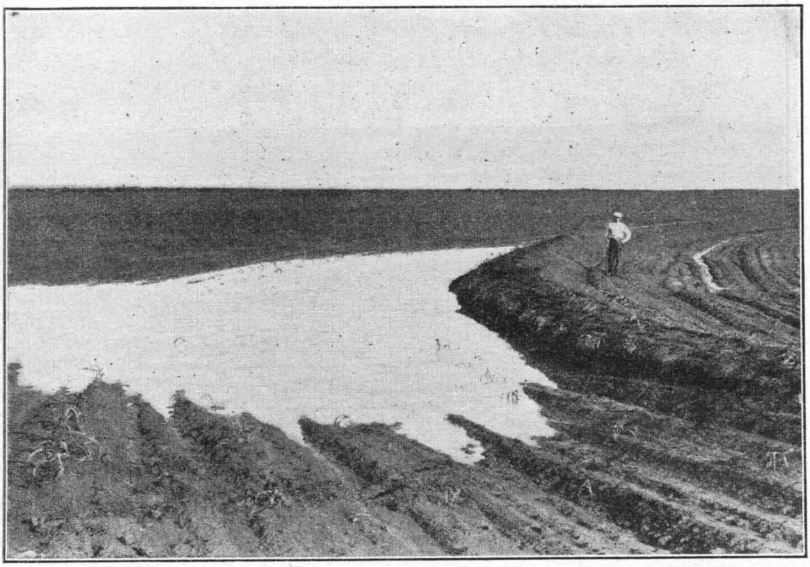

FIGURE 164.—Water impounded above terrace across a gully. Where the terrace embankment is not sufficiently wide seepage through the terrace often results in washing out terrace embankment

embankment is the best insurance against such failures. If the terrace has not been built high enough to provide for settlement, failure may occur from the overtopping of the terrace after settlement. A good plan is to increase the height of the terrace embankment at least 25 per cent at gullies and depressions to allow for settlement and then to check the height of the embankment occasionally as an insurance against an undue amount of settlement.

Other Causes of Failure

Other causes for failures of terraces are neglect or careless maintenance. Many farmers seem to think that after a terrace is once constructed it requires no more attention and often condemn the practice of terracing because of failures due solely to lack of maintenance. Careful maintenance is as essential to the proper functioning of a terrace as are adjustments and repairs to the satisfactory operation of

FIGURE 165.—Showing the cutting away of terrace embankment by erosion at bend

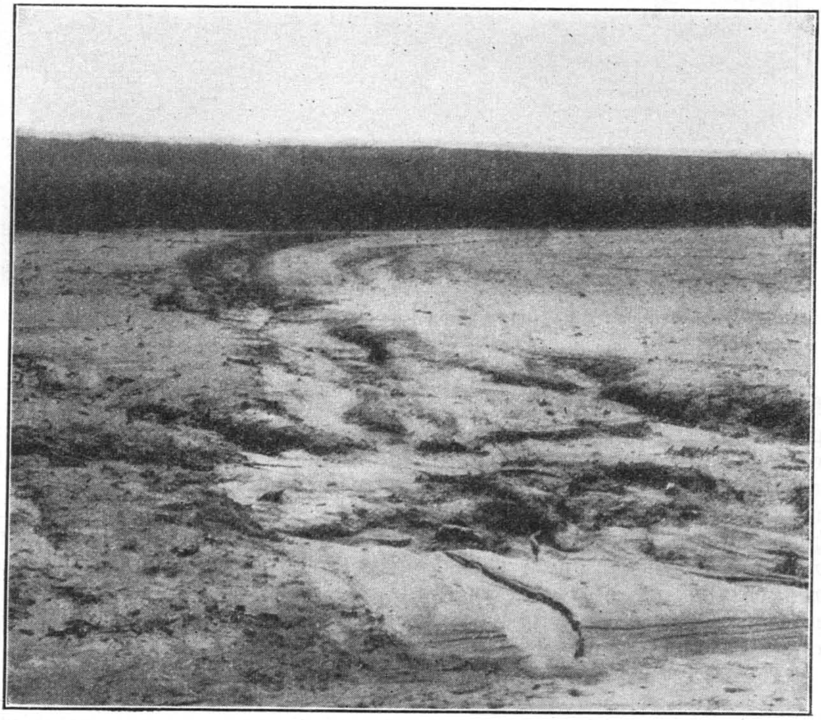

FIGURE 166.—Erosion of a gully between terraces due to concentration of water in furrow left below upper terrace and later breaking over at a low point in furrow

an automobile. Total disregard of maintenance in either case invariably produces disastrous results.

Where systematic maintenance is practiced not much work is required each year to keep the terraces built to the required height and width with a plow or by making a few rounds with a terracing implement. Where erosion of terrace embankments occurs at sharp bends due to the cutting action of the water as shown in Figure 165 it should be prevented by the seeding of the embankment to grass. The formation of gullies on the land between terraces, as shown in Figure 166, can often be stopped by preventing the concentration of water immediately below a terrace in furrows left after construction. This form of erosion between terraces is often the cause of the filling of the channel with soil during a single rain, resulting in the overtopping and breaking of the terrace. Figure 167 shows a view of a terrace channel partly filled with soil washed from the slope between the terraces.

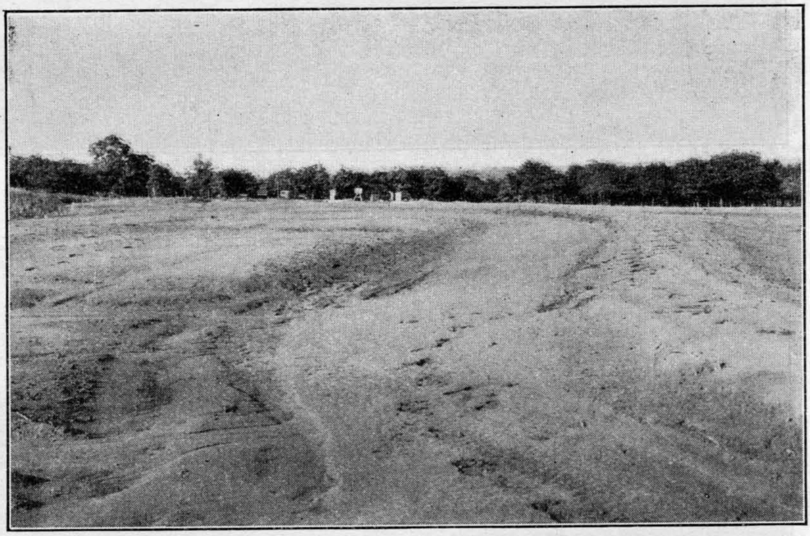

FIGURE 167.—Showing filling of terrace channel caused by erosion in draw between terraces. This draw should be seeded to grass

Where the water concentrates in a natural depression it may be found necessary, if marked erosion persists, to seed the depression to grass. Burrowing animals, large cracks that develop during dry periods, and low places in the top of the terrace caused by dragging farm machinery across are often causes of serious breaks that could be avoided by periodical examinations and a small amount of work to repair the damage. The gradual filling of a terrace channel from the movement of soil down the slope between terraces will eventually reduce the size of the terrace channel. This can be prevented by annual maintenance consisting of moving this filled-in soil from the channel to the terrace embankment.

C. E. RAMSER,
Senior Drainage Engineer, Bureau of Public Roads.

TEXTILE Buying for the Home Would Be Aided by System of Labeling

No home maker can be considered wholly successful to-day unless she is a wise and discriminating buyer. Her ability to bake good bread and sew a fine seam may still be desirable accomplishments, but in many homes both the bread and the seam are likely to be purchased ready made. Her problem is to select the best product obtainable for the money she has to spend. This is no easy matter, especially when she is trying to buy satisfactory clothing and other textile materials.

The extension service of the United States Department of Agriculture and the home-economics teachers of the country have attempted for many years to furnish so-called household tests by which the home maker could judge quality in textiles. She has been told to moisten a small spot of the material in order to discover whether it is linen or cotton, to burn a few yarns so as to determine how much wool it contains and to do many similar things which are supposed to tell her just what she is buying.

At best these methods are makeshifts. At one time they may have had some value, but that time has largely passed. To-day the cotton and linen or the cotton and wool are likely to be so mixed in the same yarn that the amount of each can only be determined by a textile specialist with laboratory facilities. New fabric finishes are being developed and applied to all kinds of materials so that their quality is not easily recognized. More confusing still is the fact that the market is flooded with so many similar materials, differing in price but so nearly identical in appearance that the ordinary household buyer can not make an intelligent choice between them. The result is that the home maker with even the best intentions and training is forced to buy largely by guess.

Retail-Store Buyers Handicapped Too

This is also true of most buyers for retail stores. Unless they have laboratories at their disposal, a facility now available to only a very small percentage, they are at as great a loss as are the women. In fact, in the majority of cases they have less knowledge of the subject than the college or extension trained home maker and in addition do not have the opportunity of watching the performance of the merchandise under actual wearing conditions.

The Bureau of Home Economics has recognized the difficulty for some time and has become interested in the possibility of setting up specifications for the more staple materials so that the home maker can select the one best suited to her purpose, within the price range she is able to pay. Grading systems involving quality specifications are used by producers and distributors of some commodities, such as meats, poultry, fruits, and vegetables. Standards for grade and staple of raw cotton have been set up by the department and are serving a useful purpose in the trade. In fact, most wholesale buying is done to-day on the basis of some kind of grades or specifications. These are chiefly the result of demand on the part of the buyers and are based on studies which have shown the type of specifications that would best describe each particular commodity. Much of this has been done by the Department of Agriculture. The Bureau of Home Economics is suggesting not only that these grades be brought into use in the retail market so that the consumer can benefit directly by them, but also that appropriate grades and standards be extended to other household commodities, such as textiles.

The question naturally arises as to what textile specifications would be most useful to the mass of consumers. In many cases this can not be answered until studies are made to determine the particular fabric characteristics of vital importance from the consumer's viewpoint. Often this will involve fundamental research as to the effect of differences in construction upon the usefulness of the fabric. A large gap now exists between the technical information in regard to fabric manufacture and the practical information of value in everyday living. This will have to be bridged before any real help can be given the household buyer. It is this type of research upon which the Bureau of Home Economics is making a beginning. For example, a study has been completed of the kinds of wear shown by bed sheets when used under hotel conditions and an investigation is now under way in cooperation with the Bureau of Agricultural Economics on the relative wearing qualities of sheets made with different grades of cotton of the same staple length.

Helpful Construction Details

There are, however, many construction details now in general use among manufacturers which would be helpful to consumers even if they would not completely solve the difficulty. From the manufacturer's point of view, this would involve printing the information on a label on the fabric. On the part of the consumer it would in some cases involve learning the meaning of a few simple terms now used chiefly by textile experts.

For instance, sheeting manufacturers specify the weight per square yard of the sheeting. This tells the total weight of fiber and finishing material and is often useful in comparing sheets of different prices. Sizing is the term used for the starch and other finishing material present in cotton fabrics. A small amount must be put on the warp yarns of every fabric so that they will not break when chaffed during the weaving process. Additional sizing is added to the finished fabric to make it appear smooth and attractive to the buyer. In extreme cases such large amounts may be used as to make the sheet or other fabric appear heavier and firmer than it is and the purchaser is misled. When the sheet is washed most of this finishing material is removed and the excessively sized fabric shows up as it really is, a very coarse, loosely woven piece of material. It would be a relatively simple and very valuable practice to tell on a label the percentage of sizing in sheets and other fabrics in which this is important. "Pure finish" is a term sometimes used to indicate that a minimum amount of sizing has been used.

The yarn count gives the number of the yarn and shows whether fine or coarse yarns have been used. The number of twists per inch in the yarn gives a numerical measure of whether it is very loosely or very tightly twisted. This is important because a yarn may be so loosely twisted that it pulls apart easily and does not wear. The number of threads per inch warp-wise and filling-wise is a measure of how closely woven the material is.

Breaking-Strength Test

Of course durability is one of the qualities chiefly desired in many fabrics and unfortunately there is as yet no standard method of determining this quickly. The nearest approach to such a test is the breaking strength of the material, often spoken of as the tensile strength. Although this is not necessarily an accurate measure of wearing quality, it is often some indication.

While in general, thread count, yarn count, twist count, weight per square yard, and tensile strength tell most of the construction story concerning a fabric, some of these items are more important in particular cases and often additional information is needed. Take the case of blankets. These items are all important in determining quality in these articles, but information about weight and tensile strength are especially useful. Two all-wool blankets may be the same size and of very similar construction but differ markedly in the amount of wool contained in each. This, of course, influences the heat-retaining properties and is of great significance when the matter of getting one's money's worth is considered. The tensile strength tells how strong the material is. In the case of blankets containing both cotton and wool, the percentage of each fiber present is of great importance to the purchaser. Under the present merchandising practice a mixed blanket is at best labeled "part wool" and this may mean anything from 95 per cent wool to one wool yarn in the selvage. The percentage could be easily designated on a label and the buyer thus told exactly what she is buying.

But certainly heat conductivity is the most important property of blankets. They are supposedly bought to keep people warm. Two things enter this property. One is how readily heat will be conducted away from a warm body through the blanket when the air outside is still. The other is how much will be lost if it is used where there is a draft or when a breeze is blowing, as is so often the case in outdoor sleeping. A blanket may be very warm in still air but so permeable to breezes that it is not warm under other conditions. "Air permeability" and "heat conductivity" of fabrics are common terms with textile specialists and methods of determining these qualities are well worked out. A purchaser who could, by looking at the labels, compare the kind of fiber, the tensile strength, the weight, air permeability, and heat conductivity of two blankets of equal size would have a logical basis for selection.

Necessity for Labeling

In fact every commodity could and should be labeled with such factual information. It would require no more ink or paper than is now used up in "sales-pressure" superlatives that really tell the purchaser nothing. Wouldn't it be fine if window shades carried labels that told what kind of fabric they were made of and their actual resistance to cracking? No vague, general claims, but statements as to exactly what kind of cleaning they will withstand and how many times a piece can be folded back and forth without cracking. That would give a real basis for choosing one rather than another. Towels could certainly be selected better if their construction details were given on the label and if such physical properties as the amount of water they would absorb and their tensile strength were emphasized rather than their glossy hems and other more superficial beauties.

Buying by specification would not mean that every purchaser would be able to buy the best on the market. Pocketbooks all have limits. But it would mean that every purchaser would know exactly what she is buying and could more wisely decide what is the best selection for her, taking all things into consideration.

RUTH O'BRIEN,
Chief, Division of Textiles and Clothing,
Bureau of Home Economics.

TICKS Are Carriers of Diseases of Man and of the Higher Animals In nature's complex many creatures of insignificant appearance and far down the scale of organic development play rôles of vast importance to the higher animals and man. This is preeminently true of certain species of ticks. Their influence is not benevolent or helpful in any sense of the word, but vicious and deadly, for they carry within their small bodies, and are capable of transmitting, some of the most dangerous diseases of which we have knowledge.

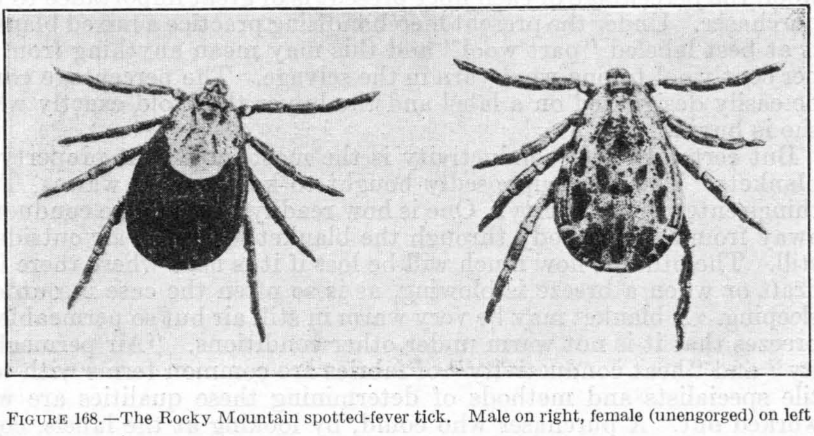

FIGURE 168.—The Rocky Mountain spotted-fever tick. Male on right, female (unengorged) on left

The discovery by Smith and Kilborne of the Bureau of Animal Industry, in 1890, of the rôle that the cattle tick plays in the transmission of splenetic fever of cattle, was one of the earliest and most important findings in medical entomology. Since that time a large number of diseases in various parts of the world have been shown to be carried wholly or largely by ticks. (Fig. 168.)

In addition to the blood diseases which ticks carry, the irritation caused by their bites is a source of great discomfort, especially in the warmer parts of the world, and furthermore, local persistent infections frequently result from tick attack. Again, a grave form of ascending paralysis may be caused by the attachment of ticks, especially at the base of the skull. This form of paralysis does not appear to be caused by a germ but more likely by some secretion of the tick, as the removal of the parasite usually results in prompt recovery.

In the United States, Rocky Mountain spotted fever is the most dangerous and widespread disease of man for which ticks are responsible. This disease occurs in the northern Rocky Mountain and the

Their influence is not benevolent or helpful in any sense of the word, but vicious and deadly, for they carry within their small bodies, and are capable of transmitting, some of the most dangerous diseases of which we have knowledge.

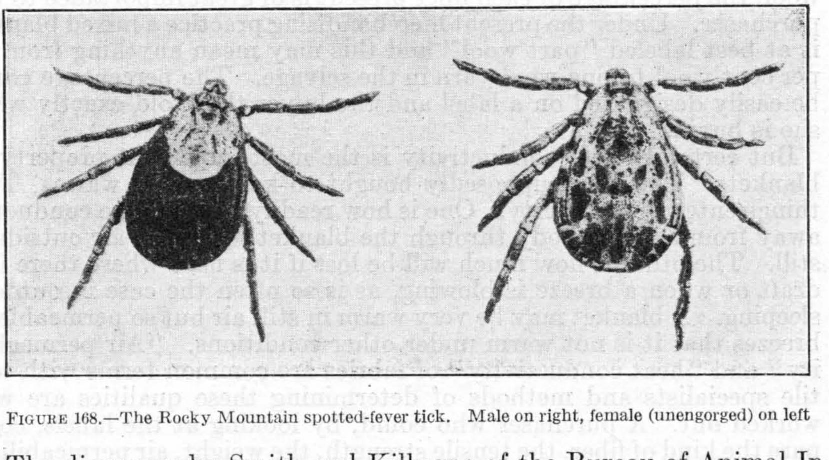

FIGURE 168.—The Rocky Mountain spotted-fever tick. Male on right, female (unengorged) on left

The discovery by Smith and Kilborne of the Bureau of Animal Industry, in 1890, of the rôle that the cattle tick plays in the transmission of splenetic fever of cattle, was one of the earliest and most important findings in medical entomology. Since that time a large number of diseases in various parts of the world have been shown to be carried wholly or largely by ticks. (Fig. 168.)

In addition to the blood diseases which ticks carry, the irritation caused by their bites is a source of great discomfort, especially in the warmer parts of the world, and furthermore, local persistent infections frequently result from tick attack. Again, a grave form of ascending paralysis may be caused by the attachment of ticks, especially at the base of the skull. This form of paralysis does not appear to be caused by a germ but more likely by some secretion of the tick, as the removal of the parasite usually results in prompt recovery.

In the United States, Rocky Mountain spotted fever is the most dangerous and widespread disease of man for which ticks are responsible. This disease occurs in the northern Rocky Mountain and the intermountain sections. Several hundred cases and several deaths occur each year. The species concerned is the common wood tick of that area, and the attachment of an infected tick for a few hours is sufficient to give rise to the disease. The development of a preventive serum by the Public Health Service, the reduction of the tick population by destroying the small wild animals upon which the young ticks feed, and the treatment of cattle, horses, and dogs to destroy the adult ticks are doing much to reduce the fear of this malady.

Tularemia Carried By Ticks

Tularemia, or rabbit fever, which has been much discussed in recent years, has been shown by R. R. Parker of the Public Health Service to be carried, at least in part, by ticks. Several cases of this disease in man have developed as a result of tick bite. Several kinds of ticks

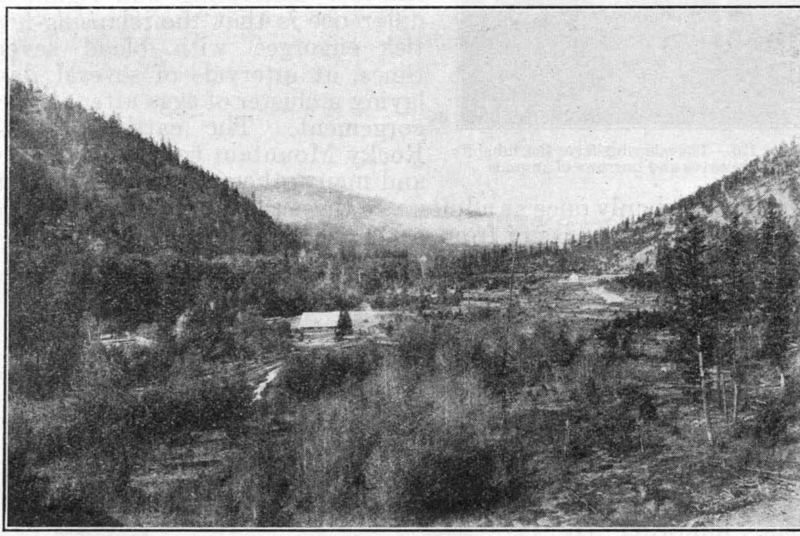

FIGURE 169.—In beautiful mountain valleys sometimes lurks a hidden menace—the Rocky Mountain spotted-fever tick

appear to play an important part in the spread of this disease among wild birds and animals, and from these hosts to man. It has been shown by Doctor Parker that this disease is transmitted hereditarily from the mother tick through the egg to the offspring. (Fig. 169.)

Wood ticks are suspected by some of being transmitters of endemic typhus of man, which is rather prevalent, especially in the Southeastern States where wood ticks are normally abundant.

Certain febrile diseases of man, known as relapsing fevers, are carried by insects and ticks. This group of diseases has been met with rarely in this country, but recently a number of cases have been diagnosed by Burford Weller and G. M. Graham, of Austin, Tex., in people who were bitten by ticks in caves which were being explored. This is the first proved instance in the United States of the transmission of relapsing fever to man by ticks. (Fig. 170.)

The occurrence in America of these and perhaps other diseases of man and of certain maladies of domestic animals makes detailed studies of the tick carriers very necessary. The distribution of the various ticks must be known, as also their local habitats, the hosts upon which they feed, how long they live, and their many peculiarities of life. In these respects ticks differ widely. Some, such as the relapsing-fever tick, will feed on almost any mammal or bird, and the period required for engorgement with blood is very short. On the other hand, the cattle tick will develop only on a limited number of species of animals, and it remains on the host for the entire period of its development, which requires from 20 to 60 days. Another interesting and significant difference is that the relapsing-fever tick engorges with blood several times, at intervals of several days, laying a cluster of eggs after each engorgement. The cattle tick, the Rocky Mountain spotted-fever tick, and many others attach to a host and fill with blood only once as adults. In these cases the female dies soon after depositing a mass of from 2,000 to 10,000 eggs. (Fig. 171.)

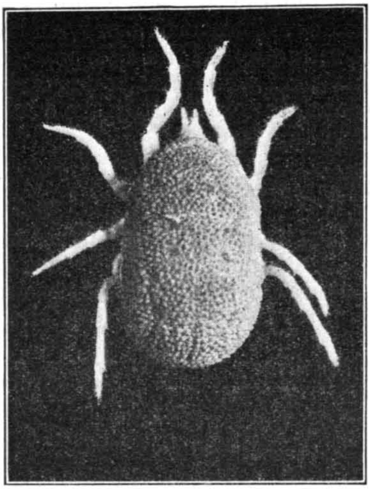

FIGURE 170.—The relapsing-fever tick inhabits certain caves and burrows of animals

All ticks, male and female, pass through several stages, viz, the egg, the larva or seed tick, the nymph, and the adult. However, the habits of the ticks with reference to feeding and development vary greatly. Some ticks, following engorgement in the different stages, drop off the host animal to shed their skins, and, consequently, must find a new host upon which to feed after each molt; other ticks lessen these hazards of life by remaining on the host while they molt and do not leave from the time they first attach as seed ticks until they become fully engorged adults. Most ticks are long-lived. Many live for several months as unfed seed ticks, nymphs, or adults, and some may survive for two or three years without food.

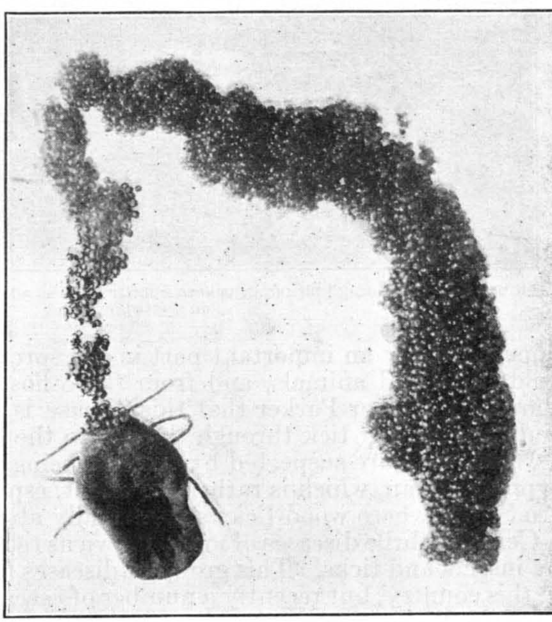

FIGURE 171.—A mass of from 4,000 to 7,000 eggs is laid by the female Rocky Mountain spotted-fever tick, after which she shrivels and dies

Tick Control Problems

These diverse habits make it impossible to apply the same control practices against different kinds of ticks, and make the control of some much more difficult than that of others. This fact indicates, too, the impracticability of attempting eradication of certain species, while in the case of others it may be perfectly feasible, as has been demonstrated with the cattle tick.

Where a tick is the principal carrier of a given disease, the importance of developing successful methods for its control is obvious. Often this is the most logical if not the only method of coping with the disease. The importance of certain ticks as annoyers of man, livestock, and poultry may well warrant the expenditure of much money and effort in control, even though no disease is carried by them.

Control methods must be based on an accurate knowledge of the life history and habits of the particular tick concerned. Since many of the ticks that carry diseases of man live at one time or another on domestic animals, the application of insecticides to these animals when they become infested at once suggests itself. The destruction of those rodents and other animals on which ticks feed is another line of attack. Most "wood ticks" are favored by the presence of brush, which not only gives them protected places in which to hide but also encourages wild animal hosts. Hence the recommendation to clear up cut-over areas and undergrowth. The protection of individuals from tick attack in areas where these parasites are numerous is not easy. The wearing of close-fitting clothing and the application to the outer garments of repellent substances, such as creosote dip or kerosene, will give a measure of protection. In areas where ticks are known to harbor disease, the examination of the body at frequent intervals and removal of all ticks present is advisable. The use of parasitic insects which destroy the ticks is receiving some attention, and this may be found to be a method which will aid in the fight against certain of these dangerous pests.

TIMBER Owners in the Southwest Find Sale for Converter Poles

Owners of timber in the Southwest have had opened for them an outlet for timber products of sizes and species not heretofore readily marketed in the region. The product, known as converter poles, is used rather extensively by the copper-smelting companies in Arizona and New Mexico. Converter poles are from 25 to 30 feet long with a minimum top diameter of 4 inches and a maximum butt diameter of 12 inches; 8-inch butt diameters are preferred. Some smelters in the Southwest accept smaller poles. The size of the poles depends upon the machinery for handling them. The poles are cut full length in the woods and loaded on cars green for shipment to the smelters. Aspen, pine, or other coniferous species and occasionally oak are used.

In the casting of copper for electrolyte refining the molten copper is treated by what is known as poling. As a final step in removing impurities, green poles are placed in the oxidized metal and as they are consumed release reducing gases which change the oxidity of the copper back to the metallic form.

As a final step in removing impurities, green poles are placed in the oxidized metal and as they are consumed release reducing gases which change the oxidity of the copper back to the metallic form.

Aspen, the species most commonly used, is usually the first tree crop that comes in at the higher elevations following fires, and its lighter foliage permits the conifers to reseed and reproduce on the burned area. Aspen also sprouts readily, so that poles can be cut from old burns that have restocked to coniferous stands or from stands of aspen which will then reproduce a new crop by sprouting. Pine poles can be obtained from thinnings, and the suppressed and defective trees removed, leaving the young stands in better silvicultural condition.

TOBACCO Graders Trained to Apply New System of Clearly Defined Grades Men are now being taught to grade tobacco in a new way. Instead of following the old methods that have been in vogue since early colonial days, the Department of Agriculture is training its graders to work with a definite system of clearly defined grades. The men to be trained have so far been drawn chiefly from two commercial sources—buyers who have been employed by tobacco firms or who have operated as independent speculators.

Each independent buying firm, whether manufacturer or dealer, has always had a more or less stable system of private grades, but there is no definite correlation between the grades of the various manufacturers and dealers. The manufacturers' grades are built around their private blends and the grades of the larger dealers usually reflect the blends of the domestic or foreign manufacturers for whom they buy.
