In an interesting account of studies with the variegated variety of the fern *Adiantum cuneatum* in the March issue of the *Journal of Genetics*, Miss Irma Andersson shows that the prothallia all sooner or later develop whitish stripes in which the chloroplasts are pale green and only half the size of the chloroplasts in the surrounding green cells. There are no intermediates, nor does any cell contain chloroplasts of both types. The purpose of this note is to direct attention to certain facts which appear to have a bearing on this sharp segregation occurring in gametophyte tissue.

There is evidence from several sources that the size of the chloroplasts in a cell is controlled and determined by the size of the cell, or, at any rate, that whatever determines the one also controls the other. Thus in tetraploid forms of *Solanum nigrum* and tomato produced by grafting, Winkler (*Zeitsch. f. Bot.*, 8: 417-531, 1916) has shown that the chloroplasts and starch grains as well as the cells and nuclei are approximately twice their normal size. Similarly, in the tetraploid *Œnothera gigas* it has long been known (Gates, *Arch. f. Zellforsch.* 3: 525-552, 1909) that the cells and nuclei are conspicuously larger than in the parent form, and van Overeem has shown recently

(*Beih. z. bot. Centlbl.* 39 : 19, 1922) that the same applies to the chloroplasts and to the xanthophyll grains in the petals. Also in the experiments of Bottomley (Proc. Roy. Soc. B, 89 : 481-507, 1917), on the effect of auximones in stimulating the growth of Lemna, his figures show (see pl. 22) that not only the cells and nuclei but also the chloroplasts are conspicuously increased in size.

In *Œnothera gigas* the gigantism of these structures is inherited, while in the Lemna experiments presumably it was not. Incidentally, this is an example of the same character being inherited in one case and not in another. But in its bearing on the fern chloroplasts it is interesting as showing how the cell as a whole controls the characters of its contained chloroplasts. The abrupt change from large dark to small pale chloroplasts in the fern prothallia seems to be of the nature of an "all or none" reaction in the genesis of the cell.

That such abrupt transitions do not always occur, however, is shown by certain striped varieties of maize (Randolph, *Bot. Gazette*, 73 : 337, 1922) in which there is a transition zone where the cells contain plastids of many intermediate sizes and depths of colour even within a single cell.

Nightingale in Uganda.

ORNITHOLOGISTS may be interested to know that in March, when in camp in the part of the Northern Province of Uganda known as West Madi, on two successive mornings I heard a nightingale singing vigorously about 8-9 A.M. : the bird did not commence at daybreak, nor did he sing at night.

From the unfinished character of the song, and the lack of fulness and richness of the notes, I suspected that the individual was a young bird which had not yet fully developed his powers.

My attention was attracted on March 13, the day I reached the camp, about 8.30 A.M., by the familiar sound, so different from that of any African bird of the locality : unfortunately, I could not see the bird in the thick bush. The spot was just such as would have been chosen by a nightingale in England : a large clump of big trees with underbush like a small copse.

The camp was Moyo, about twenty miles west of the Nile and some ten miles south of the Uganda-Sudan frontier.

I should be glad to know whether nightingales are often heard to sing south of the Sahara. I imagine that this bird was perhaps making its way northwards from its winter quarters.

Photography of Balmer Series Lines of High Frequency.

I HAVE recently performed a simple experiment with the luminous discharge through hydrogen, which has given results of some interest.

As is well known, it is difficult in the laboratory to photograph more than the first few members of the Balmer series, although higher members are well developed in the stars and nebulæ.

Prof. R. W. Wood has shown recently that fifteen or twenty of the Balmer lines can be photographed in a specially constructed tube running under very particular conditions, but I have found that an easy way of securing what appear to be similar results is merely to evacuate the hydrogen tube to a very low point, and then to cause the discharge to pass by the use of a glowing cathode.

Under these conditions, the Balmer series is brightened relatively to the secondary series ; moreover, the brightness of the higher frequency lines is enhanced.

The experiment is clearly suggested by the atomic model of Bohr.

I hope to publish a detailed account of the investigation shortly, as I am not aware of any previous experimental work along these particular lines.

Mechanism of the Cochlea.

I THINK it is evident that Prof. H. E. Roaf (NATURE, April 14, p. 498) and I approach the problem of the action of the cochlea from different aspects. He says : "A variation in pressure applied to the *fenestra ovalis*, if it is to cause a movement of the basilar membrane, must cause movement of the liquids in the cochlea." Most writers on the cochlea have started with this assumption, which is fundamental for the theories of Wrightson, Lehmann, Meyer, ter Kuile, and Hurst. But it is not possible to explain in this manner the fact that sounds can be conducted through the bones of the skull, and analysed in the cochlea in the same way as air-borne sounds. The bone-conducted sounds must be conveyed through the cochlea fluids to the basilar membrane as waves of condensation and rarefaction in the fluid. The impulses thus given to the basilar membrane must set swinging the sector of the basilar membrane in tune with their frequency. It is impossible for the sector to move without setting in movement the fluid columns between the sector and the round and oval windows which constitute its "load." Thus, the movement of the cochlea fluid originates *at the basilar membrane*. This phenomenon of bone conduction is illustrated quite clearly in my model, which gives localised responses at the same levels whether the tuning-fork is applied to the stapes or to the front or back of the brass case.

There is no reason to suppose that the case is different for air-borne sounds. We can state positively that the waves of sound do produce alternating pressure changes in the cochlea fluid, but we cannot be certain that any movement of the cochlea fluid results from these pressure changes until one or more of the sectors of the basilar membrane is set swinging.

Regarding the action of the cochlea entirely as a resonance manifestation, fluid friction counts only as a damping factor. It has important bearing on sharpness of resonance and persistence of vibration, but its magnitude is very difficult to estimate.

I am afraid I do not quite follow Prof. Roaf's suggestion as to the spiral ligament. He says "the greater bulk of the spiral ligament [in the basal coil] may be merely to resist a greater strain." Does he mean bending strain or breaking strain ? If the former, the only way in which it could so act would be by producing increased tension, as I (following Gray) have supposed. If the latter, the breaking strain of the basilar membrane would be determined by the strength of its weakest part. However strong the spiral ligament might be, it could not prevent the basilar membrane being torn if excessive force were applied to it. GEORGE WILKINSON.

Breeding Experiments on the Inheritance of Acquired Characters.[1]

By Dr. PAUL KAMMERER, University of Vienna.

ALMOST a quarter of a century has passed since I commenced to examine the inheritance of certain breeding- and colour-adaptations which I had obtained with amphibia and reptiles. I did not expect, in relatively so short a time, to obtain positive results, and, moreover, I was then well under the spell of Weismannism and Mendelism, which both agree that somatic characters are not inherited.

In the year 1909 I succeeded in ascertaining that *Salamandra atra* and *Salamandra maculosa* can be so bred as to produce a complete and hereditary interchange (of reproductive characters). The fact that *Salamandra atra,* which propagates itself in a highly differentiated manner, can be made to propagate itself in the manner of *Salamandra maculosa* need not necessarily be regarded as the acquisition of a new character, but may be an atavism. Since, however, the breeding habits of *Salamandra maculosa* can be changed to those of *Salamandra atra,* this objection is (in this case) excluded. I have hitherto always believed that no true inheritance underlay this phenomenon, but only the appearance of heredity (*Scheinvererbung*)—the external conditions applied (such as moisture) affect the germ plasm in the direct physical and not primarily physiological manner.

In view of my researches on the change of colour in *Salamandra maculosa* I could no longer entertain this belief. If the young animals are kept on a black background they lose much of their yellow marking and, after some years, appear mainly black. The offspring of these, if kept again in black surroundings, bear a row of small spots, chiefly in the middle line of the back. If the offspring, however, unlike their parents, are reared on a yellow background, these spots fuse to a band.

The yellow markings of the parent generation reared in yellow surroundings increase at the expense of the black colour of the Salamandra. If now the descendants of such strongly yellow individuals be kept on a yellow background, the yellow portions grow and appear as wide bilateral stripes. Descendants, however, which, unlike their parents, are now kept on a black background have less yellow, but proportionately far more than the background produces in the offspring of parents raised in black surroundings. The yellow markings are arranged symmetrically in rows of spots on both sides of the body.

It could now be said that the diminution of that colour which in the parents has become increased exhibited the nature of a non-inheritance. The acquired colour does not remain constant but diminishes. Ultimately, the grandchildren would have regained the same colour distribution as that of the initial parents. Therefore it could be argued we have merely an *after-effect* and *not* inheritance.

Against this view, however, we have to consider several points. (1) Young Salamandra kept on a black background, and reared from parents which had not been kept in yellow surroundings, become blacker in a much shorter time than those (on a black background) which had been reared from parents kept in yellow surroundings. (2) The descendants in my experiments are not merely placed in intermediate conditions (for example, a mixture of yellow and black backgrounds), as was done in most other breeding experiments on the inheritance of acquired characters—for example, those of Standfuss and Fischer on butterflies and of Sumner on mice. But the descendants are placed in opposite conditions: strongly yellow Salamandra are placed on a black background, and *vice versa*. Each tendency must be neutralised by the opposing stimulus; it cannot be thought that living matter behaves in this respect differently from non-living matter. (3) The yellow colour of the Salamandra, which descends from parents which have become very yellow, has at first a tendency to increase in spite of the opposing effect of black surroundings. The rows of spots of the freshly metamorphosed animals tend to fuse into stripes, just as in the case of animals brought up on a yellow background. Only later these stripes break up into spots again.

Curt Herbst, in 1919, reproached me by saying that I did not mention the augmentation of yellow pigment on a black background, and *vice versa*. It can be seen from my slides, which I have already shown in 1909 to the Congress of German Naturalists in Salzburg, and in 1910 to the International Zoological Congress in Graz, that I have made this augmentation clear. I have always emphasised this phenomenon of inheritance, which Herbst did not recognise as such.

Finally, we must not neglect how I have selected my material. For the experiments on a black background I used Salamandra which were richly marked with yellow; for those on a yellow background, Salamandra which were least marked with yellow. I used, therefore, a negative—or contra—selection to exclude the objection that I was using animals specially suitable for the colour changes which they had to undergo. I had, indeed, to contend with the fact that my animals were specially unsuitable for the experiments. Those which would have to change their colour to black were apparently burdened with a tendency to yellow, while the others which would have to produce a yellow race would have to contend against an opposing inheritance influence.

In the Vienna woods, where I had myself collected my experimental material, there were only asymmetrically spotted Salamandra (*forma typica*). My breeding experiments had changed the spotted Salamandra into the striped form. The striped race (*forma taeniata*) occurs also in the open; it is true, not in Vienna, but in districts where the earth is coloured yellow or yellowish red. In the experiments which I am about to describe I used Salamandra from the Harz Mountains, and it was found that the young of these (as in the experiment) immediately after metamorphosis already possessed their *taeniata* markings. In another case, that of Salamandra originating from the surroundings of Heidelberg, the freshly metamorphosed young were irregularly spotted, as in *forma typica*, and only arranged their markings during their growth into *taeniata*. Curt Herbst has noticed this ontogenetic recapitulation,

[1] Lecture delivered before the Cambridge Natural History Society on April 30.

and has therefore unwittingly confirmed my breeding experiments. The development of *typica* into *taeniata* is reversible, for it also happens that *forma taeniata* will change back to *forma typica*. Mr. E. G. Boulenger has confirmed this in experimental animals which he kept in the larval condition on colour backgrounds. He obtained in this way results far more beautiful and significant than my own.

At the end of the experiments, then, I have two types of striped Salamandra: first, the Salamandra which are found in Nature; and, secondly, those which have been bred in the laboratory from spotted parents. The former is an anciently established natural race, the latter a "new" laboratory race, and both of these are externally identical. I used both types for inter-crossing and inter-transplantation and also to complete my transmutation experiments.

If spotted Salamandra be crossed with naturally striped Salamandra, the offspring are of either one race character or the other in the Mendelian fashion. Spottedness is dominant over stripedness. If one crosses naturally spotted Salamandra with experimentally striped Salamandra the hybrids are of an intermediate character (stripe-spottedness) and Mendelian segregation does not occur. The hybrid indicates therefore a difference between "old" and "new" characters, even though it happens that externally both are identical. Doubtless both are heritable, but only the long-established race characteristic obeys the Mendelian laws. The new characteristic does not exhibit any atavistic tendency toward the grandparent race. These facts acquire a special interest when we recall that the vast majority of Mendelian experiments has been done on long-established race characters.

These old and new characteristics can be distinguished, not only by means of crossing-experiments, but also by means of experiments on ovarian transplantation. If ovaries of spotted females are transplanted into the naturally striped ones, then the appearance of the young is determined by the origin of the ovaries—according to the *true* mother and not according to the foster-mother. They are always irregularly spotted. If, on the other hand, ovaries of spotted females are transplanted into artificially striped ones, then, if the father is spotted, the young are line-spotted; if the father is striped, the young are wholly striped.

The ovary of the spotted female brings into the body of the naturally striped foster-mother only its own hereditary properties as effective in fertilisation. In the body of an artificially striped foster-mother this same ovary behaves as if it had been derived from the body of a striped female and as if the eggs of the striped female had been used in the crossings.

The objection cannot be raised that the operation was not thorough—that portions of the original ovaries may have been left behind in the foster-mother, as in Guthrie's experiments on fowls, which were afterwards tested by Davenport and found to be merely cases of regeneration of the original ovaries. Thanks to its enclosing membrane, the ovary of the Salamandra can be removed from the surrounding tissue as a whole. It is impossible that any remnants could have been left behind and that the descendants were derived from these remnants regenerated.

These experiments on ovarian transplantation first led me to consider the possibility of the true inheritance of somatic characters. This conception of mine was supported by the experiments of Secerov, who, to begin with, had obtained analogous changes in *Salamandra maculosa* (*forma taeniata*) by influencing the larvæ. Secondly, Secerov had measured the amount of light which was able to penetrate the interior of the body of the Salamandra. Only one-sixth of one per cent. of the outer light reached the ovaries, and the colours of the surroundings were reduced by absorption by the skin. It is improbable, therefore, that there could have been any direct colour influence on the cells of the ovary and a colour-adaptation by "parallel induction." After considering this, together with the results of transplantation, only one plausible hypothesis remains, namely, that the colour changes become inherited by a "somatic induction"; by a process similar to, if by no means the same as, that which Charles Darwin had already imagined in his theory of Pangenesis and Cunningham and Hatschek brought forward later on to explain the phenomena of heredity.

The different reactions of old and new, inherited and acquired, characters in transplantation and crossing, I have tried to make intelligible by an analogy, I must confess, provisional and crude. A new piece of clothing irritates, but this irritation diminishes the longer the clothing is worn, and it ultimately disappears. Likewise, there is a morphological irritation from each part of the body, and this diminishes in the same way. When there have been recent changes the irritation is stronger. Under suitable conditions of duration and intensity the irritation penetrates to the germ plasma. There it renders permanent a potentiality for repetition of the actual change which brought it into play. In a new character, as time goes on, the morphological irritation diminishes. Its germ-plasmic induction is no longer effective. It now belongs to the past. For the present it is no longer necessary, because without it the corresponding tendency is fixed in the germ cells. The *inductive dependence* is a relation existing between the germ plasm and only newly acquired characters. Between germ plasm and old characters, the morphological irritation of which has by use long since disappeared, there exists a complete independence as demanded by Weismann's theory and proved by Mendel's experiments.

I will now touch briefly on further results of my experiments, though these now deal not with inheritance but with changes induced on one generation. Since it is just these experiments which are cited as evidence against the inheritance of acquired characters, it will not be out of place to give a brief refutation of this, as I think, mistaken interpretation. I have succeeded in developing the rudimentary visual organ of Proteus unto a full-sized functioning eye by red illumination to which the animals were exposed for five years from birth. The degeneration of the eyes in cave-dwelling animals, according to the other view, cannot be made hereditary. It is only a non-hereditary modification, a mere environmental change. Otherwise it would be impossible, by exposure to light for a single generation, to undo what life in darkness for so many generations had produced.

What contradicts this view is that exposure to ordinary daylight is not effective. In daylight the skin which covers the rudimentary eye is filled with a dark pigment. This considerable but by no means complete absorption of light due to the pigment is sufficient to arrest the development of the eye, so that the normal degeneration occurs. Red light, however, causes no pigmentation in the skin, and only under the influence of this chemically inactive light is the regression overcome.

The misinterpretation of these data allows me to make a further general observation. In order to prove completely that acquired characters are inherited we must produce at least one alteration of an inborn property. But if we only recognise those properties as hereditary which are unchangeable, then we have *from the very outset* excluded all heritable transformations, and at the same time rendered useless any investigations of the matter. If that which changes cannot be hereditary, and if that which is hereditary cannot change, we can only predict the immutability of species and therewith dogmatically leave on one side, not only the inheritance of acquired characters, but also the whole theory of evolution.

All existing objections, which rendered insoluble the inheritance of acquired characters, apply also to my breeding experiments on Alytes, and I myself would not have attached any special significance to this were it not that it is a result of just these experiments which has aroused the keenest interest in England—the development of a nuptial pad in the male Alytes. In male frogs, which pass their mating-time in water, there appears before mating, usually on the inner fingers, a rough, horny, glandular, dark-coloured pad. On the other hand, in Alytes, which mate on land, no trace of such a pad is to be seen. Yet it can be made to appear after several generations by compelling the Alytes to mate in water, like other European frogs and toads. This compulsion is brought about by raising the temperature, under which condition the mating animals stay longer in the water than usual, for if they did not do so they would run the risk of being dried up. Later in life compulsion becomes unnecessary. The stimulus of warmth produces an association through which henceforward the Alytes take to the water of their own accord when they wish to mate.

Of the many changes which gradually appear in this water breed during the various stages of development—egg, larva, and the metamorphosed animal, young and old—I will describe only one, the above-mentioned nuptial pad of the male. At first it is confined to the innermost fingers, but in subsequent breeding seasons it extends to the other fingers, to the balls of the thumb, even to the underside of the lower arm. After spreading, it exhibits an unexpected variability, both in the same individual and between one individual and another. The variability in the same individual is shown by the characters altering from year to year and in the absence of symmetry between the right hand and the left. In one specimen the dark pad extended to all the other fingers and almost over the whole of the left hand. On the right hand it was never so marked, and it was even less developed later, because the skin was stripped from this hand in the living animal for the purpose of histological investigation. The present skin and pad formation next to the inner finger is to be ascribed to regeneration in the mating season which followed. Microscopical preparations show the difference between the thumb skins of the mating male Alytes in the control breed and the padded skins of the water breed. The skin on the thumb of the normal male is subject likewise to an annual change in thickness. Alytes has already in its natural state a tendency to pad formation, and therefore does not display such a striking novelty as microscopic observation would lead one to think.

The great variability and extent of the pad, which can be produced by cultivation, and its independence of the testes, as castration experiments show, render the hypothesis possible, that what we are dealing with is an artificial creation of a new function. On the other hand, the Alytes pad can be interpreted as an atavism; or again, since the tendency was already there, one can quite well deny that the character has been acquired. Further, the influence of the heat responsible for the change penetrates the whole body of the cold-blooded animal and may therefore penetrate to the germ plasm in a purely physical manner. It is true that when four generations have altered in a similar manner, even after the stimulus has been removed, it is not very plausible that parallel induction should be the cause, and the subsequent appearances a mere after-effect. But as the atavism objection can always be raised, it is not very clear to me why just this experiment (with Alytes) is so often looked upon as an *experimentum crucis*. In my opinion it is by no means a conclusive proof of the inheritance of acquired characters.

Not content with any of the previous experiments, I carried out, before 1914, what may really be an *experimentum crucis*. I have written a few words on it in my "Allgemeine Biologie." There has been no detailed publication as yet. The subject is the Ascidian, *Ciona intestinalis*. If one cuts off the two siphons (inhalent and exhalent tubes), they grow again and become somewhat larger than they were previously. Repeated amputations on each individual specimen give finally very long tubes in which the successive new growths produce a jointed appearance of the siphons. The offspring of these individuals have also siphons longer than usual, but the jointed appearance has now been smoothed out. When nodes are to be observed, they are due not to the operation but to interruptions in the period of growth, just as in the winter formation of rings in trees. That is to say, the particular character of the regeneration is not transferred to the progeny, but a locally increased intensity of growth is transferred. In unretouched photographs of two young Ciona attached by their stolons to the scratched glass of an aquarium, the upper specimen is clearly seen to be contracted; the lower is at rest and shows its monstrously long siphons in full extension. They were already there at birth, for it was bred from parents the siphons of which had become elongated by repeated amputation and growth.

In those animals with artificially lengthened siphons we can, furthermore, combine with the amputation at the front end another amputation at the hinder end. At the hinder end—in the coils of the intestine

—lies the generative organ, an hermaphrodite gland. We remove the whole of this part of the body and leave the front part to regenerate and to reproduce a new generative organ; that is, *new germ plasm is formed from somatic tissue.* It has been established already in several species of animals and plants that Weismann's "continuity of germ plasm" is not obligatory but, at most, a facultative continuity. The long-siphon Ascidians with regenerated germ plasm give birth to progeny also long-siphoned. In this way the most familiar objection brought against the inheritance of acquired characters—the claim that there is a direct influence on the germ plasm—is, I think, definitely removed. The local character of the operation in cutting off the siphons renders this chief objection almost inapplicable. We might, however, still argue that physical influence still obtains; that while I am cutting the siphons at the head, a direct physical reaction is taking place on the germ plasm. In this case there would already be established that tendency which would give rise to an apparent inheritance in the progeny.

But now we cut away all the generative organ, with all its germ cells and its active and latent tendencies. We await the growth of a new generative organ. The regeneration takes place at a time when there are no further disturbances influencing the body. Nevertheless, the growth to which it gives rise is still affected. The change therefore cannot have been lying preformed in the original germ plasm. It can have come ultimately from nowhere but from the changed body.

The present circumstances are scarcely favourable for the furtherance of these researches in heredity in my impoverished country. During the War experimental animals, the pedigrees of which were known and had been followed for the previous fifteen years, were lost. I am no longer young enough to repeat for another fifteen years or more the experiments, with the results of which I have been long familiar, before I attempt to break new ground. The necessities of life have almost compelled me to abandon all hope of pursuing ever again my proper work—the work of experimental research. I hope and wish with all my heart that this hospitable land may offer opportunity to many workers to test what has already been achieved and to bring to a satisfactory conclusion what has been begun.

The Earth's Electric and Magnetic Fields.[1]

By Prof. W. F. G. Swann, University of Minnesota.

I.

Quite apart from those more spectacular manifestations of atmospheric electric phenomena associated with the thunderstorm, we have to recognise the following facts, as pertaining to the ordinary quiet day:

(1) The earth is charged negatively to such an extent as to give rise to a vertical potential gradient which amounts to about 150 volts per metre at the surface of the earth, and goes through fairly regular variations throughout the day and throughout the year, variations amounting to 50 per cent. or more of its total value.

(2) The potential gradient diminishes with altitude until its value at 10 kilometres is practically negligible compared with that at the earth's surface, a result which is brought about by the existence, in the atmosphere, of a positive charge, the total amount of which below the altitude 10 kilometres is practically equal to the negative charge on the earth's surface.

(3) The atmosphere is a conductor of electricity. The conductivity near the earth's surface is so small that a column of the air one inch long offers as much resistance to the flow of the electric current as would a copper cable of equal cross section extending to the star Arcturus and back twenty times over.

(4) In spite of the smallness of the conductivity of the atmosphere at the earth's surface, its amount is nevertheless sufficient to ensure that 90 per cent. of the earth's charge would disappear in ten minutes if there were no means of replenishing the loss.

(5) The conductivity increases with altitude at such a rate that its value at an altitude of 10 kilometres is about fifty times that at the earth's surface, and there is indirect evidence to substantiate the belief that at altitudes of the order of 100 kilometres it may attain a value more than 10^{11} times that at the earth's surface. Such a conductivity would cause the upper atmosphere to act, practically, as a perfect conductor in its relation to phenomena in the lower atmosphere.

(6) There is some evidence for and some against the view that our atmosphere is traversed by a radiation of cosmical origin, and of penetrating power ten times, or more, that of the gamma rays of radium.

A potent factor contributing to the conductivity of the atmosphere is the radioactive material in the air and soil. There are, on the average, about 1·5 molecules of radium emanation per c.c. of the atmosphere over land, yet this small amount is sufficient to contribute very appreciably to the ionisation there. On the basis of the known amounts of radium and thorium emanations in the atmosphere, and of radioactive materials in the soil, we could account fairly well for the ionisation of the lower atmosphere. The conductivity of the air over the great oceans is, however, practically as great as it is over land, and is very much greater than can be accounted for by the radioactive materials, which are negligible in amount in the ocean and in the air over it. The assumption of a penetrating radiation would provide a cause for the ionisation known to exist over the sea. If, however, we are unwilling to admit the existence of such a radiation, the ionisation over the ocean remains to some extent a mystery, and may have to be attributed to a small spontaneous ionisation of the gas.

The great problem of atmospheric electricity is, of course, the explanation of the maintenance of the earth's charge. The replenishment to be accounted for is small, amounting to only 1000 amperes for the

[1] Portions of a lecture on "Unsolved Problems of Cosmical Physics," delivered before the Franklin Institute on December 20, and published in full in the Journal of the Franklin Institute.

whole earth. As regards the positive charge in the atmosphere, there is little difficulty provided that we can account for the maintenance of the negative charge on the earth. For, even though a theory which accounted for the latter did not immediately imply the former, the known fact of the increase of atmospheric conductivity with altitude, combined with the law of continuity of flow of the electric current, would be sufficient to bring the positive charge into evidence. One of the earliest theories of the earth's charge is due to C. T. R. Wilson, who supposed that the atmospheric ions would serve as nuclei for the precipitation of rain, and that the drops would form more readily upon the negative than upon the positive ions, with the result that rain would be, on the whole, negatively charged, and would thus constitute the replenishment of the loss by conduction. The difficulty confronting this theory lies in the fact that the conditions necessary for the precipitation of rain on ions to form drops of appreciable size, do not readily occur in the atmosphere, and in the still more potent fact that, so far as measurements go, 90 per cent. of the rain which falls is positively charged. Thus, while rainfall may constitute a factor in the replenishment of the earth's charge, it is not one which operates in the right direction to serve as the sole cause.

Another theory of replenishment, depending ultimately upon gravity for the separation of the charges in opposition to the electric field, is that due to Ebert. It constitutes a modification of an earlier theory due to Elster and Geitel. Ebert's theory invokes the fact that if an ionised gas be passed through a fine tube the negative ions diffuse to the walls of the tube more rapidly than do the positive ions. Ebert supposes that, during periods of fall in barometric pressure, the air in the pores of the soil, which is ionised on account of the radioactive material therein, becomes drawn out into the atmosphere, positively charged on account of its having deposited an excess of negative ions in the interstices of the soil. Rising currents of air are then invoked to explain the transference of the positive ions to appreciable altitudes, against the electrostatic attraction of the negative. This theory has been criticised on account of the insufficiency of the charging action resulting from the diffusional process, on account of the smallness of the upward convection current of positive electricity as measured experimentally, and on account of the fact that it may be shown to predict a diminution of potential gradient with altitude such as would result in the gradient itself being practically negligible at an altitude of a kilometre.

The precipitation theory, and the Ebert theory, are of a type in which the replenishing action takes place over a limited region of the earth's surface at any one time, in such a manner that the positive electricity which is the counterpart of the negative charge on the earth is to be found in this limited region of the atmosphere. Under such conditions, the negative charge will be held on the portion of the earth's surface which lies in the immediate vicinity of the positive, and the potential gradient will be confined to this region. A partial way out of this difficulty can be found, however, if we admit the existence of a highly conducting layer in the upper regions of our atmosphere. In this case, the charge separation sets up a potential difference between the layer and the earth, so that the potential gradient, which would otherwise be confined to the region of replenishment, is shared as it were by the earth as a whole. Thus, for example, calculation shows that if a charged cloud is to be found at an altitude h above the earth's surface, and if H is the altitude of the conducting layer, and R the radius of the earth, the hemisphere of the earth which is symmetrically remote from the charged cloud receives R/H times the number of tubes of force which it would receive in the absence of the layer, and h/H times the number which it would receive if the negative charge on the earth and the positive charge in the cloud were spread uniformly over the earth and atmosphere respectively. It may be remarked, moreover, that this action of the conducting layer provides a partial loophole for escape from the particular objection to the Ebert theory which is founded on the impossibility of the positive charge reaching an altitude of more than a kilometre or so. Even such a small separation in the region of replenishment would make its own contribution to the potential gradient at other places through the medium of the conducting layer. The contributions in these places would be of a perfectly normal type, the variation with altitude being determined only by the nature of the variation of conductivity with altitude, in such a manner as to keep the vertical conduction current density independent of altitude.

In 1904 G. C. Simpson proposed a tentative theory of the earth's charge, in which it was assumed that the sun emitted negative and positive corpuscles of high penetrating power. The former were supposed to pass right through our atmosphere and penetrate the earth, while the latter were caught in the atmosphere. Such a degree of penetration is very much greater than any we are familiar with in the laboratory, for the beta rays of highest energy investigated will pass through only about 10 metres of air.

We can account for the replenishment of the earth's charge if we suppose that the atmosphere emits high-speed negative corpuscles. The earth will then charge up on account of the corpuscles which come from the molecules of air lying within striking distance of it. Such a possibility was examined by the writer in 1915. So far as the replenishment of the charge is concerned, the average range of the corpuscles may be made as small as we please by supposing a sufficiently copious emission of corpuscles. It turns out, however, that appreciable values of the potential gradient become confined to altitudes comparable with the average range, so that for this reason a large range must be assumed. This difficulty is avoided in a somewhat similar theory suggested by the writer, and somewhat later, but quite independently, by von Schweidler. According to this theory, the emission of corpuscles from the atmosphere is caused by the penetrating radiation which, coming from above, and being of a very hard type, ejects the corpuscles almost completely in a downward direction. If we assume that only three corpuscles are emitted per c.c. per second, by the penetrating radiation, an average range of nine metres in air at atmospheric pressure is sufficient to account for the replenishment of the earth's charge.

Two main difficulties confront any corpuscular theory of the earth's charge. The first arises from the failure to detect any charging effect, as a result of the influx of corpuscles, in the case of a mass of insulated metal surrounded by a thin metal shield to protect it from the potential gradient. The second arises from the fact that, in so far as the replenishment of the earth's charge requires the entry of 1500 corpuscles per sq. cm. per second, and, a corpuscle moving with a velocity approximating that of light produces about 40 ions in each centimetre of its path, we should expect a rate of production of 60,000 ions per c.c. per second. Experiment reveals a rate of production of less than 10 ions per c.c. per second, and these are attributable, for the most part, to known causes.

As regards the former difficulty, experiments to detect the charging effect were made by the writer in 1915, and more recently by von Schweidler, without finding any such effect. Unless we assume corpuscular ranges so great that there is negligible absorption in the test body, this result opposes any theory which invokes corpuscles shot into the earth from regions outside our atmosphere, or from the atmosphere itself as a result of direct spontaneous disintegration. The experiment is not so much in conflict with theory in the case where the corpuscles are emitted by the penetrating radiation, however. If the penetrating radiation is sufficiently hard to pass through the test body without appreciable absorption, it can be shown that it will eject as many corpuscles from the lower side of the body as it injects on the upper side.

Serious as the difficulty concerned with the ionising action of the corpuscles seems at first sight, there is a natural way of avoiding it, providing that we assume the corpuscles to have velocities so closely approximating the velocity of light that their tubes of force become crowded very greatly towards the equatorial plane. In these circumstances, if a corpuscle [2] is to give even a small finite amount of energy to an electron in the process of ejecting it from an atom, it must give it in an infinitesimal time, and such a phenomenon would require the payment of an infinite tax in the form of energy radiated. A full consideration of the details of the action shows that the reaction on the electron, due to its radiation, is such that, for any ionisation potential of the atom, there is a velocity sufficiently near to that of light, such that a corpuscle having that velocity would be unable to produce any ionisation in the gas.

The ionisation potential of oxygen, which is less than that of nitrogen, is 15·5 volts, and on the classical theory of electrodynamics a corpuscle would fail to ionise oxygen or nitrogen for all velocities in excess of 200 metres per second below the velocity of light. It may be of interest to remark that, in order that an electron should strike down into our atmosphere in the vicinity of the equator and reach the earth's surface, without being bent back by the earth's magnetic field, it would have to possess a velocity nearer to that of light than the above value, so that the very fact that it could reach the earth would be sufficient to ensure that it would not ionise on the way. Moreover, as another illustration of the same principle, it may be remarked that the above value for the velocity lies between the two limits, 400 metres per second less than that of light, and 4 metres per second less than that of light, assigned by Birkeland as the limits between which the velocities of negative electrons from the sun must lie in order that they shall be capable of accounting for the aurora. Of course, failure to ionise would prevent corpuscles from functioning as regards the aurora, and the figures in question are only cited for their general interest. There are other reasons for believing that the aurora is not caused by negative electrons.

Once we assume these high energies for the corpuscles, they carry with them the possibility of very great penetration, as may be shown from a consideration of the circumstances which determine absorption in the atmosphere. This penetrating power is enhanced by the diminution of the power of the corpuscles to communicate energy to the electrons by which they pass. Thus, while, as regards the mere explanation of the earth's charge, we may avoid the assumption of long ranges, as in the theory which invokes the penetrating radiation to eject the corpuscles from the air, we find it necessary to postulate, for the corpuscles, velocities closely approximating the velocity of light, in order to explain the absence of ionisation, and this of itself implies long range as a consequence.

(*To be continued.*)

[2] The word "corpuscle" is merely used to distinguish the high-speed electron, the ionising powers of which are under discussion, from the electron in the atom.

The Royal Academy, 1923.

THE private view of this year's Exhibition of the Royal Academy took place on Friday, May 4. The juxtaposition of the Royal Society and the Royal Academy suggests something deeper than the accident of both being dependent upon the patronage of the wealthy and the hospitality of the State. On either side of the wall that separates the academies of art and science the work is alike also in this—the impulse of the worker is to represent and thereby to preserve the visions that he has seen, that others might have seen if they had been gifted with the insight that sees things hidden from the rest of the world by the blinding candour of Nature. One uses paint or clay, and the other the printing-press or the experimental table; and however dependent either may be on the smile of the wealthy or the favour of the potentate for the means to "carry on," the satisfaction of achievement in the effort to express what they alone have seen with the mind's eye redresses for either the adverse balance of many an account. A year's Proceedings of the Royal Society show what the fellows wish to hand on to posterity as expressing their searching into Nature: so the yearly exhibition at Burlington House represents the messages to which the artists of to-day have dedicated their power of insight.

Passing through the galleries for the first time one wonders what message the artist is trying to convey and whether he has succeeded. There can be little doubt that 200 (*Still Life*, by Meredith Frampton) aspired to give the impression of china ducks and flowers, and has succeeded; and the same may be said of an impressive study of huge Atlantic waves close at hand, with a tiny ship in the background, 558 (*Henry Hudson, 1607*, by Norman Wilkinson); but what the message is in 15 (*Little Dancer*, by Glyn Philpot) is less obvious: it is perhaps the beauty of gradations of subdued colour. So also the piece by the same artist, 170 (*Penelope*), and 34 (*Youth*, by F. Cayley Robinson), and in a drab monotonous way 155 (*Hayling Island*, by Oliver Hall). There are others, on the contrary, who use vigorous contrasts instead of gentle gradations. Such are 36 (*Rocks, Tregiffran*, by Robert M. Hughes), 53 (*Sennen Beach*, by Laura Knight), and 234 (*Wiltshire Downs*, by Edward Buttar), and even more impressive as an appeal to the sense of beauty of colour, saffron with blue shadows and pink sky, 151 (*An Autumn Evening in the Western Highlands*, by Adrian Stokes), and 264 (*Seagulls Nesting*, by Charles Simpson), a vision of the colours of spring. Not always satisfying are these schemes; 366 (*Sons of the Sea: Polperro, Cornwall*, by John R. Reid) makes one think of the artist's colourman rather than Nature's beauty.

One of the striking features of the pictures by the well-known artists is the sensation of vivid illumination. Marked discontinuities of light and shade give the effect, obviously desired, in 25 (*Ariñez on the Battlefield of Vitoria, Spain*, by James P. Beadle), 72 (*Glebe Place, Chelsea, 1922*, by George Henry), 175 (*Lovers of the Sun*, by H. S. Tuke), 278 (*Market Jew: Thursday*, by Stanhope A. Forbes), and 174 (*An Italian Lemon Garden*, by H. H. La Thangue): in the last the discontinuities are perhaps too strong for real pleasure. There is a wonderful sense of luminosity from discontinuity of colour alone without very marked shadows in another picture by the same artist, *The Mill Stream* (64), and also in 336 (*The Finish*, by Harry Fidler).

A juxtaposition of colours that one may call iridescence is artfully used to convey the sensation of local luminosity in 126 (*Golden Summer, Cornish Coast*, by Julius Olsson), and 191 (*Surf-bound Shore*, by the same artist), and 565 (*The Coastwise Lights*, by Harry Van der Weyden); also, but less successfully, for the illumination of the misty atmosphere of a setting sun of vast dimensions in 379 (*The Fading Day*, by Fred Hall). Some artists boldly paint a parti-coloured background and let the spectator regard it as sky if he please. That is noticeable in the colour scheme of 19 (*The Trojan Women*, by Charles Ricketts), in 226 (*The Sons of Ellis Hajim, Esq.*, by Charles Sims), and 229 (*Brood Mares and Foals at Southcourt Stud*, by Alfred J. Munnings).

As a fellow-student of Nature one cannot but feel that the sky must be a very exasperating part of an artist's subject unless it is all blue, or all grey, or all pink. When there are clouds with definite shape and movement the representation of Nature's varying mood is very difficult. The natural sky, even when it is most complex, is not chaotic: it has lines and touches that suggest order, a horizontal alignment, a characteristic shape, the detail of an outline, but so subtle and so transient that, while the student is meditating its features, they are gone. Apparently only the more noted artists challenge the heavens with a presentation of this subtle order in disorder, and not with complete success. 137 (*Tilty Church*, by George Clausen) shows clouds of easily recognised shape, but lacking the characteristic detail of outline. The most successful skies succeed by evading the real problem. The beautiful picture of *The Port of London* (213), looked at from above, by W. L. Wyllie, makes an atmosphere of native smoke and excuses the sky. Almost the same artifice is used in another picture by the same artist, *A Storm is Coming* (217). Details are also avoided by a general "all-overishness" in 162 (*The Lowlands of Holland*), 310 (*In from the Sea*), both by Robert W. Allan, and 370 (*A Grey Sea*, by the Hon. Duff Tollemache), and in a beautiful Scottish snow picture (124) by Joseph Farquharson. The challenge is evaded in 236 (*Summer Morning, St. Ives*, by Charlton Fortune) by filling up the sky with seagulls; but it is deliberately taken up by Arnesby Brown in quite a number of pictures—3 (*September*), 79 (*The Swing Bridge*), 130 (*The Waiting Harvest*), 148 (*The Watch Tower*): the disorder is there patent, but the whisperings of order in a disordered sky are missing. No more successful in this respect are 178 (*A May Morning at Southcourt*, by A. J. Munnings), 203 (*The Mountain Stream*, by Lewis T. Gibb), 335 (*Dover and Castle from the North*, by Frank P. Freyburg).

There is a peculiarity about natural skies; without any effort one is conscious that one is watching either the plan of an extensive layer or the elevation or profile of individual clouds. It is only occasionally that one gets that sort of satisfaction out of a picture. It is very nearly complete in 207 ("*If the clouds be full of rain, they empty themselves upon the earth*," by Frank Walton), in a picture by R. Vicat Cole, and in 484 (*Tintagel*, by Algernon Talmage). One misses it in 199 (*The Blue Pool*, by the late Mark Fisher), and in 259 (*Before the Ruined Abbey*, by Sydney Lee). It has often been remarked that the Greeks and Romans had no names for the forms of clouds which we have learned to recognise so easily. The exhibition suggests that the reason lies very deeply set.

As one leaves the galleries the questions as to what message the artists meant to convey and whether they have succeeded recur. Among the pictures most satisfying in answering both questions at first sight we may name 47 (*The White Sands of Scilly*, by Julius Olsson), 124 ("*Some gleams of sunshine mid renewing storms*," by Joseph Farquharson), already mentioned, 333 (*Green-clad Hills, Lake of Annecy*, by Terrick Williams), and 636 (*Winter Evening, Engelthal*, by Adrian P. Allinson).

Judging from experience outside, one might have been afraid that the Academy of 1923 with its multitude of portraits would have been a nightmare of horn-rimmed spectacles: it is not so. There is only one specimen, *Portrait of the Painter*, by the late Sir J. J. Shannon. The pervading influence of the War has also passed away except in the sculpture rooms and in the satiric picture by Sir William Orpen.

Scientific worthies are not very conspicuous in the collection. There is a bronze bust of the late Dr. Ludwig Mond, and one of the late Sir James Dewar (by G. D. Macdougald); also a marble bust of Sir J. J. Thomson, by F. Derwent Wood, as well as the portrait by Fiddes Watt.

Current Topics and Events.

THE growth of our knowledge of stellar physics during the present century has been surprisingly rapid. It has arisen by combining the results of researches of most varied kinds. The older astronomy of position has afforded the data for the positions, distances, and motions of the stars, which were a preliminary to the establishment of the theory of giant and dwarf stars, and also to the detection of the possibility of finding parallaxes by the spectroscope, and so distinguishing the giants from the dwarfs. In another field, the discovery of radium, and radio-activity generally, has revolutionised ideas on the nature of the atom, and led to the detection of analogies between chemistry and dynamics. Prof. Eddington, whose lecture on "The Interior of a Star," delivered at the Royal Institution on February 23, is printed as a supplement to the present issue, is one of the leading pioneers in this field. His earliest astronomical work was concerned with stellar distances and proper motions; but he has recently worked more on the physical side. Prof. Eddington was one of the first to point out the importance of light pressure in causing the distension of giant stars, and also to suggest that the immense duration of their output of energy is explicable by their drawing on the store of energy in the atom. This was first offered as a tentative explanation, but Prof. Eddington now makes it definitely. A remarkable confirmation of the correctness of the accepted views on stellar physics was afforded by the close agreement of the diameter of Betelgeuse, as given by the interferometer, with that deduced from the study of the distribution of energy in the spectrum, which led to a value of the temperature and surface brightness.

THE approaching visit to London of Prof. H. A. Lorentz, of the Teyler Institute at Haarlem, and the University of Leyden, is being eagerly awaited by physicists. Prof. Lorentz is the *doyen* of mathematical physicists. In 1880 he developed from electromagnetic theory a connexion between refractive index and density (known by his name), which holds good through great ranges of density, though requiring a small correction for extreme states as recent experiments on carbon dioxide have demonstrated. At the present time, Prof. Lorentz is acclaimed in the main for the fundamental work he has done in connexion with the electromagnetics of moving bodies. In this work he has served as an intermediary between the old electromagnetics and the modern doctrine of relativity. Einstein's results agree mainly (though not exactly) with those which Prof. Lorentz had obtained, "the chief difference being that Einstein simply postulates what I have deduced with some difficulty and not altogether satisfactorily from the fundamental equations of the electromagnetic field" (Lorentz). Prof. Lorentz contributed to the explanation of the magneto optic phenomena discovered by Zeeman and others. "I may refer in the first place to the intensely stimulating influence of H. A. Lorentz's theories. It is difficult to find adequate words to express my indebtedness to Lorentz's personal inspiration and to his theories" (Zeeman). Prof. Lorentz visited the British Association at the Birmingham meeting in 1913, and made important and guarded contributions to the discussion on radiation and the quantum theory. His first lecture in London is at 5.30 P.M. on May 17, at University College, Gower Street. Admission is free, without ticket. Three other lectures by Prof. Lorentz, at the same place, have been arranged to be delivered in the early part of June. He is also lecturing at Cambridge (Reid Lecture), at Manchester, and elsewhere.

SHORTLY after the death of Dr. W. H. R. Rivers in June last, it was suggested that the eminence of his services to science should be recognised by some form of memorial; but it was not found possible to take any further steps at the time. A few of Dr. Rivers's friends have now formed a small committee with the view of giving the proposal practical effect. Among those serving are: Sir Charles Sherrington, Sir William Ridgeway, Sir Humphry Rolleston, Sir James Frazer, Dr. Henry Head, Dr. A. C. Haddon, Mr. Henry Balfour, Prof. G. Elliot Smith, Dr. C. S. Myers, and Prof. C. G. Seligman. This committee has now issued an appeal for subscriptions to a fund of which Dr. L. E. Shore of St. John's College, Cambridge, acts as treasurer. The fund will be devoted to the promotion of those sciences in which Dr. Rivers was particularly interested, but the decision as to the manner in which this will be effected will rest with the subscribers, of whom a meeting will be summoned in due course. It is permissible to express a hope that the committee and subscribers will decide to devote the fund to some object which it is known that Dr. Rivers had closely at heart, such as, for example, the assistance of the publication of scientific memoirs for which ordinary scientific or commercial channels are not available on the ground of cost.

DURING the summer of 1922 a member of the Cambridge Natural History Society was in Vienna and made the acquaintance of Dr. Kammerer, who appeared to be willing to visit England, should an opportunity occur. After further correspondence with Dr. Kammerer, the matter was placed before the council of the society in March last, and it was then decided that Dr. Kammerer should be invited in the name of the society to give a lecture at Cambridge. The invitation was accepted by Dr. Kammerer, and the lecture is published elsewhere in this issue. All expenses of the journey were provided for by contributions from members of the society, and on April 25 Dr. Kammerer arrived in England, and has since been the guest of the society.

THE Croonian lecture of the Royal Society will be delivered on June 21 by Dr. F. F. Blackman, who will take as the title of his lecture "Plant Respiration as a Catalytic Process."

DR. JOHN PALIBIN, director of the Botanical Garden at Batoum, has accepted the post of assistant to the museum director in the principal botanical garden of Petrograd, where he hopes to have more opportunity for those researches in palæobotany in which he has won distinction.

AT University College, London, on Friday, May 11, the chairman of the College Committee (the Rt. Hon. the Viscount Chelmsford) is to unveil a tablet commemorating the munificent gifts for the new chemistry building made by Sir Ralph Forster, Bt.

A LOAN collection of pictures painted by Miss Edith Cheesman in Mesopotamia will be on view in the North Gallery of the Imperial Institute from May 7 from 10 A.M. to 5 P.M. daily, except Sundays. Admission is free. The pictures, which are in oils and water-colours, are illustrative of life and scenery in Mesopotamia and include both portraits and landscapes.

A MASTER is required for service on the Colonial Government ship *Discovery*, whose duties will be mainly research in whaling in the Antarctic. Full information and forms of application are obtainable, by letter, from the Secretary, *Discovery* Committee, Colonial Office, S.W.1. No special form is necessary for candidates abroad. The latest day for the receipt of applications is May 31.

THE Air Ministry announces that the Royal Air Force pageant, which was instituted in 1920, will take place on Saturday, June 30, at the London Aerodrome, Hendon, by arrangement with the Grahame White Company. It is hoped that the King will be present. The pageant now affords the general public an annual opportunity of observing developments both on the flying and technical sides of the work of the Royal Air Force.

THE Faraday Society will hold a general discussion on "The Physical Chemistry of the Photographic Process" on Monday, May 28, in the Hall of the Institution of Electrical Engineers, Victoria Embankment, W.C.2. Prof. W. D. Bancroft, of Cornell University, will open the proceedings at 3 P.M. with an introductory address on "The Theory of Photography." This will be followed by detailed consideration of the subject, subdivided as follows:—(1) "The Physical Chemistry of the Vehicle and of the Emulsion"; (2) "Reactions in the Plate during Exposure"; (3) "Development and Characteristics of the Developed Plate"; (4) "Adsorption Reactions in Photographic Films." Each section will be introduced by a preliminary address and followed by general discussion. Among those who will read papers are Dr. T. Slater Price, Dr. F. C. Toy, Mr. Olaf Bloch, Mr. T. Thorne Baker, M. Clerc, Prof. Luther, and Prof. Goldberg. Several communications will be made from Mr. S. E. Sheppard and other members of the staff of the Eastman Kodak Company, and papers are also expected from Dr. Chr. Winther, Dr. Lüppo-Cramer, and Prof. L. Plotnikov. Between the afternoon and evening sessions a complimentary dinner will be given at the Hotel Cecil to Prof. Bancroft and the other guests. Members of the Chemical Society are invited to attend this meeting. Full particulars may be obtained from the Secretary of the Faraday Society, 10 Essex Street, London, W.C.2.

THE New York correspondent of the *Times* states that Lieuts. Macready and Kelly completed a non-stop aeroplane flight across the United States from New York to San Diego on May 3. The distance traversed was approximately 2600 miles and the time is given as 26 hours 50 minutes 38⅗ seconds.

M. GEORGES BARBOT crossed and recrossed the English Channel on May 6 in a small monoplane fitted with a two-cylinder 15 h.p. engine, thus winning a prize of 25,000 francs offered by *Le Matin* for the complete journey. M. Barbot left the aerodrome at St. Inglevert at 6.20 P.M. and arrived at Lympne at 7.21 P.M.; the return journey was commenced at 8.1 P.M., and the aeroplane arrived over St. Inglevert aerodrome at 8.45 P.M.

WE learn from *La Geographie* for February that a wireless station has been erected at Mygbugten, on the east coast of Greenland, in lat. 73° 30′ N., and has been functioning since last October. The station is due to the enterprise of the Norwegian Meteorological Service. Weather reports are sent by wireless telegraphy to the station on Jan Mayen, and thence to Christiania. The Greenland station and those on Jan Mayen, Iceland, Bear Island, and Spitsbergen almost encircle the Greenland sea.

AT the Hull meeting of the British Association in September last there was a discussion in the Section of Anthropology upon the genuineness of some bone implements known as the "Holderness Harpoons" (see NATURE, October 7, p. 481, and December 2, p. 735). Mr. O. J. R. Howarth, secretary of the Association, writes to say that though several references have recently appeared to a committee of the British Association as having pronounced upon the question, no committee was appointed by the Association or its anthropological section to investigate this subject.

AT the annual general meeting of the Manchester Literary and Philosophical Society held on April 24, the following officers and members of council were elected: *President*, Prof. H. B. Dixon; *Vice-Presidents*, Mr. T. A. Coward, Prof. A. Lapworth, Mr. C. E. Stromeyer, and Prof. F. E. Weiss; *Secretaries*, Dr. H. F. Coward and Prof. T. H. Pear; *Treasurer*, Mr. R. H. Clayton; *Librarians*, Mr. C. L. Barnes and Dr. W. Robinson; *Curator*, Mr. W. W. Haldane Gee; *Other Members of the Council*, Prof. W. L. Bragg, Prof. S. Chapman, Rev. A. L. Cortie, S.J., Prof. S. J. Hickson, Mr. F. Jones, Laura Start, Mr. R. L. Taylor, Mr. W. Thomson, and Mr. L. E. Vlies.

THE council of the Institution of Civil Engineers has made the following awards in respect of papers read and discussed at the ordinary meetings during the session 1922–1923: Telford medals to Mr. H. W. H. Richards (London) and Mr. E. O. Forster Brown (London); a George Stephenson medal to Mr. Asa Binns (London); a Watt medal to Mr. A. B. Buckley, jun. (Winchester); Telford premiums to

Mr. W. A. Fraser (Edinburgh), Mr. S. L. Rothery (Calexico, U.S.A.), Mr. Mark Randall (Johannesburg), and Mr. D. E. Lloyd-Davies (Cape Town); an Indian premium to Mr. D. H. Remfrey (Calcutta); a Manby premium to Mr. F. M. G. Du-Plat-Taylor (London); and a Crampton prize to Mr. F. W. Jameson (Kimberley).

An appreciation of the scientific work and discoveries by Sir James Dewar was broadcasted by Prof. J. A. Fleming on May 4 from the London station 2 LO. Prof. Fleming first referred to Sir James Dewar's work on the liquefaction of air, oxygen, and hydrogen, and the invention of the silvered vacuum vessel for storing these liquids. Closely related with this work was the discovery of the use of charcoal cooled in liquid air for the production of high vacua. Sir James Dewar also made important discoveries in spectroscopy and in connexion with the production of physiological electric currents by the action of light. His work in chemistry contributed to the invention of cordite, while soap films and their behaviour in dust-free air occupied his attention until the last day of his working life. Sir James Dewar's investigations were undertaken in the first instance purely out of a disinterested desire to increase scientific knowledge, but the results have in nearly every case produced numerous beneficial and practical applications.

At the annual meeting of the members of the Royal Institution held on May 1, the following officers were elected: *President*, The Duke of Northumberland; *Treasurer*, Sir James Crichton-Browne; *Secretary*, Sir Arthur Keith; *Managers*, Mr. S. G. Brown, Dr. J. M. Bruce, Sir Dugald Clerk, Prof. J. A. Fleming, Sir Richard Glazebrook, Earl Iveagh, Sir Alexander C. Mackenzie, Mr. Robert Mond, Sir Edward Pollock, Prof. A. W. Porter, Lord Rothschild, Sir David Salomons, Mr. W. Stone, Sir Alfred Yarrow, The Right Hon. Lord Justice Younger; *Visitors*, Sir Harry Baldwin, Prof. William A. Bone, Mr. A. Carpmael, Dr. E. Clarke, Mr. E. Dent, Dr. T. W. Dewar, Mr. G. H. Griffin, Mr. W. E. Lawson Johnston, Col. F. K. McClean, Sir Malcolm Morris, Dr. W. Rushton Parker, Mr. W. Peacock, Major C. E. S. Phillips, Mr. H. M. Ross, and Mr. S. Skinner. Sir J. J. Thomson has been elected honorary professor of natural philosophy, and Sir Ernest Rutherford professor of natural philosophy. The Duke of Northumberland has nominated the following gentlemen as vice-presidents for the ensuing year: Dr. Mitchell Bruce, Lord Iveagh, Sir Edward Pollock, Lord Rothschild, Sir Alfred Yarrow, The Right Hon. Lord Justice Younger, Sir James Crichton-Browne (Treasurer), and Sir Arthur Keith (Secretary).

A catalogue (No. 259) of books in all branches of chemical science and technology, including the textile industries and agriculture, has just been issued by Mr. W. Bryce, 54 Lothian Street, Edinburgh. It should be very useful for reference. The same bookseller also issues a short list of second-hand books in technology, the classics and general literature, surplus government stock, which are offered at greatly reduced prices.

Our Astronomical Column.

The April Meteor Shower.—Mr. W. F. Denning writes: "This event occurred on the nights of April 21-23. The weather, however, was not very favourable on the night of expected maximum, April 21, and few meteors could be seen owing to clouds. The special display of Lyrids supplied nearly half the total number of meteors observed on the three nights, and the radiant point was in the usual position at about $272^{\circ}+33^{\circ}$.

"It sometimes happens that when the Lyrids are not very abundant, meteors generally are very scarce, and this appears to have been the case on the recent occasion, the hourly rate of apparition being only 3.

"There are a considerable number of radiant points in activity at this period of the year, but the great majority of them are extremely feeble, and an observer must watch the sky for a long period before they may be recognised. Two meteors seen on April 20 last were each recorded at two stations and the paths indicate radiants at $271^{\circ}+35^{\circ}$ and $310^{\circ}+59^{\circ}$."

Temperature and Density of the Upper Atmosphere deduced from Meteors.—Prof. F. A. Lindemann and Mr. C. M. Dobson contribute a paper on this subject to Proc. Roy. Soc. (Series A, vol. 102, No. A 717). They deal with the large number of doubly observed meteors discussed by Mr. Denning, and give reasoning which leads to the conclusion that during most, if not all, of the meteor's visible track, the molecules of air impinge on a layer of compressed air in front of the meteor. Evaporation goes on from the surface of the meteor, and in general the meteor is wholly consumed long before reaching the ground. Long-enduring trains are explained as the slow recombination of ions separated by the energy of the meteor. The meteors are shown to be very small particles. One as bright as a star of the first magnitude would be 1 mm. in diameter. One as bright as the moon would be 2·5 cm. in diameter (mass 62 gm.). Discussion of the observed phenomena on these lines leads to determinations of the temperature and density of the air at different heights. It is concluded that the isothermal layer, already discovered by *ballon sondes* to extend to a height of 25 km., goes on up to 50 km.; but that above that height the temperature again rises to 280° or 300° abs. The density of the air at 100 km. (about the lower auroral limit) comes out 100 times that previously assumed; it is suggested that it may not be hopeless to reproduce the auroral spectrum in the laboratory, if the corresponding density is 10^{-8} instead of 10^{-10}.

It is suggested in explanation of the high temperature of the upper air that it is largely composed of ozone, which is heated by the infra-red radiations from the earth.

Prof. Lindemann describes in Mon. Not. R.A.S. for January a method which he is using of photographing meteors simultaneously at stations some distance apart, so as to get their height very accurately in order to apply a more rigorous check to his conclusions.

Research Items.

A Roman Fortified House near Cardiff.—In the Journal of Roman Studies (vol. xi. Part i), Mr. R. E. M. Wheeler gives an elaborate account of a fortified Roman villa, about two miles west of the west bank of the river Ely, at the point where that river, though still tidal, first becomes fordable. He concludes that about A.D. 300 this work fell into line with the general defensive and offensive activities of the period. At a time when Romano-British towns seem to have built or strengthened their walls as the Welsh tribesmen did, it is not unnatural that a private householder should have followed the same example on a smaller scale. It is indeed rather matter for remark that other examples of domestic fortification in the late Roman period have been so rarely observed or recorded. The closest analogy is perhaps the partially excavated house and baths within the Castle Dykes near Ripon.

An Old-World Cubit in America.—In *Ancient Egypt*, Part iv. 1922, Prof. W. M. Flinders Petrie directs attention to excavations made by the School of American Research at Santa Fé, New Mexico, where the measurements of buildings indicate a unit of 20·7 inches. This figure accords exactly to the well-known Egyptian cubit: 20·62 in the best early examples, 20·65 in later cubit rods, 20·76 on the Roman Nilometers. Babylonia had a rather longer type, 20·88 in. for the cubit of Gudea's plotting scales, and this was also the standard of Asia Minor, 20·6 to 20·9, with a mean of all of 20·63 in. "How could this reach New Mexico? It was evidently Asiatic. We have evidence from weights of an Asiatic diffusion of a Babylonian original over India, China, and Etruria. If the cubit similarly passed to China, it might thence reach North America. It has been already pointed out how the cross at Palenque (Southern Mexico) was in its detail of ornament derived from Italian crosses of about the eighth century, probably carried to China by the Nestorian mission. By the same route the Asiatic cubit may have passed over to the New World at some earlier period."

Marriage Customs in Medieval India.—In a paper published in the last issue of the Bulletin of the School of Oriental Studies, Sir G. Grierson directs attention to an epic still recited in Northern India describing the war between the Rajputs of Bundelkhand and Delhi. When a Raja had a marriageable daughter he used to send a challenge to neighbouring Rajas, who attacked him, and the contest for the bride was accompanied by serious loss of life on both sides. No exact parallel to this custom has been traced, and it looks as if the bard had exaggerated the details of the mock fight which occurs on the occasion of a wedding. The view that this is a survival of marriage by capture is now generally abandoned, and anthropologists are disposed to believe that the mock fight is a symbol of a contest between the powers of good and evil. The final victory of the good spirits is carefully arranged beforehand, and thus the fertility and happiness of the union is assured.

Submarine Weathering of Rock-material.—K. Hummel of Gieszen (*Geologische Rundschau*, vol. 13, p. 40, 1922) gives the name "halmyrolysis" to the processes of decay and reconstruction, akin to weathering, that go on in rock-material on the floor of seas and oceans. He gives special attention to the origin of glauconite, and attributes its absence from fresh-water deposits to the facts that the salts in sea-water are essential to the reactions that build it up, and that certain marine bacteria also play a part. The organic matter, the humic acid, and the energy of oxidation on sea-floors are not sufficiently different from those in lakes to account, as others have suggested, for the absence of glauconite from fresh waters. We may hope that the author will expand his views (p. 102) on phosphatisation on the sea-floor, which he regards as beginning with the absorption of phosphorus by gels consisting of calcium carbonate. The colloidal character of the material for which A. F. Rogers has recently revived the name of "collophane" (see Nature, vol. 110, p. 292), might thus be an inheritance from previous colloidal calcium carbonate; but this would not account for the widely spread "halmyrolysis" of marine oozes and limestones without loss of the intimate structures of their shelly constituents, which were deposited as crystalline material.

Tertiary Brachiopoda of Japan.—Ichirô Hayasaka, whose papers on the Palæozoic Brachiopoda of Eastern Asia and the Permian Brachiopoda of Japan we have already had occasion to refer to (Nature, July 29, p. 161, and December 2, p. 749, 1922), has now dealt with the Tertiary Brachiopoda of Japan (Science Reports, Tôhoku Imp. Univ., Sendai, Second Series (Geology), vol. ii., No. 2). While the waters of the Japanese Islands are notoriously rich in these forms, no fewer than thirty-seven species of "lamp-shells" being recorded therefrom, only thirteen species and five varieties figure in the present monograph, one species and four varieties being believed to be new. Of the eighteen forms, seven are only known fossil, seven are found living in Japanese waters, while the remainder now inhabit distant regions. The occurrence in Japan of *Terebratulina septentrionalis* in the fossil state, indeed, seems to be the first recorded instance, and that, since it is to-day an Atlantic form, is the more remarkable. In an appendix one other species and another variety are recorded as coming from the Pleistocene. These last are apparently additional to the three previously recorded from beds of that age near Tôkyô in 1906.

The Inner Structure of Alloys.—The thirteenth annual May lecture of the Institute of Metals was delivered on Wednesday, May 2, by Dr. W. Rosenhain. Referring to the great accumulation of facts in regard to the properties and microstructure of alloys which have been forthcoming in recent years, Dr. Rosenhain considers that it is most desirable that there should be found a key to this maze of knowledge in the form of a general theory that will link together the mass of facts into a homogeneous whole. Such a theory is put forward, based upon the intimate knowledge of crystal structure acquired by X-rays analysis. The crystal structures found in pure metals are modified in the case of alloys, particularly in those called solid solutions, where a second kind of atom enters into the structure of the crystal and produces in it certain minute changes. Especially important is the connexion between the minute distortion of crystal structure which occurs in alloys and the behaviour of alloys on melting and freezing, while such phenomena as plasticity, diffusion, and others fall easily into line with the same type of explanation. This new theory of alloy structure is said to afford a ready explanation of the electrical properties of metals and alloys and the changes of those properties when the metal is heated or cooled, and cover the phenomena of super-conductivity found in many metals when cooled nearly to the absolute zero of temperature.

WEATHER RESEARCH ON THE KERMADEC ISLANDS.—The *New Zealand Journal of Science and Technology*, vol. v. No. 5, contains an article by Mr. D. C. Bates, director of the Dominion Meteorological Office, Wellington, on the above. The chief feature of the article is an effort to stimulate the acquiring of Sunday Island, the largest of the Kermadec Group, for a meteorological station, which it is maintained would improve the weather forecasting for New Zealand. It is shown that cyclonic disturbances commonly influence the weather at Sunday Island a couple of days or so before being felt in New Zealand or the adjacent waters. The island was first discovered in 1788 and was partially frequented by settlers in 1837, but calamities which have occurred suggest the question whether it is worth while occupying apart from weather reporting. The island is apparently of volcanic origin, and earthquakes occur about once a month. It is mountainous, with few flat surfaces; water is not easily procurable, and it is out of the track of vessels. The rainfall is said to be by no means deficient. Meteorological observations taken for nine months in 1908 show a total rainfall of 66·26 in. during the period; the heaviest monthly fall was 11·30 in. during April, the least, 3·91 in. during September. The highest temperature in the shade was 85° F. in February, the lowest 46° F. in August. Easterly winds predominate from February to May, and westerly winds from June to October. No observations are available for November, December, and January.

THE DELAY OF VISUAL PERCEPTION.—The issue of the *Optician and Scientific Instrument Maker* for April 20 contains an article by Mr. F. G. Smith which summarises the recent work of Prof. Pülfrich on the effect of brightness on the time which elapses between the formation of an image on the retina and its perception by the observer. If an object moving across the line of vision from left to right is viewed with the right eye direct and with the left through a smoked glass to diminish the brightness of the image formed on the left retina, there is a delay in perception in the case of each eye, but the delay for the left eye exceeds that for the right, and the body appears to the left of and behind the actual position it occupies. If the object is moving from right to left it appears for the same reason to the right and in front of the actual position. If it moves alternately to right and left it appears to describe a circular motion about its mean position. The experiment is easily done with a fixed and a moving pencil, and it is rather remarkable that the phenomenon has not been observed previously.

BRITISH SURVEYING INSTRUMENTS.—Several recent improvements in the design and construction of British-made surveying instruments are detailed and illustrated in a paper by W. H. Connell in the Proceedings of the South Wales Institute of Engineers, vol. xxxix. No. 1, March 15, 1923, which has been reprinted in pamphlet form by Messrs. Cooke, Troughton and Simms, Ltd., Buckingham Works, York. Modern manufacturing methods involving the extensive use of jigs render possible the attainment of great accuracy and uniform production of the parts of instruments. The use of new and improved alloys has diminished the wear of moving parts, and thus instruments retain their adjustments for longer periods. Changes in design have led to the elimination of many adjustments, only one being necessary or provided in many modern levels, namely, that for securing parallelism between the line of sight and the tangent to the curve of the bubble tube. By the adoption of the internal focussing telescope collimation errors are almost entirely eliminated, and the use of accurately fitting removable cells permits of the graticules being cleaned or exchanged without disturbing the collimation adjustment. Changes have been introduced also with the view of saving time and labour in taking readings. For, example, the bubble, compass, and staff can all be read from the eye-end of the telescope without change of position on the part of the surveyor, and the focussing screw is easily accessible no matter what position the telescope may be in.

LITHIUM CARBIDE AND HYDRIDE.—In the *Comptes rendus* of the Paris Academy of Sciences for April 9 MM. A. Guntz and Benoit give an account of some properties of a mixture of lithium carbide and lithium hydride. This homogeneous mixture can be obtained either by heating metallic lithium in ethylene or by dissolving lithium carbide in fused lithium hydride. Submitted to electrolysis this fused mixture gives an abundant deposit of amorphous carbon. This may arise from a true electrolysis of the carbide or by a secondary reaction between hydrogen from the electrolysis of the hydride and the lithium carbide. From the results of their experiments the authors are inclined to regard the first view as the correct one, the lithium carbide being ionised into its elements in the hydride solution. The minimum electromotive force required to produce the carbon deposit is about 0·05 volt.

VULCANISATION OF RUBBER.—Mr. V. V. Byzov, in the Journal of the Russian Physical and Chemical Society, 1921, vol. 53, gives an account of work he has carried out on the vulcanisation of rubber. The researches indicate that the processes of hot and of cold vulcanisation are essentially the same, and are of extreme complexity. Vulcanised rubber consists of four components, which may exist in varying proportions in different samples of rubber. The first component is crystalline sulphur, which can be extracted from the rubber by boiling acetone. In a specimen of rubber containing 2·86 per cent of sulphur, 1·57 per cent was of this type. Most of the remaining sulphur is adsorbed in the rubber, and is in the amorphous plastic condition, this form of sulphur being insoluble in acetone. While plastic sulphur, under ordinary conditions, soon crystallises, in the fine state of division in which it occurs in rubber, conditions are perfect for supercooling, as each globule of sulphur is enclosed in a protective coat of colloidal material. To this plastic sulphur is ascribed the superior elasticity of vulcanised rubber. The rubber itself undergoes isomeric change to an insoluble form, from which a hydrochloride more stable than that obtained from ordinary rubber may be prepared, and the ozonide of which gives, on hydrolysis, not lævulinic aldehyde, as does that of natural rubber, but diacetyl propane. Whether this difference is due to a different degree of polymerisation of the isoprene molecules, or whether a transposition of the double linkages has occurred, it is not possible definitely to state. The fourth constituent of vulcanised rubber is a polymorph of isoprene disulphide $[C_{10}H_{16}S_2]_n$, but this is not as a rule present to any great extent. Thus vulcanisation of rubber is not a reversible process, and the problem of the recovery of pure rubber from an already vulcanised material, important in the waste rubber utilisation industry, appears to be an impossible one, as no means are known whereby the insoluble isomeride of rubber can be converted into the natural form.

The Forthcoming Pasteur Centenary Celebrations at Strasbourg.

WE have already announced that the Government of the French Republic has desired to commemorate this year the centenary of Louis Pasteur, and Strasbourg, where this illustrious savant commenced his scientific and university career, has been very fittingly chosen as the scene for the celebrations. Chief among these will be an international scientific exhibition—L'Exposition Internationale du Centenaire de Pasteur—which has been organised with the object of setting forth the fruits of Pasteur's work, not only in the domain of medicine but also in those of industry and agriculture. This exhibition will be officially opened on June 1 in the presence of the President of the French Republic, members of the French Government, and scientific delegates from all over the world. On the same day a monument erected to the honour of Pasteur in the Place de l'Université will be inaugurated, and a further permanent memorial is to take the form of a Museum of Hygiene. This will consist of a collection of exhibits illustrative of the various researches of Pasteur, and will constitute a history, in concrete form, of the early years of the science of microbiology.

The International Exhibition promises to be a most extensive and complete demonstration of the manifold results of Pasteur's work, both in pure and in applied science. It is to be organised in twelve groups, namely, microbiology, chemistry and chemical industry, collective hygiene, general hygiene, physical training, town hygiene, alimentary hygiene, food industries, refrigeration, agriculture, silks and sericulture, and finally a group devoted to scientific literature. In order that the exhibition should attain to that plane of excellence which would make it at once worthy of the man in whose honour it is being held, and an attraction to men of science, the organisation of the various groups and their sections has been entrusted to those who, by their work, are specially qualified in the various branches of science represented.

The groups of microbiology and collective hygiene are naturally the largest and perhaps the most interesting. The former, under the presidency of Dr. Roux, comprises in all nine sections. There will be a section devoted to diseases of man, including bacteriological and immunological technique, and sections dealing with vaccinia and vaccine institutes, tropical diseases and hygiene, diseases of plants, veterinary diseases, diseases of silkworms and other insects, parasitic insects, nitrification and sterilisation of soil —a most comprehensive list. The group of collective hygiene, with its six sections, is to deal with matters of the greatest importance, such as industrial diseases, tuberculosis, venereal diseases, cancer, maternity and infant welfare, military hygiene, and the organisation and installation of hospitals; and the names of such well-known scientific men as Dr. Calmette and Dr. Louis Martin, among the presidents of these sections, is a guarantee of the standard of excellence which will be reached in this group. But it is not only the man of science who will find interest in this exhibition. The sciences of chemistry and microbiology find their application throughout industry and in all phases of our modern civilisation. It is one of the objects of this exhibition to emphasise this interdependence of science and industry, and, to judge from the list of industries which will be represented by exhibits in the various groups, this aspect of the question has not been overlooked.

The exhibition will remain open till October, and during this period congresses on various subjects are to be held. In this manner it is proposed to discuss such subjects as tuberculosis, housing, town hygiene, cancer, leprosy, syphilis, puerperal fever, and milk. The general secretary of the exhibition is Prof. Borrel, director of the Institute of Hygiene and Bacteriology of Strasbourg.

Chemical Characteristics of Australian Trees.

MR. HENRY G. SMITH, of Sydney, in his presidential address to the section of Chemistry at the meeting of the Australasian Association for the Advancement of Science, held at Wellington in January last, dealt particularly with the elucidation of some chemical characteristics of Australian vegetation, treating the subject in relation to the generalisations that may reasonably be advanced from the consideration of the results secured by the phyto-chemical study of the principal Australian genera, such as Eucalyptus and Callitris. This study extended over a period of more than thirty years, and was undertaken in conjunction with his botanical colleague, Mr. R. T. Baker.

Some of the chemical peculiarities brought to light during this investigation appear to be characteristic of this unique flora, and indicate a distinct uniformity in progressive characters, suggesting evolutionary processes as the directing influence in the production of the numerous groups and species which, in the aggregate, go to form the more important genera.

The genus Eucalyptus apparently originated in what is at present the western and north-western portions of Australia, and as it spread eastward and experienced varying degrees of soil and climate the conditions demanded by these new locations and climatic changes were met by the responding characteristics of the genus.

The chemical peculiarities of nearly two hundred distinct species were determined, so that many data were obtained upon which to formulate the more recent theories regarding the formation of the distinctive groups.

Eucalyptus is essentially an oil-producing genus, and already about forty distinct chemical constituents have been isolated and characterised. These include 11 alcohols; 9 aldehydes; 2 phenols; 7 esters; 5 terpenes; 1 ketone; 1 sesquiterpene; 1 paraffin; and also cymene and cineol.

The two main factors controlling the chemical sequence throughout the genus may be stated in the following terms: (1) The same species of Eucalyptus has chemical properties of a comparatively constant nature wherever found growing under natural conditions, and (2) each constituent follows the sequence of species in increasing amount until a maximum is reached in one or more of them.

These conditions are not only true for the several oil products, but may also be applied to the astringent exudations or kinos produced in varying amounts by all the species. The characteristic features of these exudations are traceable right through the genus, and are particularly noticeable with the two crystalline substances, aromadendrin and eudesmin, found in the older species of the genus. These substances become extinct when the group of "ironbarks" is reached in the sequence of evolution, and are, of course, absent in all the more recent species, such as those belonging to the "stringybarks," "peppermints," "ashes," etc. Eudesmin is a particularly interesting substance, and occurs in the kinos of some species to the extent of ten per cent.

The address also dealt with the chemical peculiarities of the Australian Coniferæ, and in addition with the inorganic constituents peculiar to Eucalyptus trees, instancing the small amounts of mineral matter secreted in the timbers of those species which often occur as very large trees, such as *E. regnans*, *E. pilularis*, etc., a condition that suggests the reason for their continued growth and great size.

The occurrence of manganese, and its importance, were also discussed, the conclusions being based upon the results of much experimental work. It was shown fairly conclusively that the presence of manganese in such minute quantities cannot be considered as accidental, but a necessary constituent for successful growth of these trees, and that some species belonging to certain groups require a larger amount of manganese than is necessary for the growth of those belonging to other groups. The whole question evidently hinges around the action exerted by the enzymes in the structural formation of forest trees and their chemical constituents, and is thus a subject requiring long-continued chemical research and experiment before a reasonable solution of the problem can be expected.

Sunshine-Recording.

IN the sunny southern countries of Europe less general interest appears to be taken in the recording of sunshine duration than is the case in England, where a certain therapeutic importance is attached to an allotment of sunshine which in winter undoubtedly falls below the optimum, although probably not to a greater extent than it rises above the optimum during a Mediterranean summer. However this may be, it is interesting to find the subject discussed in a short article by Guilio Grablovitz in the comparatively new Italian publication *La Meteorologia Pratica* for July and August 1922.

Various objections are raised to the continued use of the Italian words *insolazione* and *soleggiamento* to denote sunshine, the term *eliofania* being advocated instead, which would be anglicised to *heliophany*. It appears that the two former terms have medical significance in connexion with bad and good effects of exposure to the sun, from which our corresponding word "insolation," which is virtually equivalent to the more familiar "sunshine," is free.

Discussion in the paper turns upon the proper dates for replacing the equinoctial card by the summer and winter ones in the well-known Campbell-Stokes sunshine recorder, in which the sun's rays, focussed by a glass ball, leave a charred record. It is argued that the dates officially adopted for the change, namely, February 22, April 20, August 23, and October 22, when the declination of the sun is 12°, might with advantage be altered to March 1, April 11, September 3, and October 15, when the declination is 8°; because in the latter case, during the passage of the sun through a range of 47° between the solstices, the equinoctial, summer, and winter cards would each be used through an equal range, approximately of 16° ($16 \times 3 = 48$), whereas in the adopted practice the equinoctial card covers a range of 24° ($12 \times 4 = 48$). This is a purely technical point to be settled by reference to the design of the instrument; but on wider grounds, astronomical and climatic, the dates actually adopted seem more natural because, the solar declination being then 12° N. or S., that is, practically half-way between 0° and 23½° N. or S., they mark what should be regarded as the real boundary between the solstitial and equinoctial periods of the year.

In connexion with sunshine-duration recorders, one can scarcely refrain from commenting upon the inadequate character of instruments which give no information about the quality or intensity of the recorded sunshine, and from expressing the hope that these will gradually be superseded by radiographs like the Callender recorder and Ångström pyrrheliometer, which indicate the amount of solar energy received in a given time. Such radiographs may not be all that is desired, but at least they show the difference between the intensity of insolation on different days, at different seasons, and in different latitudes or altitudes. They can, for example, differentiate in comparable measured terms between the fitful sunbeams of December and the fiery rays of June; or show, again, that a hot day in England with, say, an air temperature of 90° F. is thermally less fierce than a day in Italy having the same air temperature but under a force of insolation unknown in Northern Europe. The point is that equivalent air temperatures are not truly climatically equivalent unless associated with the same intensity of insolation, and it is well known what an important factor in the economy of living creatures is the direct radiation of light and heat.

L. C. W. B.

Trieste and Marine Biology.

DR. M. STENTA, director of the Natural History Museum in Trieste, delivered an address, in October 1921, at the Trieste meeting of the Italian Society for the Advancement of Science, on the important part played by Trieste in the study of marine biology, and the address has recently been published (*Atti Soc. Ital. Progr. Sci.*).

Dr. Stenta referred to the observations of Abbot Fortis published in 1771 on the islands of the Quarnero, and those of Abbot Olivi (1792), who gave, in his "Zoologia Adriatica," a catalogue of the animals of the Gulf of Venice. Almost all the naturalists who visited Trieste in the first half of last century were German; of these, two may be named—I. L. C. Gravenhorst, who recorded (1831) the results of his studies on various molluscs, echinoderms, and Anthozoa; and J. G. F. Will, who gave an account (1844) of the anatomy of Scyphozoa, ctenophores, and siphonophores. K. E. von Baer came in 1845 from Russia to Trieste to search for larvæ of echinoderms, but the results in that and in the following year were not very satisfactory. His visit, however, was fruitful in another respect, for he encouraged Koch, a young Swiss merchant resident in Trieste and an ardent collector, in his project of founding a museum of the Adriatic fauna, which became the centre of studies on the Gulf of Venice. Johannes Müller spent the autumn of 1850 in Trieste working on the development of echinoderms and worms, and in the neighbouring bay of Muggia he discovered in *Synapta digitata* the parasitic mollusc *Entoconcha mirabilis*.

Among many who worked at the museum between 1850 and 1870 were Oscar Schmidt, who carried on researches on sponges; A. E. Grube, who examined the annelids and discovered the parasitic rotifer *Seison nebaliae*; and Kowalevsky, who described (1868) the remarkable sexual dimorphism in *Bonellia viridis*. In 1874 the Adriatic Society of Natural Science was founded, and the 27 volumes of its Bulletin are rich in observations on the biology of the area.

In 1875 the Institute of Marine Biology was established by the Austrian Government, and many famous naturalists have worked in its laboratories, *e.g.* Metschnikoff, on intracellular digestion and phagocytosis; Kowalevsky, on medusæ; Driesch, on the development of isolated blastomeres; the brothers Hertwig, F. E. Schultze, K. Grobben, and Hatschek.

In 1900 the zoological station was enlarged and reorganised under the new director, Prof. C. I. Cori. A list of the more important investigations carried on at the laboratory from that time until 1915 is given by Dr. Stenta, but it is too long to quote here. Mention may, however, be made of Friedländer's investigation of the constitution of the purple secretion of Murex, for which 14,000 specimens were collected; Heider's work on the development of Balanoglossus; and Przibram's researches on regeneration in Crustacea. There were also several investigations in applied zoology: the culture of sponges, the coral fishery, and parasitic protozoa of fishes.

We gather from the concluding part of the address that the Italian Royal Committee for Marine Investigation, which took over the zoological stations at Trieste and Rovigno, proposes to suppress the former, and Dr. Stenta puts forward a plea for its retention.

Animal Nutrition.[1]

TWO series of Research Bulletins which have recently reached this country from America provide remarkable examples of the laborious—one may almost say meticulous—methods which distinguish much of the work now being conducted at the Agricultural Experiment Stations in the United States. The bulletins in question come from the stations attached to the Universities of Missouri and Minnesota respectively. In both cases the aim was to find out by actual chemical analysis the constitution of the bodies of cattle at various ages. In the case of the Minnesota investigations, sixty-three bullocks, at all ages from three months to two years and over, were slaughtered and analyses made of the bodies, not merely as a whole, but under such divisions as flesh, offal, skin, blood, etc. In the case of the Missouri investigations, thirty animals were slaughtered and analysed in much greater detail. Separate figures for all descriptions of edible joints and for each organ of the body are given. It does not require much acquaintance with chemical routine to realise the extraordinary labour involved in reducing the separate parts of the body of an animal to a fine pulp from which uniform samples of every description of tissue can be drawn. So far as this country is concerned, the attempt has been made only once—by Lawes and Gilbert many years ago—and then with difficulty three animals in all were completely analysed.

The object of these investigations may be stated very simply. The animal food consumed by man represents vegetable food converted by stock into "meat." It is desirable to know the extent of the waste involved in this process of conversion. Incidentally, we also wish to know the relation between the amount of this waste and the age of the animal, progressively. The older and larger the animal, the greater the waste, and consequently the more costly the product. Above all, it is desirable to ascertain the relation between protein consumed and protein stored, for the most costly food of all is vegetable protein, supplied in the form of costly oil-cakes; furthermore, as the raw material is generally imported from abroad, the economic loss in Great Britain is very great. There can be no doubt that, as matters stand, millions of money are being wasted by farmers in bringing beasts to a state of fatness required neither by the taste of the modern consumer nor by the human body's need for fat. The supplies of cheap vegetable carbohydrates, from which animal fat can be manufactured, are now greater than they were in our grandfathers' time, but the farmer still goes on producing from imported feeding-stuffs rich in protein, animal fat in wasteful quantity. More than 30 per cent. of the body weight of a "fat beast" is merely fat. Thanks to the labours of these American workers, this point can now be driven home. We can trace at every stage of an animal's growth what happens to the food it consumes, and how as it grows older its conversion factor grows smaller, until, ultimately, it stores only one-twentieth of what it consumes: how again it turns a larger proportion of costly protein into fat, rejecting more and more of nitrogenous matter.

In these days when, we are told, British agriculture is faced with ruin, it is unfortunate that agriculturists apparently cannot be persuaded to give up one of the most costly and wasteful processes of their industry. It is not the farmer alone who is to blame. Both the butcher and the housewife conspire to maintain the demand for excessively fat meat, and while the market demand is for fat stock, it is only to be expected that the present extravagant system of "fatting" beasts will continue.

University and Educational Intelligence.

BIRMINGHAM.—Announcement is made of the Walter Myers studentship (value 300*l.* for one year) for research in any branch of medicine or pathology approved by the selection committee. The studentship is tenable at any approved university, laboratory, or other institution in the United Kingdom. Candidates may be of either sex, and must be graduates in medicine of the University of Birmingham of not more than five years' standing. The holder of the studentship will be required to devote his whole time to research. Further information may be obtained from the Dean of the Medical Faculty of the University.

CAMBRIDGE.—As announced in our issue of May 5, p. 621, a fund has been established by the family of the late Henry P. Davison, of New York, for the purpose of giving English University men a year's residence and study in the American Universities of Harvard, Yale, and Princeton. Three of these scholarships will be available for next year for Cambridge. The scholars will be selected from undergraduates or bachelors of arts now in residence, the election being on the basis of character, scholarship, and fitness to represent the University. There is to be no examination.

LEEDS.—In memory of the 326 members of the University who fell in the War, a piece of sculpture by Mr. Eric Gill, which will be fixed to the outer wall of the University Library, will be dedicated at the University on Friday, June 1. The University owes this impressive memorial to the generosity of the late Miss Frances Cross of Coney Garths, Ripon.

London.—Prof. E. D. Wiersma of the University of Groningen will deliver a free public lecture on "The Psychology of Epilepsy" at 5.15 o'clock on Thursday, May 24, in the Robert Barnes Hall, The Royal Society of Medicine, 1 Wimpole Street, W.1. The lecture will be in English.

Manchester.—The following resignations are announced: Dr. A. V. Hill, from the Brackenbury chair of physiology, on appointment to the Jodrell chair of physiology in the University of London; Mr. J. P. Headridge, from the lectureship in dental metallurgy; and Dr. J. Gray Clegg, from the lectureship in ophthalmology.

Arrangements are being made for broadcasting University public lectures by joining up the University with the Metropolitan Vickers Broadcasting Station.

It is stated by the Hong-Kong correspondent of the *Times* that Sir Catchick Paul Chater has presented a sum of 30,000*l*. as a contribution towards the general purposes of the University of Hong-Kong.

The Ramsay Memorial Trustees will, at the end of June, consider applications for two Ramsay Memorial fellowships for chemical research. The value of the fellowships will be 250*l*. per annum, to which may be added a grant for expenses not exceeding 50*l*. per annum, and one will be limited to candidates educated in Glasgow. Full particulars as to the conditions of the award are obtainable from Dr. Walter W. Seton, Secretary, Ramsay Memorial Fellowships Trust, University College, London, W.C.1.

The Board of Education has just published a list of fifty-two holiday courses, which will be held at different times during the present year but mostly in the summer months. Nineteen of these courses are organised by Universities and University Colleges (of which nine are held in connexion with the tutorial classes of the Workers' Educational Association), seven by Local Education Authorities, and the remaining twenty-six by various educational bodies. In addition to general courses for teachers there are special courses, among which are the following: economics, gardening, geography, geology, handwork, international relations, languages, librarianship, medieval and modern universities, mine-surveying, physical training, psychology, social service, speech training, and the Victorian Age. The dates of each course, the fees, principal subjects of instruction, address of Local Secretary, and other details are given with each entry. This list can be obtained direct from H.M. Stationery Office, Imperial House, Kingsway, London, W.C.2, or through any bookseller, price 6*d*.

Examination and inspection of secondary schools in the United States are undertaken by several independent and, in many cases, overlapping agencies, namely—State officers of education, universities or colleges, and accrediting associations such as the Association of Colleges and Secondary Schools of the Southern States, the New England College Entrance Certificate Board, and the North Central Association of Colleges and Secondary Schools. In 1913 the United States Bureau of Education prepared a directory of schools (more than 13,000) which had satisfied or been "accredited" by these various agencies as equipped for preparing students for colleges requiring 15 "units" for unconditioned admission, and a fourth edition of the directory has recently been published as Bulletin, 1922, No. 11. The definitions of standards involved in the processes of "accrediting," as set out in the Bulletin, are instructive. One on which the various agencies are all agreed is the above-mentioned "unit" of measurement of secondary school work: a year's study in any subject, constituting approximately a quarter of a full year's work, on the assumption that the school year is from 36 to 40 weeks and that the study is pursued for 4 or 5 periods (of from 40 to 60 minutes each) per week, it being understood that a satisfactory year's work in any subject cannot usually be accomplished in less than 120 sixty-minute hours or their equivalent. The subjects recognised by the various accrediting bodies vary greatly: the College Entrance Examination Board, for example, permits the inclusion of English, mathematics, languages, history, science, and drawing only, whereas the University of California accepts also mechanic arts, agriculture, home economics, music, book-keeping, and stenography and typewriting. Almost all the State universities specify among their admission requirements three units of English and two and a half of mathematics; nearly half of them require at least one unit of science; more than half require history and foreign languages; only three require a classical language.

"The Rising Cost of Education" in America is one of the main subjects dealt with in the recently published 17th annual report of the president of the Carnegie Foundation for the Advancement of Teaching. During the past thirty years, while the national income increased by 500 per cent., the expenditure for public schools—elementary and secondary—rose by 700 per cent., and for universities, colleges, and technological schools by 1400 per cent. During the last decade the pace of growth increased, and an increasing share of the cost was transferred to the Federal treasury. The people still believe in education, but are becoming somewhat critical as to whether the system for which they are paying is altogether justifying itself in its results; and, in any case, the fact has to be faced that the cost of schools cannot be indefinitely increased: "Education must reckon with economic necessity." So far the president's review discloses a situation identical with that brought to light in Great Britain by the Geddes report. Analysis of the factors shows that in America, as in England, the increase in salaries since the War has been very great, but that in America it has been specially pronounced in the colleges: in the institutions associated with the Foundation, professors' salaries rose in four years by 28-83 per cent. The main purpose of the report, however, is to emphasise the fact that the rise in cost has been largely due to a change in the conception of education itself and the part the school is to play in the social order: to the widespread notion that formal education is not only the one way to advancement but also "the panacea for all social and political disorders"; to the admission to high schools and colleges of great numbers of pupils ill fitted for them; to the so-called "enrichment" of the curriculum with a great variety of subjects in which a mere smattering of knowledge is imparted; to the introduction of vocational training into the high schools; and to "acceptance of the notion of scientific research as the primary object of the college teacher." "Both financial necessity and educational sincerity require a return to a feasible and educationally sound conception of the school."

Societies and Academies.

LONDON.

Royal Society, May 3.—**Leonard Hill** and **A. Eidinow**: The influence of temperature on the biological action of light. The biological action of light is accelerated by warmth and retarded by cold. This is true for bacteria, infusoria and human skin. The temperature coefficient for infusoria, between 1° and 20° C., is about 3·0. By adequate exposure to cool air over-action of the sun on the skin can be prevented. The proven success of heliotherapy applied to children with surgical tuberculosis can probably be secured for cases of phthisis if these are no longer exposed in hot sun-boxes, but suitably stripped and exposed in cool air.—**F. A. E. Crew**: Studies in intersexuality. I.—A peculiar type of developmental intersexuality in the male of the domesticated mammals. Individuals, regarded as females during the earlier part of their lives, later assume the behaviour and the secondary sexual characters of males. They form a series according to the degree of imperfection of the external genitalia and the relative degree of development of the derivatives of the Wolffian and Müllerian ducts. In all there were paired but mal-descended testes. The condition appears to be the result of the absence during the period of differentiation of the sex organisation of that minimum stimulus provided by the sex-differentiating substance, of the sex-hormone, in a zygotic male. The Wolffian and Müllerian ducts pursue an equal and parallel development. The degree of intersexuality varies with the stage during the period of sex-differentiation at which the necessary minimum stimulus was exhibited. Since the assumption of the secondary sexual characters of the male type is normal in time, either the minimum stimulus is ultimately exhibited, or else there is a different threshold of response to the action of the sex-differentiating stimulus on the part of various structures belonging to the sex-equipment.—**E. J. Morgan** and **J. H. Quastel**: The reduction of methylene blue by iron compounds. The restoration of the power to reduce methylene blue to boiled milk by means of ferrous sulphate solution is due to the inorganic constituents of the milk. Methylene blue is reduced by ferrous sulphate solution in the presence of sodium hydroxide, carbonate, bicarbonate or phosphate, and of the sodium salts of acids such as acetic, tartaric, or citric. Ferrous sulphate solution alone will not effect any perceptible reduction. Two ferrous molecules always react with one of methylene blue. The mechanism of the reduction appears to depend on the relative affinities of the oxygen acceptor for the hydroxyl ion and of the hydrogen acceptor for the hydrogen ion.—**C. F. Cooper**: The skull and dentition of *Paraceratherium bugtiense*. A genus of aberrant rhinoceroses from the Lower Miocene deposits of Dera Bugti. A complete lower jaw, a nearly complete skull, parts of three other skulls, several fragments of lower jaws, numerous loose teeth, and parts of the milk dentition found in Baluchistan are discussed. The lower pair of incisors have the form of tusks turned downward. Even in the oldest specimens they show practically no signs of having been used. The condition of the premolar dentition shows the animal to be in an early state of evolution, but on a side line, with some possible connexion with the early North American Aceratheres. Similar teeth were found in Turkestan by Borrissyak and described by him as belonging to Indricotherium (=Baluchitherium), and a skull has been discovered in Mongolia by the American Museum expedition and attributed to Baluchitherium. It has the enormous length of 5 ft., as against a skull length of 3 ft. in the present form, which makes it the more probable that the two genera are properly separated.—**W. L. Balls**: The determiners of cellulose structure as seen in the cell walls of cotton hairs. The use of plane and circularly polarised light and of immature hairs shows that the reversals of the spiral fibrillar structure appear in full number, as soon as the secondary wall is visible, indicating predetermination thereof during growth in length. On development of the pre-cellulose, the primary wall shows a pair of opposed spirals with pitches corresponding to that of the slip spirals of the secondary wall. These slip spirals are structurally connected with the quicker pit spirals and invariably opposed to the latter in direction; the tangents of their angles are in the ratio of 4 : 1, which suggests polymerisation from the pre-cellulose of the primary wall. The rotation of the plane of polarisation by a single layer of secondary cell-wall is inverted on opposite sides of a reversal point; thus the molecular structures of the right-hand and left-hand areas would seem to be mirror-images. The probable space-lattice conformation of cotton and other celluloses seems to indicate a modernised restatement of Nägeli's micellar theory.—**I. de B. Daly**: The influence of mechanical conditions of the circulation on the electro-cardiogram. Exercise in man produces changes in the electro-cardiogram which are similar to those obtained in anæsthetised animals by simultaneous stimulation of both stellate ganglia. Partial or complete denervation of the heart was produced in a dog. Alterations in the mechanical conditions of the circulation were brought about (i.) by partial compression of the systemic aorta at various levels in the body, and (ii.) by changing the conditions of the artificial circulation of the heart-lung preparation. The most marked changes in the electro-cardiogram occurred when the arch of the aorta was partially clamped. The form of the electro-cardiogram of the denervated mammalian heart probably remains unaltered when the increase in work of the heart is produced in a physiological manner.

Zoological Society, April 10.—Dr. A. Smith Woodward, vice-president, in the chair.—**G. C. Robson**: The snail *Planorbis sufourii* Graells, the intermediate host of *Schistosoma* (*Bilharzia*) *hæmatobium*, in Portugal.—**C. F. Sonntag**: On the anatomy, physiology and pathology of the chimpanzee.—**K. Kostanecki**: On a remnant of the omphalo-mesenteric arteries in the manatee.

Royal Microscopical Society, April 18.—Prof. F. J. Cheshire, president, in the chair.—**D. W. Cutler**: The Protozoa of the soil. Data were obtained from 365 consecutive daily counts of the numbers of bacteria and protozoa in a normal field soil. Fourteen-day averages of the total numbers showed marked seasonal changes; the organisms being most numerous in November and fewest during February. An inverse relationship exists between the numbers of bacteria and the active amœbæ. A two-day periodicity obtains for the active numbers of one species of flagellate. Azotobacter, in the presence of Protozoa, can fix more atmospheric nitrogen than when alone. Experiments on the reproductive rate of *Colpidium colpoda* show that, according to the age of the parent culture, death of some of the organisms follows inoculation into fresh medium; also that death occurs even during the period of maximum reproduction.—**A. C. Seward**: The use of the microscope in palæobotanical research. Microscopical investigation can be applied to plants which have been preserved in different states, are of different geological age, and belong to various divisions of the vegetable kingdom, and reference was made to the examination of fragments detached from imperfectly petrified stems which cannot be cut into sections. Petrified roots of a Cretaceous fern were described in illustration of the difficulty of distinguishing between inorganic and organic structures. The architectural basis of plant organs has been remarkably persistent through the ages. Recent palæobotanical discoveries have thrown little light on the problem of evolution.

Manchester.

Literary and Philosophical Society, April 24.—Mr. W. H. Todd, vice-president, in the chair.—T. H. **Pear**: A new type of number form. The numbers appear to be on small square blocks. It is possible, by imaging a series of them tilted backwards, to see at a glance a numerical series like 1, 2, 4, 8, etc., or even 1, $\frac{1}{2}$, $\frac{1}{4}$, . . . $\frac{1}{128}$. To see this last fraction it is necessary, in imagination, to approach the form very closely. Complex numbers like $\sqrt{-1}$ and $\sqrt{-9}$ can be seen vaguely in undefined areas in the neighbourhood of 1 and 9 respectively. The form even represents a billion and a trillion, though it is difficult to see beyond a source of light (to look into which is like looking at the sun) which exists near the place representing a million.—W. J. **Perry**: The neurological basis of human behaviour in society. A calm, happy, peaceful behaviour is normal for man as he is at present constituted. Since this type of behaviour is universal among peoples in the "food-gathering" stage of culture, it must have been acquired at an early stage in the evolution of man, who, in the course of the development of civilisation, has, speaking generally, exhibited war-like, cruel, and angry types of behaviour to an increasing degree. An explanation is sought by considering man's brain as consisting of two distinct parts—the optic thalamus and the cerebral cortex, or neo-pallium. The optic thalamus represents the dominant part of the brain of the lower vertebrates. The cortex is concerned with "epicritic" sensibility, the thalamus with emotional tone. The increasingly violent behaviour of man as civilisation has proceeded can be referred to stimuli, due to certain social institutions, which, by unduly exciting the thalamus, undermine the control established by the cortex. The removal of those institutions should therefore have tremendous effects on human behaviour.

Dublin.

Royal Dublin Society, April 24.—Prof. J. A. Scott in the chair.—A. E. **Clark**: Evidence of displacement of Carboniferous strata in County Sligo. Accurate plotting of the igneous dykes on the N. coast of Co. Sligo shows that a strip of country four miles wide, lying just W. of Aughris Head, has been displaced southwards between parallel faults for a distance varying from a quarter of a mile on the W. side to three-quarters of a mile on the E.—E. J. **Sheehy**: The comparative values of protein, fat, and carbohydrate for the production of milk fat. By feeding lactating goats for successive periods with carbohydrate, fat, and protein the relative values of these materials have been ascertained. Protein (in excess of that required for milk protein and for body maintenance) and carbohydrate are equal in value, and fat is $2\frac{1}{4}$ times as valuable as either. In rations containing less than a certain quantity of fat, however, the substitution of extra fat for some of the carbohydrate gives results which credit fat with a value much higher than $2\frac{1}{4}$ times that of carbohydrate. In addition to its food value, fat in the ration stimulates milk fat secretion, but a small quantity suffices for the latter purpose.—T. J. **Nolan** and H. W. **Clapham**: The utilisation of monomethylaniline in the production of tetryl. In the nitration of monomethylaniline, metanitrotetryl is formed in addition to tetryl; also crude tetryl formed from commercial dimethylaniline frequently contains the same impurity. The use of monomethylaniline for the manufacture of tetryl has, apart from its cost, been hitherto regarded with disfavour. Tetryl containing not more than almost inappreciable quantities of metanitrotetryl can be obtained in good yield from monomethylaniline if the latter, before nitration, is converted into its nitroso derivative. The nitroso group influences the course of the nitration.

Paris.

Academy of Sciences, April 9.—M. Albin Haller in the chair.—A. **Guntz** and **Benoit**: The ionising power of fused lithium hydride.—Maurice **Lecat**: The generalisation and modifications of a theorem of Frobenius.—E. O. **Lovett**: Certain functional properties of conics and their generalisations.—Maurice **Fréchet**: The existence of ($\mathfrak{D}$) classes not complete.—M. **Mandelbrojt**: Taylor's series with gaps.—H. C. **Levinson**: The gravitational field of n bodies in the theory of relativity.—Ernest **Csilser**: Some dynamical and geometrical properties of movement resulting from the conditions of M. Angelesco.—G. **Laville**: The propagation of maintained waves along an iron wire. The experimental results are in good agreement with the formula developed from Maxwell's equations, but the formula deduced from Kirchoff's theory leads to results not in accord with experiment.—G. **Vavon** and A. **Husson**: Catalysis and steric hindrance. A study of the reduction of cinnamic acid and esters and alkylcinnamic acids and esters by hydrogen in the presence of a platinum catalyst. The experimental results are in agreement with the predictions of the theory of steric hindrance. J. F. **Durand**: The action of acetylene on zinc ethyl. Acetylene was passed into a solution of zinc ethyl in petroleum ether, and the yellow solid produced rapidly separated. It gave the reactions of a zinc acetylide; water gave acetylene and zinc hydroxide. Mercury diphenyl treated in a similar manner gave no reaction.—W. J. **Vernadsky**: Mendelejeffite, a new radioactive mineral. This mineral, found near Sludjanka (on lake Baïkal), is a calcium urano-titano-niobate, containing about 23·5 per cent. of U_3O_8. Its crystalline form is described.—Ph. **Schereschewsky** and Ph. **Wehrlé**: Elements of a synthesis of the French and Norwegian methods of weather forecasts. —Ch. **Janet**: The ontogenesis of *Volvox aureus*.—Lucien **Daniel**: Variations of perfumes under the influence of grafting. Experiments on grafting with wormwood (*Artemisis Absinthium*) have shown that the modifications in the leaves and seeds are accompanied by changes in the character of the essential oil: the taste and perfume may improve or deteriorate with differences in the species grafted.—Raphael **Dubois**: Tears and the functions of the lachrymal gland. An enzyme has been isolated from the lachrymal glands of the cow: it is neither an oxydase nor a peroxydase, but is a diastase hydrolysing starch like ptyaline; the name lacrymase is given to it.—M. **Lopez-Lomba** and Mme. **Randoin**: The production of scurvy in the guinea-pig and young rabbit by means of a new food regime, complete and in biochemical equilibrium, deprived only of the factor C. A food is described containing all the necessary constituents except factor C. The animals fed with this ration, plus 3 c.c. of lime juice (factor C), made normal growth. All the other animals fed with the same ration, minus factor C, after a short period of rapid growth, developed scurvy and died.—E. Lesné, Christou, and Vaglianos: The passage into the milk of the C vitamins introduced by other means than the mouth.—E. Fernandez Galiano: The rhythmic contractions of Vorticella.—A. L. Herrera: The imitation of plasmodia and chromatic structures by sodium silicate coloured with ivory black and drops of alcohol in diffusion. If drops of absolute alcohol are allowed to diffuse into a syrupy solution of sodium silicate coloured with ivory black, remarkable imitations of cells, nuclei, and chromatic structures are produced. The structure can be preserved fairly well by washing the card with weak alcohol to remove traces of alkali.—A. Policard: The mineralisation of histological sections by calcination, and its interest as a general histochemical method. The method, described in detail, permits the localisation of the mineral elements in the positions they occupy in the living tissue.—René Jeannel: The evolution of the copulatory apparatus in the genus Choleva. The sexual characters in this genus, both in the male and female, are more trustworthy than the external characters in defining the species.—Lucien Semichon: The preparation of wine by continuous fermentation: selection of the ferments by the alcohol already formed. Natural fermentation is due to elliptical yeasts, wild and apiculated yeasts, Dematium, spores of cryptogams, and various bacteria, all of which are objectionable except the first. Sterilisation of the must, followed by the introduction of a pure yeast culture, is economically impracticable. In a must containing 5 per cent. of alcohol the growth of the elliptic yeasts is favoured and the objectionable organisms do not develop freely. In practice, the addition of this amount of alcohol is not possible, but the same result can be obtained by a process of continuous fermentation. A portion of the must is started fermenting with a cultivated yeast, and after the necessary amount of alcohol has been produced, fresh must is added at a constant rate. The method has been successfully applied on the large scale.—Auguste Lumière and Henri Couturier: Barometric depression and anaphylactic shock. Guinea-pigs, sensitised by egg albumen, are partially protected against anaphylactic shock by placing under a bell jar in an atmosphere at about half the normal atmospheric pressure. The mortality in the animals thus treated was 40 per cent. against 80 per cent. when the animals were allowed to remain under normal pressure after the second injection.—Jules Amar: The law of vivireaction in pathology.

April 16.—M. Albin Haller in the chair.—Emile Picard: The singularities of harmonic functions.—Charles Richet: The spleen, a useful organ, but not essential. An account of experiments on the comparative effects of starvation of dogs with and without the spleen. Animals can survive for long periods after removal of the spleen: the experiments prove that animals without the spleen require more food to maintain their normal weight, and die more quickly than normal animals when deprived of food.—M. d'Ocagne: Normals of quadrics along their lines of curvature. Charles Nicolle, Et. Burnet, and E. Conseil: The micro-organism of epizootic abortion, distinguished from that of Mediterranean fever by the absence of pathogenic power for man. *Micrococcus melitensis* (the organism of Maltese fever) and *Bacillus abortus* present striking similarities in their morphological characters, cultures, and pathogenic power towards the animals commonly used in laboratory experiments; but *B. abortus* proves to be innocuous to man. Cultures injected into five voluntary subjects caused neither fever nor any other trouble: hæmocultures remained sterile and the agglutinating power was generally not developed.—Georges Bouligand: The singularities of harmonic functions.—Gaston Bertrand: The problem of Dirichlet and the potential of the simple layer.—G. C. Evans and H. E. Bray: Poisson's integral generalised.—André Planiol: The influence of velocity and of temperature on the friction losses in explosion motors. The engine was driven by an electric motor and the power used measured electrically: in one set of experiments the air port was fully open, in another the air admitted was reduced to a minimum. The frictional losses were found to be a linear function of the turns per minute, the rate of increase being much larger than was expected. Experiments were also made on the effect of varying the temperature of the cooling water.—Wladimir de Belaevsky: A problem of elasticity in two dimensions.—M. Mesnager: Observations on the preceding communication.—Antonio Cabreira: A method of obtaining the geographical co-ordinates at any height of a star.—Charles Nordmann and C. Le Morvan: Observations of the Pleiades with the heterochrome photometer of the Paris Observatory. A new method for determining stellar parallax by photometry. The photometric measurements given show that, for the stars of the Pleiades studied, there exists a clear relation between the intensity distribution in the visible spectrum and the absolute magnitude of the star.—P. Noaillon: Superficial circulation.—M. Hadamard: Remarks on the preceding communication.—Albert Pérard: Study of some mercury and krypton radiations with the view of their applications in metrology. The results of a large number of comparisons with the red cadmium line are given, with the view of detecting the presence of satellites of feeble intensity. None of the lines compared (neon, krypton, mercury) behaved as a simple symmetrical line.—Léon and Eugène Bloch: Spark spectra of higher order. Reply to a claim for priority by M. Dunoyer.—M. A. Catalan: Spectrum series and ionisation and resonance potentials of chromium and molybdenum.—L. J. Simon and A. J. A. Guillaumin: The determination of carbon and hydrogen by the use of a mixture of sulphuric acid and silver bichromate. The principle of the method is the determination of the carbon dioxide produced by heating a known amount of substance with a measured excess of the oxidising mixture, and the determination of the excess by the addition of an easily combustible substance (potassium methylsulphate), and a second measurement of carbon dioxide. Results of the application of the method to ten organic substances of varying types are given.—M. Lespieau: Some derivatives of the glycerol $(OH)CH_2 . CH(OH) . C \vdots C . CH_2(OH)$.—A. Wahl and W. Hansen: Isoindigotine and indine. Isoindigotine has been proved to be identical with Laurent's indine.—M. E. Denaeyer: The rocks collected by MM. Chudeau and Villatte in the central Sahara.—E. Schnaebelé: The tectonic origin of the valleys of the eastern slopes of the Vosges.—Louis Besson: Observation of a parhelion of 90°.—René Souèges: The embryogeny of the Valerianaceæ. The development of the embryo in *Valerianella olitoria*.—Pierre Georgévitch: The rôle of the centrosome in kinesis.—Mlle. Lucienne Blum: Modification of plants submitted to culture under glass. Comparative studies of the same plants grown under glass and in the open air. Under glass the plant appears to be stabilised at an earlier stage of its growth. The organs of secretion are always more abundant in the plant under glass.—Henry **Cardot** and Henri **Laugier**: The adaptation, transmission of acquired characters, selection by vital concurrence in the lactic ferment.—Edouard **Chatton** and Mme. M. **Chatton**: Sexuality provoked experimentally in an Infusoria, *Glaucoma scintillans*. Predominance of the conditions of the medium in its determinism.—Jules **Barrois**: The development of Echinoderms.

CALCUTTA.

Asiatic Society of Bengal, April 4.—M. A. **Wali**: Hinduism according to Muslim Ṣufis. Some Sufi scholars of India conclude that India, like other countries, has produced prophets and saints, and that the teachings of the Vedas and Upanishads are in accordance with the Muslim Scriptures.—W. **Ivanow**: A "witch-case" in medieval India. A curious and complete case of sorcery in the form technically called envoûtement from the Siyaru 'l-Ārifīn (± A.D. 1530) which is translated and annotated.—H. **Mitra**: Epigraphic notes.—H. C. **Robinson** and C. B. **Kloss**: Some remarks on Mr. C. Stuart Baker's new volume on the Birds (second edition) in the "Fauna of British India." A number of corrections are proposed for the Malaisian and eastern Indo-Chinese species dealt with.—Zoological results of the Percy Sladen Trust Expedition to Yuñnan in 1922, under the leadership of Prof. J. W. Gregory:—J. C. **Brown**: An account of the country traversed by the Expedition.—N. **Annandale**: Land molluscs. Eighteen species and one local race are represented, of which five species (all belonging to the genus Buluminus or Ena) and one race of *Helicarion resinaceus* Heude are described as new.—B. **Prasad**: Bivalve molluscs. Six species of Corbicula from W. Yunnan, a Unionid and a Sphærium are recorded from Lake Tali.—S. W. **Kemp**: Decapod Crustacea. Three crabs and a prawn of the genus Caridina were collected. One of the crabs is a new species of Potamiscus, while another (*Potamon atkinsonianum*) is interesting as being a Himalayan form. The Caridina from Lake Tali is new and is remarkable on account of the secondary sexual characters of the male.

Official Publications Received.

Diary of Societies.

SATURDAY, MAY 12.

ANNUAL CONFERENCE OF THE UNIVERSITIES OF GREAT BRITAIN AND IRELAND (at King's College), at 11.—Sir Theodore Morison and others: Discussion on The Financial Outlook of the Universities.—Sir W. Henry Hadow and others: Discussion on Music as a University Subject.—Sir William H. Beveridge and others: Discussion on the Universities and Training for Administrative and Municipal Life.—A. Greenwood, the Master of Balliol, and others: Discussion on Labour and the Universities.

MONDAY, MAY 14.

VICTORIA INSTITUTE (at Central Buildings, Westminster), at 4.30.—Prof. T. G. Pinches: Assyro-Babylonian Israel Likenesses and Contrasts.

ROYAL GEOGRAPHICAL SOCIETY (at Lowther Lodge, Kensington Gore), at 5.—Prof. J. W. Gregory: The Banda Arc; its Structure and Geographical Relations.

FARADAY SOCIETY (at Chemical Society), at 7.50 (Annual General Meeting); at 8.—E. P. Perman and H. L. Saunders: The Vapour Pressures of Concentrated Cane Sugar Solutions.—E. W. J. Mardles: The Elasticity of Organogels of Cellulose Acetate.—D. Stockdale: An Example of Polymorphism in an Intermetallic Compound.—A. L. Norbury: Some Experiments on the Hardness of Spontaneous Annealing of Lead.—F. C. Thompson and E. Whitehead: Some Notes on the Etching Properties of Alpha and Gamma Forms of Tricarbide of Iron.

ROYAL SOCIETY OF ARTS, at 8.—S. S. Cook: The Development of the Steam Turbine (3). (Howard Lectures.)

TUESDAY, MAY 15.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Prof. A. C. Seward: Arctic Vegetation of Past Ages. (Tyndall Lecture.)

ROYAL STATISTICAL SOCIETY, at 5.15.—D. R. Wilson: On Some Recent Contributions to the Study of Industrial Fatigue.

INSTITUTE OF TRANSPORT (at Institution of Electrical Engineers), at 5.30.—G. J. Shave: The Design and Maintenance of Commercial Motor Vehicles.

ROYAL PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN (Pictorial Group), at 7.

ROYAL ANTHROPOLOGICAL INSTITUTE, at 8.15.—J. H. P. Murray: Native Administration in Papua.

SOCIOLOGICAL SOCIETY (at Leplay House, 65 Belgrave Road), at 8.15.—Dr. G. Slater: The Psychological Basis of Economic Theory.

WEDNESDAY, MAY 16.

ROYAL METEOROLOGICAL SOCIETY, at 5.—M. de Carle S. Salter and J. Glasspoole: The Fluctuations of Annual Rainfall in the British Isles considered cartographically.—A. W. Clayden: (*a*) An Improved Actinograph. (*b*) Note on the Influence of a Glass Shade.—Capt. E. E. Benest: Notes on the "Sumatras" of the Malacca Straits.

GEOLOGICAL SOCIETY OF LONDON, at 5.30.—W. B. R. King: The Upper Ordovician Rocks of the South-Western Berwyn Hills.—Prof. W. J. Pugh: The Geology of the District around Corris and Aberllefenni (Merionethshire).

ROYAL MICROSCOPICAL SOCIETY (Industrial Applications of the Microscope Section), at 7.—L. Taverner: The Principles and Application of Technical Metallurgical Microscopy.—W. M. Ames: Applications of the Microscope in the Manufacture of Rubber.

ROYAL SOCIETY OF ARTS, at 8.—L. Gaster: Industrial Lighting and the Prevention of Accidents.

SOCIETY FOR CONSTRUCTIVE BIRTH CONTROL AND RACIAL PROGRESS (at Essex Hall, Strand), at 8.—Earl Russell: Progress and the Law (to be followed by a discussion).

THURSDAY, MAY 17.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Prof. E. G. Coker: Engineering Problems solved by Photo-elastic Methods (1). Improvement in Apparatus: Contact Pressures and Stresses.

ROYAL SOCIETY, at 4.30.—Dr. A. E. H. Tutton: (1) A Universal Interferometer. (2) A Wave-length Torsometer and its Use with the Universal Interferometer.—Prof. L. N. G. Filon and F. C. Harris: The Diphasic Nature of Glass as shown by Photo-elastic Observations.—Prof. C. E. Inglis: Stress Distribution in a Rectangular Plate having two Opposing Edges sheared in Opposite Directions.—Prof T. H. Havelock: Studies in Wave Resistance—Influence of the Form of the Water-plane Section of the Ship.—W. M. H. Greaves: A certain Family of Periodic Solutions of Differential Equations, with an Application to the Triode Oscillator.

INSTITUTION OF MINING AND METALLURGY (at Geological Society), at 5.30.

RONTGEN SOCIETY AND THE ELECTRO-THERAPEUTIC SECTION OF THE ROYAL SOCIETY OF MEDICINE (First Annual Joint Meeting) (in the Barnes Hall, Royal Society of Medicine), at 5.30.—Dr. A. W. George: The Pathological Gall Bladder. (Mackenzie Davidson Memorial Lecture.)

CHEMICAL SOCIETY, at 8 (and Informal Meeting).

FRIDAY, MAY 18.

ROYAL PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN, at 7.—Discussion.

ROYAL INSTITUTION OF GREAT BRITAIN, at 9.—W. M. Mordey: Recent Studies in Alternating Magnetism.

SATURDAY, MAY 19.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—J. B. McEwen: Harmonic Evolution.

PUBLIC LECTURES.

MONDAY, MAY 14.

UNIVERSITY COLLEGE, at 5.—Prof. G. Dawes Hicks: Kant's Theory of Beauty and Sublimity. (Succeeding Lectures on May 22 and 28.)

TUESDAY, MAY 15.

GRESHAM COLLEGE, at 6.—A. R. Hinks: Astronomy. (Succeeding Lectures on May 16, 17, and 18.)

THURSDAY, MAY 17.

UNIVERSITY COLLEGE, at 2.30.—Prof. W. M. Flinders Petrie: Recent Discoveries of the British School of Archæology in Egypt. (Lecture repeated on May 23 at 5, and 26 at 3.)

ST. MARY'S HOSPITAL (Institute of Pathology and Research), at 4.30.—Prof. F. G. Hopkins: An Oxidising Agent in Living Tissues.

KING'S COLLEGE, at 5.30.—Principal L. P. Jacks: The Higher Education and the Community of Nations (Hibbert Lecture).

UNIVERSITY COLLEGE, at 5.30.—Prof. H. A. Lorentz: The Rotation of the Earth and its Influence on Optical Phenomena.—Dr. C. Pellizzi: Bernardino Telesio e la filosofia europea (in Italian.)

School and Sex.[1]

IN 1920 the Consultative Committee of the Board of Education was reconstituted by Order in Council, and two urgent problems, of scientific character and far-reaching importance, were referred to it almost immediately for inquiry and advice: namely, first, what degree of differentiation is desirable, for boys and girls respectively, in the teaching of secondary schools; and, secondly, what use can be made, in the public system of education, of psychological tests. On the subject of the former reference the committee has received a vast body of evidence from a long list of witnesses—from medical men and psychologists, from teachers and examiners, from employers and business men; and the results of its inquiries have now been brought together in the pages of the report before us.

The first chapter, largely the work of the committee's secretary, Mr. R. F. Young, provides an admirable history of the curriculum in secondary schools for boys and girls; and this brief chronological survey is followed by a descriptive account of the present system of secondary education, so far as it bears upon the terms of the committee's reference. The education of what was once considered to be the weaker or the gentler sex has passed through two opposite phases, and is entering upon a third. The first was a phase of emphasised sex-difference based upon a supposed sex-inequality. It was the stage of feminine accomplishments and nothing more; it was also, therefore, a stage of educational inefficiency. During the second period—a period of reaction—education was based upon an assumed equality of the sexes; and reformers claimed, and endeavoured to secure, an identity of education for boys and girls, regardless of sex-difference. This, too, has not been entirely successful. The committee now discovers signs of a third stage—a stage which its own report will undoubtedly strengthen and reinforce—which recognises that equality does not demand identity, and would allow the widest possible freedom for all individuals, no matter which their sex might be, to develop their special talents, and to prepare themselves for their future duties, according to the peculiar tastes and capacities of each.

It is, however, the central section of the report which will command the greatest scientific interest. Here the committee has collected together all the available evidence dealing with the physical and mental differences between boys and girls during the critical years of development.

The known facts regarding the anatomical and

[1] Board of Education: Report of the Consultative Committee on Differentiation of the Curriculum for Boys and Girls respectively in Secondary Schools. Pp. xvi+193. (London: H.M. Stationery Office. 1923.) 2s. 9d. net.

physiological differences between the sexes are concisely summarised in a special appendix by Dr. J. G. Adami. The point of chief significance is the peculiarly rapid growth of the girls during the earlier phases of puberty. It is remarked that, as a consequence, the girl is almost adult while the boy is still adolescent. The memorandum ends by noticing that some of the most significant physiological differences are to be found in the activities of the glands of internal secretion; and, since recent research shows that these glands are intimately connected with emotional activity, this subtle physical difference is not without a deep psychological bearing.

As regards psychological differences generally, the committee has found that two opposing views appear to be entertained by various persons who have expressed opinions upon the subject. The first view maintains that "the higher the level reached in the development both of species and of individuals, the greater is the sex divergence"; and concludes that "educationally the first and safest classification is that which is based upon sex." The second view insists that "sex is the cause of only a small fraction of the mental differences between individuals," the divergences of man from man, and of woman from woman, being far greater than those between one sex and the other.

The committee has reviewed the few scientific investigations carried out upon this problem both in England and in America, and has manifestly decided that the weight of the evidence is upon the side of the second of these alternative beliefs. It has been stated, upon statistical grounds, that the largest sex-differences are physical differences—differences in height, in weight, and in bodily strength. Intellectual differences are far smaller; and here again the wider divergences are discovered not upon the higher but upon the lower levels of the mind, namely, in processes involving simple sensory or motor activity, in sensation and in movement; in the higher and more complex processes—in general intelligence and in ability to reason—the differences during the school period are extremely small. In memory and retentiveness, it is true, girls seem to surpass boys, and women to surpass men; nor is this without an obvious educational bearing. But of all psychological differences the most significant are those that relate to temperament and character. It is the quality of her emotions which, in the mental sphere, chiefly distinguishes the woman from the man.

Thus, inborn sex-differences in mentality are far slighter than has been popularly assumed. On the other hand, the cumulative result of the emotional divergence, and still more of the difference in social functions, has resulted in wide separation of interest and outlook, which is only in a small degree innate and ineradicable, and is chiefly due to tradition, and to the varying play of educational influences, whether conscious or unconscious.

In actual educational attainments, the differences vary considerably according to the circumstances of teaching. Where boys and girls have been taught together in mixed schools, the differences may be barely discernible; but where they have been taught in distinct departments, there the divergence is wider. Such differences can be measured easily by means of standardised scholastic tests.

The chief ascertainable differences appear to be the following: boys are better at arithmetic, mathematics, physical sciences, classical languages, geography, and drawing; girls are better at reading, spelling, handwriting, English composition, English literature, and possibly history, modern languages, and biological sciences. Here very plainly the effects of interest and tradition are at work quite as much as constitutional differences of intellectual capacity. The part played by the two factors, however, can only be disengaged by further inquiry.

Indeed, the most suggestive paragraphs of the whole report are those in which the committee emphasises the need for further research. It is pointed out that the provisional conclusions arrived at rest mainly upon the casual impressions and subjective opinions of schoolmasters—men of considerable practical experience, but of little or no psychological training; and it is urged that there is both room and need for a widespread co-operative inquiry, in which strict scientific methods shall be employed, and in which teachers, psychologists, and medical men shall all take part.

Science and Superstition of Primitive Mankind.

The Golden Bough: a Study in Magic and Religion. By Sir James George Frazer. Abridged Edition. Pp. xiv+756. (Macmillan and Co., Ltd., London, 1922.) 18*s*. net.

SIR JAMES FRAZER'S "Golden Bough" is in many respects the greatest achievement of anthropology—a science the short life-history of which allows still of a rapid survey and a correct apportionment of values. The book, like no other work, expresses the spirit of modern humanism—the union of classical scholarship with folk-lore and anthropology. The marble forms of antique legend and myth are made to lend their beauty to the crude and queer customs of the savage and the uncouth usages of the peasant, while the Gods and Heroes of Olympus receive in exchange the vitalising breath of life and reality from their humbler yet more animate counterparts.

It is difficult to review a new version of the work in the ordinary manner. It would be as presumptuous to assess the value of a universally acknowledged masterpiece of literary art and a classic of scholarship as it would be unnecessary to indicate the scope of a work known to every cultured man, a work which has exercised paramount influence over several branches of learning and has created new lines of scientific research. But though it is superfluous to praise the book or to explain it, the appearance of the abridged edition seems an opportune occasion for us anthropologists to undertake a little examination of conscience with regard to this classic. We all admit that we owe an immense debt to the author of the Golden Bough and to his work, but have we acquitted ourselves well of an obligation, have we given him his due in return? By this I mean, have we taken all that has been offered to us and made the most of it? Have we followed his lead to the end of the road, have we searched everywhere where the light of the Golden Bough has shone?

For this is the difference between the economic and the spiritual order of things: that in the former it is good to receive material benefits, and, speaking without cant, painful to give them; while in matters of the mind it is a joy to bestow but a burden to take, since this has to be done in an unselfish submission of the spirit, and requires obedience, discipline, and patience.

Surveying the immense influence exercised by this and Frazer's other works on contemporary humanistic literature, it might appear as if this quarry of inspiration and fact, however rich, must have by now become nearly exhausted. Literally half the subjects of modern anthropological argument and controversy have been submitted by Frazer for discussion: totemism, problems of the taboo, origins of kinship and chieftainship, primitive conceptions of the soul and spiritual life—the list could be drawn out indefinitely by going into more detail. In Great Britain, in France, in Germany and the United States, whole schools of anthropological science have flourished or grown rankly, respectively, on the ground broken and first cultivated by Frazer. It is enough to mention the names of Crawley, Marett, Durkheim, Hubert and Mauss, Van Gennep, Wundt, Freud and his school (in their anthropological studies), who in their work, some of it of the very first rank, are more or less dependent on Frazer and his initiative. Yet it would be easy to show that even this immense and most valuable Frazerian literature has left enormous areas within the enclosure of the Golden Bough ready for further cultivation.

It is not from the side of theory, however, that I wish to approach this great work, but, as a field-worker, from the point of view of actual research among savage races. The test of a scientific achievement lies in its power of anticipation and of prophecy: a sound theory must be the forerunner of empirical discoveries, it must allow us to foreshadow new facts not yet ascertained by observation. It is not when a man talks to us about things we have seen already, but when, from his study, he can foretell unsuspected events, can direct us towards unforseen treasures of fact, and guide our researches in unexplored countries, it is only then that the value of his theories is put beyond doubt or cavil. This is well known in natural science, where the value of a theory is always gauged by its lead in the laboratory or in the field. In humanistic and historical science the honour of a prophetic voice has been reserved to its youngest off-shoot, anthropology. For though "history never repeats itself" when we watch it over a relatively brief span, interested in its detailed course of accidental happenings, yet the evolution of culture, taken as a whole, is submitted to definite rules and regularities, and human nature, broadly viewed, as it breaks through the media of various civilisations and stages of development, remains the same, and, being subject to laws, is thus capable of prediction.

The Golden Bough has had a triumphant career in this respect. One after the other the main supports of the lofty edifice, which at first might have appeared entirely carved out of the author's creative imagination, were traced to the solid bedrock of fact by subsequent discoveries among the backward races. The most fantastic feature in the ritual of Aricia, the succession by murder, led the author to the theory of the killing of divine kings, carried out by certain savages, in order to prevent their end by disease or senile decay. This theory, when first emitted, had only partial and meagre evidence in recorded fact. But the brilliant discoveries of Dr. and Mrs. Seligman about the divine kings of the Shilluk, about their violent end, regularly inflicted after a term of reigning, and about the spiritual succession by the transmission of the soul, confirmed Sir James Frazer's theoretical assumptions in every detail. Following this, field-work has brought, and is still bringing, fresh evidence, enough to prove that Frazer's researches have revealed an institution of the greatest importance among backward races.

Sir James Frazer was the first to express the view that before humanity had begun to worship spiritual beings there was a stage of belief and ritual, essentially magical, in which man assumed a fixed order of Nature, subject to the power of specific incantations and rites. Modern research among savages, in the measure as it penetrates more deeply into the comprehension of native ideas, tends to establish the correctness, not only of the general assumption of the magical stage in evolution, but also of Sir James's detailed theories of the psychology of magic. The nature of primitive kingship and power; the paramount rôle played by the taboo and its psychology; the importance of harvest ritual and ceremonies among savages—in all this it would be easy to show what copious results recent field-work has produced by following the suggestions and inspirations of the Golden Bough.

An irrefutable though somewhat external proof of this is to be found in the ever-increasing bulk of the book as it passes through successive editions, a score of new instances appearing to testify to the truth of some of Frazer's fundamental propositions, where previous evidence was able only to supply a few.

To mention only the other masterpiece of Sir James Frazer, "Totemism and Exogamy," we find again, after some thirty years, a small volume expanded into four large ones by the rich harvest of facts which followed the theoretical forecasts of the author. The ignorance of paternity, at first observed by Spencer and Gillen among one tribe only, was at once recognised by Frazer as of extreme importance for the early forms of totemic belief and organisation and kinship. Here again this forecast was confirmed, not only by further researches of Sir Baldwin Spencer in the north of Australia, but also by the discoveries of Dr. Rivers in the New Hebrides, and by the findings of the present reviewer among a number of Papuo-Melanesian tribes of Eastern New Guinea. There this ignorance is of extreme importance in shaping the matrilineal ideas and institutions of the natives, and is also closely connected with their totemism.

There seems to be some need of emphasising this empirical fecundity of the book—that is, its essentially scientific value. The great admiration which this work has inspired as a literary masterpiece and as a classic of comparative history, folk-lore, and archæology, seems to have overshadowed the merits of the book as an organiser and director of field-work. These merits are due, not only to the learning and to the constructive craft of Sir James, but also mainly to his genius in understanding the fundamentals of human nature, especially of the nature of primitive man, such as we see him represented by the peasant and the savage. In no other work can we find the same intimate understanding of savage modes of thought and behaviour, the same unfailing capacity to interpret the savage's customs, ideas, and traditions from his own point of view, the same prophetic intuition of what is really important with the native and what is secondary. It is because of that that no other work of anthropological theory has received such brilliant confirmation from later researches in the field, nor is any one of them likely to stimulate future research to the same degree as the Golden Bough.

To substantiate this last forecast I should like to indicate, on one more point, this suggestive quality of Frazer's theories. I mean the very *Leitmotiv* of the book, the importance of vegetable cults for primitive magic and religion, the enormous concern of primitive mankind for the soil's fertility and for its conditions, the sun, the rain, and the weather. Over and over again, in the course of the long and devious explanations of the ritual of Nemi, we meet with the magic of the skies and of the soil, with the worship of trees, with the belief in the influence of sex on vegetable fertility, with harvesting customs and superstitions, with Gods and Goddesses of the teeming forces of Nature.

The reader remains under the impression that the interest in the vegetable world has exercised an overwhelming influence over the formation of magical and religious belief and ritual; that these, like the luxuriant mantle of green which covers our earth, have grown out of the union of the skies with the earth's fertility.

This view, indeed, is not expressed by the author, who even, in the preface to this new, abridged edition, repudiates an extreme form in which this opinion has been imputed to him, the view, namely, that all religion starts from tree worship. "I am so far from regarding the reverence for trees as of supreme importance for the evolution of religion, that I consider it to have been altogether subordinate to other factors." This, of course, is quite true, but if, instead of tree worship, we take the wider complex of religious phenomena, the cult of vegetation, or rather of vegetable fertility and its conditions, I for one would fully endorse the view that here we have one of the very taproots of religious growth. I perceive, moreover, that this aspect of the Frazerian theories opens up new lines of empirical research of the greatest promise and importance.

The Golden Bough, in this regard, shows us primitive man as he really is, not an idle onlooker on the vast and varied spectacle of Nature, evolving by reflection a sort of speculative philosophy as to its meaning and origins, but an eager actor, playing his part for his own benefit, trying to use all the means in his power towards the attainment of his various needs and desires: supply of food, shelter, and covering; satisfaction of social ambitions and of sexual passions; satisfaction of some æsthetic impulses and of sportive and playful necessities. He is interested in all things which subserve these ends and are thus immediately useful. Round these he develops not only his material technique, his implements, weapons, and methods of economic pursuit, but also his myths, incantations, rites, and ceremonies, the whole apparatus of primitive science and superstition.

Among all forces of Nature useful to man, the earth's fertility occupies quite a privileged and special position in the mind of the savage. Vegetable life—in its perennial periodicity of active exuberance and relative rest in the tropics; of life and death in the cold and temperate zones; of barrenness and fertility in certain periodically irrigated deserts—exhibits a regularity and system, a dependence on causes and motives, which seem to be almost within the control of man, yet from time to time so baffling to all his endeavours as to keep his interests, hopes, and fears constantly alive. On this borderland, where man's self-sufficiency utterly fails him, yet where he perceives a clear order; on this ground, so vital to himself and so clearly subject to the play of some extraneous regularities or wills, here the ideas of magic and religion, always a cross-breed of reflection and emotion, flourish most abundantly. Especially where man begins actively to shape the forces of Nature in agriculture, magic ranges itself side by side with technical efforts and becomes a controlling factor of immense importance.

It would be natural to expect, therefore, that among savages there exists public magic of fertility, and that, on the sociological side, this leads to the early forms of chieftainship and kingship, while on the side of belief it leads to important developments of ritual and cult.

Here we touch on the sociological aspect of Frazer's theories of early magic. He clearly recognises the existence of a special class, who, by their magical knowledge, can acquire social importance: "the public magician occupies a position of great influence, from which, if he is a prudent and able man, he may advance step by step to the rank of a chief or king." The author further proceeds to show how very important these specialised magicians are, both in that they perform their services for the whole community, thus forming an integrating power, and also in that they are the first examples in the evolution of mankind of specialists freed from the ordinary burdens and occupations of their fellow-tribesmen, and able to devote themselves to one pursuit. The evidence which Sir James is able to adduce in support of his theory of public magic and of its sociological importance is great, but not quite adequate to substantiate all his theories. Thus, among the forms of public magic, Sir James can find examples only by referring to sunshine, rain, and weather. Even this material does not allow him to demonstrate in detail how political power and social influence arise from the exercise of the magical functions. We are led to inquire: If vegetable and fertility rites are so important, how is it that there are no departmental magicians of agriculture on record? Why does the public magician only control the conditions of fertility and not fertility itself? How can magical influence grow into political power? These questions seem at first sight to qualify and invalidate Frazer's theories of early kingship and magic. Yet here again, recent results of field-work among primitive people allow us to settle these doubts and cavils in a manner once more triumphant for the book, which shows itself to have been ahead of the material at the author's disposal.

In ethnographical researches done among some Papuo-Melanesian tribes of Eastern New Guinea, I found myself at once in the thick of a social and psychological situation such as is postulated by the Golden Bough. The office of the chief coincides there with that of the public magician. To the control of rain and sunshine the chief owes an enormous proportion of his executive power, which he uses to strengthen his position and to enforce his general will. A faithful disciple of the Golden Bough, I turned my attention to the institutions associated with agriculture. Then gradually I began to see that Frazer's theories of the sociologies of magic, of the rôle of the public magician, of the departmental control of natural forces, rested on much more solid foundations than he himself had been able to realise with the material in hand, and that this can be demonstrated on the book's own territory, that of vegetable cults. For not only do there exist in these tribes departmental magical rites of fertility, not only are they the most important ones, ranking even before the weather rites and always carried out by the chief, but also we can study there the sociological mechanism by which the garden magician obtains his political power.

In each community we find a garden magician, who performs his ritual for public benefit. These functions are always vested in the headman of the community. In villages which are capitals of a district and governed by a chief, he himself carries out the magic of vegetation. In this rôle, the headman or chief commands not only a high respect, as the man who has in his hands the forces of fertility and who knows how to tap them, but he also takes an actual lead in the practical pursuits accompanied by the magic. For the magical ritual is intimately bound up with the technical activities. It imposes a regularity in time, and compels people to work in order and in organised groups. This refers to several forms of public magic, such as canoe-building, fishing, and overseas expeditions, but most conspicuously to garden magic. In this, the magician controls the work of the whole community during the course of the year, gives the initiative to the various stages, has the right of reprimand and punishment, is regarded as the man responsible for success and failure, and receives tributes from his fellow-villagers.

Here again we see that, starting from one of those theories of the Golden Bough which go far ahead of the available evidence, field-work reaches interesting and important discoveries. In this case it leads to the study of primitive economics, a chapter very much neglected by the traveller and amateur ethnographer, and even by the specialist, which promises, however, to yield results of some importance. For I have no doubt that my confirmation of Sir James's theories from a limited ethnographical area will be followed by other more important discoveries all the world over.

Thus the Golden Bough, far from being a classic in the sense of having attained the fulness of its glory and deserving honourable rest, is a book which still has some hard service in the field before it, a book which should be n the kitbag of every ethnographic explorer. A modern ethnographer, in his researches among savages, must, while making his observations, remain still in contact with theoretical literature in order to receive from it constant inspiration and guidance, especially if he is bent on doing intensive field-work, if he is willing and able to remain for months and years among the same tribe and study it by means of their own language and by personally taking part in the tribal life. In such study I derived constant inspiration and benefit from the works of Westermarck, Karl Bücher, Ratzel, Marett, Hubert and Mauss, Crawley and Rivers, some of which I actually have re-read while in the field, others again in the intervals between my expeditions. Alas! at that time the twelve volumes of the Golden Bough were too heavy and costly a burden to carry across sago swamps, to paddle over lagoons in an outrigger always ready to capsize, or to keep in a tent or thatched hut by no means rain- and insect-proof. Now the more fortunate field-worker can easily take with him, handle, and constantly refer to the new, one-volume, abridged edition.

To the student in his library, this abridged edition will no doubt only serve as a handy guide, as a sort of explicit digest, or to the beginner as a preliminary introduction. The full version is indispensable to the student, and it is also the most fascinating and instructive reading to the layman. But no doubt many a one who was at first shy of tackling directly the Golden Bough will, in the short edition, find a bridge to the full work, which is not only the most important achievement of Sir James Frazer, but also the last word of modern anthropological scholarship.

B. Malinowski.

Modern Cosmogony.

The Nebular Hypothesis and Modern Cosmogony: being the Halley Lecture delivered on May 23, 1922. By J. H. Jeans. Pp. 31+4 plates. (Oxford: Clarendon Press; London: Oxford University Press, 1923.) 2*s*. 6*d*. net.

DR. JEANS'S analysis of the modes of rupture of fluid masses under the influence of excessive rotation or of the gravitation of other bodies, earned him the Adams prize of the University of Cambridge in 1917 and the gold medal of the Royal Astronomical Society in 1921. The results appeared in his "Problems of Cosmogony and Stellar Dynamics," published in 1919. The relation between his book and the pamphlet under review is that while the book was a theoretical work with an observational commentary, the Halley lecture is an account of observations with a theoretical commentary.

The Laplace-Roche theory of the development of a rotating and condensing gaseous mass showed that it would be flattened at the poles, and, if strongly condensed towards the centre, it would ultimately become lenticular, with a sharp edge. The next stage was believed to be that this edge would open all round, and the matter would pour out to form a ring. The rings of Saturn were claimed as an example of this process, but it is now known that they could never have passed from the gaseous to the solid state if they had been first produced in this way at their actual distance from the planet. The heavens have been searched for other bodies showing rings of Laplacian type, but none has been found.

Numerous nebulæ, however, show the flattened and lenticular forms indicated by the early stages of the theory, and Jeans considers that they are true examples of it. Other nebulæ show lenticular centres, with definite indications of detached matter around the equatorial sharp edge, and the more of this matter there is, the clearer does it become that it is not in the form of a ring or series of rings, but of spiral arms. In fact, known nebulæ afford examples of every intermediate stage, from the flattened symmetrical mass, through the lenticular form, to the typical spiral nebula, and it is difficult to resist the conclusion that this gradation corresponds to an actual course of evolution. This evidence is beautifully presented in the published lecture.

Although the astronomical evidence for such a phenomenon is strong, it calls for a dynamical explanation. We need to know why the matter is ejected almost entirely at two opposite points and not uniformly all around the equator. Jeans suggests, with much plausibility, that the equator would be distorted by the gravitation of surrounding bodies, and that, however small the distortion was, it would suffice to localise the ejection at two opposite points, and hence two arms would be formed instead of a ring.

Van Maanen, at Mount Wilson, has measured the motions of identifiable parts of spiral nebulæ. The motion is curious. The arms are approximately equiangular spirals, and the matter constituting them is moving outwards along the arms, its velocity increasing the farther it recedes from the nucleus. The nucleus is rotating with the arms. Now, this motion is just what Jeans deduced from theoretical considerations, taking into account the viscosity of the mass. The time of rotation of the nebula, and the velocities found spectroscopically, together give an estimate of the distance of the nebula M. 33 as 2000 parsecs, and of its diameter as 30 parsecs. The mass of the whole is about 100,000 times that of the sun. The nebula in Andromeda probably has a mass 20,000,000 times that of the sun.

The velocity of the arms of M. 33 is such that the whole of the visible matter must have been within the nucleus 200,000 years ago; and as we must suppose that the nebula is older than this, matter must be continually ejected. Jeans gives strong ground for believing that it condenses to form stars of mass comparable with the sun.

The method of rupture of much denser and smaller masses is next considered. Jeans has already shown that a star will break up into two fragments comparable in mass if it rotates sufficiently rapidly. Some double stars show such light variations and velocities in the line of sight as indicate that they are in close contact, agreeing with the hypothesis that they have just been formed by the fission of a single star through excessive rotation. Their periods of revolution and their spectral type (B) agree with further predictions of the theory. In some cases a stationary calcium atmosphere surrounds both components; this is readily explicable as the original atmosphere of the star, which has not yet attached itself to either component, but will divide into two when the components get far enough apart.

The last few pages give a short summary of the tidal theory of the origin of the solar system. The disruption of the sun by the tidal action of a passing star is supposed to have led to the formation of the planets. Jeans considers that such an event may have happened to some other stars, but that these constitute only a small fraction of the stars we know. The majority of the stars are probably unattended by planets, and perhaps the earth is the only body in the universe capable of supporting life.

Harold Jeffreys.

Military Mining.

The Work of the Royal Engineers in the European War, 1914–19. Military Mining. (Published by the Secretary, Institution of Royal Engineers, Chatham.) Pp. x+148+61 plates. (Chatham: W. and J. Mackay and Co., Ltd., 1922.) 12*s.* 6*d.* (7*s.* 6*d.* to members of the I.R.E.)

The volume before us describes a most arduous branch of the work that the Royal Engineers were called upon to carry out in the War—a branch, the final success of which was largely due to the technical skill of civilian coal-miners from Great Britain working under mining engineers from the Colonies and abroad.

The book is divided into three sections dealing with (1) the history of mining during the major operations of the campaign, (2) mine rescue work, and (3) technical considerations.

At the end of the first battle of Ypres "the study and practice of military mining were suddenly revived by the discovery that stationary trench systems brought back all the old features of fortress warfare." Before the end of 1914 at least two mines were exploded by the enemy under our trenches. This caused a demand for special mining units, and in February 1915 the first party of British miners arrived in France. By the end of June 1916, operations had extended so much that a total force of 25,000 men was employed in this work, and during that month no less than 227 mines were blown on the British front, 101 by us and 126 by the Germans.

The greatest of many successful mining achievements during the war was the deep-level attack at Messines on June 7, 1917, when on a narrow front and in the space of 30 seconds mines were fired containing nearly 1,000,000 lbs. of high explosive. "The moral effect of these explosions was simply staggering," writes General Ludendorff in his Memoirs, and he attributes to them the success of our attack. This scheme was remarkable also for the long period of preparation (it was begun in the previous summer) and the consequent anxiety lest its extent should become known to the enemy. A month before the attack they were clearly heard in deep workings at Hill 60, but it was correctly calculated that their gallery would just pass clear over ours, and they were allowed to go on working.

In addition to offensive mining an immense amount of work was done by tunnelling companies in the construction of dug-outs, communication tunnels, and road repair, and during the summer of 1918 in the removal of mines and traps left by the enemy as they retired.

Owing to the number of casualties in the early days of mining, chiefly caused by carbon monoxide from the detonation of high explosives, rescue work became of great importance, and was effectively organised under Lieut.-Col. D. Dale Logan. The next step was the formation in 1916 of a special medical service for tunnelling companies, all the officers of which had been for years in mining practice. A well-deserved tribute is paid to the work of these officers and of the rescue men, whom it was found necessary to select with the greatest care owing to the very trying nature of their work.

The apparatus and methods used are described at some length. It is worthy of note that "with small exceptions there appeared to be a total absence of any regular mine-rescue organisation along the whole German front."

In the technical section of the book a large amount of information is given on such subjects as disposal of spoil, listening instruments, and the work of the mine schools. It also discusses the main principles which gradually became evident as underground warfare developed, the most important of which may be summed up in the statement that "the best form of defence is attack." By a strenuous application of this idea "the enemy was reduced underground by the autumn of 1917 to a state of absolute passivity on the entire front."

Our Bookshelf.

Encyclopædia of Veterinary Medicine, Surgery, and Obstetrics. Edited by Prof. George H. Wooldridge. In 2 vols. Vol. 1: *Veterinary Medicine.* Pp. xiv + 546 + xxiii. Vol. 2: *Surgery and Obstetrics.* Pp. viii + 547-1106 + xxx. (London: H. Frowde and Hodder and Stoughton, 1923.) 2 vols., 6*l.* 6*s.* net.

To describe this work as an encyclopædia is a little misleading. It comprises two volumes, the first of which deals with veterinary medicine and the second with veterinary surgery and obstetrics, but they are distinguished from what are commonly called text-books on the same subjects only by the fact that a large number of authors have collaborated in their production. The preface expresses the hope that the work will be found useful to veterinary students, owners of animals, and members of the medical profession, as well as to the general veterinary practitioner; but it is obvious that the guiding consideration in the production of the work has, quite rightly, been the requirements of the practising veterinary surgeon.

No veterinary work on exactly the same plan has previously been published in Great Britain, but it may safely be said that as a practical and scientific treatise it is superior to any of the previous English text-books on the same subjects. In a work to which more than thirty authors have contributed, absolute uniformity in style and other qualities of the different sections is not to be expected, but for the most part the language is clear and concise, and the information is up-to-date. A notable defect, especially marked in the first volume, is that the amount of space devoted to different diseases appears to bear no close relationship to the importance of the subject. It seems impossible to imagine any good reason for allowing seventeen pages to horse-sickness, which is a purely African disease, and six pages to snake-bite, while tuberculosis is only allowed ten pages, and glanders, epizootic abortion, foot-and-mouth disease, and rabies together occupy only sixteen pages. The value of many of the articles is enhanced by good illustrations, and the publishers' share of the work has been well done.

Archives de morphologie générale et expérimentale. Fascicule 14 (*Morphologie expérimentale*): *Le Déterminisme et l'adaptation morphologiques en biologie animale.* Par Prof. R. Anthony. Première partie: *Déterminisme morphologique et morphogénie.* Pp. 374. (Paris: Gaston Doin, 1922.) 28 francs.

This work is an attempt to describe the form and structure of animals in so far as they can be shown to be determined by morphogenetic factors in the environment. The author begins with generalities about life, evolution, and variation, sketches the history from the earliest times of a rational explanation of morphology, upholds the Lamarckian doctrine with the usual inconclusive arguments, and incidentally places the Emperor Julian as a precursor of Lamarck. Thence he passes to the description of observations and experiments on the effect of external factors on structure, more especially in molluscs and vertebrates.

Although there appears to be little in this account which is actually new, yet Prof. Anthony has brought together a number of interesting facts showing how closely structure is correlated with function—how, for example, the shape and size of muscles and the relative lengths of muscle fibres and tendons are regulated according to the motions to be executed, also the shape and internal structure of bones. It follows that in many cases they can be altered experimentally.

These observations, however, seem to us to prove, not that the Lamarckian theory of evolution is correct, but that organisms are the products of the interaction of the physical basis of heredity with the environment in which they develop. This fundamental conception, long ago appreciated by the botanist with regard to plants, is still but imperfectly understood by the zoologist.

Department of Scientific and Industrial Research. Memoirs of the Geological Survey. Summary of Progress of the Geological Survey of Great Britain and the Museum of Practical Geology for 1921, *with Report of the Geological Survey Board and Report of the Director.* Pp. iv + 189. (Southampton: Ordnance Survey Office; London: E. Stanford, Ltd., 1922.) 5*s.* net.

For many years past, geologists who wish to keep pace with research in the stratigraphy or petrology of our islands have found that they must not overlook the annual volumes modestly entitled "Summary of Progress of the Geological Survey." The issue for 1921 contains a paper by E. E. L. Dixon on "The Retreat of the Lake District Ice-Cap," and the formation of fluctuating lakes held up by glacier-dams. The relations of kames and outwash-mounds of various kinds are considered, and the protruded products of sub-glacial melting, where clearly connected with a "feeding esker," are well styled "esker deltas." Foreign geologists may be puzzled at the frequent occurrence of the name of Lamplugh in a glacial paper as that of a village at the foot of Owsen Fell. On p. 129, Dr. R. Kidston provides a new example of how the determination of the species of Carboniferous plants enables the "practical man" to determine the horizons of his coal-seams. The lists of species from the beds now shown to be Westphalian in the Durham and Northumberland Coalfield contain some revisions of genera, and several new forms are mentioned. May we suggest that the printing of the titles of such papers on the cover of the "Summary of Progress" would do much to bring the publication into line with the convenient bulletins of the United States Geological Survey? G. A. J. C.

Comparative Ethnographical Studies, 5: Deductions suggested by the Geographical Distribution of some Post-Columbian Words used by the Indians of S. America. By Erland Nordenskiold. Pp. xiv + 176. (London: Oxford University Press, 1922.) 18*s.* 6*d.* net.

THE fifth volume of Baron Nordenskiold's valuable series of Comparative Ethnographical Studies deals with the distribution of words used by the Indians for certain post-Columbian elements in their culture—the domestic fowl, horses and cattle, the banana, iron, firearms, scissors—and certain partly post-Columbian elements—European knives, needles, and fish-hooks. Of these words some are of Spanish or Portuguese derivation, others are of native invention and are onomatopœic, as sometimes for the fowl, or purely descriptive.

The author's main interest lies in the historical deductions to be drawn from the distribution of these words. It affords clear evidence, not only of the course of the diffusion of culture, but also of trade routes and of tribal migrations. In many instances, confirmation is afforded by comparison with the accounts of the early chroniclers. It is interesting to note that European culture elements had reached the Aymara and Quichua from the East before Pizarro came into contact with them from the West. This valuable contribution to the history of the Indians of South America in post-Columbian times will cause students of South American civilisation to look forward with eager anticipation to the author's promised study of pre-Columbian culture on similar lines.

The Industrial Applications of X-rays. By P. H. S. Kempton. (Pitman's Technical Primers.) Pp. xiii + 112. (London: Sir Isaac Pitman and Sons, Ltd., 1922.) 2*s.* 6*d.* net.

MR. KEMPTON'S little book gives a good introduction to "radiomateriology," that is, to the examination of materials by means of X-rays. The art has made great strides since the War, and by means of the powerful high voltage apparatus now employed, steel forgings and castings several inches thick can be satisfactorily tested. Examination by X-rays is of particular value for detecting flaws in metallic products and for examining welds and joints made by brazing or soldering. It is also specially useful for examining timber, reinforced concrete, electrical insulating materials, and precious stones. The author describes the apparatus used in industrial radiology and gives interesting radiographs. Complete installations for the X-ray examination of materials are described, and due stress is laid on the importance of protective screens and safety devices. In the table of spark-gap voltages given, it is interesting to note that for a given spark-gap the disruptive voltage increases with the size of the spherical electrodes up to a certain value and then diminishes for larger electrodes. This is in accordance with theory.

Inca Land: Explorations in the Highlands of Peru. By Hiram Bingham. Pp. xvi + 365 + 45 plates. (London: Constable and Co., Ltd., 1922.) 24*s.* net.

IN this volume Prof. Bingham describes a part of the work accomplished by the four expeditions of Yale University and the National Geographical Society to Peru between the years 1909 and 1915. Where so much is new and of absorbing interest it is difficult to select any one discovery as outstanding; although in archæology most will, no doubt, agree that the exploration of the ruins of Machu Picchu has been the most important in its results. This site, with its magnificent and, in some respects, unique architectural remains, is held by the author to be probably the Tampu Tocco to which the pre-Inca people, the Amautas, retired when the country was invaded from the south about A.D. 800, and from which the first Inca, Manco Ccapac, began to extend his Empire about A.D. 1300. Fascinating, too, is the story of the search for Uiticos, the lost stronghold of Tupac Amaru, the last of the Incas, defeated and killed by the Spaniards in 1572, and for the "white rock over a spring of water," the site of the Temple of the Sun burnt by two zealous Spanish friars in 1568. The results obtained by these expeditions were little short of remarkable, and have added enormously to our knowledge of the geography, archæology, and natural history of the country.

Laboratory Manual of Physical Chemistry. By Prof. Albert W. Davison and Prof. Henry S. van Klooster. Pp. viii + 182 + 32 pages of sectional paper. (New York: J. Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1923.) 10*s.* net.

THIS "Laboratory Manual of Physical Chemistry" covers only twenty-four experiments, but these are set out in detail with full references to the literature. An ample supply of blank pages is provided, together with ruled spaces for filling in experimental data; tables of atomic weights, densities, vapour-pressures, and refractive indices are also given, with logarithm-tables and a sufficient supply of squared and triangulated paper to provide for the whole of the experiments suggested. The manual, therefore, becomes the student's note-book as well as his text-book, and will enable him to place his own results on his bookshelf in a more orderly manner than is usual.

Causes and Consequences. By Sir Bampfylde Fuller. Pp. x + 291. (London: J. Murray, 1923.) 12*s.* net.

THE author of this book discourses on many things, indeed, on all things which concern science and philosophy, with an easy-flowing style and irresponsible dogmatism. His description of insects as "brainless animals" has already evoked a lengthy correspondence in the Press, and he might easily be called to account for a hundred other equally confident and artlessly simple-minded statements. Thus, for example, he tells us "it seems clear that some of the theories connected with the name of Professor Einstein are based upon a confusion of time and space with rhythm."

Adsorption and Hæmoglobin.

As I have in other places entered a plea for more consideration of the possibility that adsorption may play some part in the phenomena of the taking up of oxygen by hæmoglobin, a few remarks on the letter by Mr. N. K. Adam in NATURE of April 14 may be permitted me, chiefly with the object of making clear my attitude in the matter. It is briefly this. Nearly all, if not all, of the workers on the problem direct their attention only to the investigation and interpretation of these phenomena from the point of view of mass action in a homogeneous system. Now, while this may ultimately turn out to be the correct view, it must not be overlooked that hæmoglobin under most conditions exists in the form of colloidal aggregates. Thus, surface phenomena may intervene and should receive due consideration, even if only to be put on one side. This has not been attempted to any serious extent, since Wo. Ostwald showed that the data of the taking up of oxygen by hæmoglobin could be expressed by an adsorption formula. It is true that such a formula, as Mr. Adam says, contains two arbitrary constants, and fitting it to the experimental data does not prove anything as to the nature of the phenomena. But the same statements may be made with regard to the widely accepted Barcroft-Hill expression.

Any criticism that I venture to make is not to be understood as doubting the value of the data that are being obtained, but rather as directing attention to certain gaps in our knowledge which require to be filled up before further progress in the interpretation of the facts can profitably be made. There is, as it seems to me, some risk of building elaborate hypotheses on assumptions which are not clearly demonstrated. It appears sometimes that workers are so convinced that the mass action view is all that is necessary, that they are not interested in testing the truth of these assumptions. If it is found that an experimental result can be explained on the lines of mass action formulæ, however elaborate, it is taken as confirming the view; but other hypotheses might be found equally well to satisfy the case, if seriously examined. Compare, for example, Langmuir's formulæ for the adsorption of a gas by a crystal surface with the Hill-Barcroft formula. I am sometimes inclined to wish that it were possible for an investigator who knew nothing about previous theories to attack the problem as a new one.

But to be more precise—it is undoubtedly a very important fact that when hæmoglobin has taken up all the oxygen that it can, this oxygen is in the proportion of one molecule to each atom of iron in the molecule of hæmoglobin. It is natural to believe that the iron and oxygen are directly united. Mr. Adam's assumption that the oxygen is "locally attracted" rests on this belief. Are we quite certain that it is the case? And even if it were, we know too little about the forces which bring about adsorption to be able to exclude the possibility of local foci, as it were. On the view of chemical combination, in the strict sense, between oxygen and iron, is not the greater affinity of hæmoglobin for carbon monoxide than for oxygen rather puzzling? There is also the problem of methæmoglobin, another compound of hæmoglobin and oxygen, but one which does not give up its oxygen to a vacuum. I have not been able to find in the literature dissociation curves of oxyhæmoglobin continued beyond the saturation point in the presence of excess of salts or of carbon dioxide. On the purely chemical theory, with sufficient concentration of oxygen, the saturation point should still be in the same proportion of iron to oxygen. In connexion with the relations between hæmoglobin and carbon dioxide, no proof has yet been given that the union is of a different nature from that with oxygen. It is still uncertain whether the hæmoglobin that combines with carbon dioxide is a sodium salt.

To put the question in another way—does hæmoglobin free from sodium combine with carbon dioxide, or does it not? But if hæmoglobin, as worked with, is a sodium salt, osmotic pressure measurements give no direct information as to the molecular weight of hæmoglobin. It appears to be accepted by most of those working on the problems that oxyhæmoglobin is a much stronger acid than hæmoglobin itself. It is true that to explain the carriage of carbon dioxide by mass action formulæ, this is necessary. But is it impossible to put the question to more satisfactory experimental test than has yet been done? Again, the cause of the widely divergent results obtained by different investigators of the heat of combination between oxygen and hæmoglobin has not been adequately made out. While, therefore, the data which are being accumulated in so many places are of the greatest value in relation to the actual behaviour of hæmoglobin under certain conditions, I find it impossible to interpret them on the basis of any theory until the questions above mentioned are answered.

A subsidiary point, but one about which agreement is desirable, is the use of the name "polymerisation" in place of the more usual one, in relation to colloidal behaviour, of "aggregation." It would be of advantage if clear definition of these terms, together with that of "association," could be agreed upon.

It is perhaps to the point to recall those processes which obey the unimolecular law as deduced from mass action, at all events in a part of their time course, although we know that as a whole they are much more complex than simple chemical combinations.

Turning to Mr. Adam's criterion of adsorption, I agree that it is impossible to define it by the nature of the forces concerned. It seems to me, however, that it is only shown when a sufficient number of atoms are joined to form a surface. To adopt the criterion of the whole surface becoming uniformly covered when the concentration rises to a certain value, neglects, I think, those cases where two or more substances are adsorbed simultaneously. Mr. Adam appears to accept Langmuir's views. While these explain many cases, there are others where the range of the forces concerned extends beyond one molecule. According to Evans and George (Proc. R.S., A, 103, p. 192) the thickness of the layer of carbon dioxide on glass amounts to that of five or six molecules. Chemical forces in the ordinary sense seem to be excluded here. Moreover, accepting the probability of orientation on an inert surface, like that of charcoal, by affinity of certain groups for the water of the liquid phase, it is difficult to see how the increased concentration itself is initially brought about. But, after all, is it not rather an idle discussion to make definite distinctions between chemical and physical forces in the region of atomic properties? Does not the Braggs' crystal model indicate that the forces responsible for cohesion, chemical union, and electrical behaviour are one and the same? The recent discovery that in the crystal of beryllium acetate an oxygen atom has four *equal* valencies suggests also a reconsideration of the doctrine of "residual valencies," as used by Langmuir in his theory.

The Complex Anisotropic Molecule in Relation to the Theory of Dispersion and Scattering of Light in Gases and Liquids.

OBSERVATIONS by Cabannes,[1] the present Lord Rayleigh,[2] Gans,[3] and others have shown that the light scattered by various gases in a direction at right angles to the incident beam is not completely polarised. This is accounted for by Cabannes in terms of a *simple anisotropic molecule* of the type first used by Langevin [4] in 1910 to account for electric and magnetic double refraction. Such a molecule contains a single dispersion electron acted on by unequal quasi-elastic restoring forces along the principal directions and capable of vibrating with three different frequencies.

The present writer has extended the theory to gaseous and liquid media composed of *complex anisotropic molecules*, in which there are any number of dispersion charges the principal directions of which are not parallel. For an isotropic medium in which all molecular orientations are equally probable, a general dispersion formula of the Lorentz type is derived.

In *gaseous media*, owing to rapidly varying changes of position, each molecule contributes independently to the *intensity* of the scattered radiation. For unpolarised incident light of intensity I, the *depolarisation* is measured experimentally as the ratio of minimum to maximum intensity when the light scattered at right angles to the incident beam is examined by a Nicol prism, and as observed in gases is a quantity characteristic of the molecule. The intensity $I_s\theta$ scattered in a direction θ with the incident beam of wave-length λ, to a distance r from a volume $\bar{V}$ is given by the formula

$$\frac{r^2 I_s\theta}{\bar{V}I} = \frac{1}{2}\frac{\pi^2}{\lambda^4}\frac{(\mu^2-1)^2}{n} \cdot \frac{6(1+\rho)}{6-7\rho}\left\{1+\frac{1-\rho}{1+\rho}\cos^2\theta\right\}, \quad (1)$$

where μ is the refractive index corresponding to molecular density n.

The corresponding formula for the coefficient of extinction by scattering is

$$K = \frac{8\pi^3}{3\lambda^4}\frac{(\mu^2-1)^2}{n} \cdot \frac{6+3\rho}{6-7\rho}. \quad . \quad . \quad (2)$$

A remarkable feature of these formulæ is their *invariance* with respect to such details of molecular structure as number and magnitude of dispersion charges and mutual orientation of principal directions.

In *liquids*, from the observations of Martin,[5] Lord Rayleigh, Kenrick,[6] Raman,[7] and others, it is now definitely established that dust-free liquids are able to scatter light. According to Smoluchowski [8] and Einstein,[9] the explanation of this phenomenon, first observed near the critical point of a liquid, lies in fluctuations of molecular density due to thermal agitation. Since a volume of linear dimensions small compared with a light-wave contains several million comparatively stationary molecules, it is necessary in dealing with liquid media to sum the components of the electric vector in the scattered light-wave from each molecule. In these circumstances, it may be shown that equally probable orientations of complex anisotropic molecules within this small volume would result in the scattered light being completely polarised, contrary to observation. It is concluded, therefore, that *liquids have an extremely fine-grained crystalline structure*, the crystalline aggregates being supposed to be incapable of withstanding stress owing to molecular vibrations, and to be continually breaking up and re-forming under the influence of these elastic waves, which according to Debye's [10] theory constitute the energy of thermal agitation. If we suppose the energy of one degree of freedom to be associated with the random pulsations of these crystalline aggregates, we derive instead of (1) the following formula for scattering,

$$\frac{r^2 I_s\theta}{\bar{V}I} = \frac{1}{2}\frac{\pi^2}{\lambda^4}(\mu^2-1)^2\frac{6(1+\rho)}{6-7\rho}\frac{RT\alpha}{N}\left\{1+\frac{1-\rho}{1+\rho}\cos^2\theta\right\}, \quad (3)$$

where, in addition to the symbols already defined, R is the gas-constant per gram molecule $=83{\cdot}2 \times 10^6$ C.G.S., N is Avogadro's constant $=6{\cdot}06 \times 10^{23}$, T is the absolute temperature, and α is the *adiabatic* compressibility.

As in the case of the preceding formulæ, (3) enjoys the property of invariance with respect to details of molecular structure, and it is derived on the hypothesis that the molecules in each crystalline aggregate are not greatly disturbed from perfect alignment by angular oscillations which result in a diminution of the depolarisation ρ as the critical point is approached, as has, in fact, been recently observed by Ramanathan [11] in the case of liquid ether.

For light scattered at right angles to the incident beam, Martin has shown that the inverse fourth power law holds good for benzene and water. For $\lambda=4358$ Å. and 20° C., we find for $r^2 I_s(\frac{1}{2}\pi)/(\bar{V}I)$ the following comparisons,

Benzene	$21{\cdot}5 \times 10^{-6}$ (calc.)	$26{\cdot}0 \times 10^{-6}$ (obs.).
Water	$1{\cdot}85 \times 10^{-6}$ (calc.)	$1{\cdot}77 \times 10^{-6}$ (obs.).

Formula (3) also accounts theoretically for the relative scattering of some twenty organic liquids studied by Martin.

This satisfactory agreement between theory and observation goes far to justify the hypothesis of the crystalline structure of liquids as just described. To this view strong support is lent by the observations of Debye,[12] Keesom,[13] and more recently of Hewlett,[14] on the scattering of a beam of X-rays by various liquids.

Although the results thus far have been based on a general type of "static" molecule, the theory is by no means opposed to the modern conceptions of the "dynamic" atom. For wave-lengths long compared with molecular dimensions, we may suppose those perturbations which contribute principally to dispersion to consist of forced oscillations of each atomic system of electrons with respect to the corresponding positive system.

The Adhesive Apparatus of the "Sucking-fish."

It is regarded in text-books[1] as a well-established fact that the adhesive organ of the "sucking-fish" (Echeneis and Remora, etc.), and a somewhat similar structure in Pseudecheneis and certain other freshwater fish, functions as a "sucker"; in other words, it enables the fish to adhere by the creation of a vacuum, or at any rate a partial vacuum, between the ridges and the rim of which it is constituted. Observations on Pseudecheneis and its allies in natural conditions led both Dr. Annandale and myself to doubt whether this belief is well founded.

It is very significant that, as several observers have noted, Echeneis can be detached from its hold quite easily by either thrusting it forwards or sideways,[2] while the so-called rim of its adhesive apparatus is entirely absent as a raised ridge in fresh material or well-preserved specimens. The whole structure,[3] moreover, differs in almost every respect from the true sucking disc present on the lower surface of the fish Garra[4] (Discognathus) and of the tadpoles[5] of *Ranæ Formosæ*.

I have recently had an opportunity of conducting experiments on the living Pseudecheneis, and have also had the great advantage of being able to consult Prof. C. V. Raman on the physics of adhesion both in this genus and the true Echeneis. We are convinced that the apparatus of these species, unlike that of Garra and the tadpoles mentioned above, is not a true sucker but essentially an elaborate device for producing the maximum amount of friction. It is correlated in a very interesting way with the shape of the fish. The upper surface of Echeneis and the under surface of Pseudecheneis are flattened to increase frictional area, while the lower surface of the former and the upper surface of the latter have adopted such a form that an advantage is taken of the swift current, which, instead of dislodging the animal, presses it against the substratum. The pressure exerted by the current increases friction, for friction is proportional to two factors—the coefficient of friction and pressure. The coefficient of friction is increased by the presence of a large number of strong spines, all of which are directed backwards on the lamellæ of the pad of Echeneis, and by innumerable microscopic epidermal spines[6] found on the ridges of the adhesive discs of hill-stream fishes. The plates bearing the spines in Echeneis point posteriorly, with the result that the spines come into action against the opposing surface when the fish is pressed backwards by the current, but are released when the movement is in the opposite direction. The enormous difference in the frictional coefficient for forward and backward movement is easily noticed when a finger is passed over the pad of a preserved specimen of Echeneis. It is also possible that the ridges and grooves in these fishes assist in increasing friction much in the same way as the ridge- and groove-patterns to be found on the tyres of motor cars.

Echeneis can cling to smooth surfaces in the absence of currents.[7] The strong spines on the lamellæ are quite sufficient to render this possible, and the phenomenon is not at first sight so remarkable as the power of adhesion in opposition, as it seems, to a strong current.

This note is written chiefly with the object of bringing this new view of the mechanism of the so-called sucker to the notice of other workers, particularly of those who are in a position to make observations on living specimens of Echeneis, Remora, etc. I hope myself shortly to undertake fuller studies of the morphology and histology of the adhesive pad with the view of elucidating the subject further.

Vertical Change of Wind and Tropical Cyclones.

In his article on the birth and death of cyclones (London Meteorological Office, Geophysical Memoirs, No. 19, 1922) Sir Napier Shaw makes the interesting suggestion that the shearing of the head of a tropical cyclone with reference to its foot, by difference of velocity at different levels in the air which carries it, might cause its dissolution. If the hypothesis that the movement of a cyclone is due to its being embedded in a flowing current of air is correct, it will of course be admitted that if there is a considerable gradient of wind upwards, positive or negative, then there must be a continual shearing of the cyclone and the shearing must either be continually countered by the cyclone, or it must die. But the question is, whether there are occasions when a cyclone has to face such a strong vertical gradient of wind, and if there are, what vertical gradient a cyclone can stand and continue to live? With regard to the first point, from an examination of the symmetry of temperature and pressure Sir Napier Shaw remarks:

"If isobaric surfaces are also isothermal surfaces there is no change of wind velocity with height. In any case one would have to assume approximate uniformity of direction and speed for a thickness of several kilometres, in order to get a definite connected body of air in stable motion. Perhaps for the levels between four and eight kilometres there are enough occasions of little change of wind velocity between those levels to furnish convenient circumstances for the persistence of a sufficient number of cyclones or cyclonic depressions."

The atmospheric conditions in the region surrounding a cyclonic depression are so different from those of normal weather, that it is perhaps quite incorrect to assume that the vertical gradient of wind, which a cyclone has to encounter, is roughly of the same order as the gradient derived from the observations of the motion of pilot balloons under normal conditions. As pointed out by Sir Napier Shaw, it is also a matter for careful consideration, what is actually presented to us by the motion of a pilot balloon in a cyclonic depression. The irregularities due to local turbulence or the changes incidental to an inclined axis will appear in the results with as much weight as the examples of fundamental structure. Perhaps the altered condition of the atmosphere in which a fully developed cyclone finds itself does not permit of too much change of wind velocity with height, and then all our conjectures regarding the supposed effect of a vertical gradient of wind on a cyclonic system will appear futile.

If a cyclone is to be considered a stable dynamical system consisting of a vortex with a ring of maximum velocity, as Sir Napier Shaw considers it to be, and "protected from the ordinary vicissitudes of weather by the *enormous momentum* of a vortex with a high rate of spin," then as a vortex will generally, except perhaps for the fact that air is not a perfect fluid, form a closed system or end on boundaries, we shall have to assume that in a cyclone the dynamical conditions extend from the ground surface to considerable heights. Perhaps also the entire length of the vortex and not simply the length where the sustaining energy is supplied is effective in offering resistance to extraneous forces, because the energy wherever it is supplied will distribute itself over the entire length. The high degree of permanence of the type of motion is also suggestive that its enormous momentum does offer considerable resistance to all forces of destruction. A small vertical gradient of wind, if there is such a gradient at all, will therefore probably not shear a cyclone out of existence. It will perhaps deform the cyclonic system or make its axis inclined to the vertical; but if the gradient is considerable and of long duration, and if the struggle to maintain its circulation and to remain reasonably erect proves too much for the cyclone, it will eventually die.

The possibility of the axis of a cyclone being inclined to the vertical has long been surmised, and Sir Napier Shaw himself has advanced arguments attempting to give definiteness to the meaning of this idea ("Manual of Meteorology," Part IV., p. 145). It should, however, be remarked that the axis of a cyclone being inclined to the vertical will have a definite meaning only if the whirl is supposed to extend to heights comparable to the diameter of the core and not simply to 3 or 4 km., that is, only a little beyond the levels where the sustaining energy is supplied, as suggested by some meteorologists, including Eliot and Dallas.

If, on the other hand, we do not consider the cyclonic system and the flowing current, if any, as two distinct systems, and seek for an explanation of the movement of cyclones in the mechanism of the cyclonic system itself, then the consideration of the shearing of a cyclone due to a vertical gradient of wind does not arise at all. Consider, for example, the storms which form in the Indian seas. The centrifugal force in these storms, especially at the outer margin, is not strong enough to keep the monsoon winds feeding into them revolving in a circular path, with the result that these winds after taking a small turn deviate from the circular path and carry the cloud ahead of the storms. The precipitation and the consequent latent heat set free in front of the storms reduce the pressure there, necessitating a readjustment and a shifting of the isobars. This will in general account for the movements of these storms. It is, of course, implied in this explanation that it is not the general drift of winds that makes a cyclone move, but that the movements of the cyclone involved in its mechanism make the outlying winds adjust themselves to the motion.

A Levitated Magnet.

PRESUMABLY all interested in magnetism have tried to keep a magnet in suspension, by the repulsion of like poles balancing its weight. In common with others, I have always failed to do this with steels hitherto available. The experiment fails through inability of the small magnet to resist having its poles reversed, or diminished in strength, by the intense field necessary for levitation.

Recent research on magnetic steels has, however, produced steels having the necessary resistance against reversal of polarity and with the necessary strength of magnetic field.

I find that the experiment of flotation can be shown by using very simple apparatus. The best results have been obtained by using a solid rod of special steel, 2½ inches by $\frac{3}{16}$, weighing about twelve grams. This rod is enclosed in a flat glass cell, slightly larger, giving clearance of about 1 mm. between the ends and sides, so that the rod may be able to move freely. This glass cell should be open at the top, and have a vertical height of about 3 inches. The bottom should also be made of thin glass—old photographic plates (quarter plates) answer very well for making this glass enclosure, adhesive tape being used for joining the glass plates, which may be separated by flat pieces of wood or glass slightly thicker than the steel bar, to give sufficient clearance. The magnetised rod should rest freely on the glass bottom (Fig. 1).

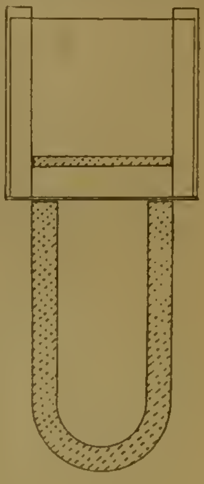

FIG. 1.

Holding the cell vertically, it is lowered slowly towards the poles of a horse-shoe magnet, held vertically. If the poles of the horse-shoe magnet are of the same sign as the opposing poles of the magnetic rod, the latter will rise and oscillate up and down in its enclosure. When properly adjusted in the field of a good magnet the rod will remain permanently poised about half an inch above the poles, which should be about the same distance apart as the poles of the levitated magnet.

Good bar magnets may be used, thus enabling the correct separation of the poles to be found experimentally.

A much greater distance of separation may be obtained by using an electro-magnet. In this case the cell must not be placed on the poles before turning on the current or the rod magnet will be reversed before it has time to rise and it will remain on the floor of the cell, being attracted. The same may happen if the cell is lowered awkwardly so that only one pole of the rod can rise: some reversal then takes place, necessitating remagnetisation of the bar. The particular steel used by me I owe to the kindness of Mr. W. H. Glaser, who tells me it contains 15 per cent cobalt and is known as "cobalt chrom" steel.

Science and Economics.

F. S. M., the writer of the article "Labour and Science in Industry," in his rejoinder to my letter (NATURE, April 14, p. 498) does not seem to grasp my main point, that the present economic system has no sound *physical* foundation, and that it was an element of physical reality—for example, the laws of the creation of wealth as distinct from debt—that I wished introduced into the proceedings of the Economics section of the British Association. If the section has been proceeding on this road for a good many years now, as claimed, I apologise. But I am surprised at the slow progress it has made.

My "we," in the phrase "economic system under which we perish," was meant to be fairly catholic, and I have no objection to including the Russians and Chinese, though I think they may outlast us. My information about Russia is largely from schoolboys, who write to be told the latest about the atom; and about China, that the children work in mills twelve and fourteen hours a day, much as we worked ours here at the same stage of the industrial system. But on the question whether *we*, the British, are perishing or not, the statistics obtained during the medical examinations for compulsory military service were, to say the least, disquieting.

In reply to your correspondent, Mr. W. W. Leisenring (April 28, p. 571), the object of the examination I advocated is to find out what the physical basis of economics is, because I think it is entirely the opposite of what the economists seem to believe. There is no question of altering it. The natural laws in connexion with energy and matter were not known or understood when the present system was formulated. The system is a reflection of certain passing conditions, —an *ad hoc* system, good enough perhaps fifty years back, but perilous to-day. It should now be possible to found broadly the physical basis, embodying modern knowledge of the laws of energy and matter and the two undeniable principles of the Physiocrats and Karl Marx to which I made allusion. That human nature is admittedly imperfect is no reason why physical nature should be distorted to suit it, even if that were possible. Because drivers are imperfect and of uncertain individuality we do not insist on imitating their idiosyncrasies in the cars they drive. Rather we try to make them "fool-proof."

Mr. Leisenring deduces from my letter that "the natural obvious truths of the nineteenth century as interpreted economically are, in this century, both unscientific and senseless." I accept the deduction, much as I would if the words "spring" and "autumn" were substituted for the contrasted centuries; but I am not clear why Mr. Leisenring should disagree with my statement that no one pretends to understand the present system. His eulogy of it, whether historically justifiable or not, was couched in the past tense, whereas my criticism of it was couched in the present tense. With regard to the present financial system, however, if there is one defect it does not suffer from, it surely is age. Such a system as the present has never even been attempted before. It is an absolute innovation; and to suggest that it has evolved through several centuries *pari passu* with science, and that its ultimate basis is character and ability, merely shows that it is not understood. Its ultimate basis is credulity, and, by the standards of the Codes of Laws and social formulæ of all great civilisations, it is counterfeit.

FREDERICK SODDY.

MR. W. WILSON LEISENRING'S interesting criticism of Prof. Soddy's economic views in his letter printed in NATURE of April 28, p. 571, appears to have overlooked some of the most important causes of the present confusion in the world of economics. Among these I would put first the well-known psychological process of *inversion*, whereby the *means* is mistaken for the *end*, as exemplified by the old mercantile system or fallacy of representing the accumulation of gold and silver as the ultimate goal of commerce, and as being the true basis of national prosperity. Thus "protection," "tariff reform" (and, indeed, most of the "labour" or trades union ideals) are no more than survivals of a belief that *money*, instead of being the mere instrument of exchange and a measure of market values, is of itself the end and purpose of all trade and labour activity.

A fruitful source of confusion is also ambiguous terminology. Attempts are often made to divorce the economic concept of *wealth* from private property. In their strictly economical signification "wealth" and "labour" are unmeaning apart from property and market values. The same ambiguity applies to "capital," hence all the absurdities associated with the phrase "capital levy."

I venture also to differ from Mr. Leisenring's statement that "the ultimate basis of credit in any age is character and ability." We have here another illustration of inversion. The true basis of credit is surely *reputation*, *authority*, and *familiarity*. These again depend upon systematic advertisement, or, to put it less invidiously, upon "practical instruction."

Spermatogenesis of the Lepidoptera.

IN a letter to NATURE of April 28, p. 568, Prof. J. Brontë Gatenby states his position as to the criticism, made independently by Dr. R. Bowen of Columbia University and myself, of his account of the formation of the macromitosome in the spermatogenesis of Lepidoptera. In doing so he makes a statement that, if I understand it correctly, is inaccurate and is certainly misleading.

The macromitosome is formed by the coalescence of the mitochondrial vesicles. On this point we are all agreed. The mitochondrial vesicles consist of an inner chromophobic or lightly staining material surrounded by an outer layer of chromophilic or deeply staining material. Now, Dr. Bowen and I consider that the coalescence of the mitochondrial vesicles results in "merely larger aggregates of chromophobic material, the chromophilic material running together to form more or less complete partitions between the chromophobic droplets" (Bowen, *Q.J.M.S.*, 66, p. 601). On the other hand, Prof. Gatenby considers that the coalescence consists of the flowing together of the vesicles forming first of all elongated structures and then loops of chromophilic substance which ultimately join up to form a "perfectly coiled spireme" in a mass of the chromophobic substance.

In his letter Prof. Gatenby uses the expression "whether the 'spireme' was formed of a flat ribbon, or a round string." This, presumably, indicates his conception of the difference between our views. If it does not, I have failed to grasp the necessity of this phrase. So far as I am aware, Dr. Bowen has never suggested that the mitosome is formed by the twisting of a ribbon, and I, certainly, have never used the word "ribbon" in this connexion. A mass of soap bubbles cannot be described as made up of a twisted ribbon of soap solution, whereas it can be described as a plate work, and that is the description continually given by Dr. Bowen.

I do not think that the difference between Prof. Gatenby's view and that of Dr. Bowen and myself is of as little consequence as Prof. Gatenby implies in the third paragraph of his letter. If his views as to the formation of the Lepidopteran mitosome are adopted, then the Lepidoptera are unique among all the insects in which spermatogenesis has been described. This is a view that one would hesitate to adopt, especially in view of the fact that practically all other recent workers on the spermatogeneses of all other insects agree more or less closely with the account of the plate-work mitosome of Dr. Bowen. For this reason it became important to confirm, if possible, Prof. Gatenby's description. Dr. Bowen carried out his work on the Lepidoptera especially for this purpose, and came to the conclusion that Prof. Gatenby's interpretation of the process was inaccurate. If, then, Dr. Bowen's account is accepted, the Lepidoptera are brought into line with other insects, and this is certainly an important result. In view of this it seems very unfortunate that Prof. Gatenby has stated that, apart from Dr. Bowen's new interpretation of the sperm tail, "he adds nothing new to our knowledge of the spermatogenesis of the Lepidoptera." He considers the value of Dr. Bowen's work to lie in the fact that it confirms his own drawings of the appearance of the mitosome. After carefully comparing Dr. Bowen's paper with the original paper by Prof. Gatenby (*Q.J.M.S.*, 62, p. 407) I really cannot agree that there is any confirmation whatever. One figure by Dr. Bowen (Fig. 43) superficially resembles a corresponding one in Prof. Gatenby's paper (Fig. 14). Otherwise the figures of the mitosome are totally different in the two papers.

Prof. Gatenby has not answered the criticism that I have made of his original description of the formation of the mitosome. I cannot see how the chromophilic outer surface of a drop—which, of course, has an appreciable area—can, by fusion with another drop, or even by mere elongation, become transformed into a thread-like loop that has no appreciable area. He states merely that the mitochondrial vesicles flow together, "forming, at first, elongated structures, then loops, and finally filaments." I have pointed out (*Q.J.M.S.*, 66, p. 665) that I consider the figures that accompany this description inaccurate and misleading. Further, if such a process does take place, surely it would be possible to observe the intermediate stages, and would not these, in any case, be some sort of plate work? If Prof. Gatenby would enlarge upon his somewhat brief description it might help to clear up the differences between our views.

With regard to the opinion of the late Prof. Doncaster on the formation of the mitosome I should like to add a few remarks. In 1919 I had the privilege of assisting Prof. Doncaster in working out the spermatogenesis of the louse *Pediculus corporis*. We divided the work into two, he dealing chiefly with the chromosome aspect, while I dealt mainly with the cytoplasmic inclusions. At first Prof. Doncaster was inclined to believe that the mitosome was formed in the manner described by Prof. Gatenby, and, in fact, in the original notes, which I now possess, there are rough drawings by Prof. Doncaster figuring the mitosome as a spireme. I could not accept this view, and explained my conception to him. Ultimately he agreed with me, and it was at this time—about May or June—that he paid the visit to Prof. Gatenby, and objected to the latter's description of the mitosome of Smerinthus. However, that he was quite prepared to accept Prof. Gatenby's description is shown by the fact that in his last book on cytology he gives Prof. Gatenby's account in full and does not, I think, refer to our own observations on Pediculus.

The Rodier System of Rat Repression.

In connexion with the article on "The Rat and its Repression," contributed by me to Nature of May 20, 1922 (vol. 109, p. 659), I have been favoured with a letter from Mr. Wm. Rodier of Melbourne, in which he complains that my attitude to his system of rat repression is unsympathetic, or that, conversely, he is misunderstood.

I should esteem it a favour if you would allow me to say that I am not unsympathetic to any means of destroying the rat—an animal which I, at least, consider to be one of the greatest menaces of modern civilisation.

The attitude I take to the "Rodier Method" of rat destruction is that its principles are so thoroughly understood by all who have studied the rat problem that I am conscious of no unfairness when I suggest Mr. Rodier harms his cause when he asserts that those who do not immediately and unreservedly become his disciples are necessarily antagonistic, or stupid.

The difficulties Mr. Rodier has to overcome are such as are presented by the attitude of authorities towards putting rats back by rat-catchers who are paid to destroy their catches; the attitude of business houses when they pay for rat-clearing and find male rats turned back; and the plight of boroughs who make it their business to destroy female rats, when they find their polygamous males mated by females from contiguous boroughs where the "Rodier Method" is not in operation.

The whole question is one of education, and my immediate object is to convince the public that the rat is one of man's most dangerous foes, and one that is too expensive to maintain. As for the Rodier method, I have an open and sympathetic mind; and I would suggest that it would help Mr. Rodier's propaganda enormously if he could show us good results that could be scientifically checked, say in an island like Tristan da Cunha, or the Isle of Man. The authorities in the former island, where I am assured rats climb trees, would doubtless welcome assistance to overcome their terrible foes.

Active Hydrogen by Electrolysis.

In 1907 Fischer and Massenez (*Z. anorg. Chem.*, 52, 202, 1907) obtained a concentration of 17 per cent. by weight of ozone when they electrolysed a solution of sulphuric acid, using a very high current density. Since ozone can be produced by this method, it would seem probable that a high current density at the cathode might aid in producing the ozone form of hydrogen. When a solution of sulphuric acid is electrolysed, using the above principle, the hydrogen that escapes at the cathode contains an active constituent which combines with pure nitrogen to form ammonia. Some of the ammonia formed is collected in the absorption bulb, but quite a large portion of it remains dissolved in the sulphuric acid solution. This active constituent in the hydrogen that is evolved at the cathode is probably the ozone form, and is produced perhaps in a manner analogous to the ozone form of oxygen. The per cent. of the active gas formed varies with the current density and the concentration of the acid.

Likewise, if a solution of potassium hydroxide is electrolysed, using a high cathode current density, the escaping hydrogen contains the ozone form which combines with pure nitrogen to form ammonia.

In the electrolysis of the acid solution the escaping hydrogen contains a fog which persists after passing through the absorbing solution. This fog is similar to, but less dense than, the fog sometimes produced by ozone when it is bubbled through potassium iodide solution.

This work is a further verification of the theory of Dr. G. L. Wendt that tri-atomic hydrogen may be produced wherever atomic hydrogen is formed.

The Low-power Aeroplane or Aviette.

By Prof. L. Bairstow, F.R.S.

MUCH attention is being paid in the general and technical press of this and other countries to flight with low-powered engines. The addition of small engines follows quickly on the gliding successes of the past year, but no marked connexion is discernible between the new features of the two types of flying machine. The change from aeroplanes having two or three hundred horse-power, and carrying a single individual, to aeroplanes of five to ten horse-power is now so striking as to have stirred public imagination. Many of those now interested are probably unaware of the flights made by A. V. Roe more than ten years ago with a nine horse-power J.A.P. engine.

There is little in the new applications which would warrant the use of the word discovery, and the change is probably due in large measure to an emancipation from the fetters of war ideas. There is reason to suppose that aeroplanes designed for official use are subject to so many restrictions that development is difficult. The advent of the low-power aeroplane is therefore welcomed as a new outlet for ideas, one which gives scope to individual initiative, and one which it is hoped will make a popular appeal.

The unofficial character of the British development of the aviette is emphasised by the offering of a prize of 500*l*. by the Duke of Sutherland for a light aeroplane of British manufacture and design; for the Duke is Under Secretary of State for Air, though he is not acting in his official capacity. A separate prize of 1000*l*., open to the world, is offered by the *Daily Mail*. The most striking conditions of the competition are: "The power unit must not exceed 750 cc. total cylinder capacity, and the prize will be awarded to the machine which flies the longest distance on one gallon of petrol, with a minimum distance of fifty miles to qualify."

Many other conditions apply which relate to ease of handling on the ground; there is also the usual vague reference to stability. It is in accordance with our present state of knowledge and application that, while the requirements for performance are always precise and well-defined, those for stability and control are valueless. In the competition rules for the low-power aeroplane there is neither definition nor means of checking aircraft as delivered in order to ensure a due measure of stability and control.

The French are, as is usual in matters relating to aviation, taking an active interest in the aviette, and in the *Times* of April 6 we find an article based on a flight by M. Barbot from Francazal to Toulouse in a seven horse-power aviette. The ideas of the flyer appear in the following quotation:

"M. Barbot, who is in Paris, expresses the belief that his aviette is the forerunner of the aero-taxi of the immediate future. He contemplates the production of a machine which will cost about five thousand francs (nominally 200*l*.), which can rise from almost anywhere and, furnished with a ten or fifteen horse-power motor, can land slowly within thirty yards of its objective and without any risk. . . . The cost will be only that of a gallon of petrol per hundred miles."

In the same issue of the *Times* is a reference to a British "power-driven glider":

"The test began yesterday at Ashton Park, Preston, of the first British auxiliary-engined glider, the Wren, designed and built by the English Electric Company at their Preston works. It is expected that the machine will provide valuable data on which to base the development of the economical aeroplane of the future. It has been constructed for the Air Ministry. It is remarkably light, being about 3 cwt., and the dimensions are: span 37 ft., length 23 ft., height 5 ft. The engine is a three horse-power A.B.C. motor-cycle engine, developed to seven horse-power, and gives a maximum speed to the aviette of forty-eight miles an hour. . . ."

These two extracts exhibit the features which define the low-power aeroplane, and in the remainder of this article it is proposed to analyse the projects and achievements in relation to the scientific knowledge involved. It will be found that the expectation of 100 miles per gallon of petrol in an aero-taxi carrying pilot and passenger is optimistic but not wildly in excess of what can be immediately foreseen, using arguments based on well-established data. On the other hand, risk is only incidentally reduced, and neither the extracts nor current technical literature show any attempt on the part of the designers of light aeroplanes to pay special attention to the fundamental problems of stability and control.

For the past eight or ten years it has been realised that all good aeroplane design tends to produce a result in which, for the most economical speed of flight, the weight carried is about nine times the resistance experienced. All high-power aeroplanes are able to exceed this most economical speed very greatly, with the result that at their maximum speed near the ground the resistance is more than one-quarter of the weight. If there be no great reserve of power, considerable height above the ground is unattainable, and the most economical speed is fixed by the design of the aeroplane, in particular by the magnitude of the load carried per unit area of wing surface. A common loading has been 7-8 lb. per sq. ft. corresponding with an economical speed of about 60 miles per hour; a reduction of loading to 2 lb. per sq. ft. would bring the best speed to about 30 m.p.h.

If the making of a specified journey be the basis of comparison, then speed in itself has no influence on petrol consumption per unit of weight carried, but the horse-power required is directly proportional to the speed. Indirectly, low speed is advantageous, since a smaller and light engine suffices for transport. Taking figures given in the Press as a basis, it appears that the aviette with a single occupant would weigh about 550 lb. all told, whereas the single-seater fighting craft weighs from three to four times this amount. The maximum speed claimed for the aviette is only about one-third of that achieved by the scout.

Further data lead to an estimation of a probable mileage per gallon of petrol. Many aero-engines exist in which the petrol consumption does not exceed 0·5 lb.

of petrol per brake horse-power per hour, and it is probable that an airscrew efficiency of 75 per cent. may be reached. With petrol weighing about 7 lb. to the gallon it will be found from those figures and a weight-resistance ratio of 9 that the number of miles possible per gallon of petrol consumed is roughly equal to thirty thousand divided by the weight of the aeroplane. To achieve 100 miles to the gallon, therefore, it would be necessary to improve on existing figures for performance, since a gross weight of 500 lb. yields only 60 miles per gallon. As an aero-taxi with pilot and passenger would weigh more than 500 lb. it would appear that M. Barbot's estimate is not to be easily achieved.

It will be noted, however, that the condition of a minimum of 50 miles per gallon in the competition rules for the Duke of Sutherland prize is reasonable. It will exclude seriously inefficient design without setting an impossible task.

In making the preceding calculations, no allowance was made for the use of energy obtained from the wind itself. As we all know, aeroplanes without engines, *i.e.* gliders, have maintained themselves in the air for several hours consecutively, utilising winds deflected upwards by a sloping hill-side. Up-currents of sufficient intensity for support are very local, and we are yet far from being able to use them for point-to-point journeys as distinct from tacking backwards and forwards in a chosen locality. The phenomenon of gliding, as we know it, does not modify the estimate of power already made, but does show how part of that power may be obtained from the wind. Langley contemplated the extraction of energy from the pulsations of the wind, quite apart from their direction, and this source of energy is probably very widely distributed. So far, however, little, if anything, has been attempted in practice in the extraction of this energy, and there is no clear lead as to the direction in which one might hopefully proceed.

For some time to come, it may be expected that the aviette will carry the main source of power for its support; economy of fuel may be obtained by utilising up-currents in the neighbourhood of flight and so using the engine in passing from hill crest to hill crest. The condition attached to the Duke of Sutherland prize that the competition is to take place over a triangular course of not less than 15 miles reduces the chances of obtaining substantial amounts of energy from the atmosphere.

Since a claim for reduction of risk has been made, it may be as well to state the view that the only contribution made to safety is in the sense that it is less dangerous to strike the ground at 30 m.p.h. than at 60 m.p.h. The inherent defects of the modern aeroplane which make for danger on stalling are quite untouched by the new application.

The low-power aeroplane can scarcely fail to react beneficially on scientific knowledge and its applications. At the moment, however, it would appear that the aviette has derived its being from knowledge obtained for other purposes and has not reached the stage of reciprocation.

[Since this article was written, a very definite advance in the practical use of the low-power aeroplane has been made by M. Barbot, who, as was recorded in our issue of May 12, p. 645, succeeded in completing the round trip from the French coast to Lympne in Kent and back again, covering about 80 miles, in a machine with a 15 h.p. engine. His time for the journey was about two hours and a quarter, including nearly half an hour's stay at Lympne, and it is stated that his petrol consumption was about two gallons.]

The Earth's Electric and Magnetic Fields.[1]

By Prof. W. F. G. Swann, University of Minnesota.

II.

Two of the most characteristic features of the earth's magnetism are the non-coincidence of the magnetic and geographic axis, and the secular variation. While a theory which is to claim any degree of completeness must account for these, one cannot resist the temptation of searching for any sort of phenomenon capable of giving a field of the order of magnitude of the earth's field in the hope that if such be found it may serve as a possible basis on which to build a more complete theory.

Attempts towards a theory of the earth's magnetism may be classed roughly in the following four groups:

(1) The earth is assumed to be made largely of iron, and to be a permanent magnet independently of its rotation, or to be magnetised inductively by an external field.

(2) The magnetic field is brought about by the rotation of an electrostatically charged system.

(3) The magnetic field arises from a state of magnetisation brought about by the rotation of the earth.

(4) The field is caused by electric currents circulating within the earth.

The high temperature of the earth's interior would be inconsistent with a state of permanent magnetisation unless the effect of high temperature is compensated in some way by that of high pressure. Induced magnetisation suffers from the same cause, and would, moreover, give a type of field totally unlike the earth's field.

As regards (2), a sphere of the earth's size, rotating with the earth's angular velocity, would have to possess such a surface charge as would give it a potential gradient a hundred million times the earth's potential gradient in order that the rotation of that surface charge would produce a magnetic field comparable with the earth's magnetic field. Even then, it turns out, as has been shown by Schuster and by the writer, that owing to the effect of the observer's motion with the earth's surface, a sign of charge which gave the right direction for the vertical component would give the wrong direction for the observed horizontal component.[2]

[1] Continued from p. 642.

[2] Inclusion of the effect due to the atmospheric positive charge annuls completely the magnetic field which would be observed by one moving with the earth.

The difficulties arising from the large electric field, and from the inconsistency in sign between the horizontal and vertical components may be avoided, at first sight, by supposing, with Sutherland, that the earth may be regarded as two superposed spheres of positive and negative electricity, the diameter of the negative sphere being greater than that of the positive. The electric field at external points would be zero, but the magnetic field would not be zero. The actual density of positive and negative electricity in the earth is so great that, if all the positive and negative electricity in a cubic centimetre could be concentrated at two points one centimetre apart, they would attract each other with a force of the order 10^{20} tons; and, on account of this, it is only necessary for the radii of the two spheres of the size of the earth to differ by 2×10^{-8} cm. (the diameter of a single molecule), in order to ensure that the two, rotating together, would give rise to a field of the order of magnitude of the earth's field. Unfortunately, however, we find that the electrostatic forces opposing even this small separation are enormous, amounting to more than one thousand million volts per centimetre at the surface of the inner sphere.

Regarding forces which suggest themselves as possibly available for causing electrostatic separations of the above or allied kinds, we have, in the first place, gravity, tending to pull the free electrons towards the earth's centre, then centrifugal force tending to make them fly to the surface. Another possibility arises from an action analogous to the Thomson effect, by which the electronic density tends to decrease as we descend towards the earth's centre, on account of the increase of temperature. These effects have been submitted to calculation by the writer, and it appears that the first gives rise to a field only 10^{-21} of the earth's field, and in the wrong direction, the second to a field about 10^{-23} of the earth's field, but of a type widely different from that of the earth, and the third to a field in the right direction but amounting to only 10^{-17} of the earth's field.

As a general rule, we may say that it is practically hopeless to seek an explanation of the earth's magnetic field on the basis of the rotation of charges which have been separated against electrostatic attraction, since the mechanical forces necessary to produce the requisite separation must be, in all cases, enormous.

If the earth were made mainly of iron, its rotation would, by gyroscopic action, bring about a partial orientation of the molecular magnets; and it has been experimentally demonstrated by S. J. Barnett that iron can be magnetised in this way. The effect in the case of the earth is, however, extremely small, and is only sufficient to account for a magnetic field 2×10^{-10} times that of the earth.

The suggestion has been made that the interior of the earth may be endowed with enormously high permeability, and that, in consequence, a very weak force would be sufficient to cause strong magnetisation therein. We must remember, however, that the very creation of a state of magnetisation within a sphere brings about an internal demagnetising field which is, as a matter of fact, equal to the external field at the equator. Hence any primary magnetising agent which is to be ultimately responsible for the earth's field must be of such intensity that it will produce, on the molecular magnets, forces at least equal to the forces which would be produced on them by a magnetic field equal in intensity to the earth's magnetic field at the equator.

Any theory attempting to account for the earth's magnetic field on the basis of currents circulating within the earth, calls for some explanation of the electromotive force wherewith to produce the currents. In this connexion it is of interest to recall a calculation by H. Lamb, to the effect that if currents were caused to circulate in a copper sphere of the earth's size, and the electromotive forces which caused them were removed, the currents would take ten million years to decay to one-third of their initial values. Attempts to account for the earth's field in this way have met criticism on the basis of the enormous currents which would be calculated by extrapolation back, even to epochs not more remote than those during which the earth's crust has been solid, so that, unless there is some reason for supposing that the conductivity is, or has been, in the past, even greater than copper, we are confronted with accounting for the enormous amounts of energy necessary to have produced the field initially.

The actual current density within the earth necessary to account for the earth's field is very small, being, for example, of the order 10^{-8} ampere per square centimetre on the surface at the equator for the case where the current density is proportional to the distance from the axis of rotation. If, taking a sphere of iron, we assume about 10^{23} free electrons per c.c., it is only necessary to suppose that the mean velocity of the electrons at the earth's surface, relative to the centre, differs from that of the periphery by one part in 7×10^{16} in order to account for this current. It is, perhaps, not too much to hope that a fuller knowledge of the mechanism of conduction in solids than we have at present may lead to an explanation of such a small difference as arising directly on account of the earth's rotation.

There is always the chance that the origin of the earth's field may have to be sought in some fundamental but small departure from the ordinary electrodynamic laws. In this connexion we may recall Lorentz's theory of gravitation, according to which gravitational forces may be accounted for by supposing that the attraction between two unlike units of charge is different from the repulsion between two like units. Paying due regard to the care necessary in defining electrical neutrality in this case, the theory may be shown to lead to the conclusion that, in order that the free electrons in a body shall be in equilibrium, the body must acquire a charge density to an extent not wholly determined by the weight of the electrons. Schuster has discussed the possibilities in this regard, but it would appear that, under the most favourable assumptions, the density would be insignificant as regards producing, by its rotation, a magnetic field comparable with the earth's field.

A greater measure of success is attained by making a somewhat similar assumption concerning the magnetic field produced by a moving charge. We first observe that a magnetic field is ultimately measured in terms of the force which it exerts on a moving electron; for even a material magnet which may be used in the measurement derives its properties from electrons rotating within it. In analogy with the case of electrostatics, where we have to deal with the forces produced by positive on positive, negative on negative, and positive on negative, we have, in addition, for moving electrons, the force due to the motion of a positive electron on a moving positive electron, the force due to the motion of a moving negative electron on a moving negative electron, the force due to the motion of a negative electron on a moving positive electron, and the force due to the motion of a positive electron on a moving negative electron. The first two of these four may be taken as the basis for defining the measures of the two types of magnetic fields produced by positive and negative electrons respectively. If, for similar motions, these four forces are all equal, a moving electron, or a magnet, would be entirely unaffected by the rotation of the earth as a whole.

If, however, the forces, due to motion, between unlike moving charges are suitably different from those between like charges in the same states of motion, it will immediately appear that the electrically neutral earth will, by its rotation, produce those forces on magnets and moving electrons which we associate with a magnet as ordinarily defined. By making the forces between electrons of like sign equal for both signs, the force due to the motion of a negative electron on a moving positive electron greater than, and the force due to the motion of a positive electron on a moving negative electron less than the forces between like electrons to the extent of about two parts in 10^{19}, we can account for the equivalent of a magnetic field of the order of magnitude of the earth's magnetic field. If we wish to combine these alterations with suitable alterations in the electrostatic forces, we can also include gravitation in the complete scheme.

The secular variation presents interesting problems for speculation. There is some evidence for the belief that the earth's magnetic axis rotates about the geographic axis once in about 500 years. This will result in induced currents, and the field we observe will be that due to these induced currents (the secondary field), and that due to the primary causes (the primary field). Taking an iron sphere of the earth's size for purposes of illustration, it works out that the flux of the secondary field through the sphere, which is, of course, related to that of the primary field, is of such magnitude as to annul almost completely the non-axial component of the primary flux, leaving only a small residual non-axial component, which lies, moreover, perpendicular to the primary non-axial component. Thus, in order that the resultant flux shall have an appreciable inclination to the geographic axis, it is necessary for the primary axis to lie very near to the equatorial plane, and yet for the primary flux to be so large that its axial component, which is small compared with it, represents the axial component which we observe. This example is given merely to illustrate the important rôle which might be played by the induced currents due to the secular variation in case the earth's interior had a conductivity comparable with that of iron.

The theory of the diurnal variation is in a better position than that of the earth's field as a whole. The suggestion of Balfour Stewart, developed in detail by Schuster, to the effect that the diurnal variations are caused by Foucault currents generated in the upper atmosphere by the tidal motion of the atmosphere across the earth's lines of force, seems well adapted to fit the facts, its chief difficulty being that it calls for a conductivity about 3×10^{11} times that found at the earth's surface. Various agencies have been invoked to account for this conductivity, namely, ultraviolet light, gamma rays, negative electrons, and alpha rays, from the sun, and finally charged atoms of gas, shot out from the sun by the pressure of light, and endowed thereby with velocities sufficient to give them the properties of low energy alpha particles. The corpuscular radiations have also been invoked to account for the phenomena associated with the aurora.

It is probable that ultraviolet light plays no important rôle, since it is capable of accounting for a conductivity less than one-millionth of the conductivity required. As regards the corpuscular radiations, the nature of the precipitation of corpuscles indicated by the aurora is of a type to correspond to a bending by the earth's magnetic field such as one would not readily associate with particles of mass as small as that of electrons. The mass of an electron increases with its velocity; but, so greatly has Birkeland found it necessary to draw upon this phenomenon in order to fit the facts, that, on the hypothesis of negative electrons, he is driven to assume velocities ranging from 400 metres per second less than the velocity of light to 4 metres per second less than that limit. Alpha particles have a mass and energy which would be better adapted to account for the aurora, as has been pointed out by Vegard; moreover, the definiteness of their range ensures the characteristic feature of the sharp boundary of the luminescence, and the magnitude of the range is fully sufficient to account for the penetration of that boundary to the altitudes observed.

The remarkable perturbations of the earth's magnetic field known as magnetic storms, which occur most frequently in association with high solar activity, suggest the entry into our atmosphere of electrified corpuscles during these periods, and it is natural to look to those corpuscles which are responsible for the conductivity and the aurora for an explanation of these storms. While alpha rays have been suggested, some of the difficulties inherent in the assumption may be gathered from considerations put forward by Lindemann. On the assumption of their production by alpha rays, these storms would call for an incredibly large amount of radioactive material in the sun. Again, a conical beam of alpha rays, such as appears to be necessary to account for the storms, would, on its journey here, suffer, by self-repulsion, an acceleration of about 10^{13} cm./sec.^{2} at its boundary, in such a sense as to make it spread, so that it could never arrive as a beam. Finally, even if the beam could reach our atmosphere, it would charge it at such a rate that the repulsion due to the charge which had arrived would, in a few seconds, attain a value sufficient to prevent the entry of any more rays.

It is for reasons such as these that Lindemann has been led to favour the view that the primary agencies responsible for magnetic storms are atoms of gas, ionised by the high temperatures in the solar prominences, and shot out of them by the pressure of the sun's radiation. He shows, moreover, that the velocities to be expected in these circumstances are such as to give the particles ranges in harmony with the requirements of auroral phenomena.

The Tercentenary of Sir William Petty.

OF the founders of the Royal Society, Wilkins was born in 1614, Goddard and Seth Ward in 1617, Evelyn and Bathurst in 1620, Willis in 1621, and Petty in 1623. Boyle and Wren were somewhat younger, being born in 1627 and 1632 respectively. Petty, whose tercentenary occurs on May 26, was thus thirty-seven years of age when the Society was inaugurated, and had already given evidence of great administrative powers. Unlike most of his fellow scientific workers, his education was gained mainly on the Continent, and he was a man of twenty-four or twenty-five when first he settled at Oxford. He was born at Romsey in Hampshire, the son of Anthony Petty, a clothier, and as a boy attended the Romsey Grammar School. From there at the age of fifteen, with a consignment of his father's goods, he crossed to France, where he entered the Jesuit College at Caen, apparently maintaining himself by the sale of his father's merchandise.

From Caen, Petty returned home, served for a short time in the navy, but at the outbreak of the Civil War went abroad again, spent some time at Utrecht and Amsterdam, and in 1644 matriculated as a student of medicine at Leyden. He is next found in Paris, becoming known to Hobbes, Sir Charles Cavendish, and other English refugees, and attending the meetings of Mersenne, from which ultimately sprang the Paris Academy of Sciences. Once more at home he took up his father's business, invented a process for duplicating letters, and in 1648 published his tract on education, "Advice to Mr. Samuel Hartlib, for the Advancement of Some Particular Parts of Learning." He proposed the establishment of a College of Tradesmen, with botanical theatre, observatory, etc., the members of which "would be as careful to advance arts, as the Jesuits are to propagate their religion."

Petty next removed to Oxford, where he was able to associate with the philosophers who during those troublous times kept the lamp of science burning. Many of the meetings which Wilkins and Boyle frequented were held at Petty's lodgings. In 1649 he took his doctor's degree in physic, and a year or two later became professor of anatomy.

From Oxford Petty was now sent by the Commonwealth Government to Ireland as physician general to the forces, where he quickly added to his reputation by reorganising the medical services. The terrible massacres of 1641 had by this time been ruthlessly avenged by Cromwell, and all who could not prove "consistent good affection" to the English Government were to be dispossessed of their lands. This resulted in some 3000 native landowners losing their property. To Petty was given the task of measuring and surveying the forfeited estates. His survey, which has been described as the first attempt to carry out a survey on a large scale and in a scientific manner, is curiously known as the "Down Survey" because it was measured "down" on maps. Besides this, Petty also made a map of Ireland, completed about 1673, largely at his own expense. By his work in Ireland Petty himself gained considerable estates in Kerry and later on set up ironworks, opened lead mines and marble quarries and started a timber trade. His duties were not carried through without gaining for him many enemies, and in the last Parliament of the Commonwealth he was impeached and for a time his fortunes hung in the balance.

With the Restoration, Petty, who disliked extremists of all parties, was received favourably by Charles II. and was confirmed in the possession of his Irish estates. He now was able to resume the society of his scientific friends, and he was present at Gresham College on November 28, 1660, when the Royal Society was formed. He became a member of the first council and often contributed papers to the Proceedings of a practical nature. He is several times mentioned in connexion with the subject of shipping, and in 1662 made some stir by the mention of a double-bottomed or twin-hulled boat which would go against wind and tide. A ship constructed to his plans made two voyages between Dublin and Holyhead and was then wrecked. The idea has been put into practice several times since the days of Petty, notably so in the case of the channel steamer *Calais-Douvres* constructed in the 'eighties of last century. At one meeting of the Royal Society Petty "was intreated to inquire in Ireland for the petrification of wood, the barnacles, the variation of the compass, and the ebbing and flowing of a brook." Among his other services to the science of his day was the part he took in the foundation of the Dublin Philosophical Society in 1684, of which he was president. He drew up for the Society a "Catalogue of mean, vulgar, cheap and simple experiments," and among his advice to the members was "that they carefully compute their ability to defray the charge of ordinary experiments fforty times per annum, out of their weekly contributions, and to procure the assistance of Benefactors for what shall be extraordinary, and not pester the Society with useless or troublesome members for the lucre of their pecuniary contribution."

Petty was full of worldly wisdom and possessed what Benjamin Martin called a "universal practical genius." One result of this was that he died a very rich man. But at a time when such studies were rare he wrote on taxes, revenue, the origin of wealth, trade, population, and the growth of cities. It is on his work as a political economist that his reputation rests. He condemned the farming of the revenue of Ireland, suggested free commercial communication between that country and England, and consistently urged upon the Government the necessity of a department for the collection of statistics. He co-operated with John Graunt, another original member of the Royal Society, in the production of a book entitled "National and Political Observations . . . made upon the Bills of Mortality," published in 1662, which may be regarded as the first book on vital statistics ever published.

A tall handsome man, Petty was known among his fellows for his unusually good temper. Evelyn said of him "there was not in the whole world his equal for a superintendent of manufacture and improvement of trade, or to govern a plantation," and Pepys refers to the charm of his society. Knighted by Charles in 1661, Petty in 1667 married a daughter of Waller the regicide, and was survived by three children. He twice refused a peerage, but his widow was created Baroness Shelburne. He died in Westminster on December 16, 1687, and was buried in the Abbey Church at Romsey.

Obituary.

Prof. E. W. Morley.

In the issue of *Science* for April 13, appears an appreciative notice by Prof. O. F. Tower, professor of chemistry in Western Reserve University, of the life and work of Prof. E. W. Morley, whose death was announced in Nature for April 28, p. 578.

Edward Williams Morley was born in Newark, New Jersey, on January 29, 1838, and in 1869 went to Western Reserve College, then in the town of Hudson, as professor of natural history and chemistry. In 1882 the College was moved to Cleveland, becoming Adebert College of Western Reserve University, and there Prof. Morley taught general chemistry and quantitative analysis until his retirement in 1906 as emeritus professor.

Prof. Morley's first work of importance, undertaken while he was still in Hudson, was on the relative proportion of oxygen in the air (1878–81). The work for which he is best known to chemists, however, was on the densities of oxygen and hydrogen and the ratio in which they combine; this was carried out at Cleveland and published in 1895. It is a remarkable tribute to his work that now, after nearly thirty years, the accepted values of these quantities are practically identical with those found by him. Prof. Morley was also eminent as a physicist, and his characteristic for precision of measurement is shown in his early papers on rulings on glass and on the probable error of micrometric measurements. While at Cleveland, he collaborated with Prof. A. A. Michelson in the development of the interferometer, and with this instrument the well-known Michelson-Morley experiment on the relative motion of the earth and the ether was carried out. The experiments, though giving negative results, were resumed later in conjunction with Prof. D. C. Miller.

The accurate work on the determination of the relative atomic weights of hydrogen and oxygen won for Prof. Morley the Davy medal of the Royal Society in 1907; while in 1904 he had been elected an honorary fellow of the Chemical Society. He was also an honorary member of the Royal Institution. In the United States he received the honour of being made president of the American Association and of the American Chemical Society in 1895 and 1899 respectively. He died on February 24, about a month after his eighty-fifth birthday.

Sir Shirley Murphy.

Shirley Murphy's name during the last thirty years has been a household word in the ranks of public health workers; and his work as medical officer of health for the county of London during a period of twenty-two years was marked by great improvements in the administrative control and prevention of disease. From this post he retired a few years before the War, but at its onset his services were utilised in taking charge of the sanitary services of the London area, for which work he was created K.B.E. in 1919, having been previously knighted in 1904.

It is, however, rather in Sir Shirley Murphy's contributions to the science of epidemiology that Nature is chiefly interested. The factors making for or reducing the prevalence of such acute infectious diseases as scarlet fever, diphtheria, measles, and whooping-cough are complex; they differ from such diseases as typhus fever, typhoid fever, cholera, small-pox, and epidemic enteritis, which can be entirely controlled, given the adequate application of general and specific sanitation. Like the uncontrolled and only partially controllable diseases enumerated above, the members of this last-named group are subject to cyclical waves, seasonal and longer waves; but the vehicles of infection can be put out of action, or by vaccination in the case of smallpox, personal immunity is obtainable. Murphy made many contributions in his annual reports and in the Proceedings of the Epidemiological Society to the study of seasonal influences on scarlet fever and diphtheria, showing that there have been in London seasonal variations in both the fatality (*i.e.* case-mortality) and age distribution of notified cases of these diseases. The cases of these diseases at ages under five form a larger proportion of the total cases at the beginning and end of the year than in its middle; and even when the necessary corrections are made for variations in age and sex of the cases, the fatality from these diseases is subject to seasonal variations. Murphy advanced the view that the change in the age incidence of death-rates from phthisis is explicable by successive additions by birth of a more resistant race, a tenable hypothesis, though not supported by international facts as to the phthisis death-rate.

The presidential address delivered by Murphy to the Epidemiological Society on "The Study of Epidemiology" is perhaps the best illustration of his wide knowledge and keen interest in epidemiological problems. At the same time it shows very clearly the complexity of factors making this study a formidable struggle with difficulties. He did much to assist in laying the foundations of a more accurate science of epidemiology; and in the pursuit of this study his annual reports to the London County Council will always be a valuable mine of information.

Murphy's work was recognised by his own profession, for he was awarded the Jenner medal by the Royal Society of Medicine and the Bisset Hawkins medal for distinguished services to public health by the Royal College of Physicians. His personality was singularly attractive; modest and unassuming, he was always ready to help his colleagues, and generous in his appreciation of their work.

Mr. Joseph Wright.

The death of Joseph Wright of Belfast on April 7, at the age of eighty-nine, removes one of the fine old school of naturalists whose interests were bounded only by the earth itself. Though prolonged attention to specific details might have seemed to outsiders a sign of a mind cabined and confined, Wright's enthusiasm over the sheer beauty of the organisms that he studied was an inspiration to the wide circle of his friends.

Joseph Wright was born at Cork in 1834, and, his parents being members of the Society of Friends, he was educated at the Friends' School in Newtown, Co. Waterford. His wife came also from Cork City, and, when he settled in business in Belfast in 1868, he brought the healthy and tolerant atmosphere of his upbringing to his new surroundings in the north. For a very long period of years Wright's daylight hours had to be at the disposal of firms for which he worked, and only on occasional holidays could he make excursions into the country. He was a warm supporter of the Belfast Natural History and Philosophical Society and of the Belfast Naturalists' Field Club. During his years in Cork he had made a fine collection of Carboniferous fossils, which is now in the British Museum; in Belfast he devoted himself mainly to the study of foraminifera, fossil and living, and was especially successful in extracting forms preserved in hollow flints or in friable chalk from the Cretaceous beds of northern Ireland. He was able to recognise forms derived from these beds in detrital deposits of the district, and he remained convinced that the occurrence of Pleistocene foraminifera in the glacial deposits studied by him necessarily implied an incursion of the sea over northern Ireland.

Wright joined, as a recognised expert, dredging expeditions in the Irish Channel and off the western coast, the latter being organised by the Royal Irish Academy. His judgment became sought by naturalists throughout our islands and abroad, and many of his correspondents, while appreciating the fulness of his knowledge, must have remained ignorant of the life of hard work and devotion in the intervals of which his researches were carried on. Those who became personally acquainted with him in his home could not fail to recognise his truly lovable personality.

Wright was elected a fellow of the Geological Society of London in 1866, and in 1896 received the honour of the award of the proceeds of the Barlow-Jameson fund. He contributed numerous papers to scientific journals, and his unique collection of foraminifera, mounted by his own hand, is now among the treasures of the National Museum in Dublin.

An excellent account of Wright's life and work, to which we are indebted for some of the details given above, appeared in the *Belfast Telegraph* for April 7.

Mr. Sidney H. Wells.

Mr. Sidney H. Wells, who died at St. Leonards on March 28, was formerly Director-General of Technical, Industrial, and Commercial Education in Egypt. Born in 1865, he was educated for the engineering profession at Birkbeck and King's College, London, and in 1885 he won a Whitworth Scholarship. Four years later he founded the Institution of Junior Engineers, of which he was chairman for five sessions. In 1889 he became a master at Dulwich College on the science and engineering side. Two years later he removed to the University of Leeds as senior assistant in the engineering department, and in 1893 he returned to London at the age of twenty-eight to become the first principal of the Battersea Polytechnic.

In 1906 Mr. Wells was requested by Lord Cromer to visit Egypt and report on technical education, certain branches of which had been previously entirely neglected. As a result of this visit, Mr. Wells was offered in 1907 the newly created post of Director-General of Technical, Industrial, and Commercial Education, a position which he held until his retirement eighteen months ago owing to continued ill-health. His fifteen years' work in Egypt was that of a pioneer, and the agricultural, commercial, and industrial schools which are to-day flourishing in all the larger towns of that country and in many of the provinces owe their existence entirely to Mr. Wells's untiring energy and far-seeing wisdom.

For his War work as Director of Civilian Employment for the Egyptian Expeditionary Force in 1917–19 Mr. Wells was made C.B.E.; he was twice mentioned in despatches, and held the second-class orders of the Medjidieh and the Nile. He was vice-chairman of the Egyptian Commission of Commerce and Industry, 1916–18.

Mr. Wells was an Assoc. M.I.C.E. and an original member of the Faculty of Engineering of the University of London, of which he was afterwards secretary, and also secretary of the Board of Studies. He was formerly a member of council of the Headmasters' Association, a member of council and for four years honorary secretary of the Association of Technical Institutions, and a member of the Examinations Board of the City and Guilds Institute, of the Teachers' Registration Council, and of the Consultative Committee of the Board of Education. He was the author of various text-books.

General E. A. Lenfant.

By the death of General E. A. Lenfant at the age of fifty-eight, France has lost one of the most noteworthy explorers of her African empire. He began his work in Africa in 1898, when he studied the course of the Senegal, and later the floods of the Niger. In 1901–2 he twice traversed the middle and lower Niger, passing the rapids successfully and collecting much useful information on the regime of the river and the geography of its valley. In 1903 Lenfant was again sent to Africa to investigate the possibility of water transport from the coast to Lake Chad. On this occasion he explored the Logone, a tributary of the Shari; the Kabi, a tributary of the Benue; and Lake Tuburi, which lies between the two. Between 1906 and 1908 Lenfant's explorations were in the western part of the Ubanghi-Shari country, around the head waters of the Shari. He showed that the Bara-Shari is a branch of the Shari, and that the Pende, which is the same as the Logone, provides the best route from the Sanaga to the Shari, and so to Lake Chad. Lenfant was the author of several works on Africa, including "Le Niger" (1903), "La grande route du Tchad" (1905), and "La découverte des grandes sources du centre de l'Afrique" (1909).

We regret to announce the following deaths:

Prof. J. Cox, lately professor of physics in McGill University, Montreal, on May 13, aged seventy-two.

Dr. G. H. Hume, for many years lecturer on physiology in the University of Durham College of Medicine, Newcastle-upon-Tyne, on May 8, aged seventy-seven.

Prof. C. Niven, F.R.S., lately professor of natural philosophy in the University of Aberdeen, on May 11, at seventy-eight years of age.

Colonel G. F. Pearson, formerly Inspector-General of Forests in India, on April 25, aged ninety-six.

Lieut.-Colonel J. C. Robertson, according to the *Times*, director of hygiene and pathology at Army Headquarters, Simla, and in 1912 sanitary commissioner with the Government of India, on May 14.

Current Topics and Events.

THE director of the Royal Botanic Gardens, Kew, undoubtedly does a public service when he forces upon the attention of the House of Commons and the general public the undesirable results that may follow from the thoughtless lack of control of smoke production in neighbouring industrial suburbs. There can be no doubt that heavy deposits of soot such as are borne by the evergreens at Kew are clear indication of atmospheric contamination which will markedy lower the vitality of the plants in the Gardens and in some cases may actually prevent their successful cultivation. When smoke particles are so numerous gaseous contamination with sulphurous acid is to be feared, and the evidence is conclusive that these acid impurities directly injure green foliage at the same time that their accumulation in the upper layers of the soil may injure root growth. The experimental results obtained by Drs. Crowther and Ruston and their colleagues in the agricultural department of the University of Leeds have supplied convincing examples of the extreme consequences that may follow industrial pollution in an industrial area, and the Kew authorities are wise in directing public attention to the danger before it has reached more serious proportions. At present, probably the greatest damage arises at Kew from the deposits of dark-coloured tarry material upon the leaf surfaces cutting down the supply of light which reaches them and clogging the pores through which are carried on gas exchanges vital to their healthy existence. Apparently the atmospheric pollution at Kew can be traced in the main to the industrial area on the opposite side of the Thames, and it is to be hoped that, as a result of the action taken by the director of the Gardens and by the Coal Smoke Abatement Society, prompt steps will be taken to bring about a cessation of a nuisance which, it must be emphasised, has frequently been shown to be capable of prompt control.

ARRANGEMENTS have now been completed for the celebration of the centenary of Pasteur at Paris and Strasbourg. The programme is as follows:—At Paris on Thursday, May 24, there will be a reception by the President of the French Republic at the Elysée; on Friday, May 25, a visit will be paid to the Institut Pasteur and tomb, and in the afternoon there will be a ceremony at the Sorbonne under the presidency of the President of the Republic; on Saturday, May 26, there will be a visit to the Ecole Normale, followed by a reception at the Hôtel de Ville; on Sunday, May 27, a reception will be given by the Sociétés d'Amitiés Françaises à l'Etranger, and there will be a *soirée* at the Opera and at the Théâtre Français; on Monday, May 28, there will be a banquet at Versailles; and on Tuesday, May 29, l'Institut de France is giving a garden-party at Chantilly. Thursday, May 31, will be spent at Strasbourg; the Pasteur monument will be unveiled, and a banquet will be held at midday; in the afternoon a visit will be paid to the Palais du Rhin, and the Pasteur Museum and the Hygiene Exhibition will be opened. The celebrations will conclude with a reception at the Hôtel de Ville in Strasbourg.

THE question of the deterioration of stonework in buildings is a matter of general economic importance. In the cases of our historic buildings and ancient monuments, prevention of the serious decay and gradual demolition of tooled surfaces and main structures constitutes a special problem which has engaged the attention of many investigators for a considerable time without, however, finding any generally satisfactory solution. The investigation involved is very complex and needs to be approached from different angles with the help of wide scientific knowledge. Accordingly, it has been decided to set up under the Department of Scientific and Industrial Research a special committee of the Building Research Board to report on the best methods by which decay in building-stones, especially in ancient structures, may be prevented or arrested. The following committee has been appointed: Sir Aston Webb (*Chairman*), Mr. R. J. Allison, Prof. C. H. Desch, Mr. A. W. Heasman, Mr. J. A. Howe, Sir Herbert Jackson, Dr. Alexander Scott, and Mr. H. O. Weller. All communications should be addressed to the Secretary, Department of Scientific and Industrial Research, 16 Old Queen Street, S.W.1.

PRACTICAL broadcasting was discussed at an informal meeting of the Institution of Electrical Engineers on April 23. Mr. Shaughnessy, of the Post Office, in opening the discussion, pointed out that in America official reports are calling for a radical change in present arrangements so as to remedy the existing confusion. The problem for the British authorities is how best to serve the potential listeners in Great Britain, the number of whom he estimated at about two millions. The amateur experimenters are in a very small minority. The possible alternatives are (1) a super-station, (2) a number of broadcasting stations of medium power, and (3) any number of irresponsible stations. The method adopted has been to form eight areas, each served by a medium power-station, the wave-length of each station being as different as possible within the prescribed limits from that of neighbouring stations. They had been placed at the centres of thickly populated districts, for this is the justification for a popular entertainment. There is no easy way of detecting those who have circuits which interfere with the general distribution. The average listener wants to select his programme, but if he is too near a broadcasting station it is very difficult to tune it out. Those who are some distance away from a station have a much better chance of picking up the programmes given by several stations. The tendency at present is to send out sounds which can be readily heard on the cheapest type of crystal set. The general opinion was that it was advisable to encourage the use of the best apparatus.

THE Botanical Society of South Africa was founded in 1914, when with a membership of 352 it commenced its task, not merely of developing a general interest in botany in S. Africa, but also of assisting the establishment and development of a National Botanic Garden at Kirstenbosch. The value of the Society to the work of the Garden has been repeatedly acknowledged both by the former honorary director, the late Prof. Pearson, and the present honorary director, Prof. R. H. Compton. More than 3000*l.* has been handed over to the Garden from the Society's income, while special grants to specific pieces of developmental work have brought into being the rockery in the Dell, the pond in the Great Lawn, and a part of the Aloe Kopje. At the same time, still more valuable work has been done in interesting South Africans in the great scheme of which the shell as yet alone exists at Kirstenbosch, and many of the devoted collectors now supplying plants from all parts of S. Africa for the Garden were first brought into touch with the Garden through the Society. It is good to learn through its Journal (Part ix. for 1923) that its membership steadily increases and approaches its first thousand. The report for 1922 of the honorary director to the Trustees of the Garden has just been issued, and shows unmistakably the need there is for the efforts of such a society, which may with growing authority press more firmly the claims of these gardens upon the State. It is plain that the lack of capital prevents essential developments in the proper housing of a trained personnel, without which the real development of these gardens, an essential requirement for South Africa's future prosperity, cannot possibly take place.

THE American Chemical Society has undertaken the issue of two series of monographs—a "Scientific Series" under the editorship of Prof. W. A. Noyes, G. N. Lewis, L. B. Mendel, A. A. Noyes, and J. Stieglitz, and a "Technologic Series" under a Board of seven editors. This policy is one that carries with it certain risks. The mere fact that a book is required to be commercially successful is in itself some guarantee that the book is wanted, that a suitable author has been selected, and that the writing will be done carefully. When, however, a scheme is launched for stimulating artificially the production of books, there is a very serious risk that the standard created by these special conditions may be lower than when no outside stimulus to production is used. The conditions are, indeed, very similar to those which prevail in the publication of original papers. When a society has ample funds for publication, and is able to take the initiative in inviting authors to submit papers, it is only too probable that the standard of publication will fall below that which prevails when (for financial reasons or otherwise) the space available is so restricted that a very rigid censorship of papers is necessary. The particularly high standard now reached in the Journal of the American Chemical Society is indeed largely due to these limitations, which often prove a blessing in disguise, not merely to the readers of the Journal, but also to the authors of papers, who are compelled to adopt a high standard of clarity and conciseness. In its new enterprise, the American Chemical Society has been fortunate in securing a number of contributions which will bear comparison with work produced under more normal conditions; but there are already indications that unless a very stringent standard of writing and editing is maintained, inferior material may obtain publicity, as a direct result of the intervention of the Society in a field which has usually been reserved for private enterprise.

IT is announced in *Science* that the City of Philadelphia, through its board of directors of city trusts, made the annual presentation of the John Scott medal awards at a special meeting of the American Philosophical Society on the evening of April 10. The recipients were: Sir Joseph Thomson, for his researches on the physics of the electron; Dr. F. W. Aston, for his development of the mass-spectrograph and his studies of isotopes; Dr. C. Eijkman, of the University of Utrecht, for his researches on dietary diseases; Dr. Arthur Louis Day, director of the Geophysical Laboratory of the Carnegie Institution of Washington, for his researches on optical glass. The awards, which are made annually by the City of Philadelphia, are provided from the income of the John Scott fund, and they are made upon the recommendation of an advisory committee of five, consisting of representatives from the National Academy of Science, the American Philosophical Society, and the University of Pennsylvania.

AT the meeting of the Linnean Society held on May 3 Dr. John Isaac Briquet was elected a foreign member. Dr. Briquet received part of his early education in Scotland, and has always retained a pleasant recollection of his sojourn there. His botanical publications extend over the last thirty years, very largely upon Labiatæ and the botany of Switzerland. The most important works by which he is known in the botanical world are the "Texte synoptique," drawn up to guide the International Congress at Vienna in 1905, a quarto volume of 150 pages, and his "Prodrome de la flore de Corse," which began in 1910, and reached a second part in 1913. As director of the Botanic Garden at Geneva, conservator of the Herbarium belonging to that city (formerly "L'Herbier Delessert"), and professor in the University, his energies have been of late years largely absorbed in his administrative duties.

ON March 18 the National Acclimatisation Society of France conferred on Prof. A. Henry its large silver medal. This honour, which was bestowed in recognition of his services to forestry and to horticulture, could not have had a more worthy recipient. Prof. Henry's services to botany have not been less valuable. It is now nearly forty years since he began to collect plants in Central and Western China, largely over areas new to Europeans. Of his industry and efficiency in that work all the important herbaria in Europe and some in America contain ample evidence. By foresters and arboriculturists his name will always be held in high esteem as the joint author with the late Henry John Elwes of "The Trees of Great Britain and Ireland," for the botanical part of which he was responsible. Since the conclusion of that fine work Prof. Henry has taught forestry, first at the University of Cambridge, and latterly at the Royal College of Science, Dublin. He has made important investigations into the origin of hybrid trees, especially of poplars and the London plane, and recently has been studying the geographical races of Corsican pine and European larch, which has involved several journeys to their natural sites in Poland, the Carpathians, and other parts of Europe.

THE sixth annual general meeting of the Society of Glass Technology was held in Sheffield on April 18. Prof. W. E. S. Turner was re-elected president. The other officers elected were: *Vice-Presidents:* Mr. E. A. Coad-Pryor and Mr. W. J. Gardner. *Members of Council:* Mr. F. F. S. Bryson, Miss Violet Dimbleby, Major G. V. Evers, Col. S. C. Halse, and Mr. T. Teisen. *General Treasurer:* Mr. J. Connolly. *American Treasurer:* Mr. W. M. Clark. *Hon. Secretary:* Mr. S. English. *Auditors:* Mr. Edward Meigh and Mr. Dennis Wood. The president's address on "The Year in Review in the World of Glass-making" was taken as read. A general discussion followed on works organisation. Mr. W. W. Warren opened the discussion with a paper on "Organising for Production from Pot Furnaces." The case for "Tank-furnace Works Organisation" was presented by Mr. T. C. Moorshead, who said that the difficulties, troubles, and failures which beset the factory manager every day may all be traced to inefficiency on the part of the management, and probably to three things: (*a*) lack of foresight, (*b*) lack of a thorough knowledge of the factory operation, and (*c*) lack of initiative. The causes for these losses of efficiency can be grouped under five headings: (1) faulty material, (2) poor labour, (3) poor attendance, (4) large labour turnover, and (5) machine and mechanical breakdowns.

THE anniversary meeting of the Linnean Society will be held on May 24, when the High Commissioner for New Zealand will receive the Linnean gold medal on behalf of Mr. T. F. Cheeseman of the Auckland Museum, New Zealand.

DR. MORLEY FLETCHER has been nominated to represent the Royal College of Physicians at the commemoration of the centenary of the birth of Louis Pasteur, to be held in Paris on May 24 and in Strasbourg on May 31-June 1.

PROF. J. B. LEATHES's subject for the Croonian lectures of the Royal College of Physicians, to be delivered on June 7, 12, 14, and 19, is "The Rôle of Fats in Vital Phenomena." The FitzPatrick lectures, on the "History of Medicine," will be delivered in November by Dr. C. J. Singer.

A VACATION course for mechanics and glassblowers is to be held in the last half of August next in the workshops of the Physical (Cryogenic) Laboratory of the University of Leyden, of which Prof. H. Kamerlingh Onnes is the director. Information concerning the course can be obtained from Dr. C. A. Crommelin, The Physical Laboratory, Leyden, Holland.

THE council of the Royal Society of Edinburgh has awarded the Makdougall-Brisbane prize (1920-1922) to Prof. W. T. Gordon for his paper on "Cambrian Organic Remains from a Dredging in the Weddell Sea," published in the Transactions of the Society within the period, and for his investigations on the fossil flora of the Pettycur Limestone, previously published in the Transactions.

DR. FRANK SCHLESINGER informs us that Yale University Observatory has given a contract to the J. B. McDowell Company, Pittsburgh, U.S.A., for the optical parts of a 26-inch photographic telescope of thirty-six feet focal length. It is expected that this telescope will be in use within a year. It is to be erected at a site south of the equator, probably in South Africa or in New Zealand.

ON Saturday, May 19, at 2.30 P.M., a display of dancing will take place at the Alexandra Palace Theatre in aid of the Royal Northern Hospital. The performance deserves mention not only in view of its worthy purpose, but also because one of the items is a floral ballet written for the occasion by Dr. G. Rudorf, a chemist who is inspector in charge of non-metallic materials for the Air Ministry. The ballet, which lasts three-quarters of an hour, is scored for full orchestra, and will be conducted by the composer.

APPLICANTS for grants from the Chemical Society Research Fund must be made, upon a prescribed form, on or before June 1, addressed to the Assistant Secretary, Chemical Society, Burlington House, Piccadilly, W.1. The income arising from the donation of the Goldsmiths' Company is to be more or less especially devoted to the encouragement of research in inorganic and metallurgical chemistry, and the income from the Perkin Memorial Fund is to be applied to investigations relating to problems connected with the coal-tar and allied industries.

IN connexion with the Falkland Islands Government ship *Discovery* which is now being fitted out for marine researches, mainly on whales and whaling, in the Antarctic and other waters, a director of research will shortly be appointed. Candidates should preferably be graduates in natural science with a record of research work in biology and experience in the carrying out of scientific work at sea. Applications must be sent by June 15, upon a prescribed form if the applicant be resident at home (for those abroad the form is not required), addressed to the secretary of the *Discovery* Committee, Colonial Office, S.W.1.

MR. WILLIAM MUIR (538 Romford Road, London, E.7) sends us a note of a curious individual habit developed by a house-sparrow. During the greater part of two years this bird came to the sill of a particular window and tapped forcefully and persistently on the glass: this occurred daily during some periods and was maintained for hours at a time. Many sparrows were often present, but no more than the one ever took part in this performance.

MR. LOUIS STROMEYER, of Kolar Gold Field, Mysore State, South India, whose book "The Constitution of the Universe" was noticed in our issue of March 10, p. 319, has sent us a courteous protest against the review, particularly on the ground that it contained no direct detailed criticism of his theory. He contends that the review "would have been more to the point had it averred that the theory was incomprehensible and thus could not be criticised at all." This was substantially our view, with the addition that such parts as could be understood were so frequently wrong as to exclude the author from any right to serious and lengthy attention in our columns.

WE have received a letter from Mr. Leonard Hawkes with reference to Dr. Jeffreys' conclusion (noticed in NATURE of April 28, p. 585) that the Pamir earthquake of February 18, 1911, was the result of a great landslip. Mr. Hawkes directs attention to the view that the earthquake originated at a considerable depth below the surface and was itself the cause of the landslip. The point is dealt with by Dr. Jeffreys, who considers that the energy in the seismic wave was approximately equal to that which would be developed by the impact of the falling mass on the ground, and not greatly in excess, as it would have been if the rock-mass were loosened by a deeply-seated earthquake.

OWING to the proportions to which it has grown, the book department of Benn Brothers, Ltd., has been formed into a separate branch of the business, to be known as Ernest Benn, Ltd. Sir Ernest Benn, chairman of Benn Brothers, Ltd., will be chairman also of the new company, and the managing director will be Mr. Victor Gollancz, who for the past two years has been manager of the book department of Benn Brothers, out of which the new business has developed. This development will involve no change in general direction or financial control, and the address is the same as that of the parent company, namely, 8 Bouverie Street, London, E.C.4.

A SPECIMEN of a new fountain pen, called the "Research Fountain Pen," has been submitted to us by the manufacturer, Mr. A. Munro, 65 Preston Road, Winson Green, Birmingham, and we have used it with much satisfaction. The pen has two reservoirs, one of which is first filled with ink in the usual way, and the ink is afterwards transferred as required to a reservoir at the nib end by pulling out a knob and pushing it in again. The walls of the reservoirs are made of celluloid, so that the amount of ink in either of these can be clearly seen. It is claimed that the pen will not blot or leak, and that when it contains ink it will always write without being shaken. The pen certainly has some decided advantages, and so far as we have tested it the claims made are fully justified.

MESSRS. W. HEFFER AND SONS, LTD., Cambridge, have in the press "The Expert Witness," by C. Ainsworth Mitchell, which will deal with, among other things, methods of identification by means of patterns on the feet; by the pores of the skin; by the detection of latent prints on paper, etc.; methods of estimating the age of ink in writing, and the application of X-rays to the identification of old masters.

Our Astronomical Column.

MAY METEORS.—Meteoric phenomena are usually somewhat scarce in May, but fireballs are often more abundant than in other months. The chief display of shooting stars, next perhaps in importance to the Aquarids of Halley's Comet, is a shower radiating from a position eastwards of Corona and near ζ Herculis at about $247° + 29°$. They are swift white meteors of average magnitude and moderately short paths, and have been most plentifully observed on about May 18 and 24, but further observations are required to determine the epoch of maximum. Fireballs are occasionally recorded from Scorpio and from the western region of Aquila in May, and a few very slow-moving meteors are seen in some years from near Capella. Although the meteors visible at this time of the year are not equal in number to those appearing on autumn nights, they are of considerable interest, and have never been sufficiently observed. The bulk of the observations in this department of astronomy has been accumulated in the last half of the year, and it follows that many of the meteoric systems visible in the spring season have been comparatively neglected.

IRREGULARITIES IN THE MOON'S MOTION.—Prof. Newcomb regarded the irregularity in this motion, the period of which is about $2\frac{1}{2}$ centuries, as the most perplexing enigma in astronomy. Mr. Walter Child, of Ashford, Middlesex, has made a suggestion which, although of no practical value, is worth mentioning, as it recalls one of the exact solutions of the 3-body problem. He points out that there is a conical space behind the moon, 83,000 miles long, which is perpetually invisible to us. In this space he locates a moonlet, which he supposes to influence the moon's motion. It is true that there is an exact solution of the 3-body problem with the bodies in a straight line. The distance behind the moon comes out almost 40,000 miles for a particle of small mass; it would be greater if the mass were comparable with that of the moon (Mr. Child's diagram places it much too near the moon). It is also true that the larger solar perturbations on the particle would be the same as those on the moon, since they depend only on the ratio of mean motions. But in view of the fact that the configuration would involve an incredibly exact adjustment, and is unstable, it is undeserving of serious consideration. Moreover, Mr. Child does not explain how the arrangement could give rise to perturbations of long period without causing any short-period ones. Strangely, he seems to imagine that the moon's librations stand in need of explanation; the extraordinary thing would be if they failed to exhibit themselves. They are the natural consequence of an appreciably uniform rotation combined with an orbital motion that is far from uniform; also of the inclination of the moon's equator to the orbit-plane.

Research Items.

Fire-making in the Malay Peninsula.—The fire-piston for the production of fire is used in a limited area among the Shans and people of Pegu in Burma, among the Khas and Mois, in the Malay Peninsula, Western Sumatra, Java, Bali, Lombok, parts of Borneo, and in Mindanao and Luzon. Seven specimens of the implement deposited in the Perak Museum are described by Mr. Ivor H. N. Evans in the Journal of the Federated Malay States Museum (vol. ix. Part 4). They are made of buffalo-horn, wood, and tin. Mr. Evans finds that in two out of three attempts he can make fire by means of it. The important part is the binding of a rag near the distal end of the piston, which acts as a washer, and prevents the escape of air. This must be so adjusted that it allows the piston to pass smoothly down the cylinder when the piston-head is struck sharply with the palm of the hand, and it must not be so tight that there is difficulty in withdrawing the piston fairly quickly, nor so loose that air can escape from within.

Records of British Coleoptera.—In the *Entomologist's Monthly Magazine* for April Messrs. J. C. F. and H. F. Fryer record a species of weevil, *Sitones gemellatus* Gyll., from Sidmouth. Its occurrence in this country was scarcely to be expected. The only British species of Sitones with which it could be confused is *S. cambricus*, which lacks the mesosternal tubercle, and has the sides of the prothorax much more rounded. The same writers also record the very local beetle *Dibolia cynoglossi* from Chatteris, Cambs., where it occurs on Galeopsis. It is an extremely agile insect, and so quick in its movements that it is almost impossible to take it by ordinary sweeping. This may perhaps account for the absence of records in Britain, Cambridgeshire being apparently the first addition to its known distribution since Mr. Donisthorpe's discovery of it at Pevensey in 1902. Messrs. Fryer further record *Chrysomela marginata* at roots of *Reseda lutea* (?) in the Breck sand district, near Mildenhall. The record is not conclusive evidence as to the food-plant of this insect, but it is suggestive that the larval instars may be spent on that plant.

A Taxonomic Study in the Cruciferæ.—Vol. 9, No. 3, of the Annals of the Missouri Botanical Garden is mainly occupied by a very full taxonomic study of the genus Thelypodium and its immediate allies (Chlorocrambe, Caulanthus, Streptanthella, Warea, and Stanleyella) by E. B. Payson, which has been carried out with the view of throwing light upon the phylogeny of the Cruciferæ. The genus is characterised by the possession of a gynophore or stipe which raises the ovary and fruit above the torus; while sometimes nearly negligible, in the species *T. laciniatus* and *T. eucosum*, the stipe is usually more than two millimetres long. In view of the fact that a very characteristic stipe is frequently found in the Capparidaceæ, a close study of the species of Thelypodium would seem to be a necessary step toward the fuller examination of a favourite phylogenetic view which relates the ancestral form of the Cruciferæ closely to the Capparidaceæ. It is further of interest to find that the characteristic septum traversing the pod in the Cruciferæ shows a striking peculiarity in the genus Thelypodium, although no developmental series can be traced in this character and its interpretation is very difficult. Extending nearly or quite from end to end of the pod, through the middle of the septum, is a broad region composed of cells elongated parallel to the marginal framework, and in this region the cell walls are more or less closely compacted. No species are now admitted to the genus Thelypodium that do not exhibit this type of septum.

A Journal of Helminthology.—The new *Journal of Helminthology*, edited by Prof. R. T. Leiper, is primarily intended as a medium for the prompt appearance of original communications by the staff of the Department of Helminthology at the London School of Tropical Medicine. Up to the present no British journal has dealt solely with this branch of parasitology, and Prof. Leiper is to be congratulated on this latest addition to scientific literature. The Journal is to be published bi-monthly, and the subscription is 25*s.* a volume. The first number (price 5*s.* net) contains five papers, three of which have a direct bearing on medical and veterinary science. Dr. A. J. Hesse contributes a paper on the free-living larval stages of *Bunostomum trigonocephalum*, a common intestinal nematode of the domestic sheep. Although this parasite is closely related to the hookworm, infection does not take place through the skin but by the mouth; moreover, the embryos at the infective stage exhibit negative thermotropism, whereas hookworm embryos are positively thermotropic. An epidemic of ascariasis on a skunk-farm has resulted in an inquiry, by Dr. T. Goodey and Mr. T. W. M. Cameron, into the morphology and life-history of *Ascaris columnaris*, a common parasite of the skunk. The results of their experiments indicate that the larvæ of *A. columnaris*, in the course of their migrations in the body of the definitive host, pass through the lungs, as is the case with *Ascaris lumbricoides* and *A. megalocephala*. Dr. M. Khalil re-describes a trematode (*Xenopharynx solus* Nicoll, 1912) from the gall-bladder of a "Hamadryad" (*Naja bungarus*); he also emends the genus Xenopharynx. Dr. G. M. Vevers contributes two papers. The first deals with the genus Paragonimus, which contains all the mammalian lung flukes of America and the Far East. He confirms Ward and Hirsch's view that the cuticular spines are the only trustworthy structures on which to distinguish the four species of the genus, and also suggests that more than one species occurs in man. His other paper contains a descriptive account of some new helminths from British Guiana.

Linkage in Sweet Pea.—In a paper on linkage in the sweet pea (*Lathyrus odoratus*), Prof. R. C. Punnett (*Journ. Genetics*, vol. 13, No. 1) reviews the work begun by Bateson and Punnett nearly twenty years ago, much of which is now classical in the history of genetics. He considers the relation between the number of linkage groups and the haploid number (7) of chromosomes, and concludes that the two will eventually be found to correspond. The numerous pairs of characters such as purple-red corolla, long-round pollen, and erect-hooded standard are given new symbols according to the linkage group to which they belong, and provisional "chromosome maps" of five of the linkage groups are made, based on the percentages of crossing-over. The number of linkage groups at present appears to be eight, but there are several groups with as yet untested possibilities of low-grade linkage, and it is anticipated that the number of linkage groups will in this way be eventually reduced to seven, as the chromosome theory of heredity demands.

Destructive Distillation of Bones.—Mr. E. V. Aleksejevski, in the Journal of the Russian Physical and Chemical Society, 1921, vol. 53, describes a research he has carried out, at the request of the Russian Government, on the dry distillation of large quantities of bones which have accumulated in the towns of the Tersk district since 1914. He finds that the quality of the bone charcoal obtained is better if horizontal retorts are used, instead of vertical ones. The ammoniacal liquor produced by distillation from such retorts contains more than twice as much ammonia as was usually obtained by the old method. The bone charcoal left in the retorts has a medium carbon content, and possesses a high degree of efficiency as a decolourising agent, for which purpose it is used in the beet sugar industry. It may with advantage be used as a contact catalyst, as, for example, in the direct synthesis of phosgene from carbon monoxide and chlorine, or in any other reaction of gaseous combination. Its catalytic power is found in a number of cases to compare very favourably with that of cocoanut-shell charcoal, which is considered to be the most efficient carbon containing contact catalyst.

Correlation of Upper Air Variables.—Mr. P. C. Mahalanobis contributes two Memoirs to the Indian Meteorological Department (Volume xxiv. Part ii.) entitled "The Errors of Observation of Upper Air Relationships" and "The Seat of Activity in the Upper Air." He comes to the conclusion that Chapman's corrections to W. H. Dines's correlation coefficients are open to doubt. But he has fallen into error in stating that Douglas's coefficients are based on true heights. In a footnote in the Professional Notes of the Meteorological Office, No. 8, Douglas explains how he obtained his heights. He (Douglas), in the quotation given, merely meant that he did not use altimeter heights based on the erroneous supposition of a uniform temperature of 50° F. In the second Memoir Mr. Mahalanobis discusses the height at which the correlation coefficients between the five variables are numerically greatest and obtains a much lower value than 9 kilometres. However, he seems to have confused the T_m used by Dines, namely, the mean temperature between 1 and 9 kilometres, with the mean temperature between 0 to 9 kilometres, and this fully explains the discrepancies he finds. Leaving out the temperature of the first kilometre in forming the mean prevents the relationship between P_0, P_9, and T_m being a fixed one, whereas the relationships between the partial correlation coefficients given by Mr. Mahalanobis depend upon P_0, P_z, T_z being connected by a definite equation. If these three quantities be rigidly connected, the connexion is equivalent to reducing the independent variables from five to four, and as a matter of course the partial correlation coefficients involving the three related quantities must be 1 or −1, and the second and third order partials must take the form found by Mr. Mahalanobis.

Development Centres in the Photographic Plate.—It is well established that photographic development starts at definite points or "reduction centres" in the individual grains of silver bromide. Silberstein favours the view that the corpuscular nature of light is the cause of this, while others regard these centres as pre-existing in the grains. The practical importance of the matter is that, if the latter is true, the emulsion maker may eventually be able to control the production and sensitiveness of these centres, and perhaps even to isolate them. Mr. Walter Clark, of the British Photographic Research Association, gives some important results of his investigation of this question in the May number of the Journal of the Royal Photographic Society. He finds that a solution of sodium arsenite has no measurable reducing action on silver bromide produced by precipitation, and confirms the fact that a dilute solution of it applied to a plate renders the plate developable. This is evidence that there is in the plate something besides simple pure silver bromide, which is affected by sodium arsenite (as well as by light) to form development centres. By giving a plate a suitable exposure to light to render the centres developable and then treating the plate with chromic acid, the sensitiveness of the plate is reduced to a very low figure but always of the same order of magnitude if the action is thorough (the preliminary exposure is necessary). It appears probable that the chromic acid dissolves the "centres" produced by the exposure and that the low remaining sensitiveness is the sensitiveness of pure silver bromide.

Mass Spectra.—In a communication which appears in the May issue of the *Philosophical Magazine*, Dr. F. W. Aston gives an account of his work with the mass spectrograph to the end of 1922. The general technique has been in the main unchanged, but softer rays from the discharge tube are being used, and the photographic plates have had some of the emulsion dissolved from them to concentrate the sensitive grains more highly. Helium, nickel, lead, zinc, xenon, tin, iron, cadmium, thallium, selenium, tellurium, beryllium, aluminium, and antimony have been tested, and the constitution of nickel, tin, iron, selenium, aluminium, and antimony determined for the first time. Two new isotopes of xenon have also been discovered. Tin and probably iron show deviations from the whole number rule on the oxygen scale, and with hydrogen give three exceptions to that rule. A complete table of elements and isotopes determined by any of the positive ray methods up to the present time is given.

A French Oil-Well.—In the *Comptes rendus* of the Paris Academy of Sciences of March 19, M. Ph. Glangeaud gives a note of the oil-well of Crouelle, near Clermont-Ferrand, Puy-de-Dôme, about which some paragraphs have recently appeared in the Press. The well-log is an interesting one, particularly from the geological point of view, and much information has been obtained regarding the Oligocene facies of the district between the Puy de Crouelle and the better-known Puy de la Poix. The beds traversed seem to belong to the Upper Sannoisien and Lower and Middle Stampien stages of the system, and, according to M. Glangeaud, recall in many respects similar Oligocene beds at Pechelbronn; further, the prevalence of abundant organic material and the conditions of sedimentation are cited as being distinctly favourable circumstances to the formation and accumulation of petroleum. The well was carried to a depth of about 856 metres, but operations were subsequently interrupted by casing breaking at 787 metres, which, with consequent water trouble, curtailed developments. Notwithstanding this, M. Glangeaud regards the results as being among the most important and encouraging yet achieved in this district, still an unknown factor as regards oil potentialities. Certainly the oil obtained from the well, both in quality and quantity, seems to augur well for future developments in the area, though on general geological grounds one can scarcely be optimistic as to the possibilities of a large field being discovered in this region of France.

The Italian Society for the Advancement of Science.

THE Italian Society for the Advancement of Science is not so ancient an institution as the British Association, but its objects are identical with those of its elder sister, and its methods are in many respects the same. In its present shape it dates from 1908, and its twelfth general session was held at Catania on April 5-11. This was the first occasion on which the Society has visited Sicily, and it was evidently a matter of friendly rivalry between visitors and hosts as to which could do most to make the meeting a success. Naturally the ancient "Università dei Studi" of Catania was in the forefront, with its picturesque and convenient Palazzo in the centre of the city, and its numerous laboratories and affiliated institutes in other quarters. Some sections, however, were lodged in the municipal buildings which overlook the University Piazza; and the opening meeting was held in the spacious Bellini Theatre, only a few minutes' walk from that square. The Italian Society does not share the apprehensions of some critics of our own Association in regard to multiplication of "sections": it enjoys no less than twenty-one of these, and includes in its scope, not only the physical, biological, and statistical sciences, but also medical, legal, philosophical, and historical studies. This accords with the organisation of higher studies in the faculties of Italian universities, and certainly has the effect of bringing a wider diversity of members together, without evident disadvantages.

Two other points of contrast with the procedure of the British Association may be noticed at this point. The inaugural address was delivered, not by the president of the Society, Prof. Pietro Bonfante, but by an honoured guest, the Minister of the Interior, Signor Gentile, who was supported by representatives of the ministries of Public Works and Justice, the War Office, and by the Admiral of the local squadron representing the Italian Admiralty. Shorter addresses of welcome were given by the president, and by Dr. Alessandro Russo, Rector Magnificus of the University, but there was no specialist presidential address as with us, nor were such addresses given by the presidents of sections. The sections, being more numerous, were more specialist than with us, and the attendance at them smaller. There appeared to be no such apparatus of sectional committees as we have, and the sectional proceedings were delightfully informal, and correspondingly profitable. Papers were short and gave the main points only, leaving details to be elicited in discussion. There was little display of specimens or diagrams, and one could have wished for more frequent illustration of objects and sites.

The great variety of the sections was compensated also by the custom (which has been advocated from time to time in the British Association also) of grouping sections in three large "classes," essentially of the physical, biological, and humanist sciences, and devoting quite half of the programme on each working day to discourses of general interest, some delivered to a whole "class" of sections, which suspended their sectional meetings meanwhile, others to "reunited classes," *i.e.* practically to the Society as a whole. These more general lectures were admirably done, and in some instances led to animated discussion; exceptionally even to adjourned debate and to resolutions addressed to the Society as a whole, or to the Government. As the general, semi-general, and sectional parts of the programme alternated between morning and afternoon on different days, there was ample opportunity for local members to fit in a fair sample of the Society's work with their ordinary avocations.

Excursions and social intercourse were not forgotten. The *Regio Commissario* gave an evening reception; the Prefect of Catania gave another; there was a gala performance of Mascagni's opera *Il piccolo Marat*, conducted by the composer himself; there was a whole-day excursion round Etna, arranged through the Etnæan Railway Company, and admirably organised, both on the part of the *Congressisti* and on that of the townships on the route, which turned out in gala array with school children, banners, music, and lavish distribution of home-grown oranges. The Etnæans will long remember this invasion of the *scientisti* of the peninsula; nor will the foreign guests forget the evident pride and confidence of the peasantry in the men who are doing so much to make that *terra di lavoro* the paradise which it deserves to become. Another day was devoted to the beautiful and historic Syracuse, which is easily reached from Catania by train. More specialist excursions to factories, agricultural stations, and other local establishments were arranged for those who desired them. A serious exploration of Etna had to be postponed, owing to inclement weather, until after the meeting; but even those who are not mountaineers could appreciate the amazing film-record of a mid-winter climb to the crater-rim, and the numerous papers on the habits and products of "our mountain," which, in spite of its occasional tantrums, is regarded with a queer mixture of reverence and affection by the Catanians, and becomes an object of daily inquiry and observance even to the foreign visitor. Its full glory, however, is not revealed at Catania; for that, you must go to Syracuse on such a day, cloudless and exquisite in form and colour, as fell to the good fortune of the Congress excursion.

Italian hospitality is proverbial, and the authorities of the Province, of the city of Catania, and of the University welcomed the *Congressisti* with open arms. Visitors, and especially foreign visitors, will not easily forget the many acts of unsolicited attention and courtesy which occurred during their stay, or the evident friendliness with which the Italian Society for the Advancement of Science is regarded in the locality of this year's meeting. Not the least durable token of this interest is the enrolment in Catania of about four hundred new members of the Society.

JOHN L. MYRES.

Industrial Paints and the Health of the Worker.[1]

IT is unfortunate that a question as to the use or disuse of a paint which is, in essence, a matter of efficiency and industrial hygiene, should be complicated by international and labour politics and by trade interests. Such has, for many years, been the position of the white-lead question.

In Great Britain, at least, the weight of evidence is to the effect that for covering power and durability, especially in exposed positions, there is no white paint or paint base equal to white lead. The one serious drawback to the use of this and of other lead compounds which are dissolved by dilute acids is their

[1] Committee on Industrial Paints: Report of the Departmental Committee appointed to re-examine the Danger of Lead Paints to Workers in the Painting Trades, and the Comparative Efficiency, Cost, and Effects on the Health of Workers, of Lead and Leadless Paints, and to advise whether any modifications of the conclusions and recommendations of the Departmental Committees appointed in 1911 have become necessary. Pp. 66. (London: H.M. Stationery Office, 1923.) 2s. 6d. net.

undoubted poisonous character. So impressed were the two Departmental Committees appointed in 1911 to investigate the incidence of lead poisoning in the two largest trades concerned with painting—buildings and vehicles respectively—that they recommended that, except for special classes of work of very minor importance, the use of paints containing more than a very small percentage of lead compounds soluble in dilute acid should be prohibited.

During the War much experience was gained with many materials, and the mere omission to repaint so many buildings and other structures enabled much valuable information to be gained. In 1921 the Home Office found that the information collected in view of the consideration of the use of lead paints by the International Labour Organisation of the League of Nations, was not in the main in accord with the findings of the 1911 committees. Another Departmental Committee, with Sir Henry Norman as chairman, has therefore reviewed the whole question and come to rather different and, it may be said, more reasonable conclusions.

The Committee is satisfied that the specific illnesses of the paint trade are due to lead poisoning and not, as Sir Kenneth Goadby and Prof. H. E. Armstrong were inclined to maintain, to the fumes of turpentine or other hydrocarbon solvents. There certainly appears to be little evidence of chronic disease due to these substances when used apart from lead. The Committee considers it to be generally admitted that dust from the sand-papering of old or new paint-work is almost the only cause of lead poisoning. The introduction of a waterproof sand-paper and the prohibition of dry rubbing-down bids fair to remove this main cause, and rules as to cleanliness simple enough to be enforceable may dispel minor causes.

Sir Frank Baines, of H.M.'s Office of Works, was emphatic as to the superiority of white-lead paint over any substitute for outdoor painting of buildings. Analyses of scrapings from various public buildings confirmed the view that zinc oxide coatings had almost disappeared, exposing the old lead paint beneath. On the other hand, it must be pointed out that leadless paints seem to have given satisfaction when used on vehicles.

Great Britain is pledged to bring in legislation to give effect to the decisions of the Labour Organisation of the League of Nations, and the Committee has prepared draft regulations accepted by both sides of the Joint Industrial Council. It seems doubtful, in view of much of the evidence, whether the prohibition of white lead in internal painting should be strictly enforced, but on the whole, the regulations are salutary and should reduce the number of cases of lead poisoning, while a system of medical inspection should prevent mild cases from becoming chronic.

Lord Askwith in the *Times* of April 4 points out certain international aspects of the question, and expresses the hope, partly on economic grounds, in view of the possibility of minimising danger from white lead, that prohibition of its use for internal painting in 1927 may not be enforced.

The Duddell Memorial of the Physical Society.

In October 1920 the council of the Physical Society of London decided that Mr. W. du B. Duddell's memory should be perpetuated, and invited the council of the Institution of Electrical Engineers and the council of the Röntgen Society to join in forming a committee to collect funds for the Duddell memorial. The following were the members of the Memorial Committee so formed: Sir William Bragg, Sir Horace Darwin, Sir R. T. Glazebrook, Dr. R. Knox, Prof. T. Mather, Mr. Roger T. Smith, and Mr. Robert S. Whipple. A gratifying response was made to the appeal, nearly 700*l*. being subscribed.

The council of the Physical Society, feeling that Duddell's name will always be associated with the development of scientific instruments, has decided that the memorial shall take the form of a bronze medal to be awarded periodically to those who have advanced knowledge by the invention or design of scientific instruments or of the materials or methods used in their construction. The interest on 400*l*. (invested in 5 per cent. inscribed stock) will be given to the recipients of the medal.

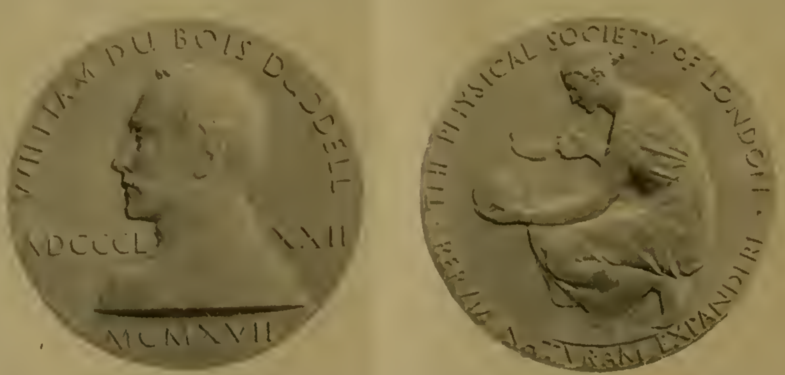

Fig. 1. Duddell Memorial medal to be presented periodically by the Physical Society of London to those who have advanced knowledge by the invention or design of scientific instruments or of the materials or methods used in their construction.

At a meeting of the Physical Society held on Friday, May 11, Sir William Bragg as chairman of the Memorial Committee handed to Dr. Alexander Russell, the president of the Society, the dies for the medal and the scrip for the investment. Sir Richard Glazebrook, speaking also on behalf of the subscribers to the Memorial Fund, dwelt on Duddell's ability and labour.

Dr. Russell, in accepting the dies, etc., on behalf of the Society, expressed his pleasure that Duddell's work, and especially his work in connexion with the Society, should be perpetuated by a memorial of this kind.

The medal (Fig. 1), which is in bronze, was designed by Mrs. Mary G. Gillick. The obverse shows the head of Duddell in profile, with his name "William Du Bois Duddell" written above it. The dates of his birth and death —1872 and 1917—are placed in Roman characters horizontally across the medal. The artist has succeeded in showing in a striking manner the alert energy of Duddell as well as the erectness of his carriage. The reverse represents the quest of science for knowledge, a symbolic figure, throwing light on the mysteries of the earth. Above the figure the words "The Physical Society of London" appear, while below is the motto "Rerum naturam expandere," which may be freely translated, "To elucidate the causes of things."

The Sir Ralph Forster Tablet at University College, London.

VISCOUNT CHELMSFORD, chairman of the University College Committee, unveiled, in the presence of a distinguished audience representative of chemical teaching and of chemical industry, a marble tablet placed in the hall of the Chemistry Laboratories at University College to commemorate the munificent donations made by Sir Ralph Forster, Bt., towards the erection and equipment of these laboratories.

Lord Chelmsford, in his opening speech, referred to the old Chemistry Laboratories erected in 1871 by the late Prof. Alexander Williamson, which, though in their time the latest thing in chemical laboratories, had proved quite insufficient and inadequate botn in space and in equipment. They had, nevertheless, proved the scene of some of the greatest discoveries made by the late Sir William Ramsay, ably supported by Prof. Collie, Prof. Baly, and Prof. Travers. He recalled how Sir Ralph Forster had intervened at the last moment with a contribution of 4500*l.* just two days before the option for the purchase of the present site of the Chemistry Laboratories was to expire on January 31, 1911. At a later date, when the question of the funds for the erection and equipment of the buildings arose, Sir Ralph Forster had again come forward, this time with a donation of 30,000*l.* Lord Chelmsford dwelt upon the need for private benefactors to carry on the work thus begun, and mentioned that a sum of 15,000*l.* is still needed to complete the physical chemical equipment and the electrical installation in the new laboratories.

The Vice-Chancellor of the University of London, Mr. H. J. Waring, speaking in the name of the Senate of the University, expressed to Sir Ralph Forster the grateful thanks of the University for his striking and timely munificence. The Vice-Chancellor developed further the theme already mentioned by Lord Chelmsford, namely, the urgent need for private benefactors for university education in this country, to supplement the funds devoted to university education by the Treasury through the University Grants Committee.

Prof. J. Norman Collie gave an interesting account of the conditions which prevailed in the old Chemistry Laboratories when Sir William Ramsay and he began their work there in 1887, and referred to the work which had been carried out in those laboratories during the time when Sir William Ramsay and himself had worked in them from 1887 until 1912.

Sir Ralph Forster replied, expressing his deep appreciation of the recognition given to his help by the perpetuation of his name in connexion with University College. He expressed his sense of the importance of the work which is being carried on at University College, not only in chemistry but also in other branches of study. Sir Ralph Forster explained that from his earliest days he had been deeply impressed by the need for providing the best facilities for university education for young men of promise, especially in science, and that it was this feeling which led him to come forward and supplement the efforts which were being made at University College for the provision of chemical laboratories of the best and most up-to-date character.

After the speeches, the company adjourned from the large Chemistry Theatre to the Hall of the Chemistry Laboratories, when the unveiling was performed by Lord Chelmsford. The tablet, which was designed by Prof. F. M. Simpson, is of white marble surrounded by a green marble border. It bears the inscription: "The Ralph Forster Organic Chemistry Laboratory, so named in grateful recognition of the generosity of Sir Ralph Forster, Bt. MCMXI."

Cinema Film of the Total Eclipse of the Sun at Wallal, Australia, September 21, 1922.

THERE have been in the past several proposals to take a cinema film of a total eclipse of the sun, but the first real outcome of these proposals is the film now being shown at the Royal Albert Hall. The pictures illustrate the experiences and the work of the astronomers of the expedition, under Prof. W. W. Campbell, to Wallal, on the north-west coast of Australia, from the time they left Perth until after the eclipse. The journey to Broome was made on the S.S. *Charon*, and afterwards on the lugger *Gwendoline*, towed by a lighthouse tender, to Ninety Mile Beach. On account of the great rise and fall of the tides, the ship had to anchor five miles out, and the astronomers with all their baggage had to be landed in boats through the surf. The equipment was then transported on donkey waggons to the site selected for the camp, and in this work the aboriginal inhabitants of the country, both men and women, gave considerable assistance. The large amount of dust, which rose in clouds wherever there was any work being done, caused great inconvenience. Nevertheless a large camp was soon set up and the assembling of the instruments commenced. The process of erection of the tower telescope and of the equatorials and cœlostats, as well as the various rehearsals in changing plates and uncovering object-glasses, are well illustrated. The part of the film showing the solar corona is good, considering that it was taken with a cinema lens, but a better picture could easily be constructed from the negatives taken by the eclipse party.

The film will enable those who are interested in scientific work to appreciate the difficulties which eclipse observers often have to face. Large and cumbersome instruments have to be transported long distances and often erected in almost inaccessible places where little or no skilled labour can be obtained. The conditions at Wallal were probably more difficult than usual, but were bravely faced and overcome. A wireless apparatus was erected to keep the eclipse party in communication with the outside world, and a weekly aeroplane service was instituted. The film is well worth seeing by those interested in the work of scientific expeditions. It would have been too much to expect that a film of this kind, taken under such difficult conditions, would come up to the standard of the films produced by special actors in artificial conditions. However, the fact that the actual work of the astronomers is interspersed with pictures illustrating the life of the natives should make the film one of more general interest. With these additions the showing of the film takes a little over an hour. The attempt to produce a film showing the actual work of a scientific expedition is one which deserves every encouragement and we wish it every success.

University and Educational Intelligence.

BIRMINGHAM.—Applications are invited for the James Watt research fellowship in the thermodynamics of internal combustion engines. Particulars of the fellowship, which is of the annual value of 220*l.*, may be obtained from the Dean of the Faculty of Science of the University. The latest date for the receipt of applications is May 31.

CAMBRIDGE.—The University proposes to confer honorary degrees on Viscount Grey of Fallodon, Lord Plumer, the Rt. Hon. Stanley Baldwin, Chancellor of the Exchequer, Sir Aston Webb, president of the Royal Academy, Mr. M. C. Norman, governor of the Bank of England, Sir Arthur Evans, Prof. H. A. Lorentz, Dr. W. H. Welch, and Prof. Niels Bohr.

The vacancy in the newly founded professorship of animal pathology is announced.

LONDON.—Notice is given that applications for grants from the Thomas Smythe Hughes Fund for assisting medical research must be sent not later than June 15 to the Academic Registrar, University of London, South Kensington, S.W.7, accompanied by the names and addresses of two references.

MANCHESTER.—The council has appointed Mr. L. J. Mordell as Fielden professor of pure mathematics as from September next. Mr. Mordell, who was awarded the Smith's prize in 1912, has won a high reputation as an investigator in the theory of numbers, and has been invited by the University of Chicago to deliver a course of lectures in that subject during the present summer.

Lord Crawford has been nominated as Chancellor in succession to Lord Morley of Blackburn.

WE learn from the *Times* that the University of Cracow has conferred on the Earl of Balfour the degree of Doctor of Philosophy, and the Polish Minister, who was accompanied by Prof. R. Dyboski (representing the Senate of the University), recently called upon Lord Balfour to present the diploma.

THE Society of Merchant Venturers, Bristol, offers for competition fifteen scholarships tenable in the day classes of the faculty of engineering of the University of Bristol, which is provided and maintained in the College. Candidates must be not less than seventeen years of age and must have matriculated. The scholarships provide free tuition: one is open to pupils in secondary schools; three are restricted to pupils of secondary schools in Gloucestershire, Somerset, and Wiltshire; ten are restricted to the sons of officers in His Majesty's service who were killed in the War; and one is restricted to a son of a citizen of Béthune who has passed either the B. ès L. or the B. ès Sc. examination. A War memorial scholarship is also offered, with a preference to a candidate who needs pecuniary help and is the son of a former student who lost his life during the War. Further particulars can be obtained from the Registrar of the Merchant Venturers' Technical College, University of Bristol.

THE programme of the summer meeting arranged by the University of Oxford Delegacy for the Extension of Teaching, to be held on July 27–August 16, contains a noteworthy list of lectures. The main subject of study will be "Universities, Medieval and Modern, and their place in National Life," and in this connexion there will be lectures on various universities, on the relation of the university to the State and to the community, and on the place of science in university study, the last by Prof. H. H. Turner. The special economic subject of the meeting will be "The Social and Economic Problems of English Country Life," and Sir Daniel Hall is giving an introductory lecture on "Agriculture and the Community." Among the lectures in this course is one by Prof. W. Sommerville on "Grasslands." Provision has also been made for a special course on the methods of research in organic chemistry. The course has been arranged to meet the wishes and needs of the science teachers in secondary schools, and will be under the supervision of Dr. F. D. Chattaway. Inquiries should be addressed to the Secretary of the Delegacy, Rev. F. E. Hutchinson, University Extension Delegacy, Examination Schools, Oxford, and marked "Summer Meeting."

IN NATURE of August 26, p. 298, reference was made to the department established by the University of Calcutta for the study of poverty, and particularly unemployment, from a purely scientific point of view apart from class or political bias of any kind. We have now received from the department the first two of a series of lectures by Capt. J. W. Petavel, principal of the Kasimbazar Polytechnic Institute, on "The New Social Question"—the question, namely, how to apply "quite practically and as a matter of business" those principles of co-operation in industry which socialists have proposed to apply by establishing State socialism. The lecturer restates the "Deserted Village" problem, which is of special interest at the present time in India. There are as yet comparatively few town-dwellers, but there is a steady and increasing drift from the country districts to centres of manufacturing industry, and the problem of unemployment of middle-class townspeople is acute. The lecturer suggests that a solution can be found in a system of combined field and factory labour colonies, the homesteads being located along radial lines of communication converging on the factories. The first step is to be the establishment of schools combined with farms and workshops within easy reach of towns. A substantial amount of the pupil's time at school would be devoted to productive work. The Vice-Chancellor of the University and many other prominent citizens of Calcutta were so impressed by Capt. Petavel's arguments that they issued an appeal last year for support for such a scheme.

THE report of the University of Leeds for 1921–22, issued recently, deals with a number of topics of more than local interest. It includes a record of resolutions passed in January 1922 at a conference at Leeds of the six universities of the midlands and north of England defining the factors of university evolution which ought, in the opinion of the conference, to be considered before any institution is raised to the status of a university, and formulating opinions regarding several other questions of university policy. The resolutions were submitted to and discussed with the University Grants Committee. There is also a copy of an important letter addressed by the same universities jointly to the Prime Minister in December 1921 stating the case against the reduction of the Treasury grants to universities and university colleges in Great Britain. Appended to this is a comparative table of grants by local education authorities to each of the six universities in 1913–14 and 1921–22. It shows increases amounting in the aggregate to nearly 100 per cent.—from 74,000*l.* to 136,000*l.*—the most striking being in the grants to Durham (5501*l.* to 16,346*l.*) and Sheffield (17,226*l.* to 39,691*l.*). The number of full-time students at Leeds in 1921–22 was 1646—the highest on record and 150 per cent. higher than in 1913–14. Reviewing the University's finances, it is stated that raising the fees payable by students has for the time being saved the situation, but that a considerable falling off in the number of students must be looked for partly owing to the departure of the ex-service students and partly on account of the limit placed by the Board of Education on the number admitted to the Training Department. Among developments at the School of Medicine the report mentions the institution of a Diploma in Nursing, and claims that Leeds is the first university in this country to introduce such a diploma.

Societies and Academies.

LONDON.

Royal Society, May 10.—A. **Fowler**: The series spectrum of trebly-ionised silicon (Si IV). Numerous new lines of silicon have been observed and have been classified in four groups representing successive stages of ionisation. They have been designated Si I, Si II, Si III, and Si IV. The spectra consist alternately of triplets and doublets, and the series constant has successive values N, 4N, 9N, and 16N. For the series of Si IV the series constant is 16N. The spectrum is similar to that of neutral sodium, Na I. Including Paschen's recent work on Al III, and the author's previous work on Mg II, which also have spectra similar to that of Na I, data are thus available for the comparison of the spectra given by four similarly constituted atoms, which differ mainly in the charge of the nucleus. The highest limit of the Si IV system is 364,117, corresponding to an ionisation potential of 40·6 volts.—Sir R. **Robertson** and W. E. **Garner**: Calorimetry of high explosives. A calorimetric bomb was devised in which high explosives could be brought to true detonation under comparable conditions as regards density of loading and confinement, without using a large quantity of explosive. In an explosive balanced in respect to total combustion, where it is possible to calculate values for heat of detonation and volume of gases, the results agree with theoretical calculations. The influence of the higher heat of formation of phenol with respect to toluene is reflected in the similar values for heat of detonation of trinitrophenol and of trinitrotoluene, although the latter has much less oxygen for its combustion. The nature of the products, and the effect of conditions under which detonation is carried out on heat generated, and gaseous reactions involved, chiefly with regard to liberated carbon, are discussed.—H. S. **Hele-Shaw**: Stream-line filter. Very thin films of coloured liquid, or liquid containing matter in very fine suspension, either lose their colour in one case, or become deprived of their suspended matter in the other, on entering such thin films. In the new form of filter, sheets of paper made impervious to the fluid containing the suspended matter are arranged in a pack. By perforating the pack with a large number of holes it is possible to get the equivalent of a number of sources and sinks. This was obtained by using high pressures, so as to force the matter from one row of holes, acting as sources between the interstices of the paper, to another row of holes, each hole in the latter acting as a sink. Filtration can be made sufficiently rapid for actual use. The colouring matter of various dyes, from what were apparently complete solutions, can be removed, and substances like peat-water rendered clear and colourless.—F. W. **Aston**: A critical search for a heavier constituent of the atmosphere by means of the mass-spectrograph. The residues absorbed in charcoal from more than 400 tons of air were dealt with. Analysis with the mass-spectrograph gives a negative result and indicates that such an element certainly does not exist to the extent of 1 part in 10^{15} of air, and probably not to the extent of 1 part in 2×10^{16} parts of air by volume. Faint bands observed in the region corresponding to masses 150 and 260 were found. The first is due to a complex molecule of mercury with a multiple charge, but no conclusion is reached in the case of the other. The results of the experiments are not in accordance with the presence of molecular krypton and xenon in the air, recently suggested.—H. E. **Armstrong**: The origin of osmotic effects. IV.—Hydrono-dynamic change in aqueous solutions. "Water" is a complex saturated with the gas *Hydrone*, OH_2. Primarily, hydrone is the sole potentially "active" constituent, but it becomes actually active only under conditions which suffice to determine electrolytic change. The vapour pressure either of water or of a solution is the measure of the proportion of free hydrone molecules present in the liquid. Although the vapour pressure is lowered in the presence of any solute, the solution acquires attractive properties. The internal activity is increased while external activity is diminished. The effect produced may be ascribed to an interaction of molecules of the solute and those of hydrone. From non-electrolytes (under the influence of conducting impurity) a simple hydrol is formed $M\langle{}^{H}_{OH}$, only a single molecule of hydrone being "distributed" upon the molecule of the solute, whatever its magnitude. In the case of potential electrolytes, a reciprocal interchange of radicles of salt and hydrone is to be postulated. Not only is the solute hydrolated, but it is also distributed upon hydrone, the salt X′R′ giving rise initially to the reciprocal systems

$$R\,X\langle{}^{H}_{OH} \quad \text{and} \quad H_2O\langle{}^{R}_{X}$$

As the concentration is lowered, under the influence of hydrone, the complex $R\,X\langle{}^{H}_{OH}$ is more and more converted into *hydronol*, $H_2O\langle{}^{OH}_{H}$. Ultimately the solution contains the solute only in the form $H_2O\langle{}^{R}_{X}$ together with an equal number of molecules of hydronol. The "distributed" reciprocal complexes, including hydronol, are the electro-chemical agents in a solution. The negative radicle in such complexes has greater residual affinity than it has in the original simple molecules. The osmotic pressure manifest in an aqueous solution is the pressure exercised by the extra molecules of hydrone attracted into it by the "distributed" complexes, one by each complex, acting as though they were present in the gaseous state. In short, osmotic pressure developed within an aqueous solution, whatever the solute, has its origin in one and the same cause and is properly spoken of as *hydrono-dynamic*—if the word be permissible: indeed, this term may be used as expressive of the general activity of water, *electro-chemical and osmotic*.—H. E. **Armstrong**: Electrolytic conduction: sequel to an attempt (1886) to apply a theory of residual affinity. Referring to the distinction which he drew in 1886 between simple and composite electrolytes—the former being electrolytes *per se*, the latter solutions of "salts"—the author directs attention to the diverse behaviour of the silver and lead haloids on electrolysis; the current being carried, as it were, by the metallic ion of the silver and by the halogen of the lead compound. The conclusion is drawn that the salts of the two metals differ in structure—perhaps thus:

$$\begin{array}{ccccc} Ag & Ag & Ag \\ I - & I - & I \\ | & & | \\ I - & I - & I \\ Ag & Ag & Ag \end{array} \qquad \begin{array}{ccccc} Cl_2 & & Cl_2 & & Cl_2 \\ Pb & - & Pb & - & Pb \\ | & & & & | \\ Pb & - & Pb & - & Pb \\ Cl_2 & & Cl_2 & & Cl_2 \end{array}$$

The assumption is made that the primarily active unit is the fundamental molecule, and that the circuit is formed by these molecules being coupled with (distributed at) the electrode face and with the complex molecules. A similar interpretation is applied to aqueous solutions.—R. W. **Wood** and A. **Ellett**: On the influence of magnetic fields on the polarisation of resonance radiation. In the case of the resonance radiation of mercury and sodium vapour, strong polarisation of the light can be produced by weak magnetic fields properly orientated, and the polarisation of the light normally present can be destroyed by a magnetic field in a certain orientation. The field strength necessary for the destruction of the mercury vapour polarisation is less than one Gauss.—W. G. **Palmer**: A study of the oxidation of copper and the reduction of copper oxide by a new method. A film of copper about 1/1000 mm. thick is prepared by chemical means on a china-clay rod, which is then clamped in a circuit carrying a small current at constant E.M.F. The film is oxidised at 130°-210° C. with gaseous oxygen at pressures up to 1 atmosphere, and the rate of oxidation determined by measurements of the resistance of the film. The rate of oxidation is proportional to the second power of the amount of metal in the film, and, for pressures up to 300 mm., to the square root of the oxygen pressure. Between 170° and 190° C. the temperature-coefficient of the oxidation is negative owing to the simultaneous oxidation of cuprous oxide first formed. When hydrogen or carbon monoxide is mixed with the oxygen the rate of oxidation is greatly enhanced after a short initial period. In the reduction of copper oxide by hydrogen and by carbon monoxide, both gases are adsorbed on the metal and reduce adjacent oxide, but with hydrogen the water formed also adheres to the metal. The rate of reduction in both cases is directly proportional to the amount of metal present, an additional term in the case of hydrogen representing the action of the water.—E. A. **Fisher**: Some moisture relations of colloids. II.—Further observations on the evaporation of water from clay and wool. The curvature occurring in the evaporation curves of clay soils, formerly attributed to shrinkage, is not found with ball clay, although this substance also shrinks on drying. This type of curvature appears only in the evaporation curves of such materials as soils, which are mixtures of colloidal and non-colloidal substances, and is due to the simultaneous evaporation of imbibitional water held by the colloidal and of interstitial water held as water-wedges between the soil grains. The former evaporates at a practically constant rate, while the latter evaporates at a rapidly diminishing rate. The linear rate-curve of wool is not inconsistent with a real shrinkage occurring, although no such shrinkage has been demonstrated.

Faraday Society, April 23.—Sir Robert Robertson in the chair.—J. H. **Shaxby** and J. C. **Evans**: On the properties of powders; the variation of pressure with depth in columns of powders. In the theoretical section an approximate mathematical solution is given of this problem for the case of powder in a cylindrical tube and in the absence of external pressure and where the surfaces of equal pressure are plane. The following equation is arrived at, $p = p_m(1 - \epsilon^{-kx})$, where p is the pressure at depth x, p_m is equivalent to $p g\mathrm{R}/2c$ and μ to $2c/\mathrm{R}$; p being the mass per unit volume of the powder, R the radius of the tube, and c a constant depending on the coefficient of friction. In columns of lead shot and of powder, the absolute value of the pressure appears to depend on the state of packing of the column, and the resulting shape of the equal-pressure surfaces.—E. E. **Walker**: On the properties of powders. (1) The compressibility of powders. The resistance offered by powders to static loads and to blows from a falling weight has been investigated. (2) The distribution of densities in columns of compressed powders. Local densities in columns of compressed powder have been measured, and from the form of the density gradient curve the distribution of pressure in a column of compressed powder has been deduced.—E. K. **Rideal**: On the rate of hydrogenation of cinnamic and phenyl-propiolic acids. Solutions of sodium phenyl-propiolate and sodium cinnamate undergo hydrogenation at equal rates of hydrogen uptake in the presence of palladium sol in large quantities. The rate of hydrogenation is governed by the rate of supply of hydrogen to the palladium in the liquid and is proportional to the square of the shaking speed, the reaction velocity being of zero order. Both old and fresh sols commence reaction with a velocity curve of zero order, but terminate in a reaction velocity curve of the first order. The salts undergoing hydrogenation as well as the hydrogen are adsorbed. The adsorbed salt remains on the surface until completely hydrogenated; thus the rate of hydrogenation of phenyl-propiolate is the same as that of the cinnamate, the former taking up two molecules of hydrogen in the same time as the latter takes up one.—Leonard **Anderson**: Note on the coagulation of milk by acid. Addition of hydrochloric acid to milk of various dilutions causes precipitation of casein, the amount of precipitation increasing with increasing amounts of acid until a maximum rate of settling of the casein occurs which is inversely proportional to the dilution of the milk. The fat globules are mechanically carried down by the casein curd. At higher concentrations of acid the casein goes into solution again, and at still higher concentration is again precipitated; this is the salting out of the casein chloride by hydrochloric acid. Emulsions of benzene and olive oil in casein solution behave in an analogous manner to milk with respect to acid and alkali. Casein is probably the protective agent for the particles of fat in milk.—A. **Taffel**: The temperature of maximum density of aqueous solutions. The decrease in the total volume which occurs when 1 gram of a substance is dissolved in water at a definite temperature has been termed the "solution-contraction" for that substance at that temperature and concentration. Solution-contraction increases as the temperature at which solution is brought about is lowered. With methyl, ethyl, and propyl alcohols, the solution-contraction decreases with the temperature. The temperature of maximum density of the solution is below 4° C. The specific effect of ions and molecules on the depression of the t.m.d. of water results from their specific solution-contraction.

Zoological Society, April 24.—Prof. E. W. MacBride, vice-president, in the chair.—Baron F. **Nopcsa**: On the origin of flight in birds.—E. C. Stuart **Baker**: Cuckoos' eggs and evolution.

Royal Microscopical Society (Industrial Applications Section), April 25.—Prof. F. J. Cheshire, president, in the chair.—W. N. **Edwards**: The microscopic structure of coal. The study of the microscopic structure of coal, though dating back to Henry Witham (1833), made rather slow progress until recent years owing to the difficulty of preparing thin sections. Much detailed work has now been done by Lomax, Hickling, Stopes, Thiessen, and others, which has considerably widened our knowledge of the mode of formation of coal, and has important economic bearings on questions of fuel economy, seam correlation, spontaneous combustion and inflammability of coal dust. Stopes recognises four fairly distinct constituents with different physical and chemical characteristics in bituminous coal. The "anthraxylon" of Thiessen, regarded as being derived from wood rather than from general plant debris, seems to correspond on the whole to the clarain of Stopes, whose classification is based on present constitution rather than probable derivation.

Physical Society, April 27.—Dr. Alexander Russell in the chair.—J. W. **Ryde** and R. **Huddart** (Research Staff of the General Electric Co.): The analysis of bubbles in glass. In order to distinguish bubbles generated by chemical action in glass from those introduced by mechanical processes, spectroscopic tests are made for the presence of nitrogen. To liberate the gas from the bubbles a specimen of the glass is placed in one limb of a quartz U-tube containing mercury; the glass is heated and disintegrated by sudden cooling, the tube being plunged into cold water at the same time that the mercury is thrown on to the glass.—H. P. **Waran**: A simple regenerative vacuum device and some of its applications. Residual traces of air foul the vacuum above the mercury column in syphon gauges and other devices. A bent capillary tube ending in a bulb attached to the top of a siphon gauge will remedy this. It enables the air to be pushed repeatedly into the vacuum of this bulb, the mercury at the bottom of the capillary preventing the subsequent return of the air. The device is regenerative in the sense that, irrespective of any progressive fouling of the vacuum, a fresh-air-free vacuum is automatically created by it every time it is brought into action.—H. **Shaw** and E. **Lancaster-Jones**: Application of the Eötvös torsion balance to the investigation of local gravitational fields. In view of the sensitivity of the balance, which measures derivatives of gravity of the order of 10^{-9} C.G.S. units, it was anticipated that a gravitational survey of the laboratory would disclose the varying effects of the neighbouring masses of the walls, pillars, etc. The consistency of the results obtained at each station and their general agreement with the calculated effects exceeded expectations, as the local gravitational field varied so rapidly that the theoretical assumption of a uniformly varying field in the neighbourhood of a station was obviously vitiated.—L. F. **Richardson**: An electromagnetic inductor. Two bicycle wheels are mounted vertically and co-axially, and are driven in opposite directions by a 4-volt motor, the driving band being constituted by an endless wire. The electromotive forces generated by the revolution of the wheels in the earth's field are thus added, the rims of the wheels being electrically connected through the driving wire. The speed of the wheels is found by counting the revolutions against a stop-watch, one of the spokes being marked for this purpose, and from this speed and the length of a spoke the E.M.F. can be found in terms of H.—F. Ll. **Hopwood**: Pulfrich's experiment demonstrating time-lag in vision. The time-lag in visual perception is greater for dimly than for brightly illuminated objects. A pendulum carrying a glow lamp at its lower end swings over a second glow lamp fixed immediately below the mid position of the swinging lamp. Both are viewed with one eye, while in front of the other eye a metal disk perforated at its centre is placed. The pendulum then appears to be a conical instead of a plane pendulum, the apparent direction of rotation changing when the disk is transferred from one eye to the other. The image seen by the obstructed eye corresponds to an earlier position of the swinging lamp than does the image seen by the free eye, in consequence of the greater time-lag in the former case.

Paris.

Academy of Sciences, April 23.—M. Albin Haller in the chair.—Henri **Lebesgue**: The singularities of harmonic functions.—G. **Bigourdan**: The propagation of Hertzian waves over great distances: the order of magnitude, in time, of the perturbations of the propagation. An analysis of the measurements obtained at five observatories of the time taken by the 300 rhythmic signals (about 4 m. 53 sec.) sent out by the military wireless station at Paris each day. The observed times are not affected by the atmospheric perturbations, nor by the receiving apparatus.—A. **de Gramont**: The use of the oxyacetylene blowpipe in spectrum analysis. Applications to mineralogy. Compared with the oxyhydrogen or oxygen-coal gas flames, there are more lines in the spectra, and the time of exposure can be shortened. Reproductions of flame spectra obtained by this method from chromite, oligiste, and lepidolite mica are given.—C. **Guichard**: The triply indeterminate systems of Ω circles.—L. **Cuénot** and L. **Mercier**: The flight muscles in the winged forms of *Drosophila melanogaster*.—N. **Gunther**: An auxiliary theorem.—Paul **Lévy**: The application of the derivative of non-integral order to the calculus of probabilities.—René **Lagrange**: Varieties without torsion.—Maurice **Fréchet**: The distance of two *ensembles*.—Alf. **Guldberg**: The problem of drawing from lottery urns.—Stanislas **Millot**: The probability of the existence of biological laws.—D. **Riabouchinski**: The paradox of d'Alembert.—M. **Sudria**: The determination of the position of flexure in a bent beam.—A. **Leduc**: A new equation of state for gases. The expression

$$p = \frac{RT}{M}\left[\frac{v}{(v-a)^2} - 3\cdot16\frac{a}{(v+a)^2}(4^x - 1)\right],$$

which is based on compressibility experiments between 1 and 2 atmospheres only, has been applied to the results of Amagat for carbon dioxide. Over a pressure range between 31 and 100 atmospheres and at temperatures from 0° C. to 100° C., the relative differences between the experimental result and that calculated from the above equation do not exceed 0·6 per cent.—Hector **Pécheux**: The magnetism of nickel. Magnetic measurements are given for three samples of nickel (the analyses of which are given) without heat treatment, after tempering and after annealing.—Nicolas **Perrakis**: Contribution to the cryoscopic study of binary organic mixtures. An account of a cryoscopic study of the systems phenol-ethyl alcohol, *o*-cresol-ethyl alcohol, phenyl ether-ethyl alcohol, benzene-methyl alcohol, benzene-isopropyl alcohol, and benzene-normal-butyl alcohol.—E. **Darmois**: The action of molybdic acid on the rotatory power of the tartaric and malic esters. An account of the changes in rotatory power produced by the action of aqueous solutions of molybdic acid and alkaline molybdates on methyl tartrate and ethyl malate.—Victor **Henri**: The production of narrow bands and wide bands in the absorption spectra of bodies in solution and in the state of vapour. A study of the conditions under which a modification of the structure of an organic substance causes the change from a line absorption spectrum to a band spectrum. For molecules containing only one double linkage, the first postulate of Bohr does not apply and the second postulate alone holds; for molecules with two neighbouring double bonds, both postulates apply, the first being determined by the existence of an electric polarity in the molecule.—M. **Sauvageot** and H. **Delmas**: Tempering extra soft steel at a very high temperature. A mild steel containing 0·09 per cent. of carbon was tempered in water, starting with temperatures from 950° C.

up to 1450° C. There was a rapid increase in the elastic limit, resistance and hardness, as the temperature rose.—E. E. **Blaise**: Syntheses by means of the mixed α-ketone zinc derivatives.—Marcel **Godchot**: The oxidation of 1.3.4-dimethylcyclohexanone and the synthesis of cyclopentane diketones. The oxidation of the above ketone with potassium permanganate gives a good yield of γ-methyl-δ-acetyl-valeric acid. The ethyl ester of this acid, treated with powdered sodium ethylate in ether solution gives α-acetyl-β-methylcyclopentanone. The latter, being a β-diketone, forms a sodium derivative capable of reacting with alkyl iodides.—Raymond **Delaby**: The action of mixed organomagnesium compounds on the epibromhydrin of ethylglycerol.—M. **Caille** and E. **Viel**: A new reagent for alkaloids and the preparation of the iodostibinates of these substances in the crystallised state. The reagent consists of a slightly acid solution of antimony chloride with potassium iodide. One part of quinine in 100,000 can be detected; it forms a yellow precipitate. The method appears to be equally sensitive with other alkaloids. By a suitable treatment the alkaloid can be recovered from the precipitate unchanged.—A. **Mailhe**: The decomposition of the formamides of the fatty amines. Isoamylformamide vapour, passed over nickel at 360° C. gives a mixture of isoamylamine and isoamyl nitrile.—M. E. **Denaeyer**: The rocks of Adrar des Iforass and Ahaggar. Two salient facts are shown by the study of the rocks from the central Sahara, their crushing, related to the existence of the Saharan folds, and the existence of alkaline amphibole granites. These rocks mark a new extension towards the west of the limits of the alkaline petrographical province of the Tchad.—E. **Chaput** and L. **Perriaux**: The existence of Albian sands and calcareous pudding stones on the high plateaux of the Côte-d'Or.—Léon **Bertrand**: The Provençal sheets to the east of the lower valley of the Var.—L. **Barrabé**: The transported origin of the Lias massif situated to the west of Narbonne.—Paul **Corbin** and Nicolas **Oulianoff**: The Mesozoic of Prarion (Arve valley).—A. **Allemand-Martin**: The Pliocene of the Cap Bon peninsula (Tunis).—Henri **Coupin**: The morphological nature of the head of the cauliflower. The head of the cauliflower is not formed by flowers, but by stems arrested in their development. This arrest is of tetratological, not parasitic, origin.—R. **Chavastelon**: A method for the preservation of wood. A solution of copper bichromate is recommended and instructions for its preparation are given. Wood thus treated is very resistant to the attack of moulds.—Fred **Vlès**, Mlle. G. **Achard**, and Dj. **Prikelmaier**: Some physico-chemical properties of the constituents of the egg of the sea urchin.—E. **Leblanc**: Experimental acerebellation in lizards.—J. **Gautrelet**: Shock and parasympathetic reactions.—A. **Policard**: The histochemical detection of total iron in tissues by the method of incineration. The section is ashed and the iron detected by the colour of its oxide under the microscope.—C. **Levaditi** and S. **Nicolau**: The mode of action of bismuth in trypanosomiasis and spirillosis.

Official Publications Received.

U.S. Department of Agriculture. Department Circular 187: List of Serials currently received in the Library of the U.S. Department of Agriculture; exclusive of the U.S. Government Publications and Publications of the State Agricultural Colleges and Experiment Stations. Arranged by Title, by Subject, and by Region. January 1, 1922. Pp. iii+358. (Washington: Government Printing Office.)

Department of the Interior: Bureau of Education. Bulletin No. 6: State Policies in Public School Finance. By F. H. Swift. Pp. iv+54. 10 cents. Bulletin No. 15: A Kindergarten First-Grade Curriculum. By a Sub-Committee of the Bureau of Education Committee of the International Kindergarten Union. Pp. vii+66. 10 cents. Bulletin No. 23: High-School Buildings and Grounds: a Report of the Commission on the Reorganization of Secondary Education, appointed by the National Education Association. Pp. xi+49. 15 cents. Bulletin No. 26: Philanthropy in the History of American Higher Education. By J. B. Sears. Pp. vi+112. 15 cents. Bulletin No 29: Statistics of State School Systems, 1919-20. Prepared by Florence Du Bois and H. R. Bonner. Pp. 68. 10 cents. Bulletin No. 30: Accredited Higher Institutions. By G. F. Znok. Pp. vii+106. 15 cents. Bulletin No. 34: Statistics of Land-grant Colleges, Year ended June 30, 1921. By L. E. Blauch. Pp. iii+67. 10 cents. (Washington: Government Printing Office.)

Diary of Societies.

SATURDAY, May 19.

Royal Institution of Great Britain, at 3.—J. B. McEwen: Harmonic Evolution.

TUESDAY, May 22.

Royal Institution of Great Britain, at 3.—Prof. W. M. Flinders Petrie: Discoveries in Egypt (1).

Royal Photographic Society of Great Britain (Scientific and Technical Group), at 7.—A. J. Bull: The Relation of Selective Absorption of Printing Colours to the Errors occurring in Three-Colour Photography.

WEDNESDAY, May 23.

Royal Microscopical Society, at 7.30.—Annual Pond Life Exhibition.

THURSDAY, May 24.

Medico-Psychological Association of Great Britain and Ireland (at Royal Society of Medicine), at 3.—Dr. C. K. Clarke: The Fourth Maudsley Lecture.

Royal Institution of Great Britain, at 3.—Prof. E. G. Coker: Engineering Problems Solved by Photo-elastic Methods (2). The Testing of Materials; The Action of Cutting Tools.

Linnean Society of London, at 5.—Anniversary Meeting. Presentation of the Linnean Gold Medal to the High Commissioner of New Zealand for transmission to T. F. Cheeseman.

Optical Society (at Imperial College of Science and Technology), at 7.30.—D. Baxandall: Telescopes from a Historical Standpoint. (Illustrated by exhibits from the collection in the Science Museum, South Kensington.)

FRIDAY, May 25.

Royal Society of Medicine (Study of Disease in Children Section) (Annual General Meeting), at 5.—Discussion on Birth Injuries.

Physical Society of London (at Imperial College of Science and Technology), at 5.—Prof. C. H. Lees and J. E. Calthrop: The Effect of Torsion on the Thermal and Electrical Conductivities of Metals.—A. Rosen: The Use of the Wien Bridge for the Measurement of Dielectric Losses.—C. R. Darling: Demonstration of an Experiment on the Production of an Intermittent Pressure by Boiling Water.—Dr. N. W. McLachlan: Demonstration of a Novel Instrument for recording Wireless Signals.

Royal Society of Medicine (Epidemiology and State Medicine Section) (Annual General Meeting), at 8.—Prof. E. L. Collis: An Inquiry into the Mortality of Coal and Metalliferous Miners in England and Wales.

Royal Institution of Great Britain, at 9.—Sir Aston Webb: The Development of London.

SATURDAY, May 26.

Royal Institution of Great Britain, at 3.—J. B. McEwen: Musical Education.

PUBLIC LECTURES.

TUESDAY, May 22.

Gresham College, at 6.—Sir Robert Armstrong-Jones: Physic (succeeding Lectures on May 23, 24, and 25).

THURSDAY, May 24.

St. Mary's Hospital (Institute of Pathology and Research), at 4.30.—Dr. B. Hart: The Development of Psychopathology as a Branch of Medicine.

Royal Society of Medicine (Robert Barnes Hall), at 5.15.—Prof. E. D. Wiersma: The Psychology of Epilepsy.

FRIDAY, May 25.

University College, at 5.—Prof. C. Spearman: Psychology as a Career.

NATURE

A WEEKLY ILLUSTRATED JOURNAL OF SCIENCE.

" To the solid ground
Of Nature trusts the mind which builds for aye."—WORDSWORTH.

The Pasteur Institute.

FRANCE is occupied this week with the celebration of the centenary of Pasteur's birth. We, in Great Britain, have made but a poor thing of the occasion. It is true that we have praised Pasteur, and published our recognition of his work; but there has been nothing to show that he takes a foremost place in our national imagination. That is the worst of being an island. We are very proud of Shakespeare, but we are slow to admit foreigners into his company; yet our national gratitude toward Pasteur, so far as it is possible to compare men so unlike, ought to be even more certain than our gratitude toward Shakespeare. It is strange and disgraceful that we have not yet set up a monument to Pasteur in London. Indeed, we have not even inscribed his name on any building to remind everybody of our national debt to him.

Things have been done better in France. It is possible that the worship of Pasteur has gone too far, in the "filming" of him. This film was exhibited at the Jubilee meeting at the Sorbonne, on December 27 last. There are really three films: one to popularise some scenes of Pasteur's life, and two for the more exact teaching of schools and institutes. *L'Illustration* for March 31 gives a delightful account, with many pictures, of these films. Doubtless we shall see them in England. Meanwhile, some of us have seen Pasteur "staged," and admirably acted by M. Guitry.

Men and women of science may or may not stand the test of acting; but they are not intended for "filming." Take some names at random—Newton, Darwin, Lister, Kelvin: films "featuring" them would be nightmares. Besides, the whole meaning and beauty of their work would be left out. Their work began in them, but did not stop there; it became the work of their followers; it took many shapes, and was extended into many new fields of thought and of action. So with Pasteur's work: he founded his kingdom in every country of the world; his influences are everywhere; and that saying of his, in the last year of his life, "Tant de choses encore à travailler," stands for the immeasurable extension of his kingdom.

We have received Dr. Calmette's report, "L'œuvre de l'Institut Pasteur pendant la guerre." This valuable report is published by the Association "pour l'extension des études pastoriennes." An English translation has been issued. The immediate purpose of this Association, which was formed in 1922, is to collect funds to help students to work on the lines which Pasteur laid down. Twenty-six members of the Pasteur Institute died on active service during the war. The cost of living is a great difficulty in the way of students who are longing for good work. The Association proposes to enrol members, whose subscriptions shall provide scholarships and endowments of research. We cannot think of a better way of using these funds. We are asked also to say that the Association has a store of bronze medals, commemorative of Pasteur, which may be obtained for 5½ francs from the Secretary, 6 rue de Messine, Paris.

Dr. Calmette's report of the work of the Institute during the War is well worth reading. He rightly makes much of the fact that the work of the Pasteur Institute was incessant and far-reaching in the years just after Pasteur's death. "In less than a third of a century, Pasteur's teachings revolutionised medicine, surgery, veterinary science; created entirely the science of hygiene for individuals and communities; gave a great impetus to colonisation, and enriched nations by the immense progress of agriculture and agricultural industries."

The War suddenly strained all the energies of the Pasteur Institute. All those workers who were not above the age for active service were mobilised. The Institute, and its branches in Lille and Algiers, were requisitioned at once for the needs of the Army. The demand for protection against typhoid was soon followed by the demand for protection against tetanus. It took only a few days to use up the antitetanic serum—140,000 doses—which was in stock when the War began. Between August 1914 and the end of 1914 the Institute was able to provide more than six million doses of sera for France alone, partly for the Army, and partly for the Public Health service. During the German offensive of March-April 1918, the Institute was providing a vast daily supply of antitetanic serum. It is worth noting that the Institute also provided, in the course of the War, as many as 1,200,000 doses of mallein for the protection of army horses against glanders. Beside all the work which was done for the Army in France, we have to take into account a vast amount of work done for other countries—Italy, Serbia, Rumania, Belgium.

Moreover, there was all the endless business of research and invention to meet the incessantly changing conditions forced on the Institute by the exigencies of war. For example, an immense amount of work was done on poison gases.

Indeed, the whole strength of the Institute was put forth unsparingly, not only for the Army but also for the civilian population. Dr. Calmette does well to praise the branch Institute in Lille. "Though it was paralysed, we may even say martyrised, by the German occupation so early as the first part of October 1914, it took its share in the common work. Our colleagues who lived there four years, immured, without any sort of communication with France, without a letter, without any journals except the political newspapers of Cologne or Frankfort, deprived of almost every means of work, with much of their material destroyed or stolen, did all that was possible with their authority and zeal to protect the civil population against the moral and material miseries of all sorts from which they suffered."

Of course, other countries were not less busy than France. They were all working on Pasteur's lines. It was he, and he alone, who inspired them. To him the Franco-German War of 1870 had brought misery; he took it as his revenge to set France, by his work, high above Germany. There are not many of us now living who can boast that we met Pasteur here in England, and shook hands with him, and heard him talk of his work. One of us had this good fortune; and remembers well the grave and unhappy look of his face, and the measured and serious tone of his voice. It was given more to his family and his friends to know something of the wonderful beauty of his life. The pity is that we in England have no memorial of him; nothing to express to France our gratitude for what he did for us.

Hormones.

Glands in Health and Disease. By Dr. Benjamin Harrow. Pp. xvi+218. (London: George Routledge and Sons, Ltd., 1922.) 8*s*. 6*d*. net.

THERE is probably no chapter in physiology which calls forth to such an extent our sense of the marvellous as that dealing with the internal secretions and the functions of the ductless glands. All the effects which have been ascribed in the imagination of mankind to the action of beneficent or maleficent fairies or deities are brought here within the domain of sober physiology as possible results of deficiency or excess of one or other of the internal secretions. The production of dwarfs and giants, change of personality, mania, dementia, and idiocy, the manifestations of love, hate, rage, and fear, the characteristics which distinguish male from female, the powers of reproduction and all associated therewith, the normal performance of the processes of digestion and metabolism, have all been shown to be bound up with the power of certain cells in the body to manufacture chemical substances which they pass into the bloodstream. It seems quite natural that the respiratory centre should be stimulated to greater activity by the increased production of carbonic acid which accompanies muscular exercise, so providing the working muscles with a sufficiency of oxygen for their needs. A further development of this correlation by chemical messengers is found in the alimentary canal, where the presence of the products of digestion in the stomach excites, by means of a hormone, the further secretion of gastric juice. In the same way the entry of the acid products of gastric digestion into the small intestine evokes in the epithelial cells lining this tube the development of a substance—secretin—which is absorbed by the blood-vessels and carried round to the pancreas, liver, and intestinal glands, so as to bring about the simultaneous secretion of the three juices the co-operation of which is necessary for the complete digestion of all classes of foodstuffs.

These are examples of the restricted action of the chemical messengers, resembling closely the reactions brought about through the intermediation of the central nervous system, so that we are justified in speaking of them as chemical reflexes. Other hormones have a much wider action, which may extend to all or almost all the cells of the body. Our knowledge of these is scarcely half a century old, and began with the discovery in England of the relation of myxœdema and cretinism to atrophy or failure in development of the thyroid gland. Later research has shown that these conditions are due to the absence of a secretion manufactured by the thyroid. This secretion has been isolated and has been found to be a substituted iodine derivative of tryptophane. On its constant presence in the blood depends the normal growth and metabolism of all the tissues of the body. Since these include the central nervous system, development of the mind is affected as well as that of the body. Absence of this secretion in early life results in the production of a stunted cretin. Increased secretion by a hypertrophied gland causes increased rate of metabolism, quickened heart-beat, excitability which may culminate in mania, changed personality—all of which may disappear when the gland diminishes in size or the hypertrophied portion is removed.

Still more wonderful and widespread in its effects is the pituitary body. This consists of two parts—one of which is derived from the brain, the other from the back part of the buccal mucous membrane of the fœtus; each part is only about the size of a pea. Increased activity of the anterior part gives rise to gigantism in the growing animal, or, when it affects the adult, the overgrowth and deformation of face, hands, and feet, which is known as acromegaly. If it were possible to isolate and administer the chemical substance responsible for these growth changes, we should be able to rival the effects of the "Food of the Gods" imagined by Mr. H. G. Wells. Atrophy of this part causes diminished growth, excessive fat production, and a condition of infantilism, with lack of development of the sexual functions. The posterior part, which in appearance seems to consist of little else but neuroglia, the supporting tissue of the central nervous system, produces some substance which can be extracted from it by boiling water, and has, in infinitesimal doses, widespread effects on the most diverse tissues of the body. This extract is sold under the name of "pituitrin." According to the conditions existing at the time of administration it may increase or diminish the flow of urine; it causes rise of blood-pressure and contraction of the uterus, as well as of all other unstriped muscle, such as that of the intestines. For these purposes it has come into actual practice as a therapeutic agent. Its presence in minute quantities in the blood seems to be a necessary condition for the contractility of the blood capillaries, so that it becomes a regulator of the supply of the nutrient blood to all the tissues of the body.

It is not surprising that these later achievements of physiological research have impressed public opinion and have had a marked effect in the United States, where the public interest in things medical is aroused every week by popular articles on medical science in the Sunday papers. The arousing of uneducated curiosity has its dangers as well as its value. Sensationalism and imagination have not only rushed ahead of the ascertained facts but have also opened the way to a shameless exploitation of the uneducated curiosity which has been aroused. It is not so many years since bits of animal organs were regarded as essential ingredients of remedies for disease as well as for love-philtres and charms. The heart of the tiger or of the brave enemy was eaten to give courage to the victors, and at the present day we find a therapeutics advertised and exploited which is nothing less than a return to the superstitious practices of the middle ages. The principle is simple. If the kidney is affected, dried kidneys of animals are administered; if there is a failure of sexual powers, ovaries or testes are administered in the same way. It is only necessary to locate the disorder in order at once to apply the appropriate remedy. Charlatanism finds an easy and profitable prey in the curious and uneducated. The only protection against its attacks lies in more complete education, and it is for this purpose that such a book as that of Dr. Benjamin Harrow is useful. The author is apparently not a medical man, but is an associate in physiological chemistry of Columbia University. Though the restriction of his knowledge and experience is apparent, the book is nevertheless of value as a dispassionate and objective statement of the facts which are so far known as to the internal secretions. Throughout the author maintains a proper sceptical attitude in face of the uncritical or prejudiced statements which have been put forward by clinicians as to the influence of various preparations of the organs involved.

There are a few errors of fact, as well as certain questionable conclusions, which might well be omitted in future editions. The statement that the action of these hormones is catalytic is unjustified and means nothing. We cannot speak of catalysis—*i.e.* a hastening of a chemical action—unless we have some definite chemical action in mind. In the case of these hormones, as in the case of drugs such as alkaloids, we have not the remotest idea how they work. It may be that their action is by catalysis of one or other of the reactions which occur in the series making up the life of the cell, but there is no evidence for or against such a statement, and there is a distinct danger that, by putting the action of drugs or hormones into such a category, we may forget our ignorance and refrain from further attempts at an analysis of the manner in which they work.

The author seems unaware of the fact so clearly brought out by Pézard, that the plumage of the cock is that of the neutral animal, desexualisation of the hen bringing about the production of the cock's plumage, which is left unaffected in the male by removal of the testes. It is not correct to speak of enterokinase as a hormone; it is a ferment which has a definite action on the trypsinogen secreted by the pancreas, converting this into trypsin. Two statements are a little surprising. In explanation of the term "thyroidectomy" it is mentioned that "dectomy" equals excision. Later on in the book the word "secretin" is stated to be derived from the Greek "to excite." These, however, are minor flaws and do not interfere with the value of the book as a whole, which can be recommended as an interesting and well-balanced account of the present condition of our knowledge on the subject of internal secretions. It is couched in such language that it will be intelligible to any educated reader with the veriest smattering of scientific knowledge.

E. H. S.

Modern Processes of Ore-Dressing.

A Text-Book of Ore-Dressing. By Prof. S. J. Truscott. Pp. xi+680. (London: Macmillan and Co., Ltd., 1923.) 40*s*. net.

IN his preface Prof. Truscott states that his work is written primarily for the service of his own students at the Royal School of Mines, and correctly observes that such a book is needed owing to the important development of flotation processes in recent years.

From the dedication—"To Almighty God, the father of our Lord Jesus Christ"—one must infer that the author has put forth his best efforts into the work, and it certainly does bear evidence throughout of painstaking care. The matter is arranged methodically; the drawings and diagrams are abundant and excellent, and their selection leaves little to be desired. The many non-essential details which are often found in descriptions of ore-dressing plants do not occur, and all the space is well employed to give the student a correct and easy understanding of the subjects described.

The book deals first with washing and sorting methods and appliances, then with the various types of machines for breaking, crushing, and grinding of ores. Next are considered the problems and appliances for sizing by screens and by water, after which water concentration is described. The latter half of the book deals mainly with flotation concentration, magnetic, electrostatic, pneumatic, and centrifugal separations.

The space devoted to flotation (one-fifth of the total text) is indicative of the rapid growth and extreme practical importance of this method of concentration, which in less than twenty years has revolutionised the treatment of low-grade ores.

On the whole, the author is to be congratulated upon his presentation of a concise view of flotation technics to the general student, since the subject matter is extensive and in some aspects recondite. Under these conditions his treatment of the practical section must be considered satisfactory, but the chapter devoted to the more theoretical aspects of the subject is somewhat involved. This is scarcely to be wondered at, since a comprehensive theory of flotation (which at almost every point involves problems in regions of molecular physics only partially explored) has yet to gain general acceptance, and is still the battle-ground of two schools of thought—those on one hand who adopt the doctrines of the later school of colloid chemists, seeking explanations for causation based mainly on electrical theories, and the other or physical school, which finds sufficient explanation by the application of purely molecular laws. Electrical theories are both proximate, as the assumed electrical or electrostatic nature of flocculation and deflocculation phenomena, and ultimate, in seeking to explain the useful properties of oils and other reagents used in flotation in terms of the electronic constitution of atoms and molecules. The physical school is concerned only with the elucidation and quantification of the molecular attractive forces exerted between the reacting surfaces at liquid-solid contacts, such as give rise to surface- and interfacial-tensions, adsorption, and so on. On these grounds the phenomena of flocculation and deflocculation also seem to be more satisfactorily explained than by the electrical hypothesis.

Prof. Truscott, however, prefers to divide his favours between the two schools, accepting molecular attractions as explanatory of most of the flotation reactions, but adopting the electrical hypothesis for flocculation. The importance of the latter factor may be judged from the generalisation, now widely accepted, that where particles in an ore-pulp can be flocculated they can be floated; conversely, when they are put into the condition of deflocculation (suspension or peptisation are other terms used) flotation of such particles will be rendered impossible. A main object of flotation is, therefore, to flocculate the valuable mineral in a pulp, and to deflocculate the gangue or unwanted mineral.

It may be pointed out that Brownian motion (p. 510, para. 6) is not due to the "inherent kinetic energy of extremely fine particles": these indeed are passive agents, their motion being imparted by the kinetic energy of the water molecules which continuously bombard them—as shown in Perrin's classic experiments. Some other statements will provoke critical comment and seem to require qualifications—such, for example, as that on p. 506, where it is stated that the necessary filming of a mineral with oil cannot be achieved if the oil be completely emulsified. In the form stated it is not a fact, and theoretically it seems to overlook the phenomena of adsorption.

It should be mentioned that the book makes no serious attempt to deal with many of the problems which invariably confront the designers of mills, such as grades for launders and pipes, wet and dry pulp elevators and pumps, ore-bin construction, automatic feeders, etc. This, however, cannot be regarded as a shortcoming, and is perhaps to be commended, for the student should not be encouraged to imagine that he is fully competent to design a plant. It should be sufficient for him to obtain a thorough understanding of all ore-dressing appliances and methods in general use, and it is difficult to conceive how he could obtain so much sound knowledge so readily, and conveniently prepared for him, as he can in this book. Prof. Truscott apparently refrained from showing partiality towards any particular machines or methods, and has been cautious in his references to their merits or demerits. Practically everything said may be accepted as trustworthy, though a few statements noticed in respect of metallurgical matters are not strictly correct; for example, that much high-grade lead ore is smelted in reverberating furnaces, that zinc necessarily renders slags pasty, and that lead is highly objectionable in the retorting of zinc. These slight inaccuracies do not, however, affect the arguments they are used to illustrate.

L'Évidence de la théorie d'Einstein. Par Prof. Paul Drumaux. Pp. 72. (Paris: J. Hermann, 1923.) 6 francs.

OF all the books on the Principle of Relativity which it has been our good and ill fortune to peruse during the last three years, there are none which have given such food for thought as those of Profs. Eddington and Whitehead. Other books, and their name is legion, fall into several well-defined classes. Among those before us are two serious and well-executed books addressed to students of experimental physics by Dr. Norman Campbell and Dr. Max Born. We are glad to note a cessation of the flood of popular accounts in which, mainly without success, more and less well-equipped writers have felt called upon to try their skill at hitting off the average man's understanding. Then there are the books in which metaphysicians have told us the effect which their reading around the subject, largely in semi-popular treatises, has had upon their thinking in regard to theology, sociology, and things in general. To this very important branch of the literature Prof. Wildon

Carr adds a new edition of his valuable book, which he has extended by a new chapter giving a more detailed description of Einstein's theory. Then there is a group of bare expositions of Einstein's theory, following closely his published work, with little digression or reflection. To this class belong the works of Drs. Silberstein and Kopff, which are mainly a record of lectures given by the authors in Toronto and Heidelberg respectively. Einstein's own volume, entitled "The Meaning of Relativity," is disappointing, as it falls straight into the same group, and gives us little more light on the *meaning* of relativity, save a re-emphasis that it is mainly a matter of mathematics. Prof. Murnaghan in his volume is more specially concerned with the pure mathematics, and seeks to lessen the difficulties of "The Absolute Differential Calculus" in any number of dimensions by tracing the whole subject through in an elementary manner. Prof. Drumaux writes a bright, readable, and well-balanced account of the theory; his general conclusions are admirable.

But the latest works of Profs. Eddington and Whitehead have characters of their own. We are exceedingly glad to have kept Prof. Whitehead's book by us until we have had an opportunity of seeing in book form the matured results of Prof. Eddington's mathematical investigations and his speculations as to the interpretation to be placed upon it all. We should recommend all those who are puzzled by the higher flights of his imagination to sit down to Prof. Whitehead's book, and after worrying through his first four chapters on physical principles to come back to Prof. Eddington and reconsider what he has to say. For while we yield to no one in our admiration for the work which the latter has done in emphasising the necessity for a thorough revision of the basic ideas of physical science, there remains an obstinate feeling that some of the more fascinating glimpses which he gives us may not stand a thorough logical examination. Prof. Whitehead, on the other hand, is a conservative. He acknowledges and presupposes the magnificent stroke of genius by which Einstein and Minkowski assimilated time and space, but, as he says, "The worst homage we can pay to genius is to accept uncritically formulations of truths which we owe to it."

Accordingly, the major part of his book is devoted to a logical consideration of the spatio-temporal character of events. Chapter II. consists of a lecture on "The Relatedness of Nature," given to the Royal Society of Edinburgh. It emphasises the fact that in our contemplation of Nature we are regarding events and processes. Descartes considered "stuff" (matter, ether) as being separable from the concept of process, realising itself at an instant, without duration; and to him "extension" was an abstract from the more concrete concept of "stuff." Space is thus essentially dissociated from time. But if, as Prof. Whitehead does, we find in events the ultimate repositories of the varied individualities in Nature, then we obtain the four-dimensional space-time as an abstract from those events. Space and time are thus correlative abstractions which can be made in different ways, each way representing a real property of Nature. The "event" or "point-event" which is made fundamental by many writers is therefore a pure abstraction, a fundamental element in the deductive and synthetic conceptual model which we have formed of Nature, holding the same place in it as the "point" in Euclid's elements of geometry.

So far we should find complete agreement between Einstein, Minkowski, Eddington, and Whitehead. It is when we come to the next chapter that we begin to feel that new ground is being broken, for Prof. Whitehead has perceived that the careful scrutiny of fundamental ideas necessitated by this unification of space and time has not yet been thoroughly carried out. The whole question of the nature of measurement and how it is at all possible has to be tackled, and we must begin by analysing the notion of "equality." In accordance with the ideas above, the fundamental step must be the matching, not of permanent bodies, but of passing events. "How time is to be got from the relations of permanent bodies completely puzzles me." "Why this pathetic trust in the yard measure and the clock?" he exclaims. So, starting from the simple idea of equality, we are led on into all those speculations concerning the character of the universe which have been raised by Einstein's theory.

We are left at the end of this chapter with a sense that "equality" and "measurement," far from being the sure foundation of physics, are either crude and primitive modes of experimentation or else the finishing touches to a wonderfully wrought conceptual picture of Nature. Here we think Prof. Whitehead and Prof. Eddington will be in sharp disagreement, and here we think remains still much room for clear exposition and hard thinking. While we welcome Prof. Eddington's authoritative exposition of the mathematical theory of relativity, our doubts as to the logic of his fascinating general account of the theory are confirmed. In the first section the fundamental hypothesis is stated that "everything we can know about a configuration of events is contained in a relation of extension between pairs of events. This relation is called the *interval*." The equality of intervals is to be tested observationally. We are told to take a configuration of events, namely, a measuring-scale, and lay it over a distance AB, and observe that A and B coincide with two particular events P, Q (scale-divisions). It seems to us that a scale-division is not an event at all, but a world-line or chain of events. We are then to do the same to a distance CD, and so prove the equality of the distances AB and CD. We are told that in this experiment time is not involved, and to conclude that in space apart from time the test of equality of distance is equality of interval. Yet the essence of a measuring-scale is its permanence in time. We stumble badly over these opening paragraphs, and are glad to get on to the mathematical developments where all goes smoothly.

The same confusion of thought, as it seems to us, occurs again in the interpretation of Einstein's law of gravitation which is Prof. Eddington's own (§ 66). Einstein's law is equivalent to the statement that the radius of spherical curvature of the three-dimensional section of the world at right angles to any direction in the four-dimensional continuum has the same constant length $\sqrt{(3/\lambda)}$. A "more precise statement of this result" is said to be that "the radius of curvature of the world at any point and in any direction is in constant proportion to the length of a specified material unit placed at the same point and orientated in the same direction." In this more precise statement the word direction is used in the first instance for a direction in the four-dimensional world, but "the length of a specified material unit placed at the same point and orientated in the same direction" can only be interpreted as referring to three dimensions.

We do not raise these criticisms in any captious spirit. We believe there is a great deal to be said in favour of the general point of view stressed by Prof. Eddington that the uniformities revealed in Nature by physical experiment would not have been found if our physical measurements had not been made with apparatus which is itself part of Nature and is therefore pervaded by the universal relations. But the picturesque and concise language employed from time to time in this book may only too easily persuade the reader that he has understood when he has in reality only shirked the issue.

Thus, after thanking the author for his very complete account of the existing state of the theory and its speculative developments, we return almost gladly to Prof. Whitehead's conservatism, and read his chapter on some "Principles of Physical Science." We are almost grateful for his old-fashioned belief in the fundamental character of simultaneity, adapted to the novel outlook by the qualification that the meaning of simultaneity may be different in different individual experiences. We admire his cautious tread along these unexplored paths, and we should welcome him as our critic in the task that urgently needs undertaking, of examining the precise position to be allotted to the notion of "measurement" in the conceptual universe of the relativist.

Fossil Mammals from Bolivia.

Mammifères fossiles de Tarija. Par Prof. M. Boule, avec la collaboration d'A. Thevenin. (Mission scientifique G. de Créqui-Montfort et E. Sénéchal de la Grange.) Pp. vii + 255 + 27 planches. (Paris: H. Le Soudier, 1920.)

FOR more than three hundred years a great accumulation of bones has been known in the highlands of Bolivia near the small town of Tarija. The bones are scattered in confusion through a deposit of sandy mud, the parts of a skeleton rarely in natural association; and they are often well exposed in the little ravines which mountain torrents and streams have cut through the deposit in all directions. During the final years of the last century a large collection of the specimens was made by some local residents, Messrs. Echazù, and when the Marquis de Créqui-Montfort was exploring the country in 1903 he purchased this collection, and eventually gave it to the National Museum of Natural History in Paris. The Marquis has now generously provided the means for the publication of the handsome volume before us, in which Prof. Boule, assisted partly by the late M. Thevenin, makes the new discoveries available for science. The work is dated 1920, but was only distributed last year.

All the bones in the deposit at Tarija belong to mammals, most of them large, closely resembling those found in the sand and mud of the pampa of Argentina and in the caves of Brazil. They date back either to the latter part of the Pliocene or to the early part of the Pleistocene period, and are therefore of special interest, because they represent the time when the mastodons, tapirs, horses, llamas, deer, peccaries, and higher carnivores had just come south from the northern hemisphere over the newly-emerged land of central America, and had mingled with the strange edentates, rodents, toxodonts, and macrauchenias which were indigenous to South America, and soon became, for the most part, exterminated in their rivalry with the invaders. Altogether, thirty-five species of large size are represented, and their remains are described in detail by Prof. Boule, with the aid both of beautiful plates in photogravure and of numerous effective text-figures.

The individuals of several species are rather small compared with the corresponding forms found in the Argentine pampa and other favoured regions, for Tarija is at present nearly 2000 metres above the sea, and even at the beginning of the Pleistocene period, when the elevation was possibly less, the conditions cannot have been very genial. When the assemblage of animals in question was living in that country, however, there must have been both greater warmth and more moisture to provide sufficient vegetation. The mastodons, tapirs, and perhaps macrauchenias, must have inhabited damp forests on the edge of swamps. The giant ground-sloths, Megatherium and Mylodon, could scarcely exist without forest vegetation. The numerous and varied small horses and llamas were as usual adapted for life on grassy plains. The Glyptodon was also probably a feeder on grass, and the Toxodon, which may have fed on dry scrub, seems to have been comparatively rare. When conditions began to approach those now met with at Tarija, all these animals would be either exterminated or driven to lower regions.

Like all his other descriptive works, Prof. Boule's account of the mammalian remains from Tarija is much more than a technical treatise. It summarises and briefly discusses our knowledge of the evolution of most of the groups represented. It teems with facts and suggestions which will interest both zoologists and geologists. It is a most valuable contribution to palæontological science. A. S. W.

Our Bookshelf.

The Journal of the Institute of Metals. Edited by G. Shaw Scott. Vol. 28. Pp. ix+1010. (London: The Institute of Metals, 1922.) 31*s*. 6*d*. net.

THE new volume of the Journal of this Institute is very bulky, owing to an increase in the number of pages occupied by papers and also in that of the abstracts. Two general lectures are included, one being by Sir Ernest Rutherford on the relation of the elements, and the other by Dr. Hutton on motion study and vocational training, the latter subject being a new one in this connexion. The sixth report to the Corrosion Committee is mainly concerned with the influence of colloidal corrosion products on the process, and contains much interesting matter, although the theory remains in a very imperfect state. The authors do not commit themselves to the support of any of the theories proposed in this field, and consider that several different processes are possible. A further contribution to the subject of the age-hardening of the light aluminium alloys is made by members of the staff of the National Physical Laboratory, and the hypothesis originally proposed to account for ageing is confirmed by the newer work. Several other papers deal with the properties of aluminium and its alloys. A curious binary system is that studied by Mr. M. Cook. The alloys of antimony and bismuth form a continuous series of solid solutions when allowed to solidify slowly, but if, by rapid cooling, a heterogeneous structure is obtained, prolonged annealing does not lead to diffusion. This paper contains some excellent photo-micrographs. Other papers include a general survey of eutectics by Mr. F. L. Brady, and a method of deriving a value for the absolute hardness of metals from the Brinell test by Mr. F. W. Harris, as well as several contributions on technical matters.

The abstracts section shows a great increase in bulk, and the literature of metallurgy has evidently been searched very thoroughly; but some space might be saved by the avoidance of duplication, and by omitting papers which are merely popular summaries of existing knowledge, containing nothing new. It is always difficult to decide where the line should be drawn in such cases, but the fact that the present volume extends to more than 1000 pages proves that discretion is desirable in the admission of abstracts to this important Journal.

The Gold-Headed Cane. By Dr. William Macmichael. A new edition, with an Introduction and Annotations by George C. Peachey. Pp. xxiii+195+5 plates. (London: Henry Kimpton, 1923.) 18*s*. net.

WE recently directed attention to an edition of the "Gold-Headed Cane" edited by Dr. F. R. Packard of Philadelphia (see NATURE, March 3, p. 281). The present volume, which represents the fifth edition of the work, is edited by Dr. George C. Peachey, who is well known in the medical world as the historian of St. George's Hospital and as a writer of various articles of medico-historical interest. In a scholarly introduction Dr. Peachey points out that the only two discoveries of real value which had issued from English thought before the Restoration were the work of physicians, namely, the discovery of terrestrial magnetism by Gilbert in 1603 and the demonstration of the circulation of the blood by Harvey in 1628. In the later period, however, and notably with the death of Sydenham in 1689, the year in which the autobiography of the "Gold-Headed Cane" begins, the leading physicians of the period whose lives are related by the Cane were remarkable for their success in practice rather than for any important additions they made to knowledge. No important contributions were made to medical literature by Radcliffe, Mead, Askew, or Pitcairn. An exception, however, must be made in favour of Matthew Baillie, whose position in the history of medicine as the first great English pathologist is not mentioned by Dr. Peachey.

The present edition, which is more sumptuous than any of its predecessors, contains in addition to the original illustrations six fine photogravure portraits of Radcliffe, Mead, Askew, the Pitcairns, and Baillie.

Everyday Life in the New Stone, Bronze, and Early Iron Ages. Written and Illustrated by Marjorie and C. H. B. Quennell. (The Everyday Life Series, II.) Pp. x+119. (London: B. T. Batsford, Ltd., n.d.) 5*s*. net.

MR. AND MRS. QUENNELL must have found their little review of the Neolithic and succeeding Ages vastly more difficult to write than their earlier book on the Old Stone Age. Not only is the material more heterogeneous in character and more widely scattered, but on many points with which they have had to deal summarily there is also a lack of agreement among archæologists. The limitations of space and the requirements of their public have precluded any discussion of controversial matters. To bear this in mind is to disarm criticism on points which, in a more ambitious undertaking, might call for extended discussion.

Notwithstanding the vast amount of ground which has been covered and the mass of material which they have had to bring within the compass of their little book, the authors have produced an excellent and very readable popular account of the peoples of the later prehistoric ages in North-Western Europe and, in particular, of Britain. Without entering into detailed criticism, it may be suggested that more stress might have been laid upon early trade connexions between Britain and the Baltic and their bearing upon the archæological and ethnological problem. The synoptic chronological chart of ancient civilisations in parallel columns will be invaluable to those who have not made a special study of prehistoric archæology.

Der fossile Mensch. Von E. Werth. Zweiter Teil. Pp. 337–576. (Berlin: Gebrüder Borntraeger, n.d.) 12*s.* 8*d.*

This is the second part of a comprehensive treatise on the handiwork of early man. It begins with the middle of a sentence on p. 337 and ends in a similar way on p. 576, and the reviewer has not seen what went before or came after these broken sentences. The volume consists of a very detailed and exceptionally well-illustrated account of palæolithic flint implements, and gives information relating to the extinct fossil animals and plants associated with the various types of implements and to the problems of the glacial periods.

Throughout the book very full bibliographical references are given to memoirs written in the German language, and occasionally to those written in French; but works written in English and information which can only be obtained at first hand in English memoirs, such, for example, as that relating to the discoveries at Piltdown and elsewhere in Britain, are wholly ignored. Moreover, the views expressed in the book are strictly orthodox, and the author is very cautious in referring to matters which do not fall into the old scheme of interpretation adopted by him.

Although the work is called "Der fossile Mensch," there is, at any rate in this part, no reference to the fossilised remains of man. The book is a valuable work of reference for flint implements and for German ideas regarding problems of chronology. The author refers Pithecanthropus to the oldest interglacial period and assigns the Cromer Forest-bed to the same horizon.

G. Elliot Smith.

The Andover District: an Account of Sheet 283 of the One-inch Ordnance Map (Small Sheet Series). By O. G. S. Crawford. (Oxford Geographical Studies.) Pp. 99. (Oxford: Clarendon Press; London: Oxford University Press, 1922.) 7*s.* 6*d.* net.

Mr. Crawford's memoir covers an area which, as he points out, is not particularly well adapted to treatment on the lines of natural regions. In the main he contents himself with indicating the larger divisions, and has taken his units chiefly on a geological basis. On these lines he divides the area into three main natural regions—Andover, the belt of high ground between Basingstoke and Savernake, which is crossed by the Winchester and Newbury Road, and the Vale of Kingsclere. In addition, a portion of the London Tertiary basin and of the Vale of Pewsey come into the north-east and north-west corners respectively. Each of these is studied in detail in respect of its physical and economic aspects. In the latter section Mr. Crawford deals with a subject which in part he has made peculiarly his own, and his analysis of the relations of prehistoric Roman and modern settlements and of early and recent lines of communication in this area will be highly appreciated by archæologists and students of topography.

A number of useful appendices deal with such subjects as measurements, grouping of parishes, prehistoric sites, Anglo-Saxon bounds, forest regions, place-names, and the like. The volume is well illustrated by photographs and numerous plans prepared from the Ordnance Map.

Air Ministry: Meteorological Office. The Marine Observer's Handbook. Third edition (with corrections to September, 1922). (M.O. 218.) Pp. iv + 99. (London: H.M. Stationery Office, 1922.) 5*s.* net.

This book is prepared exclusively for the use of navigators and seamen who keep a record of the weather; it is especially intended for the mercantile marine. There are many essentials in the keeping of the Meteorological Log for the Meteorological Office, among which may be mentioned the uniformity of scales, much of which is new to the ordinary navigator. Instruments, if required, are loaned by the Meteorological Office, which in return for the instruments supplied claims possession of the Meteorological Log. Among the observations required are wind direction and force, barometer, temperature of air and sea, cloud, weather, state of sea, the set and rate of current, and other features of interest. The handbook shows how the observations should be made, and how the results are used for the advantage of seamen and others.

The present-day navigator has many advantages quite unknown to navigators in bygone days, especially with respect to wireless reports, which enable any captain afloat to make for himself by the aid of messages from other adjacent vessels a synchronous chart showing the weather conditions by which he is surrounded. Storms may thus be avoided, and advantage can be taken of favourable weather conditions.

C. H.

Cours de chimie inorganique. Par Prof. Fréd. Swarts. Troisième édition, revue et augmentée. Pp. iv + 734. (Bruxelles: M. Lamertin, 1922.) 50 francs.

The third edition of Prof. F. Swarts' "Cours de chimie inorganique" includes new matter dealing with the constitution of the atom, isotopes, and catalysis. It is perhaps the best book of its type that has appeared in French, but English students would probably prefer to learn chemistry from text-books of similar scope published in their own language.

Outlines of Theoretical Chemistry. By Prof. Frederick H. Getman. Third edition, thoroughly revised and enlarged. Pp. xi + 625. (New York: J. Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1922.) 18*s.* 6*d.* net.

Prof. Getman's "Outlines of Theoretical Chemistry," which appeared just before the War, received a drastic revision in 1918. The third edition has been brought up-to-date by the inclusion of recent work on isotopes and on atomic structure, but retains most of the features of the preceding edition.

Letters to the Editor.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, nor to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Gravitation and Light-Pressure in Spiral Nebulæ.

PROF. LINDEMANN'S idea that the spiral nebulæ may be clouds of particles small enough to be repelled by light is of considerable interest. But we must remember that light carries with it another potential influence which it exerts when it encounters matter, namely, the power of ejecting an electron with an energy of the same order as that of the electron responsible for the light. Star-light, therefore, should be able to eject electrons with enormous energy; and this kind of induced radio-activity may have several partly unforeseen results. A stellar variety of spectrum is one of them, if a continuous spectrum can be composed of a multitude of fine lines, with gaps only where the specific exciting radiation was absent.

Unpolarised self-luminosity is surely more likely than mere reflection of incident light. The reddened light from the centre, observed by Mr. Reynolds, might well be a sunset effect, due to vision through a number of small blue-reflecting particles; the phenomenon does not harmonise so well with the idea of borrowed light.

I suppose that Dr. Jeans's spiral polar arms might occur in a Lindemann cloud as in any other enormous quasi-gaseous mass.

The fact that some few of these nebulæ are approaching the galaxy, instead of rapidly receding, may be accounted for by the suggestion that in these few the particles have aggregated into larger groups (as they may under some kinds of electrification), so that gravitation once more predominates over light-pressure.

The excessive transparency of space seems limited to our own extensive neighbourhood, for in remote regions opacity will set in sooner or later, and all stray radiation—however enfeebled by distance—will sooner or later be re-absorbed, with perhaps exciting and generative material consequences. The birth as well as the death of matter seems not hopelessly beyond our scope. OLIVER J. LODGE.

Breeding Experiments on the Inheritance of Acquired Characters.

ALTHOUGH I agree with Dr. Kammerer in holding the opinion that somatic modifications do, sooner or later, affect the gametes or reproductive cells in such a way as to produce an inherited development of a corresponding change of structure, I regret that the evidence presented in his lecture printed in NATURE of May 12 is in some respects open to the objection that it is not in accordance with the present state of biological knowledge. Another objection, which may be partly due to the fact that the lecture is only a brief summary, is that the evidence does not include sufficient detail, or precise comparison with controls.

For example, Dr. Kammerer states that "Thanks to its enclosing membrane, the ovary of the Salamandra can be removed from the surrounding tissue as a whole," which, according to the context, is not the case with the ovary of birds. I have never heard hitherto of the existence of an enclosed ovary in any amphibian. Unless I am altogether mistaken, the germinal surface of the ovary is exposed to the coelom in Salamandra as in other Amphibia, and the ova escape through this surface as they do in birds, and not into an internal cavity of the ovary as, *e.g.*, in teleostean fishes. If the latter were the case it would be very difficult to understand how ovarian transplantation could be carried out as in Kammerer's experiments.

The fact that Mendelian segregation occurs when naturally spotted Salamandra is crossed with naturally striped Salamandra, but not when it is crossed with experimentally striped specimens, suggests that in the former case the striped character is gametic, while in the latter it is not. But if the experimentally striped character is not gametic, what becomes of the heredity? Kammerer says doubtless both are inherited, but the long-established character obeys the Mendelian law, the new character does not. But T. H. Morgan has shown that new gametic characters in Drosophila obey Mendelian laws from their first appearance. Newness or oldness has nothing to do with Mendelism. A slight degree of heredity is possible, then the experimental striping causes only a slight change in the gametes. Then I presume the natural striping has been caused by exposure to yellow surroundings (soil) for thousands of generations and has become completely gametic, or almost so.

The difference in Mendelian behaviour then would be due to the fact that the natural striping is almost entirely gametic, the experimental striping almost entirely somatic. Such a result would agree with the result of my own experiments on the production of pigment on the lower sides of flat-fishes, supposing it to be true that spotted salamanders occur in Nature on dark ground, striped (yellow) specimens on light or yellow ground.

On the other hand, in the experiments on the results of ovarian transplantation Kammerer puts forth the extraordinary conclusion that the soma of the naturally striped female has no influence on the ova derived from a spotted female, but the artificially striped soma makes the ova derived from a naturally spotted female behave as though they came from a striped female. Here we have a complete gametic change due to somatic influence, while according to the Mendelian experiments there was little or no evidence of gametic change. Such contradictory results *may* be true, but it would require a great deal of corroboration to prove them.

Kammerer states that the case of *Ciona intestinalis* affords an *experimentum crucis*. He certainly exhibited photographs of living Ciona in the parents of which the siphons had been several times amputated. In these young specimens the siphons were "monstrously long," and had been so "from birth." Putting aside the fact that Ciona is not, I believe, viviparous, where were the controls? I have a very strong suspicion that all young Ciona when extended under favourable conditions (*e.g.* supply of oxygen and food) have "monstrously long" siphons. The evidence required is a large number of exact measurements, under the same conditions, of the siphons in the young of parents which were subjected to amputation, and in those of uninjured parents. J. T. CUNNINGHAM.

East London College, Mile End, E., May 12.

Vertical Change of Wind and Tropical Cyclones.

THE first step towards forming an opinion about the physical processes which operate in the formation and maintenance of tropical cyclones is a clear understanding of the structure of the atmosphere in which the formation takes place. A feature of the atmospheric structure which is gradually asserting itself is the resilience of stratification due to the increase of potential temperature with height. We have always recognised isothermal structure as stable, still more so an inversion of lapse rate; but, when one thinks of it, it is clear that the datum for stability is the lapse rate of the saturation adiabatic for upward movement, and that of the dry adiabatic for downward movement. Anything on the isothermal side of these lines implies stability and resilience upon displacement, gradually and continuously increasing up to the isothermal condition and beyond that to inversion.

Since the stratification is only disturbed by saturated air sufficiently warm, the successive layers of the atmosphere in ordinary conditions may be regarded as independent layers, easily capable of motion along surfaces of equipotential temperature, but unable to move up or down across those surfaces. In this respect the layers are like a pack of cards, deformable with a certain amount of resilience, very slippery, but not interpenetrable. The impenetrability of one layer by another is quite inexorable at the bottom, where there is a discontinuity of density between land or water and air, and at the top of the troposphere, where there is thermodynamic discontinuity no less effective in the end, though the effort involves much greater sacrifice in the way of displacement required to produce the necessary resilience. Between these two extremes of resilience the surfaces of equipotential temperature are nearly horizontal. Expression is usually given to the principle of resilience by regarding the motion in any layer as being limited to the horizontal. Of course, the limitation excludes the cases of penetrative convection which sometimes occur, and also the eddy effects due to the motion of a layer relative to the next above or below. But one is as rare as heavy rainfall, and the other, though never absent, is very small in magnitude. Thus for a first survey both may be left out of account.

Also, to begin with, it is best to think of the atmosphere as made up of a number of layers of finite thickness, and not attempt the gradation of an infinite number of layers of infinitesimal thickness. There is often a natural sorting of the structure into irregular strata; but, for the moment, let us think of twenty layers each half a kilometre thick between the ground and the stratosphere, the two boundaries the resilience of which must eventually balance the internal stresses of a quasi-permanent cyclonic vortex.

The motion in each of the twenty layers except the lowest will adjust itself to the distribution of pressure in that layer. The law of the lowest stratum is different. In consequence of surface friction there is a flow across the isobars, with all the disturbing consequences thereof.

As we regard the undisturbed medium as a pile of twenty horizontal layers, so we must regard a cyclonic system as made up of a number of independent layers. We must consider the vortical motion produced in the medium as twenty separate rotating discs, not as a unified rotating column. There is practically nothing in the structure to prevent the slipping of one disc of revolving fluid over another to any extent. The unit of cyclonic activity is not a column reaching from earth to heaven, but a layer, say half a kilometre thick, with a mass of fluid revolving according to its own laws between the upper and lower boundaries.

In these circumstances, if the centres of the revolving masses were accurately superposed to begin with, it would be a marvel of Nature if they remained so. Since pressure is transmitted, the displacement of one would alter the distribution of pressure for all beneath, the inflow at the bottom would affect the mass-distribution of those immediately above, and the relative motion at the surfaces of separation would add further complications.

If all this be correct, what might once have been a vertical revolving column, in a stream of which the velocity varied with height, would soon have become a number of separate and more or less degraded revolving discs. If there happened to be a thick enough layer in the original medium without any height-change of velocity, there might be enough organised rotational energy to preserve the original identity: otherwise the energy would soon be lost in eddies and ultimately in frictional heat.

I am not sure whether Mr. Banerji (NATURE, May 19, p. 668) realises that that was the kind of structure which I had vaguely in mind three years ago when I wrote the remarks in Geophysical Memoir, 19, to which he refers. The lapse of time has enabled me perhaps to think it out more clearly and to develop further the condition for no change of velocity with height. If one imagines a number of masses of saturated air overcoming the resilience locally, passing through a series of superposed layers of air and removing therefrom automatically, by eviction, a vast quantity of air amounting in the aggregate to millions of tons, each layer must set up its own scheme of pressure and rotation independently of the others. As a means of making a rotating column the experiment could scarcely succeed if, by the time that the removal was complete, the centres of the upper systems were displaced horizontally a long way from the lowest; the superposed pressures and the incidental relative motions would certainly spoil the symmetry and in time destroy the unity of the system.

The monsoon winds, of the peculiar behaviour of which Mr. Banerji speaks as being sufficient to account for the movements of the cyclonic storms in Indian seas, belong to the lowest kilometre and are therefore not properly amenable to the distribution of pressure. To my mind surface winds are primarily disturbers and destroyers of ordered vortical motion. A well-organised cyclone may succeed in feeding on their energy and thus increasing its own vigour in the way which Dr. Fujiwhara described recently to the Royal Meteorological Society. In Geophysical Memoir, 19, I was not dealing with that part of the subject, but only with the initial stages of the creation of the vortex.

The Relation of Actinium to Uranium.

AT present the most likely view of the origin of the actinium series is that uranium II undergoes a dual change in which about 96 per cent. of atoms form ionium and the radium series, and the remainder form uranium Y, the product of which, proto-actinium, is the parent of the actinium series. An alternative view is that uranium I undergoes the dual change. In 1917 Piccard from a consideration of the Geiger-Nuttall relation put forward the view that the actinium series might arise from an isotope of uranium, actino-uranium, of atomic weight 240, present in ordinary uranium to the extent of about 8 per cent. Partly from experimental work carried out by Mr. W. P. Widdowson and myself, and partly from a survey of certain general relations in radio-activity, I have come to a different view, which I think represents the facts more adequately than these others. I agree with Piccard in thinking that the parent substance of the actinium series is an isotope of uranium, of atomic weight 240, not genetically connected with it; but differ principally in thinking the atomic weight of actinium is not 232, and that uranium Y is not the immediate parent of proto-actinium.

The scheme is as follows:

Element.	Period.	Atomic Number.	Radiation.	Atomic Weight.
Actino-uranium I .	$>5 \cdot 10^9$ years	92	α	240
Uranium Y_1 . .	25·5 hours	90	β	236
Uranium Y_2 . .	Probably very short	91	β	236
Actino-uranium II .	$>2 \cdot 10^4$ years	92	α	236
Parent of proto-actinium . .	>20 years	90	β	232
Proto-actinium .	$<1·2 \cdot 10^4$ years	91	α	232
Actinium . . .	20 years	89	β	228
Radio-actinium, etc.	19·5 days	90	α	228

This scheme was arrived at from a consideration of the periods of corresponding members of the three disintegration series. Successive radio-active transformations may be classed in three ways:

(1) Four α-particles (five in the uranium series) follow each other without the expulsion of a β-particle.

(2) An α-particle is followed by two β-particles in succession and then an α-particle.

(3) An α-particle is followed successively by a β-, an α-, and a β-particle.

In the three known examples of the first type each product has on the average 800 times the period of its successor. (For the uranium series the ratio is 766, for the thorium 764, for the actinium 918.) Yet the periods of average corresponding members of the three series (in the order given) are in the proportion of 5×10^5, 50, and 1. Now the difference in atomic weight between the uranium and the thorium series is 2 only. I have assumed that if a time ratio of 5×10^5 to 50 corresponds to 2, a ratio of 50 to 1 corresponds to so small a fraction as to be negligible. If this be justifiable the atomic weights of the thorium and actinium series become identical. It follows that actinium has an atomic weight of 228 and so cannot be genetically connected with uranium if α- and β- be the only particles expelled in radio-active transformations.

I have found interesting relations connecting the periods of the bodies of the second and third types of successive transformations, but the only thing necessary for the scheme to be deduced is that in both these types the period of the first β-particle is greater than that of the second. There are in all, excluding the change, parent of Pa$\rightarrow$Pa$\rightarrow$Ac$\rightarrow$RdAc, ten examples of the second and third types known, in all of which this relation holds. It is consequently not unreasonable to suppose that the parent of proto-actinium has a longer period than actinium and consequently cannot be uranium Y. As the latter is very probably genetically connected with actinium, and is undoubtedly a product of a body of atomic number 92, it must be an isotope of the parent of proto-actinium probably with an atomic weight 4 units greater. To connect it with the parent of proto-actinium it is simplest to suppose that it is followed by a quick-changing product uranium Y_2, corresponding to uranium X_2, which is the parent of an isotope of the original actino-uranium, and this immediately precedes the parent of actinium as shown in the table above.

The scheme, so far as I am aware, does not seriously contravene the results of experimental work, and appears to be nearer what one would expect by analogies from the thorium and uranium series and the lower part of the actinium series than those previously proposed. None of the new proposed data given in the table contravene the Geiger-Nuttall relation. Moreover, they appear to make Fajan's rules connecting the order of the atomic weights of isotopic α-ray and β-ray bodies with the order of their periods more nearly exact than hitherto they have appeared to be. To Fajan's α-ray rule there have been hitherto three exceptions; on the new scheme there is only one. The two exceptions to his β-ray rule do not exist in the new scheme.

Our experimental work on the relative activity of uranium and its products in pitchblende leads to a ratio in the amounts of actinio-uranium and uranium I in uranium of about 5 to 95. But the experimental results to be expected on the assumption that uranium II breaks up dually in this proportion to form the actinium and radium series lead to so similar a result that at present our experimental work is insufficiently advanced to lead to a decision.

Mr. W. G. Guy in this laboratory has been for some time engaged with me in repeating Dr. O. Hahn's work on uranium Z as described in the latter's publication of 1921, and has independently come to very similar results to those described in Hahn's second and recent paper. He confirms Hahn's important result that uranium X_1 breaks up dually, in both cases with the emission of a β-particle to form uranium X_2 and uranium Z in a ratio of about 997 to 3. He has also measured the periods of uranium Y, uranium Z, and uranium X_2 accurately, and finds them to be 25·5 hours, 6·69 hours, and 70·5 seconds respectively. These agree with the published values. Dr. Hahn does not appear to have noticed that the branching ratio, which he gives as 996·5 to 3·5, is approximately equal to the reciprocal of the periods of the two bodies formed. This agreement may be a coincidence. If it is not, it would not be difficult to deduce from it information which might throw light on the mechanism of disintegration.

Slag mistaken for a Meteorite at Quetta.

Wide publicity has been given in the Press to a story of a fall of a large meteoric mass in Quetta, Baluchistan Agency.

The Geological Survey of India has always paid particular attention to falls of this kind, and, within an hour of the receipt of the news in Calcutta, was in telegraphic communication with the authorities in Quetta, and the receipt of specimens was anxiously awaited. Ultimately, approximately two hundred-weights of material were carefully examined, and found to be entirely a glassy slag in which were embedded bits of iron wire and thin iron bands.

So far as can be judged, the sequence of events was as follows: A large stack of baled bhoosa (chopped straw) of about five hundred tons weight was fired by a flash of lightning during a heavy thunderstorm, and a mass of slag some five tons in weight was left behind. A bystander suggested that this mass was of meteoric origin.

Vision and Light Sensitiveness.

In my former letter (NATURE, April 14, p. 498) I endeavoured to avoid dogmatism on this very obscure subject, and aimed rather at stimulating further research in what seems to be a phenomenon of great importance Though I go all the way with Mr. Locket (NATURE, April 28, p. 570) in cautioning the utmost reserve in accepting my hypothesis, especially as, in my letter, it is supported, and designedly so, by no more definite evidence than the flicking of a fly; still, in the interests of research, I feel called upon to add some comments to his letter.

I have collected a large mass of evidence which, however, cannot be published *yet*, as it is far from complete. Moreover, as much of it appears to contradict the conclusions of great authorities, some of whom Mr. Locket mentions, it obviously cannot be urged until I have repeated each essential portion of it more than once, and explored in each experiment every possibility.

First of all, then, I submit that it is of the utmost importance to differentiate clearly between *sensitiveness to light* and *vision*, both in experiment and in deduction; for vision is by means of eyes, light sensitiveness not necessarily so. Plateau has proved (*Journal de l'Anat. et de la Physiol.*, 1886, p. 431) that certain myriapods distinguish between light and darkness by the general surface of the skin; though Forel and Lord Avebury have proved this not to be the case with ants. It would be interesting to know if it is so in Typhlopone, where there are no eyes. Wherever there are eyes I think we may, for the present, assume that there is sensitiveness to light, but this is far different from presuming that there is vision. I have been unable to discover any evidence for vision in the Epeiræ studied, or in *Tegenaria domestica* or *Agelena labyrinthica*, when proper precautions have been taken. In these instances a fly, with the wings cut off, will not disturb them; but, if the fly have wings or stumps of wings with which it can buzz in the forceps then the case is very different. The necessity for taking every precaution may be shown by the extreme sensitiveness of *T. domestica* to the presence of carbon dioxide, so that even slight breathing on the specimen causes movement. Though this spider will revive after a collapse of five minutes in a vacuum at 6 mm. of mercury, though it will live for some minutes apparently with comfort in coal gas, an atmosphere of carbon dioxide kills it instantly.

Another precaution, most essential to success, is to avoid casting shadows on the animal under observation; in the case of the black-bellied tarantula (*Lycosa narbonnensis*), and in very many others, there is a manifest seeking for light. This is most apparent when the young are on the parent's back. Here, possibly, lies the solution of this enigma. This spider carries her young on her back with, so far as I can see, no food for about six months. These fasting youngsters grow strong, expend energy, and certainly do not become emaciated. Do they get their energy from the air alone? Do they possibly get it from the sun, as vegetable life does? I cannot yet answer this. Here the investigation would extend from the pigment-spot in *Euglena viridis* to the facts of modern heliotherapy.

Turning to Mr. Locket's remarks on the ants, the species employed for the most part were *Formica fusca* and *F. sanguinea*. In these insects Forel (*Rec. Zoolog. Suisse*, 1887) has proved that there is normally sensitiveness to light which is destroyed by varnishing the eyes, and Lord Avebury mentions ("Ants, Bees, and Wasps," 13th edition, p. 405) their sensitiveness to "ultra-violet rays much beyond our limits of vision." This same authority says quite plainly (*op. cit.* pp. 273, 272, 266, 256, 251) of *Lasius niger* that, "though it seems clear that they are helped by sight," they do not trust much to their eyes, and are "little guided by . . . surrounding objects." In another experiment, "if she [the ant] were much aided by sight, then she would have had little difficulty in finding her way back." On the other hand, he concludes from further work (pp. 268, 270) that by altering the *position of the lights* "the ant went wrong," and that, "in determining their course the ants are greatly influenced by the direction of the light." Here the difference between mere *light sensitiveness* and *vision* is strongly supported.

Forel's experiment ("Senses of Insects," pp. 124-128), noted by Mr. Locket, had seemed to me conclusive until I repeated it, taking care to supply several control ants the eyes of which were varnished with a transparent fluid. From the results I concluded that the difficulty in finding home was as much due to the annoyance of being handled and varnished as to being hoodwinked.

When working on the flies, including both species mentioned by Mr. Locket, I did not varnish the eyes; I used a second sheet of glass between the fly's back and the moving object. Still this experiment with the second glass was not repeated often enough to allow me to state my results with assurance, and I agree with Mr. Locket that varnish should have been employed. With regard to the motion of air,—and this is the kernel of Commander Hilton Young's hypothesis,—vibration due to sound waves and simple air currents must be treated separately. Many insects and spiders are extremely sensitive to the former, and there can be no doubt that the fly is sensitive to the latter, though I doubt whether to the extent suggested by Commander Hilton Young.

I cannot agree with Mr. Locket in his use of the ocelli as an explanation. It was, I think, Johannes Müller's opinion that they were especially useful for close vision. But we have the authority of Plateau, Forel, Réaumur, Marcel de Serres, Dugès, Lord Avebury, and others, that varnishing of these organs made no difference. Though many, with Forel (*Rec. Zoolog. Suisse*, 1887), Lebert ("Die Spinnen der Schweiz"), and Pavesi (*Ann. Mus. Civ. di Genova*, 1873, p. 344), suggest that the ocelli serve for vision in semi-darkness, and the eyes for vision in full light, the experiments I have made in this field, necessarily obscure, have been fruitless, so far as I have been able to devise them.

The instance of the male Attid, given by Mr. Locket, I have not worked on yet; as well as the many examples of what appears to be lethal fascination as in *Mantis religiosa*. There is clearly an enormous amount of work to be done,—so far I have not touched the scorpions,—and I speak, as I did in my former letter, only of those species which I have studied, necessarily few relative to the vast kingdom under discussion. So I can end no better than again, with Mr. Locket, cautioning reserve.

Phosphorescence caused by Active Nitrogen.

In a letter under this title in NATURE of May 5, p. 599, Prof. E. P. Lewis announces his recent discovery that active nitrogen excites phosphorescence in a number of solid compounds. I should like to mention that during the summer of last year I observed the same phenomenon in the case of an

X 2

aluminium compound, which does not, however, occur in the list of substances given by Prof. Lewis.

In resuming, during July last, a series of spectroscopic investigations begun in 1913 on the lines of earlier work by the present Lord Rayleigh and Prof. Fowler, I attempted a preliminary observation of the spectrum resulting from the introduction of the vapour of aluminium chloride into the stream of active nitrogen. After a long exposure a solid deposit was produced on the inside of the afterglow tube, and when the stream of active nitrogen was passed through the same tube a few days later the deposit exhibited a bright green fluorescence. It was hoped that this observation might be recorded in a future paper, after opportunity for further spectroscopic work had occurred. In view of Prof. Lewis's announcement, however, perhaps this note by way of corroboration is not out of place.

The Dissolution of the Conjoint Board of Scientific Societies.

ACTING under the instructions of the Executive Committee, we have now wound up the affairs of the Conjoint Board of Scientific Societies.

Everything connected with the "List of Scientific Periodicals" has been placed in the hands of the Trustees who have been appointed to carry out this publication. The work on the List is now well advanced.

The Royal Society has agreed to accept the custody of filed records and documents related to the work of the Board and its Committees, with the exception of that just mentioned. These have now been lodged with the Society, except the records of three Committees, at present in the hands of their secretaries for final revision before lodgment with the Society.

Copies of the proceedings of the Board have also been deposited with the British Museum, the Royal Society of Edinburgh, the Patent Office, Sir Arthur Schuster, Sir Herbert Jackson, and Prof. W. W. Watts. Sets of printed matter have been also handed to the Department of Scientific and Industrial Research, the National Physical Laboratory, the Science Library, the University of London, the Imperial College of Science and Technology, the British Museum (Natural History), and the London Library.

The Capture of Electrons by Swiftly Moving Alpha Particles.

THE swiftly moving α-particle produces a large number of ions in its passage through a gas, as is evidenced by the beautiful Wilson photographs of α-ray tracks. It is a matter of some surprise that at the act of ionising a molecule, or immediately after, the α-particle does not attach one or more of the free electrons to itself. The approach is very near and the force is that due to a double charge.

The experiments of Rutherford, Marsden and Taylor, and others indicate that the swiftly moving α-particles begin to take up electrons when the velocity has decreased to 0·4 of the initial value ($v_1=0{\cdot}4\ v_0$). The recent experiments of Henderson (Proc. Roy. Soc., January 1, 1923) indicate that at this velocity the α-particle takes up one electron. It then continues its smashing career through matter without change until the velocity is reduced to 0·15 of the initial value ($v_2=0{\cdot}15v_0$). At this velocity, approximately, the α-particle takes up a second electron and becomes a more or less harmless atom of helium.

The limiting velocities at which the α-particle captures the first and then the second electron seem to be rather definitely fixed. The initial velocity from radium-C is $v_0=2{\cdot}06\times10^9$ cm./sec. The velocity at first capture is $v_1=0{\cdot}4v_0=8{\cdot}2\times10^8$ cm./sec. The velocity at second capture is stated by Henderson to be at least as small as $v_2=0{\cdot}15v_0=3{\cdot}1\times10^8$ cm./sec.

It is desired to point out here that this failure to capture an electron may be due to the high velocity of the α-particles. The free electron will at once start toward the α-particle. If the latter is moving with a velocity greater than the velocity of fall (parabolic velocity) of an electron into the K ring, the electron will fail to reach the K ring and effect a combination. Having this situation in view, I have calculated the limiting parabolic velocity for an electron falling into the K ring of (1) a doubly charged α-particle and (2) one having a single charge. The radius of the K ring is given by $a=h^2/4\pi^2meE$, where E is the excess nuclear charge in each case. This velocity is given by $\frac{1}{2}mv^2=Ee/a$. From these considerations the calculated velocity for the first case is $v_1=6{\cdot}2\times10^8$ cm./sec. In the second case the charge E is single, and the velocity $v_2=3{\cdot}2\times10^8$ cm./sec. The experiments are necessarily not very exact, but the agreement is sufficiently close to suggest that this may be the proper explanation of the action.

From this point of view, all α-rays, of whatever initial velocity, should capture the first and second electrons at the same velocity. This is a matter of sufficient importance to determine experimentally.

Recent Auroræ.

MAGNETIC disturbances and associated phenomena have perhaps a special interest when they occur during the minimum period of sunspot activity, owing to the comparative rarity of these events at this time. When, therefore, I read in NATURE of April 21, p. 534, the account by Father Cortie of the recent disturbances, it reminded me of observations I had made of the aurora in activity on the dates referred to. On February 25, in a very clear sky, with a nine-days-old moon shining, the northern horizon was seen to be brightly illuminated by auroral light at 8.45 P.M. for about half an hour, but no streamers were seen. On March 24, again in first-quarter moonlight, but a very hazy sky, I saw an auroral display of unusual beauty at 9 P.M. over Bassenthwaite Lake. The arch was elevated ten degrees, with streamers and lances shooting upwards for, in some cases, another thirty degrees. The length of the arch I could not measure, owing to each end being hidden by lofty mountains, but it was visible for sixty degrees. It was clear-cut below, and merged gradually into the moonlit haze above.

The reflection of the streamers in the perfect mirror-like surface of the lake, and the shining arch flanked by snow-capped heights, dimly seen in the misty moonlight, combined to form a picture of indescribable beauty.

Recent Experiments in Aerial Surveying by Vertical Photographs.[1]

By Prof. B. Melvill Jones and Major J. C. Griffiths.

I.

It is proposed to describe in these columns the results of experiments on aerial surveying that have been in progress at the University of Cambridge since 1920. The experiments were made possible by the co-operation of the Royal Air Force and the Department of Scientific and Industrial Research with the chair of aeronautics at Cambridge. They were suggested in the first place by Mr. Hamshaw Thomas of Cambridge as the result of his experiences of air-mapping in Palestine during the War. The authors wish to acknowledge their debt to Mr. Thomas, not only for the original suggestion, but also for valuable advice during the progress of the work.

To make an accurate survey by air, it is necessary to have information concerning the position and orientation of the camera at the moment of exposure. If the ground concerned is flat and the tilt of the camera is known, the photograph can easily be re-projected to give a true plan. When the ground is hilly, two photos of the same area, taken from known points, and with known tilts, will provide information from which a complete model, or map with contours, can be constructed.

If three points that are accurately known in position occur in a photo, it is possible to find the position and orientation of the camera from internal evidence in the plate itself. This process is called "re-section." It is thus theoretically possible to map an indefinite area of country from a single base of three known points, for these points could be made to occur in the first two photos, which could then be used to determine the positions of other points, from which further photos could be re-sected, and so on. In practice this process would lead to accumulations of error which, with the methods yet available, would soon become prohibitively large. It is for this reason necessary, if the re-section method is to be used at present, to provide a net of ground-surveyed control points such that three will occur in most, if not all, the photographs.

When the aerial map is merely required to record changes, or to fill in detail in a country that has already been closely surveyed, as, for example, in the war mapping of the Western Front, or in the re-mapping of towns in peace, many accurately surveyed points will already exist and the re-section method will be the obvious one to use. When, however, the problem is to map large areas of unsurveyed country, as, for example, the interiors of Australia or Africa, the cost of providing so many ground-surveyed points will generally be prohibitive. This will be especially the case when the country is flat and heavily wooded.

It is, however, precisely in connexion with large areas of this nature that the outlook for aerial surveying, on a large scale, is most hopeful. In such cases it will not, in general, be practicable to spend much money per square mile of survey, so that it becomes necessary to employ methods that neither require a close preliminary ground survey nor involve too much office labour per photo. Both these conditions rule out the re-section method for work of this class.

Now exact determination of the position and orientation of the camera in space, by methods that are independent of the photo itself, is a matter of great difficulty, but it happens that an exact plan of level country can be constructed from overlapping photos, without knowing the exact position of the camera, provided that all the photos are taken from the same height and with the camera axis vertical. The reason for this is that all such photos will show a true plan of the ground to the same scale, and therefore they can be shuffled together, until the detail joins up everywhere and a true plan is formed.

If, therefore, a camera can be kept at a constant height, with its axis vertical, and moved about over the ground, so that the whole country is covered by overlapping photos, it will be possible to construct a continuous plan of the ground from contact prints straight from the original negatives; and it will not be necessary to provide for known points to appear on each photo, or to determine the position of the camera at each exposure. Moreover, the heavy office work involved in re-secting and re-projecting each photo will be avoided entirely.

Such a process is strictly accurate only when applied to absolutely flat country, but when working from 10,000 feet, as we do, undulating country up to about 500 feet local differences of level can be classed as sufficiently flat from this point of view. It must also be remembered that flat country is often the most difficult to survey from the ground, and is therefore the country in which an alternative method is most required.

We are thus led to the conclusion that the economical mapping of moderately flat country, by means of vertical photographs, depends upon the accuracy with which the camera can be maintained at a constant height, with its axis vertical, and upon the ability of the pilot to fly so as to cover all the ground with photographs that will neither overlap too much nor leave gaps. The experiments at Cambridge have been concerned mainly with the accuracy obtainable in these operations, given suitable apparatus and sufficient training in air routine.

Finding the Vertical.

The problem of keeping a constant height is quite straightforward and easy to understand; the only difficulty is to do it. The problem of keeping the camera axis vertical is complicated by the fact that all forms of apparatus that are designed to indicate the vertical are disturbed by horizontal accelerations of the aeroplane, which often persist in one direction for so long as twenty seconds at a time. It is possible to devise gyroscopical instruments that will seek the vertical so slowly as to average out these disturbances, but much experience has been gained with instruments of this type during the War, and this experience was not encouraging, mainly owing to the liability to failure of the delicate apparatus required.

In aerial surveying it is, however, necessary to fly

[1] Substance of two lectures delivered at the Royal Institution on February 15 and 22.

very straight and steadily in order to cover the ground correctly, and, when one is flying straight and steadily, simple vertical indicators such as the spirit level indicate truly.

Now it had been found, in connexion with bombing experiments during the War, that it is comparatively easy to fly very straight and steadily when no other condition is imposed, but that it is much more difficult to do so when trying to pass over a pre-arranged point. The reason for this is that the pilot normally estimates the horizontal and vertical by reference to the horizon, and, when forced to look at the ground beneath him, is quite unable to distinguish the true vertical from the apparent vertical as distorted by acceleration.[2] It is obviously necessary to look at a point in order to get over it, so that the reason for the distinction between merely flying straight and flying straight over an object is at once apparent. To overcome this difficulty it is necessary to devise methods of carrying out the survey with the minimum attention to the ground beneath.

We decided to divide our experiments into two groups as follows:

1. To study the accuracy with which it is possible to keep the camera at a constant height with its axis vertical, when the difficulty of finding a predetermined track is reduced to a minimum.

2. To find out how to fly over a predetermined straight track without losing accuracy from that determined above.

In connexion with the first group of experiments, we were fortunate in having near Cambridge a stretch of very flat country covered with numerous well-mapped and easily identified points and traversed by two large straight canals, more than twenty miles long, called the Bedford Levels.

It is easy to fly down a long straight landmark of this nature with very little attention to the ground immediately beneath. We therefore flew along these canals at about 10,000 feet, keeping as straight and level as possible, and taking a series of photographs at regular intervals. We then developed these photos and, from them and a 6-inch Ordnance Map, calculated the position and orientation of the camera at the moment of exposure by the method of re-section.

The re-section was very laborious, but eventually, after about two years' work, we obtained results for 170 exposures, and these showed a probable error of tilt of about 1° from the vertical and a probable variation of height from the mean of a flight of 40 feet. The distribution of errors in both tilt and height was quite normal.

From this data it is clear that the tilt of the camera axis from the vertical seldom exceeded 2° and that the height of the camera seldom varied more than 100 feet from the mean of each flight. Simple calculations, supported by previous experience in Palestine, lead to the conclusion that such errors should not introduce serious errors into maps made on the assumption that the axis is vertical and the height constant. This excludes, of course, errors that are cumulative over large distances.

[2] It is easily shown that a pilot, looking down at a point beneath him and trying to fly so as to pass over it, will tend to fly along one of a series of curves of which the equation is $p\rho=$const., where p is the perpendicular from the origin on the tangent from the point where the radius of curvature is ρ. These curves in general never pass over the required point (*i.e.* the origin).

COVERING THE GROUND WITHOUT GAPS.

The second problem was to cover the required country to be surveyed without leaving gaps and without losing accuracy. It is on this problem that most attempts at commercial surveying have broken down, the primary cause of failure being the inability of the pilot to distinguish between the true and apparent vertical. So long as the pilot is allowed to look constantly down at the ground, in an endeavour to cover it accurately, tilts up to six or more degrees are liable to occur, and the tracks that are made under these conditions are often so curved as to cause large gaps between the strips of photos.

By experiment we have found that the best way to solve the difficulty lies in allowing the pilot to locate his position by reference to the ground beneath, at the start of each flight only, and insisting that he must fly henceforward without further reference to the ground.

To do this in such a way that successive flights on the out and return journeys will cover the ground in parallel strips, it is necessary, first, to find and allow for the wind at the height in question. This we do by a method that was developed by the Air Ministry for purposes of aerial navigation, and we have brought the routine to such a pitch that within ten minutes after reaching the survey height, 10,000 feet, we can find the wind and make all necessary calculations for compass courses, etc. It requires considerable training and experience before this can be done.

However good the methods employed, the strips on successive journeys will not be exactly parallel, and, since they are located only at one end, their length will obviously be limited if gaps are to be avoided. We find that this limit comes out at between 10 and 15 miles. The starting points for the strips are either marked on existing maps or on preliminary strips of photographs, taken along the edges of the mosaic at right angles to the mosaic strips; these preliminary strips are called "indication strips."

The pilot, therefore, begins by getting over a point, as accurately as he can, and then taking up a pre-calculated compass bearing as quickly as possible. A difficulty may here be experienced owing to the well-known fact that compasses on aeroplanes are affected by a change of course and do not settle down on a true bearing until the aeroplane has been flying straight and steadily for some time. If the pilot has managed to get over the starting point while flying on the correct bearing, this difficulty will not arise, but when working from tractor aeroplanes, as we are forced to do, one cannot always manage this, because the lower plane obstructs the view of the point during the approach, unless the approach is made in a curve.

To overcome this difficulty we use an apparatus designed by the Royal Aircraft Establishment. This consists of a free gyro that can maintain its orientation in space for some ten minutes, without reference to the movements of the aeroplane. We release this gyro while flying on the required course, just before reaching the starting point, and use it to return to the correct course immediately after passing the point. We consider that an apparatus of this nature will always be a great help in aerial surveying, especially when working from tractors, but we think that a survey could be successfully carried out without it when working from pushers. When flying without this apparatus, either more skill is required, or the beginnings of each strip will be rather less accurate than they might be.

The photographic strips themselves can be kept straight by flying on a distant point near the horizon, but this operation can be much assisted by another gyro instrument that controls the rudder through a relay and thus keeps the aeroplane on a straight course automatically. This apparatus relieves the pilot of the most fatiguing part of his work and, by allowing him to concentrate more on such things as maintaining constant height and speed, improves the general quality of his work. We have carried out surveys both with and without this instrument, and, while we have proved that accurate work can be done without it, we should always recommend its use in any large surveying scheme.

Area covered in a Flight.

We have found from experience that 100 sq. miles is about the area that can conveniently be covered in one flight. This requires about 80 minutes flying on the actual mapping and about three hours from ground to ground. This amount of work is about what a crew can perform regularly, day by day; hence it follows that aerial surveying by these methods can be carried out at the rate of about 100 sq. miles per day. If the separate strips are made ten miles long, the average day's work will, therefore, cover a square of ten miles to the side.

We have found that an area of 100 sq. miles, involving about 130 photos, forms a convenient unit for compilation, for, although we have compiled a very successful map of 225 sq. miles in one unit, we consider this to be too large for economical work. The method, therefore, that we favour for mapping large areas, is to compile the prints of each day's work into separate mosaics and, after reproducing these to any required scale in a large camera, or photostat, to fit these larger units together in the same way as the individual prints were fitted.

(*To be continued.*)

Science and Radio-Communication.[1]

By Sir Richard Glazebrook, K.C.B., F.R.S.

Problems in which there is a close connexion between theory and practice can be found in every branch of engineering, perhaps with more striking effect in electrical and metallurgical science, in the laws of stress and strain in structural materials, and in the fatigue of parts subject to vibration, rather than in the questions which pertain more closely to the domain of civil engineering. Let me deal first, briefly and incompletely it must be, I fear, with that branch of electrical engineering—radio, or wireless telegraphy—which at present exercises such a fascination over the popular mind, which is already and will be to a greater extent in the future a link to bind together all nations of the earth. Sir William Anderson, in the first James Forrest lecture delivered thirty years ago, refers to Preece's early experiments between Lavernock and Flatholme, a distance of eight miles, as a startling consequence of electro-magnetic theory. Now the earth is girdled with a wireless chain depending from two, or at most three, great stations. I have just received from the International Union for Scientific Radio Telegraphy details of a scheme for the determination of longitude in which the principal co-operating stations will be Bordeaux, Annapolis, and Pearl Harbour.

In the year 1865 Clerk Maxwell read before the Royal Society his paper on "The Equations of the Electro-Magnetic Field." It was an attempt, which has stood the test of time—the conditions which led Lorentz and, later, Einstein to introduce certain modifications were not dealt with by Maxwell—to apply mathematical reasoning to those principles, enunciated by Faraday, on which the construction of generators and motors, transformers, and practically all electrical machinery is based. This reasoning led him to the result that the effect of changes in an electric current in a conducting wire would be propagated through space with a speed depending on the two constants[2] which define the electric and magnetic conditions of the medium surrounding the wire. The values of these constants for air can be found from electrical considerations, and hence the velocity with which electro-magnetic disturbances are propagated can be calculated. To quote his words:

> "We now proceed to investigate whether these properties of that which constitutes the electro-magnetic field, deduced from electro-magnetic phenomena alone, are sufficient to explain the propagation of light through the same substance," and his conclusion is: "The agreement of the results seems to show that light and magnetism are affections of the same substance and that light is an electro-magnetic disturbance propagated through the field according to electro-magnetic laws."

Maxwell found that when the calculations were made the resulting value for the velocity was approximately equal to the velocity of light. The work was extended in his "Treatise on Electricity and Magnetism," published in 1873. The values of the velocity of light and the velocity of propagation of electro-magnetic waves were not known then with present-day accuracy, and he concludes that they are quantities of the same order of magnitude. A glance at present-day[3] figures shows that they are identical, and the electro-magnetic theory of light is universally accepted. Nor was the result true only for propagation through air or interstellar space; such observations as were then available showed that, in all probability, it held for all transparent media, though there were discrepancies, known now to

[1] From the James Forrest lecture on "The Interdependence of Abstract Science and Engineering," delivered before the Institution of Civil Engineers on May 4.

[2] The velocity is given by $1/\sqrt{\mu k}$, where k is the inductive capacity and μ the magnetic permeability of the surrounding medium.

[3] Messrs. Rosa and Dorsey of the Bureau of Standards, discussing the various determinations of the electro-magnetic velocity, express the view that the figure $2{\cdot}9980 \times 10^{10}$ cm./sec. is accurate to 1 part in 10,000, while the best result for the velocity of light is, to the same accuracy of measurement, $2{\cdot}9986 \times 10^{10}$ cm./sec. See "Dictionary of Applied Physics," vol. ii.

be due to dispersion, which required explanation. But there was a wide gap between this theoretical deduction of Maxwell and the wireless telegraphy of to-day, which needed many more investigations in "pure" science before the bridge was complete. We at the Cavendish Laboratory—I was a student at the time—implicitly believed in its truth; but no one had received electromagnetic vibrations—at any rate, to his certain knowledge. The method of generating them and the means for measuring them were still to come.

For the former we have to go back to a remarkable paper[4] by a very distinguished honorary member of this Institution, Lord Kelvin. Helmholtz[5] seems to have been the first to conceive that the discharge of a condenser through a wire might consist of a forward and backward motion of electricity between the coatings —a series of currents in opposite directions. Lord Kelvin took up the question mathematically and investigated the phenomena. He showed that under certain conditions there would be oscillations of periodic time $2\pi\sqrt{LC}$, where L is the inductance of the coil, and C the capacity of the condenser. These oscillations must, according to the theory, give rise to waves travelling out into space with the electro-magnetic velocity. Fitzgerald, at a meeting of the British Association, had predicted in 1883 that they might be produced by utilising the oscillatory discharge of a Leyden jar, and Sir Oliver Lodge in 1887 produced and detected them. For their detection the principle of resonance was employed. Any mechanical system free to vibrate has its own period of oscillation, and the application to it of a series of small impulses at intervals coincident with the free period of the system results in a disturbance of large amplitude. So, too, an electric system having capacity and inductance has its own period of electrical oscillation, and, if this coincides with the period of incoming electrical waves, electrical disturbances of a magnitude which can be detected by our apparatus are set up. It is necessary that the receiver and the transmitter should be in tune. Lodge made use of this principle, and, by receiving the waves on wires adjusted to resonance with his Leyden jar and coil, was able to detect them. David Hughes, working in the early 'eighties, had already detected such oscillations, but was discouraged from pursuing the subject.

In 1879, in consequence of the offer of a prize by the Berlin Academy, the attention of Heinrich Herz, then a student under Helmholtz, was attracted to the problem of electric oscillations and their detection. He came to the conclusion that with the means of observation then at his disposal "any decided effect could scarcely be hoped for, but only an action lying just within the limits of observation." The investigation was laid aside, only to be revived in 1886 by a chance observation of the effect of resonance in two circuits which happened to be in tune, and his realisation of the fact that herein lay the means of solution of his problem. His paper "On Very Rapid Electric Oscillations" appeared in Wiedemann's *Annalen*, vol. xxxi. for 1887, and from this experiment came verification of Maxwell's theory, the basis of all our knowledge of wireless.

[4] *Phil. Mag.*, 1855.
[5] "Über die Erhaltung der Kraft," 1847.

Fitzgerald directed the attention of English physicists to the work at the British Association meeting in 1888, and Lodge exhibited many of the effects of the waves at the Royal Institution in 1889. The investigations which led to such brilliant results were inspired by the desire for knowledge; the idea of their practical application was entirely absent. Signalling by wireless waves was not foreshadowed until Crookes suggested it in 1892, and in 1893, the year of Sir William Anderson's lecture, Lodge heard of Branly's coherer and applied it to the rectification and reception of wireless waves. From this started the investigations of many of those whose names as pioneers are familiar to all. But another discovery in pure science was necessary to complete the work.

Edison had shown in 1883 that if an insulated electrode was inserted in an ordinary glow lamp there was a current of negative electricity from the filament to the electrode—the emission of negative electricity from a hot body had been observed by various experimenters—and Fleming made some observations about this date on the Edison effect. In 1904 he applied them to produce a valve rectifier for high-frequency oscillations by connecting one pole of his receiving circuit to an insulated plate or cylinder within a carbon lamp, of which the negative electrode forms the other pole of the receiving circuit. When the filament is made incandescent, negative electricity can readily pass from it to the insulated plate and hence into the receiving circuit; the flow of positive electricity in the same direction is checked; the lamp has a rectifying action.

Dr. Lee de Forest improved this oscillation valve a little later, making it an amplifier as well as a rectifier by placing between the filament and the plate or cylinder a grid of metal wire connected to an external source of electromotive force, by means of which its potential can be varied. There is ordinarily a current of negative electricity passing from the filament to the plate—the plate current it is called—through the interstices of the grid. By varying the potential of the grid this current can be varied, and the conditions can be so adjusted that small changes in the potential of the grid will produce large changes in the plate current; the plate current is passed through the primary of a step-up transformer, in the secondary of which is the receiving telephone, and the effect is thereby made audible. The grid is connected to one pole of the circuit receiving the incoming waves, and the small variations of potential which they produce thus give rise to large variations of the plate current, and hence the sound is amplified. By placing a number of valves in series very large amplifications are possible.

The other uses of the valve are very numerous. It is now employed as a transmitter for wireless work; while it finds many applications as a source, or rather regulator, of vibrations of comparatively short period. The Post Office has used it as an amplifier of speech, while Mr. F. E. Smith has applied it as a source of sound in connexion with the measurement of audibility. The whole of this arose from Edison's observation of the discharge of negative electricity from the heated filament.

To quote again from the first James Forrest lecture: "The engineer must banish from his mind the idea that anything can be too small or too trifling to deserve his attention." The modern development of the valve, through the researches of those who have brought it to its present excellence, has rested on a still smaller entity, the electron, a body with a mass of $0·900 \times 10^{-27}$ grams, about 1/1800 of the atom of hydrogen, carrying a negative charge of $1·591 \times 10^{-20}$ electro-magnetic units[6] of electricity, first glimpsed by Crookes, then proved to exist by J. J. Thomson.

The appearance of a Crookes tube or vacuum tube when carrying an electric discharge is well known. When the pressure is sufficiently reduced, the tube is non-luminous except for a beam of light which proceeds normally from the cathode—the negative electrode—and penetrates into the tube a distance depending on the pressure; this beam constitutes the cathode rays: if the rays strike the glass at the end of the tube, a vivid fluorescence is produced.

Crookes showed that the beam constituted a current of negative electricity; it could be deflected by a magnet. Experiments by Perrin and J. J. Thomson proved conclusively the existence of the negative charge. Thomson showed also that the stream consisted of an assemblage of minute particles—electrons. He measured the velocity of the particles and the ratio e/m of the charge on each to its mass. Further experiments, of which perhaps those of Millikan are the most important, have led to a determination of the charge on the electron, and from this and a knowledge of the ratio e/m the values of e and m are found. These values are the same whatever be the nature of the cathode from which the rays take their origin—the mass and charge of an electron are the same whatever be its source. Thus now it is scarcely too much to say that nearly all electrical phenomena are conditioned by the presence and motion of electrons. The current in a cable is a stream of electrons; a conductor is a body through which they move freely; an insulator checks their activity. The power that drives our motors comes from them; the light of the electric lamp, the heat that comes from an electric radiator, have their origin in these tiny particles; the plate current of the valve rectifier referred to above is a stream of electrons; when the grid is negatively electrified, it adds negative electrons to the stream; when it is positive, some of the electrons from the filament are stopped in their passage through its interstices to neutralise the positive electricity it possesses.

Electrical engineering in its many branches is closely bound up with the properties of an electron discovered by men whose sole object it was to advance natural knowledge. Nor is this all: for from the electron came X-rays, though this, perhaps, is scarcely the correct way of putting it, as J. J. Thomson's discovery really followed that of Röntgen. About 1894, physicists in many countries were experimenting with Crookes's cathode rays. A chance observation made by a skilled worker revealed the fact that the cathode rays produced an effect outside the tube in which they were generated. Röntgen in the autumn of 1895 was conducting an investigation with a vacuum tube wrapped in light-proof paper, and noted that a fluorescent screen of barium platino-cyanide lying near shone out when the tube was excited; if he placed opaque objects between the screen and the tube, shadows were cast on the screen, showing that rays, the X-rays, proceeded from the tube in straight lines; and it was quickly found that the rays penetrated substances opaque to light, the penetration depending on the density of the substance. There is no need to dwell on the results that have followed from this and their significance to engineers. X-rays can penetrate 4 to 5 mm. of lead, 12 mm. of tin, 75 mm. of carbon steel, 100 to 150 mm. of aluminium, and 300 to 400 mm. of wood. By their aid hidden cracks or faulty welds can be shown upon metal structures, while they have been employed for many industrial purposes, besides their use in surgery and medicine.

For some time the nature of X-rays was a mystery. Their rectilinear propagation and the absence of refraction when they fell obliquely on the surface of a medium other than air were difficult of explanation. Now it is known that they are produced by a very rapid change of motion of electrons. When the velocity of an electron is altered, an electro-magnetic wave is produced, and, starting from the electron, travels outward with the velocity of light. The frequency in this wave—in the number of vibrations per second produced—depends on the suddenness of the change of velocity of the electron. If this is very great, the frequency in the resulting wave is also very great. When a beam of cathode rays falls on the glass walls or on the anti-cathode of an X-ray bulb, the electrons are stopped almost instantaneously. Electro-magnetic rays of very high frequency—X-rays—are produced. Their wave-lengths are now known to lie between 12×10^{-8} cm. and $0·17 \times 10^{-8}$ cm. The wave-length of visible light is between 7700×10^{-8} cm. and 3600×10^{-8} cm., that of ultra-violet light lies between 3600×10^{-8} cm. and 200×10^{-8} cm., and it is to this minuteness of wave-length that the absence of refraction is due. In the hands of Sir William and Prof. W. L. Bragg, it has been the means of revealing the inner structure of materials in a manner which is of the utmost importance to engineers.

[6] One electro-magnetic unit is the charge transferred by 1 ampere circulating for 10 seconds.

Terrestrial Magnetism and the Orientation Faculty of Birds.

THE possible existence of a "magnetic sense" in animals has for long been a subject of speculation, and Lord Kelvin is numbered among those to whom the idea has proved attractive. No direct evidence in its favour has ever been obtained; but, on the other hand, there is no actual proof that some form of physiological sensibility to the phenomena of terrestrial magnetism may not exist and be a factor in that mysterious power of geographical orientation which is displayed by many animals and by primitive man.

The idea has often been invoked in the case of the especially remarkable powers of orientation which are possessed by migratory birds and by homing pigeons, and it is to be feared that much loose talk has at times been indulged in on this particular point. A recent author (F. Cathelin, "Les Migrations des Oiseaux," Paris, 1920) has gone so far as to propound a theory of migration which dispenses with instinctive behaviour in favour of "galvanotropism," and reduces birds to the status of mere automata acting under the compulsion of "des grands courants aériens électro-magnétiques équinoxiaux." Unfortunately for his argument, it is based on a conception of migration which is not consistent with many of the established facts, and it presupposes the existence of physical phenomena as to which the physicists are silent. Nor is its credibility increased by the absence of any suggestion as to a possible physiological mechanism linking the supposed physical causes to the alleged biological effects. At the best it is one of those "explanations" which call for more explaining than the original phenomena.

In these circumstances one welcomes a serious attempt, by a biologist and a physicist in collaboration, to set forth the possibilities of the case. This has been done by Dr. Rochon-Duvigneaud and Prof. Ch. Maurain (*La Nature*, 1923, 232) in respect of homing pigeons. In this paper Dr. Rochon-Duvigneaud begins by stating the biological data, and Prof. Maurain, who is director of the Institute of Terrestrial Physics in Paris, follows with a discussion of the physical facts, particularly those of terrestrial magnetism, which might be relevant. Prof. Maurain confines himself to a statement of apparent possibilities; he holds none of them as proved, and he urges the need for experimental inquiry. Whether his tentative hypothesis is sufficiently plausible from a biological point of view to constitute a *prima facie* case for further research on these lines, however, is perhaps open to doubt.

Prof. Maurain's suggestion may be stated as follows: The magnetic declination (angle of magnetic needle's lateral deviation from the geographical meridian) and the magnetic dip or inclination (angle of needle's vertical deviation from the horizontal plane) both vary from place to place over the surface of the globe. The periodical variations at any given place, and the irregular disturbances which also occur, are small in proportion to the otherwise constant geographical differences. Roughly speaking, therefore, every locality has its characteristic declination and dip. If lines be drawn through the places having the same declination, and other lines through the places having the same dip, these lines are (in Europe) roughly at right angles to each other. The lines thus serve as co-ordinates, which fix the position of any given locality like lines of longitude and latitude. Moreover, the declination and dip increase or decrease progressively as distance from a given locality is increased, except along those lines where one or other factor remains constant. So much is a matter of common knowledge.

It has then to be supposed that the pigeons are sensitive to changes in declination and dip, and indeed simultaneously sensitive to each factor independently of the other, and that when removed to a new locality the birds have a natural tendency, so to speak, to seek their own magnetic level. If a pigeon be removed to another place having the same declination but a greater (or less) dip, it would fly along the line of equal declination in the direction of decreasing (or increasing) dip. Similarly, if removed to a place having the same dip, it would follow the direction in which the declination changes towards the amount found at the home locality. Again, in the more general case of a bird removed to a place where both declination and dip are different, it would be affected by both factors and its homeward path would be the resultant of the two tendencies. (It is noted that there is no question of remembering the magnetic changes experienced on the outward journey, as a bird removed by a circuitous route will find a direct path home.)

Ornithologists will be grateful to the physicist for the statement of a possible case, but they will regret that Prof. Maurain has confined his argument to the relatively short journeys performed by homing pigeons and to the magnetic phenomena as they exist in Europe (for it is not in every part of the world that the lines of equal declination and of equal dip run at right angles to each other, and that there is only one point at which a given pair of values for these factors is to be found). They would have liked to see a case similarly stated in respect of the migrations of, say, swallows from South Africa to England (cf. NATURE, March 16, 1922, p. 346), over an area in which more complicated changes in terrestrial magnetism have to be reckoned with. Dr. Cathelin notwithstanding ("Le retour au nid reste donc pour nous une des grandes hérésies ornithologiques"), an ever-increasing volume of records of marked birds shows that swallows and others commonly perform very accurate feats of "homing" from great distances.

Returning to homing pigeons, however, we may examine the argument more closely. The physical phenomena exist, and a remarkable power of orientation is undoubtedly involved in homing; can a connexion be traced between them? The most serious objection seems to be the entire absence of any evidence of sensibility to magnetism on the part of birds or other animals; and without this physiological link speculation must needs be barren. Kelvin got negative results from his experiment of subjecting the human head to the influence of a powerful magnetic field; Du Bois observed no effect on protozoa; and the writers of the paper under discussion have similarly failed with pigeons. Within a limited field, it must be remembered, the strong electro-magnets used in such experiments are very many times more powerful than terrestrial magnetism: yet for Prof. Maurain's hypothesis we must suppose that birds are sensitive not only to minute changes in terrestrial magnetism, but also to changes in two of its factors separately. It does not seem, therefore, that the theory can be regarded as a promising one.

Prof. Maurain apparently holds, nevertheless, that there is a good case for further investigation, and he discusses in some detail the conditions necessary for an experiment on pigeons during their actual homing flight. It is not, of course, possible to interfere with terrestrial magnetism by means of artificial magnets over an area of any size, although it is admitted that pigeons find their way back as easily to lofts in great cities, where electric cables and the like cause an appreciable disturbance, as to lofts in the open country. The pigeon might be made to carry a small magnet and thus be kept within its field, but negative results would not be considered altogether convincing, because the amount of interference with terrestrial magnetism would be constant throughout; whether a portable apparatus giving varying magnetic effects could be designed is not discussed. Our author considers that the only possibility is to rear pigeons in a confined space within a powerful and varying magnetic field, and to remove them eventually to a distance under similar conditions. On being liberated for flight the birds would, for the first time in their lives, come under the undisturbed influence of terrestrial magnetism, and in these circumstances it should, by hypothesis, be useless to them as an aid to homing. We may hope that the experiment will be attempted, but until and unless some positive indications are obtained we are justified in remaining more than a little sceptical as to the existence of a "magnetic sense." A. L. T.

New General Anæsthetics.

THREE-QUARTERS of a century ago the era of surgical anæsthesia was suddenly and unexpectedly opened with ether, chloroform, and nitrous oxide. The relative importance of these three in surgery has varied at different times, but none of the many substitutes suggested has secured a permanent footing in surgery, although several have had a shorter or longer vogue.

The paramount consideration in the choice of an anæsthetic is safety, and it is recognised that this may be conduced to by avoiding the prolonged unconsciousness of ether and chloroform. This has led to the increased prominence of nitrous oxide in recent years; but while this induces rapid and safe anæsthesia, it can be used for ordinary surgical work only with difficulty, owing to the cumbrous apparatus necessary.

Within the last few weeks two new anæsthetics have made their appearance in acetylene and ethylene, each diluted with oxygen; the first hails from the pharmacological laboratory of Prof. Straub of Freiburg, the second from Drs. Luckhardt and Carter of the University of Chicago. Each is said to induce anæsthesia without preliminary discomfort and with rapid recovery afterwards. This short duration of the action is similar to that of nitrous oxide and ethyl chloride, and is associated with the rapid absorption and elimination of the anæsthetics owing to their volatility; for all four are gases at ordinary temperature and pressure.

The new anæsthetics appear to be more powerful than nitrous oxide, however, for they are efficient when mixed with oxygen, and the anæsthesia can therefore be maintained continuously without danger of asphyxia. On the other hand, they are devoid of the halogen component of ethyl chloride, which lends it an effect on the heart which is absent in the unsubstituted molecule. The introduction of these unsaturated hydrocarbons is of practical and also theoretical interest. A higher homologue of ethylene was early suggested by Snow (1853) as an anæsthetic in amylene, and more recently a purer preparation of analogous composition had some success under the name of pental. Ethylene and acetylene have to be kept under high pressure, and it may be that this inconvenience may militate against their more general use, even if the favourable reports given by their sponsors are confirmed by further experience.

Obituary.

Mrs. Ludwig Mond.

ALL friends of Mrs. Mond, widow of Dr. Ludwig Mond, will mourn her death, on May 16, at The Poplars, Avenue Road, Regent's Park, of which she had so long been the attractive figure and ornament.

Those who knew Dr. Mond intimately enough to visit his home could never think of him alone but necessarily associated him with his wife: they were an inseparable couple in thought and, in all their social interactions, as wonderfully adjusted as were the two salts he caused to interact in the great works his genius created. This came from the fact of their early intimate association.

They were first cousins; her mother was his loving counsellor when he was a youth; and they became secretly engaged before he was of age, when she was a girl of thirteen at school. Up to their marriage, after he was established in England, they maintained a constant correspondence of a most intimate character, which it has been my privilege to see in large part; it affords the most striking picture possible of the charm and simplicity of German life in those early days. Mrs. Mond's letters from the beginning show an extraordinary maturity and sobriety of judgment. It is clear that Dr. Mond's later æsthetic development was greatly due to the foundation laid during this period, mainly through the influence his wife exerted on him. In their married life she cast a spell upon all his friends which greatly added to his influence. Her ability is well brought out by Mr. T. P. O'Connor, M.P., in the *Sunday Times*, in the following few lines:

"Mrs. Mond, his wife, struck me as being almost as big a mind as her husband. In a few sentences, describing the difference between the Gothic and the Renaissance types of architecture—especially of the architecture of the cathedral—I got a clearer idea of the two ideals than I could have learned from a dozen books."

By Mrs. Mond's death, the nation comes into possession of Dr. Mond's great gift of Italian pictures and the Royal Society receives his bequest of 50,000*l*. It is a sad fact that the enterprise in which Dr. Mond was so particularly interested—the International Catalogue of Scientific Literature—the promotion of which, I know, was specially in his thoughts when he made the bequest, has been allowed to lapse almost at the moment his gift becomes fruitful. He may be said to have been the main promoter of the Catalogue and the greatest believer in its ultimate value to the scientific worker. He would have deplored nothing more than its abandonment at the time when development of the spirit of international co-operation is so imperative a need.

Unfortunately, we have lost the broad outlook which characterised Mond and his generation; Michael Foster seems to have been its last exponent in the Royal Society, the last who dared to cultivate enthusiasm. Apparently, we are no longer able to maintain continuity of thought and action; nor, when we have done well, to realise the importance of our work and take pride in carrying it to completion. We prate of science but the true spirit of scientific method is no longer in us. H. E. A.

Current Topics and Events.

By the death of Mrs. Mond, widow of Dr. Ludwig Mond, which occurred on May 16, the Royal Society becomes the beneficiary, under Dr. Mond's will, of a considerable sum of money in furtherance of scientific objects. Dr. Mond, as is well known, was a distinguished chemical technologist. He worked under Kolbe at Marburg, later under Bunsen at Heidelberg, finally becoming domiciled in England, where he secured the friendship of the leaders of British science, as also of many persons in literary and artistic circles. He was elected a fellow of the Royal Society in 1891, and died in 1909. The provisions of his will relating to gifts to science provided for the payment to the Royal Society, free of duty, of 50,000*l.*, the income to be employed in the endowment of research in natural science, more particularly, but not exclusively, in chemistry and physics, by means of rewards for new discoveries and pecuniary assistance (including scholarships) to those pursuing scientific investigations, and in supplying apparatus and appliances for laboratories and observatories, and in such other manner as the Royal Society should decide to be best calculated to promote scientific research. There was also the proviso that the Royal Society's council might allocate amounts for the publication and circulation of reports and papers communicated, and assist the preparation and publication of catalogues and indexes of scientific literature which the Society might have engaged in or might undertake in the future. To the University of Heidelberg a like sum was left, and for kindred purposes. Certain financial contingencies entailed that four years might elapse after Mrs. Mond's decease before these two bodies entered upon absolute ownership; notwithstanding, the legacies were to carry 4 per cent. interest per annum until paid up. It may be recalled that at the Royal Society's anniversary meeting of 1910 the then president referred to Dr. Mond in the following terms:—" The Royal Society has good cause to cherish his memory as that of a genial Fellow, who took an active interest in its affairs, affording it at all times the benefit of his business experience, and ever ready to aid financially any of its enterprises which seemed to him to stand in need of assistance. By his will also he has left a munificent benefaction whereby the Society will ultimately be enriched."

At the present time the phytopathological service seems to be exceptionally vigorous in the United States, owing largely to the forward policy adopted both by the Department of Agriculture at Washington and by the various agricultural colleges and experiment stations scattered throughout the different states. In *Phytopathology* for March last, the report of the fourth annual field meeting of the American Phytopathological Society makes very suggestive reading as to the range of activities of the American phytopathologist. The three earlier conferences had been devoted to potato, fruit, and cereals respectively; meeting this time in the important vegetable-growing region around Delaware and Philadelphia, the conference spent one day inspecting the sweet-potato storage house of the Johnson Potato Storage Company (with a storage capacity of 125,000 five-eighths bushel baskets), and the farms in the neighbourhood, where cantaloupes, asparagus, tomatoes, cow peas, soy beans, and especially sweet potatoes, were growing. The next day, in the New Jersey district, experiments upon the control of tomato disease, carried out by a commercial firm, trials of sweet-potato varieties for resistance to fusarium wilt, and cold-storage plants and orchards, together with official tests on fungicides, were examined. The last day was spent in the extensive "trucking sections," *i.e.* regions growing vegetables for the market, around Bustleton, where the Pennsylvania Agricultural Experiment Station has a research laboratory. Here experiments upon the control of celery leaf diseases, downy mildew of the Lima bean, lettuce drop and rhubarb crown rot were seen in progress. It is true that in Britain the plant pathologist and other agriculturists have discussed the problem of potato-growing and especially their diseases, under the auspices of the National Horticultural Society, but no opportunities for the exchange of ideas and the accumulation of experience are available in this country to British plant pathologists, such as are annually placed before some 60 to 70 phytopathologists by this field conference.

The value of the research laboratories now attached to many large firms was emphasised by Sir Richard Glazebrook in his "James Forrest" lecture to the Institution of Civil Engineers on May 4. The work of such laboratories is of necessity aimed at improving the products of the firm, but it is being realised more and more that for this purpose investigations in pure science are also essential. Probably the best-known engineering research laboratory controlled by an industrial firm is that of the General Electric Company at Schenectady. This laboratory has deliberately sought entirely new discoveries, new applications of materials, and new developments of electricity. From it have come the metalised carbon and the drawn-wire tungsten filament lamp, the nitrogen-filled high-efficiency lamp, the magnetite arc lamp, and the Coolidge X-ray tube. The development of each of these has involved investigations of great importance to pure science; Dr. Langmuir, of the G.E.C. laboratory, occupies one of the leading places among workers on the problem of the constitution of the atom. Other American laboratories are the Westinghouse Electric and Manufacturing laboratory and that of the Eastman Kodak Company; the work of the latter on light filters is well known, and has its bearing on the microphotographic work so important to engineers. There are few such great laboratories in England. But there are pioneers who recognised long ago the value of the great work which science can do for industry. Manganese steel was produced in 1882 from the laboratory of Sir Robert Hadfield, as the result of a scientific inquiry into the properties of alloys. The Brown-Firth laboratories of John Brown and Sons, and the laboratories of the Westinghouse works in Manchester have conducted and are carrying out valuable researches, and great things are looked for from the new laboratories of the General Electric Company at Wembley. The ideals which Mr. C. C. Paterson enunciated at the opening of the G.E.C. laboratory are high, and should lead to the advancement of scientific knowledge in many directions.

At a meeting of the Royal Society of Arts on May 16, a paper on "Industrial Lighting and the Prevention of Accidents" was read by Mr. L. Gaster. The early part of the lecture was devoted to a summary of progress in illuminants, after which statistics were quoted showing that inadequate lighting is a contributory cause of many industrial accidents, those arising from "persons falling" being a specially striking example of this relation. Apart from possible ill effects on the eye, great importance should be attached to the effect of unsatisfactory lighting conditions in causing industrial fatigue, and consequently ill-health, spoiled work, and diminished output. In the cotton, fine linen and silk industries it had been found that output was 5-12 per cent. less by artificial light than by daylight. A recent investigation of the National Institute of Industrial Psychology showed that by using a lamp giving four times the light of an ordinary miner's lamp the amount of coal produced was increased by more than 14 per cent. The paper, which was fully illustrated by lantern slides, including some striking views of the L.G.O. repair works taken by daylight and artificial light respectively, was largely devoted to an exposition of the various reports issued by the Departmental Committee on Lighting in Factories and Workshops. It was mentioned that a similar Committee has been appointed by the Ministry of Labour in France to deal with the subject, and that seven American States now possess codes of industrial lighting. Mr. Gaster expressed the hope that the new Factory Act will endorse the recommendations of the Departmental Committee, and that illumination will be ranked with heating and ventilation as an essential item in the interests of health, safety, and efficiency of work.

We have on several occasions referred with regret to the fact that no provision is made for a composite display of scientific discovery and achievement at the British Empire Exhibition to be held next year. In this connexion the following extract from the fourth annual report of the governors of the Imperial Mineral Resources Bureau is of interest: "The British Empire Exhibition authorities requested the Bureau to undertake the organisation of an exhibit illustrative of the mineral resources of the Empire, and the Governors set up a Committee which drew up a scheme for such an exhibit. Numerous meetings were held and the details of the exhibit worked out. We were subsequently informed that funds were not forthcoming from exhibition sources, and the Bureau then had to abandon the comprehensive scheme which they had elaborated for the illustration of the whole mineral wealth of the Empire."

A novel feature of the meeting of the British Association at Liverpool, on September 12-19, will be a scientific exhibition at which there will be exhibits of apparatus in connexion with each section of the Association, and others showing recent advances in applied science. The exhibition will be held in the buildings of the Central Technical Schools, Byrom Street, Liverpool, which have been allocated for this purpose by the Technical Education Committee of the Liverpool Corporation. The buildings are extensive and centrally situated, and the electrical and other facilities are admirably adapted for the purpose It is anticipated that all the leading manufacturers of scientific apparatus in the country will be represented. The exhibition will be open to members of the Association during the period of the meeting; but in view of the fact that it is the first of its kind, and will without doubt appeal to public interest in scientific achievement, it is intended to open the exhibition on September 10 and to keep it open until September 22, the public being admitted at a small charge.

The constitution and by-laws of the new Engineering Joint Council have just been published. This Council is defined as "an advisory body without executive powers." It was founded by the Institutions of Civil, Mechanical, and Electrical Engineers and Naval Architects, but it is anticipated also that other institutions will desire representation on the Joint Council. These are divided into Constituent Institutions and Affiliated Institutions. The latter may be transferred to the former group when the standard of their entrance examinations is sufficiently high and the number of their corporate members is sufficiently large. The Council will not initiate proposals, but will consider matters referred to it by the Council of any one of the constituent institutions. As the welfare and safety of the whole nation are largely dependent on the prosperity of the engineering industries, it was felt that they should have a larger share in the national councils. The Joint Council, therefore, has been founded to foster engineering interests and to be ready always to take immediate action in any national emergency, and it has started auspiciously. The various institutions have worked very harmoniously together, and further important developments may be expected.

The arrangements for the visit of Their Majesties the King and Queen to University College Hospital and University College, London, on May 31, are now approaching completion. As already announced, the ceremony is in connection with the great gift made in 1921 by the Rockefeller Foundation of New York for Medical Education. It will have two features, the laying of the foundation-stones of the new Obstetric Hospital and new Nurses' Home now being erected on sites adjacent to University College Hospital, and the opening of the new Anatomy Building which has already been erected in Gower Street. Their Majesties will arrive at 3.15 P.M., and the ceremony of laying the foundation-stones will take place in a pavilion to be erected in University Street. After the conclusion of the first part of the ceremony, Their Majesties will proceed across Gower Street, and the King will declare open the Anatomy Building. The gift of the Rockefeller Foundation for these important medical objects is a sum of 400,000*l.* for the erection of the buildings in connexion with University College Hospital and Medical School; 435,000*l.* for an Endowment Fund for the improvement of medical teaching and for the purpose of developing general medical education and research on modern lines; 370,000*l.* for the erection and endowment of the anatomy buildings at University College, including the extension of the physiology and pharmacology buildings. The total benefaction thus amounts to 1,205,000*l.*, and is probably the largest single benefaction ever provided in this country for educational purposes.

A PRELIMINARY announcement regarding the general discussion on the electronic theory of valency arranged by the Faraday Society, to be held at Cambridge on July 13-14, has been issued. Prof. G. N. Lewis will open the proceedings on the Friday afternoon with a general introductory address, and he will probably be followed by Mr. R. H. Fowler, who will contribute a paper intended to open discussion on the physical and inorganic side of the subject. Among those expected to speak are Sir J. J. Thomson, who will be in the chair, Sir Ernest Rutherford, Sir William Bragg, and Prof. W. L. Bragg. The Saturday morning session will be devoted chiefly to applications of the theory in organic chemistry. Sir Robert Robertson, president of the Society, will preside, and opening papers will be given by Prof. T. M. Lowry and Dr. N. V. Sidgwick. Among those expected to speak are Prof. W. A. Noyes, Sir William Pope, Prof. A. Lapworth, Prof. I. M. Heilbron, Dr. W. H. Mills, Prof. J. F. Thorpe, and Prof. R. Robinson. On the Friday evening a complimentary dinner will be given to Profs. Lewis and Noyes and other guests at Trinity Hall. Arrangements are being made to accommodate those attending the meeting in one or other of the Colleges, and it will be possible to include a limited number of non-members of the Society. Particulars may be had from the Secretary of the Faraday Society, 10 Essex Street, London, W.C.2, to whom applications should be made at once.

THE annual visitation of the Royal Observatory, Greenwich, will be held on Saturday, June 2.

THE annual general meeting of the Institute of Physics will be held in the rooms of the Royal Society, Burlington House, on Wednesday, May 30, at 5.30 P.M. In the course of his presidential address, Sir Joseph Thomson, who has recently returned from the United States, will refer to the position of industrial research there in physics.

AT the meeting of the National Academy of Sciences held in Washington on April 25, the following officers were elected: *President*, Prof. A. A. Michelson; *Vice-President*, Dr. J. C. Merriam; *Secretary*, Dr. David White; *Foreign Secretary*, Prof. R. A. Millikan; *Treasurer*, Dr. F. L. Ransome.

THE U.S. National Academy of Sciences has made the following awards: the Comstock prize to Prof. William Duane, professor of bio-physics in Harvard University, in recognition of his researches on X-rays, and the Mary Clark Thompson gold medal to Dr. Emmanuel de Margerie, director of the Geological Survey of Alsace and Lorraine.

AT the Royal Institution on Friday evening, June 15, Sir Ernest Rutherford will give his postponed discourse on "The Life History of an Alpha Particle of Radium," and his concluding lecture on "Atomic Projectiles" will be delivered on Saturday afternoon, June 16.

AT the annual general meeting of the Linnean Society of New South Wales, held on March 28, the following officers were elected: *President*: Mr. A. F. Basset Hull. *Members of Council* (to fill six vacancies): Mr. E. C. Andrews, Mr. J. H. Campbell, Mr. H. J. Carter, Sir T. W. E. David, Prof. W. A. Haswell, and Prof. A. A. Lawson. *Auditor*: Mr. F. H. Rayment.

PROF. J. P. HILL, Jodrell professor of zoology and comparative anatomy in the University of London, and Prof. J. T. Wilson, professor of anatomy in the University of Cambridge and formerly Challis professor of anatomy in the University of Sydney, have been elected honorary members of the Linnean Society of New South Wales.

AT the annual general meeting of the Institution of Electrical Engineers to be held on Thursday, May 31, there will be presented to the Institution: (1) An oil painting of the late Dr. Silvanus Thompson (presented by Mrs. Thompson); Dr. Thompson's library (presented by a number of members of the Institution and others); and (2) a bronze bust of Dr. Thompson, by Mr. Gilbert Bayes (presented by the Finsbury Technical College Old Students' Association).

NEWS has reached this country of the family of the late General Rykatchef, who was director of the Russian Meteorological and Magnetic Service until shortly before the War. General Rykatchef died on April 1, 1919, his wife on November 22 of the same year. The last survivor of three sons died on February 24, 1920. A son-in-law perished on July 6, 1919, leaving five young children. They, with their mother and her sister, who is well known to meteorologists and magneticians as her father's constant companion on his international journeys, are the only survivors of a once large family.

THE following foreign members have been elected by the Geological Society: Prof. L. Cayeux, Paris; Prof. J. M. Clarke, director of the New York State Museum, Albany (New York); Prof. H. Douvillé, Paris; and Prof. W. Lindgren, Massachusetts Institute of Technology, Boston, Mass. Foreign correspondents have also been elected as follows: Prof. E. Argand, University of Neuchâtel; Prof. L. W. Collet, University of Geneva; Prof. R. A. Daly, Cambridge (Mass.); Prof. G. Delépine, Lille; Prof. P. Fourmarier, Liège; Prof. V. M. Goldschmidt, Universitets Mineralogisk

Institut, Christiania; Prof. T. G. Halle, Naturhistorisk Riksmuseum, Stockholm; Prof. J. F. Kemp, Columbia University, New York City; Prof. C. F. Kolderup, University of Bergen; Prof. C. I. Lisson, Escuela de Ingenieros, Lima; Prof. G. A. F. Molengraaff, Delft; Dr. A. Rénier, Directeur du Service Géologique de Belgique; Prof. P. Termier, Directeur des Services de la Carte Géologique de France; and Dr. F. E. Wright, Geophysical Laboratory, Washington, D.C.

The floral ballet, composed by Dr. G. Rudorf, and conducted by him at the Alexandra Palace on May 19, in aid of the Royal Northern Hospital, as announced in last week's issue, p. 681, proved very delightful music. Specially written for a choreographic flower-story arranged by Mrs. A. E. Ormen Sperring for her pupils, the work, which lasted three-quarters of an hour, contains a great variety of melodic material. In his professional capacity as a chemist, and as collaborator with Sir William Ramsay in a treatise on the rare gases, Dr. Rudorf is well known; and he is to be congratulated upon the skill he has shown in the production of a musical work of real merit.

Mr. F. Edwards, 83 High Street, Marylebone, W.1, has just circulated a catalogue (No. 443) of some 1100 books and serials relating to anthropology, folklore, archæology, etc., some of which formerly belonged to Prof. Huxley. We notice that Mr. Edwards has also for disposal a small collection of Australian native weapons and implements of the period 1840–50, from the collection of Mr. S. T. Gill, an Australian artist.

Our Astronomical Column.

The Theory of Jupiter's Satellites.—Prof. de Sitter, of Leyden, lecturing on this subject at the University of Manchester on May 9, emphasised the interest attaching to the theory of the motion of the four Galilean satellites (to which his remarks were confined), because they illustrate the more important features in the theory of the motion of the planets round the sun, but with a time-scale reduced in a ratio of about 3000 to 1. The theory can thus be checked by observations extending over a period of a few decades, but the difficulty of deriving from the observations the masses of the satellites, and the elements of their orbits, is greatly enhanced by the intercommensurability of the periods of the three inner satellites. Though the tables published by Prof. Sampson a few years ago represented a great advance at the time of their appearance, they still require to be confirmed and extended by other methods. The commensurability of the periods renders the ordinary expressions found in celestial mechanics too slowly convergent, and necessitates the search for a new solution, starting from a periodic solution as the first approximation. The commensurability also makes the observations of eclipses and transits of the satellites less satisfactory than usual for the determination of the elements of the system. In order to counter these difficulties, such observations have to be extended over a whole period of revolution of Jupiter (12 years) and supplemented by photographs taken at selected epochs before and after each opposition. Such observations have been made at Greenwich, the Cape, and Johannesburg, and are now in Prof. de Sitter's hands for discussion. The discussion is well in hand, and the results promise to be satisfactory.

Unknown Lines in Stellar Spectra.—To all spectroscopists the paper by Mr. F. E. Baxandall on "Lines of Unknown Origin in various Celestial Spectra" (Mon. Not. R.A.S., vol. 83, p. 166) will be very welcome. Mr. Baxandall's skill in deciphering spectra is well known, so the results here collected are of special value. In the year 1910 Sir Norman Lockyer published a list of fairly prominent lines for which no satisfactory origins had been found, but since then many of them have been run to earth, notably the line at λ 4688, which is now known to be due to ionised helium, and the ζ Puppis lines due to the same element. Eliminating these lines from the list of unknowns, Mr. Baxandall gives rather a formidable table containing about 130 lines still unknown. The wave-lengths of these lines have all been observed in some source of celestial light, and the table indicates which particular source, whether sun, star, corona, nebula, and so on, in which they have been observed. The paper is accompanied by copious notes and references.

850 New Nebulæ.—Dr. Harlow Shapley, in the Harvard College Observatory Bulletin, No. 784, points out that photographs made with the Bruce telescope at Arequipa, Peru, supplement the data for nebulæ not easily reached from northern observatories. On a photograph made on September 19, 1922, with an exposure of six hours, centred on R.A. $22^h\ 40^m$, Dec. $-45°$, Dr. Shapley has found 850 new nebulæ. On the following night another exposure was made, this time for two hours only, which showed all objects brighter than the eighteenth magnitude. He points out that these new nebulæ are not of the nature of the faint irregular nebulous wisps frequently found in the vicinity of bright spirals, but are distinct nebulæ, the fainter ones almost exclusively oval or circular in form, distributed over an area of about thirty square degrees. It is interesting to note that only three nebulæ of the N.G.C. fall within this region and three from the second Index Catalogue. The brighter nebulæ are, almost without exception, elongated or show spiral structure, while the fainter ones appear largely to be globular. The shape of these latter, as Dr. Shapley points out, may be due simply to under-exposure of the plate, since many of the bright nebulæ, on a short exposure, lose the faint extensions that reveal their truly elongated shape. The interesting remark is made that on many parts of this plate at the eighteenth magnitude, the nebulæ are more numerous than the stars.

The Astronomical Society of South Africa.—A local astronomical society was formed at Capetown ten years ago; this has now been extended to include the Johannesburg society, and the first Journal of the combined body was published in February. The inaugural presidential address by Dr. Hough deals with the tides in a clear and interesting manner, explaining methods of tidal analysis and prediction, and giving an outline of Sir G. Darwin's theory of the development of the earth-moon system by tidal evolution. The society has been especially active in comet and variable star work; the former is fully dealt with in the Journal.

Research Items.

INDUSTRIAL PSYCHOLOGY AND COAL MINING.—In the Journal of the National Institute of Industrial Psychology (vol. 1, No. 6), a colliery director discusses the application of industrial psychology to coal mining. He points out that hitherto it has been taken for granted that in some wonderful way the art of coal mining is handed on from old collier to young collier and from father to son. Again, the very vital importance of the industry to the country has made it the battle-ground of conflicting interests, so that employers and trade union officials make many statements about the needs and desires of the workers, statements which are not infrequently mutually incompatible. Seeing that there is so much bias, the writer suggests that the proper person to obtain actual facts is the man of science. He therefore advocates a considerable development of the small-scale investigation done already by the Institute for one firm, so that methods of training and instruction, general conditions of work, and allied problems should be studied and the best methods discovered. Just as it has been found necessary to study methods and training for sport, so a similar study would, in the writer's opinion, be found helpful in coal mining. If industrial psychology can show how to increase output and with it wages, and yet leave the coal-getter less fatigued, it will do more for the general trade of the country than has been dreamt of.

CHEMISTRY IN MEDIEVAL ISLAM.—In the issue of *Chemistry and Industry* for April 20, Mr. E. J. Holmyard contributes an interesting article on this subject. He points out that no serious attempt has hitherto been made to study adequately the large number of Arabic chemical treatises which have come down to us—and he might have added that, in spite of this, the most dogmatic assertions about some aspects of the problem are still put forward with surprising confidence by recent writers on the history of chemistry. Chemistry was taken over by the savants of Islam from the Greek school at Alexandria about the 7th century A.D., and for five or six hundred years—namely, to the 12th century—it was almost a monopoly with them. The most famous of its votaries was Geber, or Jabir ibn Hayyan, probably born at Harran in Mesopotamia, who attained a position of eminence under the Caliph Harun al-Raschid (A.D. 786–808). The identity of Jabir with the Geber of the Latin works, which became known to Europe about A.D. 1300, although it is now denied by most writers, is, according to Mr. Holmyard, very probable, and he has important new material in this field. The leanings to mysticism which Geber and other chemists show is probably to be attributed to Neo-Platonic influences, which also tinged their chemical views. A belief in astrology, and in the connexion between planets and metals, was shared by all thinking men of the time, but played a relatively unimportant part in the chemistry of Islam. Scepticism as to the possibilities of transmutation also appeared at an early date. Mr. Holmyard gives many further details, and his paper is one which throws much light on this interesting period in the history of chemistry.

DIFFICULT AND DELINQUENT CHILDREN.—In *Psyche* (vol. ii. No. 4) Dr. R. G. Gordon discusses the problems concerned with the difficult and delinquent child. Every teacher and doctor has come across the child who does not fit in with the others, who, in spite of all efforts on the part of those responsible, persists in various forms of misbehaviour, frequently of a futile and useless character, and finally becomes ungovernable. The problem should be faced by trying to find out why such a child is difficult, and for this purpose it should be possible for every suspected child to be examined, in the first place, physically, as it is known how such factors as abnormalities in the secretions of the endocrine glands, eye strain, etc., affect mental development; then his intelligence should be tested, and thirdly, his reaction to life should be investigated. It must be borne in mind that lack of intelligence is by no means an invariable concomitant of delinquent behaviour. The writer hopes that eventually the State will provide the means for such work, but he realises that the time is not yet. In conclusion, he puts in a timely warning that the proper selection of workers for such investigation is of vital importance.

TREATMENT OF ELECTRIC SHOCK.—Sir Bernard Spilsbury and other writers discuss the condition of individuals who have been subjected to electric shock, in *Archives of Radiology and Electrotherapy*, No. 272, March 1923, p. 316. The pathological changes in the tissues in fatal cases are generally very slight—burning at the point of entrance and exit of the current and hæmorrhages beneath or in the skin and into the muscles. Although some cases may die from paralysis of the heart, many are cases of "suspended animation" due to sensory stimulation causing paralysis of respiration. In many of the last-named class the immediate application of artificial respiration will resuscitate the unconscious and apparently dead with complete recovery.

NERVES OF THE FINGERS.—In the *Journal of Anatomy* (vol. lvii., Part III., April 1923) Prof. J. S. B. Stopford, of the University of Manchester, has published a short note on the distribution and function of the nerves to the fingers. The paper is of exceptional interest and importance, because it gives a new orientation to the results of the last twenty years' researches on sensation and the interpretation of the effects of nerve injuries. With the object of settling this difficult problem once for all, Dr. Henry Head submitted himself to experiment in 1903, and had two nerves in his forearm cut across, so as to study the process of recovery of sensation. The nerves selected for this test were supposed to be distributed only to the skin, and Dr. Head assumed that when they were cut the nerves concerned with deep sensibility would remain intact. Prof. Stopford now finds that the nerves in question are not purely cutaneous, but also supply joints and some of the subcutaneous tissues. Hence the interpretation of Dr. Head's classical experiment and the far-reaching generalisations based upon it need to be re-examined in the light of these anatomical facts, which are doubly important because their reality has been established by an investigator of rare insight, who has a sympathetic understanding of Dr. Head's methods and results.

LINKED CHARACTERS IN THE MILLIONS FISH.—In a continuation of his investigations on the millions fish (*Lebistes reticulatus*), Dr. O. Winge (*Comptes rendus trav. Lab. Carlsberg*, vol. 14, No. 20) obtained a fish with a new factor for elongated caudal fin. This factor shows ordinary sex-linked inheritance, and is therefore located in the X-chromosome. In crossing experiments there is evidence that the factor may become transferred from the X- to the Y-chromosome by crossing over. It then shows male-to-male inheritance, as is the case with several spot characters in Lebistes. Later it may cross over again to the X, and so the manner of its inheritance oscillates irregularly between ordinary sex-linked and exclusively male-to-male transmission. This furnishes further evidence of the presence of active factors in the Y-chromosome of fishes. Some of the other evidence indicates that a localised sex factor is concerned in sex determination.

Peculiar Polish Wheat Cross.—In crosses between Polish and Kubanka wheat, Mr. F. L. Engledow (*Journ. Genetics*, vol. 13, No. 1) has studied the inheritance of length of glume, the respective parental lengths being about 12 mm. and 31 mm. The F_1 generation was intermediate, while in F_2 the three types could be classified by eye and approximated in numbers to the 1 : 2 : 1 ratio expected for a monohybrid difference. The segregated types bred true in later generations, while the intermediate type continued to split. The peculiarity was observed, however, that the Polish type segregated in F_2 had a mean glume length which had shifted from 31 to 24·6 mm., and this shift was maintained in later generations. The nature of this permanent modification in a character through crossing is discussed, and it is pointed out that a multiple factor hypothesis of size inheritance is insufficient to account for the results. The same phenomenon has been observed in other wheat crosses, but a complete explanation is not at hand. Perhaps the measurement of all glume lengths on each individual might aid in the analysis.

"Big Bud" of Black Currant.—This disease, caused by the currant gall mite, is widespread throughout Great Britain, and attacks and destroys black currant bushes. Hitherto no remedy has been discovered. In the orchard of the Crichton Royal Institution, Dumfries (a mental hospital), with 427 bushes, the following treatment (eighty-third annual report for the year 1922, Crichton Royal Institution, Dumfries) has been tried: The ground round the bushes was completely covered with straw and dead branches, which were then ignited (March 28, 1922). The scorched branches of the bushes were then cut off to within six inches of the ground, fresh straw was put on, and the whole again burnt. So far the treatment has been a success, for (1) less than 10 per cent. of the bushes have been lost, and (2) fully 90 per cent. have made a good recovery, showing 2-3 feet growth of healthy wood, with flower buds, giving promise of a half-crop the following (this) year, and with no indication of the mite at the end of 1922.

Date Palms of Iraq.—The Agricultural Directorate, Ministry of Interior, Iraq, has issued the third memoir of a series upon dates and date cultivation of the Iraq. In the memoir, V. H. W. Dowson briefly describes some of the better known varieties of the female palms of the Iraq and the dates they produce; the earlier memoirs have dealt with the habit, cultivation, and yield of the palms. Some of these varieties differ markedly in habit of growth and in average yield of produce, and the dates are by no means all the same, differing probably as much to the expert observer as do the different apples displayed in the shop window to the average English buyer, to whom all dates are very much alike. It is interesting, for example, to learn that the Ista-amran palm, forming some 45 per cent. of the palm population of the Shatt Al' Arab, produces a date which the Arab would class among the "hot," *i.e.* relatively indigestible dates. This palm gives relatively low yields, and yet probably one-third of the dates exported from Basrah are of this variety! Obviously, with attention turned to varieties, their quality and yield, there are great possibilities before the date industry, Iraq containing, it is estimated, some thirty million date palms; at present, the author reports, the demand for Iraq dates is only increasing in the United States. Prepared originally for the purposes of the Revenue Department of the Iraq, this memoir is a tribute to the industry of a recently constituted Administration and to its author, who confesses that its preparation has been rather a recreation than a labour, "because the date palm is so interwoven into the history, literature, and life of the Arab race."

A Causal Organism of Nasal Polypus.—In his memoir on *Rhinosporidium Seeberi* (Trans. Royal Soc., Edinburgh, vol. liii. part ii., No. 16), Prof. J. H. Ashworth has accomplished a notable piece of work, and one which forms a valuable contribution to medical biology. This remarkable organism, hitherto placed among the Sporozoa but regarded by Prof. Ashworth as a unicellular fungus, probably belonging to the Chytridineæ, is responsible for the development of a form of nasal polypus in human beings. Fortunately, it appears to be rare, at any rate among Europeans, and its geographical distribution is peculiar, including India, Ceylon, Argentina, and Tennessee, U.S.A. (one case). Prof. Ashworth was able to study the organism in the case of an Indian medical student at Edinburgh, and gives a detailed and beautifully illustrated account of the life-history. Attempts to cultivate the parasite in other animals or *in vitro* have been unsuccessful, and the method of infection is unknown.

The Devonian Formation in Australia.—Dr. W. N. Benson's "Materials for the study of the Devonian Palæontology of Australia" (Rec. Geol. Surv. New S. Wales, vol. x. pt. 2) is a memoir that will be much appreciated by geological students. It begins with an historical introduction in which the author sketches the progress in discovery of the Devonian rocks of Australia and their separation from the Silurian with which they had been formerly associated. The rocks and their contents of the several faunal provinces are next described as well as the distribution of the Australian Devonian fauna. There is also a chapter on Middle Devonian vulcanicity. An excellent bibliography and a useful register of the fossil localities follow, but what will prove of most use to the general student is the very full census and index of both fauna and flora, which forms half of the memoir and includes references to close on two hundred genera.

Upper Cretaceous Dinosauria from Alberta.—From among a collection of fossil vertebrates in the University of Alberta, obtained from Upper Cretaceous beds (Belly River formation) of the Red Deer River, C. W. Gilmore has singled out and describes, with excellent figures, some exceedingly interesting Dinosaurs (*Canadian Field Naturalist*, vol. xxxvii., No. 3). *Corythosaurus excavatus*, n.sp., is the second species of a genus the skull of which in its general outline recalls that of a bird rather than a reptile. In the case of this Dinosaur, however, the beak portion of the skull is formed by the premaxillaries, the entire upper and posterior portion of the crest being occupied by the nasal bones. Quite other in aspect is the skull of all the Upper Cretaceous armoured Dinosaurs: in them it is greatly depressed and has a broadly rounded muzzle. A well-preserved skull and right ramus, which the author tentatively refers to *Europlocephalus tutus*, Lambe, has afforded him the opportunity of contributing to the knowledge of the cranium of this group, for with the exception of the type of *Panoplosaurus mirus*, Lambe, only unsatisfactory fragments have hitherto been available. The author further directs attention to some features in the cranial structure of a specimen of Eoceratops from the same district, as well as to the first occurrence in the Belly River formation of a lacertian reptile, as evinced by the discovery of a dorsal vertebra bearing a striking resemblance in size and form to those of the genus Saniwa.

METEOROLOGY OF THE GULF OF BOTHNIA.—Several papers dealing with the meteorology of the Gulf of Bothnia and the northern part of Sweden have lately appeared. In "Ström och Vindobservationer vid Fyrskeppen" (Havsforsknings Institutets, No. 13, 1922), Mr. G. Granqvist records the wind direction and force at certain Finnish lightships, four in the Gulf of Finland and seven in the Gulf of Bothnia, during 1921. The records are of varying lengths of time, in most cases from June to November or December, but in two cases for January also. Observations were taken three times daily. In Statens Meteorologisk-Hydrografiska Anstalt, i. No. 4 (Stockholm, 1922), Dr. C. J. Ostman has a paper on "Recherches sur les grands vents près de la côte suédoise du Golfe de Botnie." The observations deal with the winds above force 7 on the Beaufort scale in eleven lighthouses and lightships. As a rule, the records are for the years 1907–1921, and cover the twelve months. The paper contains a discussion of the direction and nature of the depressions which influence the Gulf. The meteorological observations taken at the Swedish station at Abisko in Lapland during the year 1921 are published (Abisko Naturvetenskapliga Station, Stockholm, 1923). The hourly data are given *in extenso* with the legends of the tables in both Swedish and French. They include records of the water temperature in Lake Torneträsk.

RADIO IN RELATION TO WEATHER OBSERVATIONS.—Weather reports by wireless telegraphy and by the radiophone as received and disseminated in the United States from the beginning of this century to the present date are dealt with by Mr. E. B. Calvert of the U.S. Weather Bureau in the U.S. *Monthly Weather Review* for January. The history of the initiation and the development of the radio service is full of interest, and is dealt with from the year 1895, when Marconi commenced his investigations in wireless telegraphy, until the inauguration of radiophone weather broadcasting through the United States in February last. The Weather Bureau was the pioneer of all agencies of the U.S. Government in investigations and experiments in wireless telegraphy. It is stated by the author that in his opinion meteorology will advance hand in hand with radio, and that there must be close and undisturbed contact between the agencies engaged in meteorological and radio activities. Meteorology is essentially an international science, and weather has no national allegiance. Weather conditions prevailing in one country to-day may affect another to-morrow, or perhaps a week hence. The author is very strongly impressed with the importance of exchange of meteorological reports between different countries and especially among the nations in the Northern Hemisphere, in which radio must play a large and important part. Daily weather forecasts and storm warnings for all interested in agriculture ashore and for all vessels afloat in the open ocean and elsewhere have now become the common property of all. Mention is made of the forecasting demonstrated by the French training-ship *Jacques Cartier*, which carries weather experts and disseminates and broadcasts weather forecasts daily in both English and French, aided by reports from shore stations and from ships within call.

ATOMIC RADII IN CRYSTALS.—In a short paper in the Proceedings of the U.S. National Academy of Sciences for February, Dr. R. W. G. Wyckoff discusses, with the aid of numerical data, the hypothesis that the atoms of each element are of a definite size, and that crystals are built up by their packing together. The calculation of the "sphere of influence" of atoms can now be made from four independent starting-points: from metals, from the diamond and divalent metal carbonates of the calcite group, from pyrites (FeS_2), and with the aid of cæsium dichloro-iodide ($CsCl_2I$). The metals do not fit well into the scheme, calcite and related minerals present difficulties because of the two different assignments of position which have been made to the oxygen atoms, while the results from pyrites and cæsium dichloro-iodide are in substantial agreement and are chosen as offering the basis for the fairest test of the hypothesis. It is claimed that numerous results (given in the paper) not in accord with the hypothesis show conclusively that the latter is not in harmony with experiment—a result which might be anticipated on theoretical grounds, although approximate agreement is obtained in isomorphous crystals composed of only two kinds of atoms, where the interatomic distances have additive properties. In cases of compounds where the atomic environments are different, the interatomic distances may change by several tenths of an Ångstrom unit.

GASOLINE IN THE UNITED STATES.—The natural-gas gasoline industry in the United States continues to expand, and the total production of nearly 450,000,000 gallons of gasoline in 1921 exceeded that of 1920 by some 145,000,000 gallons, according to statistics recently published in an advance chapter of the Mineral Resources of the United States for 1921. The value of the gasoline produced, however, dropped to 10,000,000 dollars less than in the previous year, owing to the break in the petroleum market and the general lowering of prices. The processes involved in the production of natural-gas gasoline are constantly undergoing changes, and there is obviously still plenty of room for improvement of the plants employed. The compression process of extraction is fast giving way to the absorption process, not because the latter is technically more efficient, but because the product obtained by the absorption process is more uniform, stable, and commands a higher market price. The combination of both compression and absorption processes, however, is finding increasing favour with operators, and may quite conceivably become the standard plant of the future. Production of gasoline on a large scale is faced with certain problems which are not always easy to contend with; for example, summer temperatures frequently cause difficulty in cooling the water sufficiently for condensation, while cold weather, on the other hand, aids condensation to such an extent that pipe-line freezing occurs, interrupting the transport of the gasoline. Another problem seriously affecting the industry is that connected with waste of gas which must inevitably occur when a new well is brought in; obviously, in operating a new lease, it is not policy to install an expensive plant until the probable output of gas from several wells has been gauged; drilling these new wells takes time, and thus in developing a property much gas is initially lost which it would undoubtedly pay to treat for gasoline.

The Royal Society Conversazione.

THE first of the two annual conversaziones of the Royal Society was held at Burlington House on May 16, when Sir Charles Sherrington and the officers of the Society received the fellows and guests. In the space available it is impossible to deal adequately with all the exhibits, so we propose to group them according to subject and to give a brief account of some of the items in each group.

The National Institute of Industrial Psychology exhibited some results of the researches it has undertaken, among which were curves obtained by Dr. G. H. Miles and Mr. Eric Farmer showing the effects of encouraging rhythmical movements and of reducing needless decisions. Output increased by more than 35 per cent., despite which the workers spontaneously testified to their lessened fatigue. Mr. Eric Farmer also demonstrated the reduction of after-images produced by using a frosted glass on the miner's standard electric lamp.

The effect of temperature on the biological action of light was illustrated in a demonstration arranged by the National Society for Medical Research (Dr. Leonard Hill and Dr. A. Eidinow). Hay infusoria were exposed in shallow quartz cells to the mercury vapour lamp. The quartz cell in each case is attached to a glass cell through which water is circulated at a given temperature. The lethal power of ultra-violet rays is manifested by granulation and loss of mobility, and at 20 C. these signs appear in about one-third of the time required at 10 C. Mr. H. J. Buchanan-Wollaston had an interesting exhibit showing the value of markings on herring-scales as a means for estimating age and growth rate of the fish. Scales from the same fish may have widely differing numbers of rings; those on the outer part of the large scales should be read in groups, and the age checked by means of dorsal scales and "key-scales." The ages deduced are much less than those obtained by Danish workers.

Some developments in microscopy were illustrated by the exhibits of Mr. Conrad Beck and the National Institute for Medical Research (Mr. J. E. Barnard, Mr. John Smiles, and Mr. F. Welch). Mr. Beck showed a new illuminator for opaque objects, consisting of an aplanatic ring of glass silvered on the back surface, which enables a short focus reflector of great light intensity to be used with powers as high as 4 mm. (1/6).

The Director, Royal Botanic Gardens, Kew, showed specimens of efwatakala grass (*Melinis minutiflora* P. Beauv.), a valuable pasture grass in the tropics, reported to be repugnant to the tsetse fly. This property appears to be due either to the aroma of the oil exuded by the hairs on the leaves or to its stickiness. In another exhibit, species of Psychotria, Pavetta, and Kraussia (Rubiaceæ) with nodular swellings in their leaves, due to the presence of colonies of bacteria, were shown. The bacterium can assimilate free nitrogen from the air. The Physical Department, Rothamsted Experimental Station, Harpenden (Dr. B. A. Keen, with Mr. E. M. Crowther and Mr. W. B. Haines), had exhibits dealing with flocculation and deflocculation in soils. An automatic electrical balance, devised by Prof. Oden and Dr. Keen, gives a continuous time record of the accumulating weight of deposit from a soil suspension. Analysis of the time-weight curve thus obtained gives an indication of the type of soil.

Messrs. J. J. Griffin and Sons, Ltd., showed a "Boys" integrating and recording gas calorimeter which has already been described in NATURE (August 19, 1922, vol. 110, p. 251). Dr. Hele-Shaw exhibited his stream-line filter, which causes the fluid which has to be filtered to flow with stream-line motion. This is done by forcing the fluid down holes drilled through parallel sheets of paper impervious to the fluid itself; the fluid escapes by passing between the sheets of paper. Dirty water and oil, and water containing a dye, were all freed of foreign material. Among the exhibits of the International Western Electric Company was a low voltage kathode ray oscillograph. The instrument consists of a glass tube in which a kathode ray is generated between a hot filament kathode and a small tubular anode. The ray is rendered visible by striking a fluorescent screen at the end of the tube. It is deflected on passing between two pairs of plates to which two alternating potentials are applied. The fluorescent spot then traces out a curve which is a graph of the relation between the two potentials. Among the exhibits of the Research Department, Woolwich, was an apparatus for the detection of feeble X-ray beams by smoke clouds. A smoke cloud, having a flat top, is produced in a small chamber, below an electrode maintained at a potential of about 400 volts. Even a feeble X-ray beam striking the cloud produces ions, some of which attach themselves to the smoke particles, and the latter can be seen rising from the top of the cloud. A chronograph for use with a photographic recorder was also shown. Time intervals of 1/1000th second are recorded on a moving cinematograph record by interrupting the spot-light from an Einthoven galvanometer by means of a wheel with 20 radial vanes, which is made to revolve at 50 revolutions per second. The accuracy of the recorder for long or short time intervals is at least 1/10,000th second.

Mr. S. G. Brown exhibited a frenophone, a form of loud-speaking telephone, in which the sound is amplified by friction. The telephonic current controls the pressure of a small cork pad upon a revolving glass disc, and the variations in the resulting frictional drag are applied to the telephone diaphragm of the instrument. Very clear articulation is produced. In an exhibit by the Cambridge and Paul Instrument Co., Ltd., a phonic motor driven by a tuning-fork controls a contact on a circular rheostat, which is rotated by a direct-current motor. If the latter gains or loses speed relatively to the phonic motor, the rheostat automatically synchronises the motor with the tuning-fork. The mechanism was designed by Dr. W. Rosenhain.

Curious as well as interesting were the exhibits of Mr. Harrison Glew, who showed a bar magnet of cobalt-steel floating above the opposed poles of a fixed magnet (NATURE, May 12, p. 609), and of Mr. E. Hatschek, who had a number of permanent "hanging drop" and vortex forms produced by running gelatin sol into suitable coagulating solutions, while the device of Mr. D. Northall-Laurie, showing photomicrographs of crystals in colour mounted to show changing tints, was very striking. Colour photographs (Paget process) are taken of the subject, and the slides are constructed to allow the viewing screen to be moved across the transparency. The tint of the slide then changes from green through various intermediate colours to red, just as the tint of crystals examined under a microscope by polarised light can be made to change. There were other specimens and pieces of interesting apparatus, such as that shown by Messrs. Adam Hilger, Ltd., for optical research, but a fuller account cannot be attempted.

During the evening, Sir Richard Paget lectured on the reproduction of vowel sounds, and Mr. Walter Heape on the Heape and Gryll rapid cinema machine.

Conference of Universities.

IN the programme of the annual conference of the universities of the United Kingdom, which was held on May 12 at King's College, London, the first place was given to the subject of the financial outlook of the universities. The income and expenditure for 1921–22 of the universities and university colleges of Great Britain in receipt of annual Treasury grants are displayed in Tables 7 and 8 of the returns recently published by the University Grants Committee. The aggregate income of these institutions (Oxford and Cambridge are excluded from the returns, their grants having been "special emergency" grants) is shown as 3,578,768*l*., derived from: Parliamentary grants (35·3 per cent.), Fees for tuition and examination (35·7 per cent.), Local Authorities' grants (11·7 per cent.), Endowments (10·3 per cent.), Donations and Subscriptions (2·7 per cent.), and other sources (4·3 per cent.). Of expenditure 49·3 per cent. was on Salaries of Teaching Staff, 13·4 per cent. on other Departmental Maintenance, 13·1 per cent. on Maintenance of Premises, and 10·2 per cent. on Administration.

The outstanding feature of the situation is the cramping of university activities owing to want of funds. "The grave condition of commerce and industry," says the Committee, "has temporarily called a halt to the forward movement which derived its impulse from the experience of the War: such a halt was natural—perhaps inevitable—but it cannot be prolonged without arresting developments which can only be neglected at grave risk to national efficiency." The Committee finds in the universities' expenditure on their libraries an illustration of the parsimony which they are compelled to practise. In a report dated February 3, 1921, the Committee directed special attention to the vital necessity of proper provision for library maintenance and declared that the character and efficiency of a university may be gauged by its treatment of this, its central organ, and it now characterises the expenditure on libraries and museums in 1921–22 as "dangerously small." The whole expenditure under this head was about as much as is spent on the upkeep of their libraries by the two universities of Chicago and California. The Committee is satisfied that at practically all the universities the greatest care has been taken to limit expenditure to essentials, and to get full value out of every pound spent. It follows that if the developments so urgently necessary for national efficiency are to take place, the universities' incomes must be augmented.

The discussion at the conference followed generally the lines of Dr. Adami's paper read at the Universities' Congress of 1921, and was directed especially to the question how far it is possible and desirable to obtain increases of annual grants from Local Authorities. Sir Theodore Morison suggested that provincial universities may be regarded as beneficial alike to (1) their students, (2) the cities they are located in and the surrounding districts, and (3) the nation; and that where more than two-thirds of the university's income is obtained from the students and the nation, it is not unreasonable to look to local sources for an increase of their contribution. He adduced statistics showing that if cities which at present grant to their universities less than the produce of a penny rate, and counties and neighbouring boroughs which make grants equal to less than a halfpenny rate, were to increase their grants to these standards respectively, the English provincial universities would benefit to the extent of 55,000*l*., or 4 per cent. of their total incomes; there are, moreover, a number of counties and boroughs within the spheres of influence of universities which do not at present make grants to them. Nor should it be difficult to convince local bodies of the great value to their constituents of a flourishing university in their midst. The services the universities can render to local communities may not be measurable in terms of money, but are not the less substantial, among them being assistance in the scientific development of local industries and the fostering of a spirit of regional independence. General appreciation on the part of local authorities of the value of such services should go far to minimise the dangers, to which attention was directed by several speakers at the conference, of dependence on grants out of rates.

With the exception of a remark by the president of the Board of Education to the effect that he believed the race of "pious donors" is not yet extinct, no suggestion was made as to the possibility of increasing endowments. The income from endowments not appropriated to specific purposes is shown in the Grants Committee's tables to amount at present to 155,230*l*., or 4 per cent. of the total income; the income from appropriated endowments is 215,350*l*. Several speakers acknowledged the inestimable value of the services to the universities of Sir William McCormick's Committee in helping them to meet the crisis in their finances produced by the War. The president of the Board of Education, while assuring the universities that there is at present no disposition in Parliament to challenge their autonomy, observed that they would always need to be on their guard against claims that with the extension of State aid should go extension of State control.

In opening the discussion on "Music as a University Subject," Sir Henry Hadow made a vigorous plea for full recognition by the universities of the study of musical works as being on a par with, if not a part of, literature. This recognition would involve its acceptance as an optional subject for the B.A. degree. The discussion brought to light the fact that alike in London, in Wales, and in Scotland, the recognition of music as an optional subject for matriculation is being considered, and that the northern English universities' joint matriculation board has adopted, and the Oxford and Cambridge schools examination board is considering, an adequate music syllabus for their school certificate examination.

The discussion on "The Universities and Training for Administrative and Municipal Life," opened by Sir William Beveridge, who was ably followed by Sir Josiah Stamp, showed that the liveliest interest is being taken in this subject both within and without the universities, and that this has been greatly stimulated by the establishment last year of the Institute of Public Administration. Most of the speakers were in favour of the universities providing in this connexion, not preliminary professional training, but courses suitable for persons who have already entered on their official careers. The courses would be framed in consultation with representatives of central and local government authorities with the view of junior officials being released from their ordinary duties for attendance on them.

Mr. Arthur Greenwood, M.P., spoke on "Labour and the Universities," and a paper by the Master of Balliol on extra-mural education was read.

The discussions were marked throughout by an animation which proved that the subjects were well chosen. A report of the proceedings will, we are informed, be published by the Universities' Bureau.

The Department of Geology, University of Liverpool.

NEW GIFT FROM SIR WILLIAM HERDMAN.

ON Tuesday, May 15, the Council of the University of Liverpool accepted a gift of 20,000*l*. from Sir William A. Herdman for the provision of a new building for the Department of Geology. Sir William Herdman desired his gift to be associated with the memory of the late Lady Herdman, and that the new laboratories should bear her name. It will be recollected that, after urging for many years the desirability of the foundation of a chair of geology in the University, Sir William Herdman, in company with Lady Herdman, eventually offered the University the sum of 10,000*l*. for the purpose of endowing the George Herdman chair in memory of their only son, who was killed in action in 1916.

Largely through the foresight of Sir William Herdman and Sir Alfred Dale, the late Vice-Chancellor of the University, accommodation had been reserved in an extension of the Zoology Department. The Geological Department thus consisted of two floors and a library, but the new professor had the great advantage of dividing up the shell of the building into suitable laboratories and of equipping them for special needs. Sir William Herdman had been securing for many years valuable collections and books in preparation for the future department. The equipment of the laboratories was assisted very materially by a gift of 2000*l*. from Mrs. and Miss Holt, relatives of Lady Herdman, long well known for their great and numerous benefactions to the University. Many other donations towards equipment and the cost of purchasing collections, etc., were made by Sir William and Lady Herdman in the succeeding years, and several students in the Department had reason to be grateful for their kind and practical help.

The School of Geology, founded in 1917, has grown rapidly—not unexpected, when it is remembered that Liverpool has long been known for such distinguished amateur geologists as G. H. Morton, C. Mellard Reade, H. C. Beasley, and J. Lomas, and its active Geological Society with a sixty years' record of published work. The accommodation of the Department has for the past three years been insufficient for its needs, and Sir William and Lady Herdman frequently expressed their desire to see the school housed more fitly. Lady Herdman's sudden and lamented death last autumn prevented the new gift being a joint one, but it was a happy thought of Sir William Herdman to associate the names of wife and son with the laboratories and chair respectively.

Apart from this valuable assistance towards the furtherance of geological work, it may be recalled that in 1919 Sir William and Lady Herdman also endowed the chair of oceanography in the University.

University and Educational Intelligence.

ABERDEEN.—Dr. H. R. Kruyt, professor of physical chemistry in the University of Utrecht, delivered a University lecture on May 14, his subject being "The Electric Charge of the Colloids."

The Students' Gala Week in aid of the Aberdeen Hospitals has realised a nett sum of 4753*l*.

Prof. J. Arthur Thomson has been appointed a member of the committee of inquiry on trawling.

ST. ANDREWS.—Among the names of those on whom the Senatus Academicus has resolved to confer the honorary degree of LL.D. at the graduation ceremonial on July 6 are the following:—Sir William Henry Hadow, vice-chancellor of the University of Sheffield; Mr. Herbert William Richmond, University lecturer in mathematics in the University of Cambridge, and retiring president of the London Mathematical Society; and Sir Robert Robertson, chief Government chemist, London.

BIRMINGHAM.—The Huxley Lecture is to be delivered on Thursday, June 7, 5.30 P.M., at Mason College, by Sir Arthur Keith, who has chosen as his subject "The Origin of the British People."

Dr. H. H. Sampson has been appointed honorary assistant curator of the surgical section of the Pathological Museum, and Mr. J. S. M. Connell, honorary assistant curator of the gynæcological section.

Prof. John Robertson is to represent the University at the meeting of the National Association for the Prevention of Tuberculosis, to be held in Birmingham in July next.

The Ingleby Lectures will be delivered at 4 o'clock on May 30 and June 6 by Dr. H. Black, who will take as his subject "The Investigation of the Alimentary Tract by X-rays." The lectures are open to all medical men.

CAMBRIDGE.—Dr. W. L. H. Duckworth, Jesus College, has been elected as representative of the University on the General Medical Council.

Dr. E. Lloyd Jones, Downing College, has been re-elected demonstrator of medicine. An honorary degree of Master of Arts is to be conferred on Dr. J. T. MacCurdy, Corpus Christi College, University lecturer in psychopathology.

DURHAM.—An anonymous donor has presented the capital sum of 12,000*l*. to Armstrong College, Newcastle-upon-Tyne, the interest of which is to be devoted to the establishment of research fellowships and possibly prizes of similar character to the Adams prize at Cambridge, or in such other manner as the Council of the College may decide is best calculated to promote original work in pure and applied science and the humanities.

The Council of the College has decided to proceed immediately with the erection of a permanent library at an estimated cost of some 40,000*l*. It has long been felt that there is great need of a scholars' library on the north-east coast, and it is hoped that when the new library is built it will form a worthy centre for all students of the district, whether members of the University or not. It is understood that the Unemployment Grants Committee are favourably disposed to consider such a scheme as a work of public utility deserving assistance from public funds.

EDINBURGH.—On Wednesday, May 16, Prof. H. R. Kruyt, of the University of Utrecht, delivered a lecture on "The Electric Charge of Colloids"; and on Friday, May 18, Prof. W. de Sitter, of the University of Leyden, lectured on "Problems of Fundamental Astronomy."

LONDON.—Prof. Leonard Bairstow has been appointed as from September 1 next to the Zaharoff chair of aviation tenable at the Imperial College of Science and Technology. He has been head of the Aeronautical Department of the National Physical Laboratory, and since 1920 has been professor of aerodynamics at the Imperial College.

Dr. C. L. Boulenger has been appointed as from September 1 next to the University chair of zoology tenable at Bedford College. Since 1922 he has been lecturer in, and temporary head of, the department of zoology at the college. He is the author of a number of papers on Cœlenterata, helminthology, and other subjects.

Miss B. E. M. Hosgood has been appointed as from September 1 next to the University readership in geography tenable at Bedford College. In 1918 she was appointed assistant lecturer in geography at the College, and has been since 1920 head of that department.

Dr. John Marshall has been appointed as from September 1 next to the University readership in mathematics tenable at Bedford College. He has been junior lecturer in mathematics at University College, Dundee, and senior lecturer in mathematics at University College, Nottingham. Since 1920 he has been senior lecturer in mathematics at University College, Swansea.

OXFORD.—On May 15 a decree was passed by Convocation authorising the presentation of an address to the Universities of Paris and Strasbourg on the occasion of the celebration of the centenary of the birth of Louis Pasteur.

It has been decided to offer an annual scholarship in chemistry under the will of the late Charles Day Dowling Gibbs.

A prize in natural science has been established by Mrs. Emily Poulton, in memory of her daughter, Hilda Ainley Walker, open to women members of the Society of Oxford Home-Students.

THE Ellen Richards Research Prize of 1000 dollars, for 1924, is being offered for theses by women, based on independent laboratory research. If the prize should not be awarded, a grant may be made under certain conditions. Information respecting the prize, and application forms, are obtainable from Dr. Lilian Welsh, Goucher College, Baltimore, Maryland, U.S.A., or from Mrs. Samuel F. Clarke, Williamstown, Mass., U.S.A.

THE Dr. Edith Pechey Phipson post-graduate scholarship, value 100*l.* a year for not more than three years, will be awarded in June by the council of the London (Royal Free Hospital) School of Medicine for Women. The scholarship is open to all medical women, preferably coming from India, or going to work in India, and is for assistance in post-graduate study. The latest date for the receipt of applications (which should be sent to the Warden and Secretary of the School, 8 Hunter Street, W.C.1) is May 31.

THE Board of Education is organising short summer courses of instruction for teachers in technical and evening schools (Form 105e. U.). Engineering science and electrical engineering are dealt with at Oxford and Birmingham. Both courses commence at Birmingham on July 23 and are concluded (July 28 to August 8) at Oriel College, Oxford. The courses include practical work on heat engines, hydraulics, mechanics, materials, electrical testing, wireless, thermo-electricity and magnetic testing. Building science is divided into two courses, (*a*) building mechanics and structures and (*b*) general science and laboratory work, both at Westminster Training College, Horseferry Road, London, S.W.1. Applications to attend these courses, to be obtained and returned through the local Education Authority if the teacher is working under such an authority, must be received by the Board of Education not later than June 1.

THE Manchester Municipal College of Technology is this year celebrating its "coming of age." It originated in a Mechanics' Institution founded in 1824 with the object, common to many similar foundations of the second quarter of the nineteenth century, of "enabling mechanics and artisans to become acquainted with such branches of science as are of practical application in the exercise of their trades." Conceived without much regard to the principles of industrial psychology, the methods employed commonly failed to attract people of the class for whom they were intended, and thirty years after its foundation a vice-president of the Manchester institution remarked, "Nature was as bountiful to the working-class in talent and energy as to the higher classes," but "those for whom this institution was destined did not avail themselves of it," and "until we enforced education upon all classes, Mechanics' Institutions, successful as they might be to some classes, would not produce the great advantage they might otherwise do." The Paris exhibition of 1867 having attracted attention to a growing inferiority of English arts and crafts, a cry was again raised for technical education among workmen, and this was echoed by the directors of the Manchester institution, who in their report for 1868 approved of "recurring to a system of education, the basis of which was prescribed in the original preamble, viz. to instruct the working-classes in the principles of the arts they practise." In 1882 it was converted into a technical school, which was in 1892 taken over by the City Corporation. The College into which it has grown had in 1921–22 an income of 143,000*l.*, of which nearly 64 per cent. (more than the produce of a 4d. rate) was provided by the Corporation. Of the 6223 students 553 were taking courses of university standard. An interesting series of articles upon the work and development of the College has been contributed to the *Manchester City News* by the former principal, Mr. J. H. Reynolds.

AMONG the various links connecting abstract science and engineering is the scientific education of engineers. Thirty years ago Sir William Anderson deplored the fact that except in the noble endowments of the City and Guilds schools and the Government institutions at South Kensington in London, the movement to secure the necessary training languished for want of adequate support. Sir Richard Glazebrook, in his "James Forrest" lecture to the Institution of Civil Engineers on May 4, made reference to this, and gave a brief outline of the conditions at present. The City and Guilds College—the Engineering Department of the Imperial College—opened in 1886 with 35 students; in July 1922 there were 492 engineering students in the College, and 138 students of the Royal College of Science and the Royal School of Mines were also receiving instruction. The numbers for the Schools of the University of London and its other institutions were not quoted, but it may be said that these show corresponding increases. In the period from 1903 to 1922 London University conferred 1294 internal and 756 external engineering degrees. The growth in the provincial universities and colleges has also been very large. Among other hopeful signs is the increasing interest in the education of apprentices shown by trades unions; a report on this subject was presented at the Trades Union Congress last year. The scheme of industrial bursaries started in 1911 by the Royal Commission for the Exhibition of 1851 is for the award of bursaries to students who have done well in some branch of science and who propose to go into works. Up to December last about 19,000*l.* has been expended on 185 bursars. The scheme is an extremely useful one and could be extended with advantage. Many young men find it extremely difficult, after a successful college career, to obtain adequate works experience without causing an intolerable drain on the slender resources of their parents. It is also of interest to record that there is an increasing demand by employers for college-trained men; the associations of works and colleges were greatly strengthened during the War, and many firms now prefer men for their staffs who possess university degrees.

Societies and Academies.

LONDON.

Royal Society, May 17.—A. E. H. **Tutton**: (1) A universal interferometer. The essential feature is a travelling microscope driven by a specially constructed fine screw along a true V-and-plane guiding bed; one of the two glass reflecting surfaces is carried rigidly with it, and the amount of its motion is measured directly in monochromatic interference bands. There is an autocollimating telescope with micrometer eyepiece, a vacuum tube on the elbow tube, a constant deviation prism for the selection of the monochromatic radiation to be used, and large truly worked glass interference discs. The telescope is mounted to the right, and the driving wheel to the left, and the 30-inch long V-and-plane bed, in its rigid carrying plinth-bed, is supported on pillars at the Airy positions for no flexure, the whole being mounted on a heavy rectangular base. The large middle space on the latter is available for a large circular work-table with every possible requirement of adjustment for supporting the object or its manipulating apparatus. (2) A wave-length torsometer, and its use with the universal interferometer. This is a refinement of the Voigt instrument for determining the torsion constants of small bodies. It is essentially a miniature lathe-bed, carrying two similar but mutually reversed wheel-and-chuck fittings, the chucks for gripping the object bar ends, and the wheels, which move solidly with the chucks, for delivering the force-couple at one end and holding the object firmly at the other, the two ends being interchangeable. The power band passes round the lower half of one pulley-wheel and thence over a larger pulley-wheel on a standard. The end depending from in front of the latter terminates in a loop of the cord-band, into which the hook carried by the weight can be allowed slowly to fall, until the whole weight is acting in twisting the object bar. The torsometer is supported on the work-table of the universal interferometer. It is rigidly clamped with the two aluminium radials carried by the object bar near its two ends, in contact near their upper terminations with the blunt knife-edge ends of the two sliders. The Grayson-ruling signal is centred under the microscope when the radial under observation is just in complete contact with the slider. On delivering the weight and effecting the twist, the slide and signal move, and the movement is followed by driving the microscope by the big wheel of the interferometer until the signal mark is again centred, the number of interference bands effecting their transit being counted.—L. N. G. **Filon** and F. C. **Harris**: On the diphasic nature of glass as shown by photo-elastic observations. A block of flint glass was heated to about 400° C., when it showed some signs of softening; it was then allowed to cool under longitudinal pressure. On removing the pressure it was found to have become permanently doubly-refracting. The residual stress which should produce the observed amount of double-refraction does not balance according to the laws of statics. It is deduced that a "crypto-stress" exists, which does not manifest itself optically. This leads to the conclusion that the glass is not homogeneous, but behaves as a mixture of two components or phases.—C. E. **Inglis**: Stress distribution in a rectangular plate having two opposing edges sheared in opposite directions. Imagine a thin rectangular plate bounded by two horizontal lines AB CD and two vertical lines AD BC. The two horizontal edges, while remaining straight and unchanged in length and in distance from one another, are displaced longitudinally in opposite directions, the vertical edges being kept free from applied stress. The plate being thin, the distribution of stress consequent on this deformation is regarded as two-dimensional and the stress components are obtained through solutions of $\nabla^4 V = 0$. Along the horizontal centre line the stress starts from zero at the free edge, increases rapidly, and, for a plate in which the length is considerable compared with the depth, the stress soon assumes a constant value; but before doing so, it overshoots this value, and the curve of stress distribution in consequence develops humps near the free vertical edges. If the length–breadth ratio of the plate is 2 to 1 these humps combine to give a flat-topped curve. If the plate is square the coincidence of the humps makes the curve approximate to a parabola.—T. H. **Havelock**: Studies in wave resistance: influence of the form of the water-plane section of the ship. In these calculations the ship is represented by a vertical post of infinite depth the horizontal section of which is similar to the water-plane section of a ship. The level lines of the model are varied, while the displacement is kept constant. In this manner a comparative study is made of such problems in ship resistance as the effect of finer lines and greater beam and of the difference between straight and hollow lines.—W. M. H. **Greaves**: On a certain family of periodic solutions of differential equations, with an application to the triode oscillator. There is, under certain conditions, a discontinuous family of periodic solutions of the equations $dx/dt = \mu\xi$, $dy/dt = \lambda(x) + \mu\eta$, where $\lambda(x)$ is a function of x only, ξ and η are functions of x and y, periodic in y with period 2π, and expressible as Fourier Series in sines and cosines of multiples of y, the coefficients being functions of x, not involving t explicitly, and μ is a constant parameter. An application is made to the equation of Appleton and Van der Pol for the triode oscillator the equation of which can be reduced to a particular case of the above equations.

Geological Society, April 18.—Prof. A. C. Seward, president, and, afterwards, Dr. H. H. Thomas, vice-president, in the chair.—J. F. N. **Green**: The structure of the Bowmore-Portaskaig district of Islay. Quartzite is defined as containing a limit of 10 per cent. of felspar, more highly felspathic rocks being termed "arkose." On this definition the Islay upper quartzite is throughout true quartzite; but the so-called lower quartzite is not quartzitic, being composed of arkoses and greywacke-slates identical with the matrix of the Portaskaig conglomerate; they have been grouped together as the Portaskaig beds. Thus the dolomitic group intervenes between the Portaskaig beds and the Islay quartzite. The supposedly Torridonian Bowmore sandstone consists of arkoses and flags. The flags, which, owing to isoclinal folding, have apparently an enormous thickness, are identical in minute detail with certain siliceo-argillaceous flags that always occur in the dolomitic group next to the Islay quartzite. They are termed the Bowmore flags. Thus there is no change of facies at the supposed thrust, and its presumed line of outcrop shows that the rocks are folded up without disruption, except for some shearing on the reversed limbs of overfolds. The Loch Skerrols thrust is non-existent. The Bowmore flags are perfectly conformable to the white edge (a well-marked horizon) of the Islay quartzite; the dolomitic flags associated with them are partly or wholly cut out in places by the Portaskaig beds. The latter are probably younger than the dolomitic group. On Beannan Dubh the rocks lie in isoclinal folds with low dip, by which the Portaskaig conglomerate is brought up in anticlines. The structure of Islay is probably synclinal. Only one system of folding is required to explain the facts.

May 2.—Prof. A. C. Seward, president, in the chair.—J. Joly: The bearing of some recent advances in physical science on geology. In his lecture, Prof. Joly dealt with the subjects discussed in the article "Surface Movements of the Earth's Crust" in NATURE of May 5, p. 603.

Royal Anthropological Institute, May 1.—Mr. H. J. E. Peake in the chair.—V. Gordon Childe: The Neolithic painted pottery of south-eastern Europe. The sites in question extended from the banks of the Dnieper in the Kiev Government to the slopes of the Carpathians, and are restricted to the fertile "black earth" belt. Three groups were found: an eastern group along the Dnieper (the Tripolje culture proper) with much incised ware; a central group in Bessarabia, Moldavia, Bukowina, and Eastern Galicia, where pottery with black paint predominated, and a western group represented by Koszylowce west of the Sereth with polychrome painting. At Cucuteni in Moldavia an older phase of this culture was discovered with polychrome pottery and good spiral designs. The painted pottery comes either from large rectangular structures of wattle and daub called *ploshchadky* or from huts partly hollowed out in the earth (*zemlyanky*). No hearths have been found in the former, but the latter regularly contain an oven situated in a deeper trench filled with kitchen refuse. No authenticated metal finds were reported from Schipinitz, and at other parallel stations (except Cucuteni II.) metal was either completely absent or represented only by small implements of pure copper. Polished stone axes were also very rare, but fine flints and numerous artefacts of bone date the culture to the last phase of the stone age. The culture of the "black earth" was apparently terminated by the incursion of nomadic tribes.

May 14.—Dr. A. C. Haddon, past-president, in the chair.—Mr. J. E. P. Murray: Native administration in Papua. The principle that government of the backward races should be in the interests of these races themselves has been followed by the Australian Government in the administration of Papua. It is necessary, however, to understand the Papuan character if an intelligent native policy is to be pursued, and on this account an anthropological department was instituted. The indenture of women is not allowed in Papua except for domestic purposes under certain conditions. The indenture of women would probably result in the breaking up of village life, which would put an end to any possibility of developing the territory through native enterprise. Changes introduced into native life by the arrival of the white man can be classified as (1) moral; (2) material; for the latter the Government must find a remedy or it fails in its duty altogether. One most obvious remedy is work, not merely in the interests of the white employer, but work for the native's own interest and on his own land. The introduction of the native tax in Papua has made it possible to deal comprehensively with the question of native plantations, and plantations worked by natives in partnership with the Government. The proceeds of the tax are used only for native education and for other purposes directly for the benefit of the natives. In the future the danger to the native under Australian rule lay in "benevolent capitalism."

Linnean Society, May 3.—Dr. A. Smith Woodward, president, in the chair.—W. T. Gordon: Fossil coniferous genus Pitys. The specimens were obtained from beds of siliceous volcanic ash, at Gullane, 17 miles east of Edinburgh, and comprised a new species, showing cortex and leaves; hitherto nothing was known of the genus, except pith and wood.—R. Gurney: The Crustacean plankton of the English Lake district.—S. L. Ghose: A systematic and ecological account of a collection of Blue-green Algæ from Lahore.—J. Groves: Notes on Indian Charophyta. In 1882 representatives of the genera Chara and Nitella only were known from India. Now a Nitellopsis, a Lychnothamnus, and three species of Tolypella have been recorded. Within the past three years, in a comparatively small area, Mr. G. O. Allen added three well-marked species to the Indian flora besides rediscovering *C. Wallichii*, of which only the male plant collected in 1809 by Dr. Wallich was previously known, and establishing the occurrence of *Nitellopsis obtusa* (in Kashmir), the only previous Asiatic record of which was dependent on a poor specimen from Burmah.—J. G. H. Frew: On the morphology of the head-capsule and mouth-parts of *Chlorops tæniopus* Meig. (Diptera).—A. M. Alston: On the genital system of the wood-boring beetle, *Lyctus brunneus* Steph. Both of the ovipositor and the rectum are of great length.

Aristotelian Society, May 7.—Prof. A. N. Whitehead, president, in the chair.—L. J. Russell: Some problems in the philosophy of Leibniz. The metaphysical concept of the monad was reached in the later part of Leibniz's philosophical development and the sources of the doctrine are only to be discovered by studying his writings, many of which are undated manuscripts, chronologically. In the "Discourse on Metaphysics" (1686) we find he has arrived at the conception of created substance. It was this conception which provided for him a rational justification of his view of the relation of God to the universe and of his conception of the universe as a harmony. It was into this framework that the monadology was fitted. Leibniz seems never to have doubted the validity of the conceptions of God as the architect of the world machine, and as the ruler of the republic of spirits. The first saved him from the pantheism of Spinoza, which would have made the second irrational. The reconciliation of the two conceptions presented the chief problem of his philosophy.

Zoological Society, May 8.—Dr. A. Smith Woodward, vice-president, in the chair.—H. Burrell: Note on a hibernating female specimen of the marsupial *Acrobates pygmæus*.—F. M. Duncan: The microscopic structure of mammalian hairs, with especial reference to the hairs of the primates.

Optical Society, May 10.—Mr. T. Smith, vice-president, in the chair.—J. W. French: Stereoscopy re-stated. Stereoscopic vision is possible only within certain limits. For certain pairs of objects, whether on the same or different horizons, there are generally two extreme critical points beyond which stereoscopic vision breaks down. For certain pairs of objects on the same horizon there are two inner critical points. Objects of dissimilar form but approximately the same average angular dimensions can frequently be combined stereoscopically; thus a circle can be combined with a triangle if their average angular dimensions are about equal. When the angular dimensions are very different, combination is generally impossible; thus, for example, a thin line cannot be combined with a thick line or triangle. When the pairs of objects are dissimilar in size, there is only one pair of outer and inner critical points if the objects are on the same horizon and one outer critical point if they are on different horizons. For pairs of objects any of which can be combined together, there are two pairs of such critical points.

Royal Meteorological Society, May 16.—Dr. C. Chree, president, in the chair.—M. de Carle S. Salter and J. Glasspoole: The fluctuations of annual rainfall in the British Isles considered cartographically. Maps expressing annual rainfall 1868–1921 as a percentage of the average, fall roughly into three types, indicating respectively (i.) excess of orographical rain, (ii.) deficiency of orographical rain, (iii.) excess of cyclonic rain. The mean range of variation per annum is 35 per cent., with local extremes varying from +80 per cent. to −59 per cent. In the earlier years the maxima were generally in the east: in the middle of the period in the west: and in the later years in the south. The general rainfall varied from 136 per cent. in 1872 to 77 per cent. in 1887, the deviation exceeding 20 per cent. in only 5 years, and averaging 8 per cent. From 1868 to 1882 maxima occurred at intervals of 5 years; from 1889 to 1909 of 3 years; and from 1910 to 1921 of 2 years. There is also evidence of a long-period fluctuation with two maxima about 40 years apart. Annual pressure maps for the same series of years appear to show three main types of variation due to (i.) shifting of the S.W. wind drift to N. or S.; (ii.) changes in the gradient; (iii.) local deflections of the isobars. Type (i.) appears to determine the amount of general rainfall; type (ii.) determines the distribution of rainfall; type (iii.) affects both variables, and includes all extremely dry or wet years.—A. W. Clayden: An improved actinograph; note on the influence of a glass shade. Two similar bimetallic coils, like those used for thermographs but with 7½ turns each, are mounted about a common axis and attached to a recording pen, in such a manner that the movements of the pen register only the difference of temperature between the two coils. The axis is fixed in a position parallel to the polar axis with the coils at its ends. The instrument stands in a case so that the coil at the lower end is shaded from the sun, while the coil at the upper end is exposed under a hemispherical glass shade to full sunlight and is blackened. The records for five consecutive years from February 1914 show a rapid rise of radiation during January to April, a slight drop about the middle of May followed by a rise to June and a fall during the latter half of the year which is notably more gradual than the vernal rise. —E. E. Benest: Notes on the "Sumatras" of the Malacca Straits. These squalls usually blow from the south-west, and are more frequent between April and October. A greater number is experienced between Malacca and Pulo Penang than between Malacca and Singapore. "Sumatras" always occur at night, and are generally accompanied by thunder, lightning, and torrential rain; they seldom last more than two hours. The strength of the wind is estimated as between 40 and 55 miles per hour. A characteristic cloud formation is a heavy arch or bank of cumulo-nimbus, which rises to an estimated height of about 7000 ft. and rapidly spreads over the whole heavens.

PARIS.

Academy of Sciences, April 30.—M. Albin Haller in the chair.—A. Haller and L. Palfray: The mixed and symmetrical 1-ethanoic-1-camphomethanoic esters and their saponification products. These compounds, containing both the $(CH_2.CO_2H)$ and (CO_2H) groups, attached to the same atom of the camphor molecule, form esters which are singularly difficult to hydrolyse. —A. Calmette, A. Boquet, and L. Nègre: Rôle of the *terrain* in the evolution of experimental tuberculosis in the rabbit and guinea-pig. The interval of time between the injection of tubercle culture into a rabbit and the death of the animal through tuberculosis has been proved to be inversely proportional to the number of bacilli inoculated, the bacilli arising from the same culture. With guinea-pigs and rabbits the number of bacilli injected appears to be the main factor in determining the time of evolution of the disease, and there are no indications of a factor involving variable sensibility of the individual animals.—Georges Bouligand: The singularities of harmonic functions.—A. Sainte-Laguë: Networks.—J. Haag: The gravitational field of n bodies. A correction of an earlier note on the same subject.—Louis Roy: Gauss's theorem of least constraint. This theorem of Gauss is stated to be incorrect.—M. Cisotti: Remarks on the note "Superficial circulation" by M. P. Noaillon.—F. Henroteau: Variations of the spectrum of the star θ_2 Orionis. In addition to the absorption lines due to hydrogen and other elements, a photograph of the spectrum taken at Ottawa in 1919 and January 1920 showed fine, intense emission lines. These lines were not found by O. Struve (Yerkes Observatory) in 1922, but were present on a spectrogram taken March 2, 1923. Hence this star, class B and not variable, shows bright lines only at intervals, a new phenomenon in astronomy.—Max Morand: Certain electromagnetic consequences of the principle of relativity.—L. Dunoyer: Induction spectra and spark spectra. Reply to a criticism by Léon and Eugène Block.—S. K. Mitra: The demagnetisation of iron by electromagnetic oscillations. A study of the effects of variation of the frequency of the alternating current on the residual magnetisation. The demagnetisation increases as the frequency of the oscillations is lowered.—Félix Michaud: Deformations of jellies by the action of an electric current. When a jelly is placed between two metallic electrodes, and an electric current is passed, it contracts towards the anode, and swells out near the cathode. The nature of the metal used for the electrodes is without influence. The action depends on the colloid; gelose gives a more intense effect than gelatin.—Pierre Brémond: The persistence of the colour of the ions in ceramic colours or colouring materials obtained at a high temperature. Attention is directed to the fact that some of the colours shown by ceramic products due to metallic constituents, and produced at high temperatures, correspond with those found in the salts of the same metals, or in hydrates which are stable only at low temperatures. —Mme. and M. A. Lassieur: The estimation of antimony by means of phenylthiohydantoic acid.—Marcel Pichard: Method of analysis of cocoa butter and its mixtures with vegetable fats. The method is based on the form of the cooling curve of the melted fat, when allowed to solidify slowly.—L. J. Simon and Léon Piaux: The conversion of alanine into pyruvic acid by the direct action of oxygen. Alanine can be oxidised directly to pyruvic acid by shaking with oxygen in the presence of alkali and metallic copper, but the proportion of copper present must be carefully regulated (1 molecule alanine to ¼ atom copper) and the reaction stopped immediately the absorption of oxygen ceases.—M. Aloy and M. Valdiguié: The oxidations and reductions produced by uranium salts under the influence of light. The antioxygen effect of phenols. Uranium acetate can act like an oxidising-reducing ferment. A solution of this salt, just acid with acetic acid, when mixed with glucose and methylene blue, placed in an evacuated bulb, and exposed to sunlight, oxidises the glucose and reduces the methylene blue simultaneously.—J. **Orcel**: The prochlorites of corundum rocks. These minerals, ten analyses of which are given, are divided into two sub-groups, ripidolites defined by the ratio MgO/FeO $\leq$ 3 and grochauite, with a ratio MgO/FeO = 10.—Pierre **Viennot**: The Labourd stratum, French Basque region.—Léon **Moret**: The facies of the Senonian sponges of the Beausset basin and their conditions of deposit.—C. **Kilian**: The Immidir, branch of the "Enceinte Tassilienne," Central Sahara.—René **Jeannel**: Sketch of the stocking of Europe by the species of the genus Choleva.—R. **Anthony** and F. **Villemin**: The lobation of the fœtal kidney in the primates.—Radu **Vladesco**: Diffraction of light by the eyelashes. The diffraction bands seen under certain conditions are due to the scales forming the outer envelope of the hair.—J. **Lopez-Lomba** and Mme. **Randoin**: Contribution to the study of B avitaminosis in the pigeon.—L. M. **Bétances**: Cytohemato-genesis in the Metazoa.—A. **Weber**: The inhibiting action of the internal medium of batrachians on the fecundation and the parthenogenetic activation of their eggs. In *Rana fusca* the internal medium, lymph or blood, behaves towards the activated egg as a toxic substance, to which the egg becomes permeable after puncture, while previously it was immunised against this toxic property.—Maurice **Aubertot**: The dissemination and transport of nematodes of the genus Rhabditis by Diptera.—R. **Courrier**: Remarks on the fecundation membrane of the egg of the sea-urchin (*Paracentrotus lividus*).—Edouard **Chatton** and Mme. M. **Chatton**: The influence of bacterial factors upon nutrition: the multiplication and sexuality of the infusoria.—Robert Ph. **Dollfus**: The cestode of the fine pearls of the Meleagrina of Nossi-Bé.

Official Publications Received.

Journal and Proceedings of the Royal Society of Western Australia. Vol. 8, 1921–1922. Pp. x+52. (Perth.) 5s.

Health for School Children: Report of Advisory Committee on Health Education of the National Child Health Council, Washington, D.C. (School Health Studies, No. 1: Department of the Interior, Bureau of Education.) Pp. 75. (Washington: Government Printing Office.) 10 cents.

Diary of Societies.

SATURDAY, MAY 26.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—J. B. McEwen: Musical Education.

MONDAY, MAY 28.

FARADAY SOCIETY (at Institution of Electrical Engineers), at 3.—General Discussion on the Physical Chemistry of the Photographic Process.—Prof. W. D. Bancroft: Introductory Address—The Theory of Photography.—Section I. The Physical Chemistry of the Vehicle and of the Emulsion.—Dr. T. Slater Price: Introductory Address.—Prof. R. Luther: Effect of Treatment of Gelatin on the Sensitivity of the Emulsion.—E. P. Sheppard, F. A. Elliott, and S. S. Sweet: Notes on the Photographic Chemistry of Gelatin.—E. P. Wightman, A. P. H. Trivelli, and S. E. Sheppard: Structure of the Photographic Emulsion.—Dr. C. Winther: The Solubility of Silver Bromide in Ammonium Bromide and Gelatin.—At 5.—Section II. Reactions of the Plate during Exposure (including Latent Image).—Dr. F. C. Toy: Introductory Address—The Mechanism of the Latent Image Formation.—S. E. Sheppard, A. P. H. Trivelli, and E. P. Wightman: Exposure Theories.—Prof. R. Luther: The Relation between the Size of Silver Bromide Grains and Sensitivity.—W. C. Clark: Sensitivity of Silver Halide Grains in a Photographic Emulsion.—Dr. J. Errera: The Influence of the Dispersion of Asphalte Solutions on their Light Sensitiveness.—Section III. Development and Characteristics of the Developed Plate (including Optical Properties, Sensitometry).—O. Bloch: Introductory Address—Plate Sensitometry.—Prof. R. Luther: The Characteristic Curve.—Prof. R. Luther: Proportional Reducting Methods.—Prof. E. Goldberg: The Use of the Neutral Grey Wedge in Sensitometry.—T. Thorne-Baker: The Effect of Radiations of very small Wave-lengths on Optical Opacity and Gamma.—S. E. Sheppard and F. A. Elliott: The Theory of Development.—L. A. Jones: Recent Progress in the Sensitometry of Photographic Materials.—L. A. Jones: Some New Instruments for use in Photographic Sensitometry.—F. E. Ross: Optical Properties of the Photographic Emulsion.—At 8.—Section IV. Adsorption Reaction in Photographic Films.—Dr. Luppo-Cramer: Introductory Address.—Dr. Luppo-Cramer: Nucleus Isolation and Desensitisation.—A. L. Lumiere and A. Seyewetz: The Chemistry of the Red Toning of Sulphide-toned Prints.—Prof. R. Luther: Adsorption of Cupric Ion by Silver Bromide: Estimation of Traces of Copper by a New Catalytic Method.—Prof. R. Luther: Copper as Catalyst in Photographic Processes: Catalytic Effects in the Carbon Process.—E. R. Bullock: Theory of Photographic Due Mordanting.—Dr. J. Plotnikov: Future Problems in Photography.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Sir Walford Davies: Speech Rhythm in Vocal Music (2).

ROYAL GEOGRAPHICAL SOCIETY (Anniversary Meeting) (at Æolian Hall), at 5.30.—Presidential Address.—Presentation of Medals and other awards, etc.

ROYAL INSTITUTE OF BRITISH ARCHITECTS, at 8.—G. Scott: Tradition and Originality in Italian Renaissance Architecture.

ARISTOTELIAN SOCIETY (at University of London Club, 21 Gower Street), at 8.—C. D. Burns: The Contact of Minds.

ROYAL SOCIETY OF MEDICINE (Odontology Section) (Annual General Meeting), at 8.—Dr. S. Wallace: Observations on the Progress of Preventive Dentistry.

TUESDAY, MAY 29.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Prof. W. M. Flinders Petrie: Discoveries in Egypt (2).

ROYAL SOCIETY OF MEDICINE (Medicine Section), at 5.30.—Annual General Meeting.

ZOOLOGICAL SOCIETY OF LONDON, at 5.30.—C. Tate Regan: The Skeleton of *Lepidosteus*, with Remarks on the Origin and Evolution of the Lower Neopterygian Fishes.—Dr. C. F. Sonntag: The Comparative Anatomy of the Tongues of the Mammalia. IX. Edentata, Dermoptera, and Insectivora.—S. Maulik: New Cryptosome Beetles.

WEDNESDAY, MAY 30.

ROYAL SOCIETY OF ARTS, at 4.30.—A. J. Sewell: The History and Development of the Perambulator and Invalid Carriage.

ROYAL MICROSCOPICAL SOCIETY (Industrial Applications of the Microscope Section), at 7.—M. T. Denne: An Improved Apparatus for the Production of Photomicrographs.—C. A. Newton: A New Form of Microscope Lamp for Easy Exchange of Paralleliser and Polariser.—M. P. Swift: A Hutchinson Universal Goniometer.—At 8.—J. M. Coon: The Microscopical Examination of China Clay.—H. B. Milner: The Microscopical Investigation of Sands for various Industrial Purposes.

THURSDAY, MAY 31.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Sir William M. Bayliss: The Nature of Enzyme Action (1).

ROYAL SOCIETY, at 4.30.—Dr. E. Griffiths and Dr. G. W. C. Kaye: The Measurement of Thermal Conductivity, No. 1.—Dr. G. W. C. Kaye and J. K. Roberts: The Thermal Conductivities of Metal Crystals. I. Bismuth.—C. V. Drysdale and S. Butterworth: The Distribution of the Magnetic Field and Return Current round a Submarine Cable carrying Alternating Current.—Prof. S. Russ: The Effect of X-rays of different Wave-lengths upon some Animal Tissues.—Dr. E. F. Armstrong and Dr. T. P. Hilditch: A Study of Catalytic Actions at Solid Surfaces. Part XI. The Action of Alumina and certain other Oxides in promoting the Activity of Nickel Catalyst.—N. K. Adam: The Structure of Thin Films. Part IV. Benzene Derivatives. A Condition of Stability in Monomolecular Films.—N. K. Adam: The Structure of Thin Films. Part V.—W. B. Rimmer: The Spectrum of Ammonia.

INSTITUTION OF ELECTRICAL ENGINEERS, at 6 (Annual General Meeting).—Presentation to the Institution of (*a*) An oil painting of the late Dr. Silvanus Thompson; (*b*) Dr. Thompson's Library; (*c*) A bronze bust of Dr. Thompson, by Mr. Gilbert Bayes.

FRIDAY, JUNE 1.

ROYAL SOCIETY OF ARTS (Indian Section), at 4.30.—A. Kendall: The Participation of India and Burma in the British Empire Exhibition, 1924.

ROYAL ASTRONOMICAL SOCIETY (Geophysical Discussion), at 5.—The Variation of Latitude in relation to the Physical Properties of the Earth's Interior. Chairman, Lord Rayleigh. Speakers, R. Stoneley, Dr. H. Jeffreys, and others.

PHILOLOGICAL SOCIETY (at University College), at 5.30.—Dr. H. Bradley: Dictionary Evening.

ROYAL INSTITUTION OF GREAT BRITAIN, at 9.—Prof. H. A. Lorentz: The Radiation of Light.

SATURDAY, JUNE 2.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Dr. A. W. Hill: The Vegetation of the Andes.

BRITISH PSYCHOLOGICAL SOCIETY (at University College), at 3.—Sir Charles Walston: Some Aspects of the Philosophy of Harmonism and Future Experiments.

PUBLIC LECTURES.

THURSDAY, MAY 31.

ST. MARY'S HOSPITAL (Institute of Pathology and Research), at 4.30.—Prof. L. Hill: New Ideas concerning the Biological Action of Light.

UNIVERSITY COLLEGE, at 5.30.—Prof. A. Cippico: Ludovico Ariosto (in Italian).

FRIDAY, JUNE 1.

UNIVERSITY COLLEGE, at 5.30.—Dr. P. Lang: Contemporary Swiss Literature. (Succeeding Lectures on June 8 and 15.)

Science and Religion.

DOES a description of the world afford any evidence of the existence of God? This is the subject of a symposium in the April issue of the *Hibbert Journal*, and the discussion has particular interest for biologists. A description of the world is not merely a statement of those conceptions that we call natural laws, but it is also an interpretation of what Prof. Whitehead calls the "passage of Nature"—the evolutionary career. In this passage the various points of view taken by the writers are these: there is an increasing enrichment of what we may call the content of Nature; there is progress; and there is an effort or striving against something.

The first interpretation is made by Dr. J. S. Haldane in an argument of sustained power. The world of our experience may be known to us through the mathematical sciences, through physics, and through biology. The conception attained through pure mathematics is *bare*; it need not include objects, and it deals typically with the space and time relationships between objects. These relations, or differential equations, need not have physical meanings. The world, from this point of view, has form but no content. To construct it out of pure extension, that is, to give all natural laws geometrical meanings, is the tendency of the later relativists; thus the world is deprived of substance, or at least, the nature of this substance is ignored. Next come the physical sciences, enriching this conception by inserting objects into the world but ignoring the plain fact that its natural laws are only working hypotheses which have limited practical meanings. They are statements of the ways in which we can *act* on our physical environment. They are descriptions of our increased power over Nature.

Then come organisms—which add something new to the world. This conclusion depends on Dr. Haldane's difference from the majority of the biologists of the last generation. "Weighed in the balance of accurate quantitative investigation the mechanistic theory of life has been found wanting." What the Victorian materialism has envisaged in the organism has been "a vista of mechanisms," one inside the other, so to speak; postulated rather than really observed; incapable of explaining organic functioning, to say nothing of reproduction and behaviour. The conception is even inadequate as a means of investigation, and it is being replaced by other methods—for example, Dr. E. S. Russell's psycho-biology. Thus mechanism fails and in this failure we recognise a further enrichment of Nature. Biology becomes a science with its own fundamental conception of life.

Lastly, there is the self-conscious human personality.

This we may consider, first, as having immediate self-interest. On the strictly mechanistic outlook, it must regard all other organisms and conscious persons merely as moving objects similar to those other objects called inorganic. But even a purely physical description of the organism is not to be obtained, and by no process called scientific can the self-conscious person explain his *own* consciousness in terms of mathematics and physics. Further, he sees other organisms that are not self-conscious, and so the mere biological life-conception fails to explain consciousness in other organisms than himself. So he is bound to make yet another fundamental conception, that of the conscious, self-interested organism; but even that is not all. Almost every action that he performs—as a member of a human community—means that he recognises *other* conscious, self-interested persons like himself: otherwise he would not seek to convince them, nor would he praise, or blame, or pity, or like, or hate them. On the purely mechanistic outlook, the things that he does, every conscious minute of his life, are meaningless.

Then, even the purely physical thing is not a unit. Anything that is known to us is known only when it changes. When it changes it does so only because other things in the physical system to which it belongs also change. In the long run, the only isolated physical system that we know is the whole universe, and it is only by convention that we arbitrarily isolate a thing from all the rest of Nature. So also the functioning and behaviour of an organism means that it is acting on, or reacting with, or adapting itself to the environment—which is the whole universe. The self-conscious person (which is also a physical thing and an organism) is only such because it reacts with other self-conscious persons. Add to this the literally true conception that all organisms, conscious or unconscious, are materially and strictly continuous in the time dimension, then the whole world is one, and personality is everywhere in it.

Thus, to the physical categories of substance, necessity, relation, modality, quantity, etc., we must add those of life, consciousness, and personality. The personality is universal in time and space and is God.

Next we have Mr. Julian Huxley's interpretation of the passage of Nature as a progress. But evolution, he sees quite well, is not necessarily a passage from the "simple to the complex." It is quite as easy to look upon the "lower" organism as more complex than the "higher" one—just because it is undifferentiated. It is plain that the morphological, evolutionary series of changes is *irreversible*, and that the goal towards which all organic races tend, as they specialise, is extinction. How, then, to define "progress"? There is a series of changes that have led up to the human race; let us attach a series of "values" to these changes, thus making a one-to-one correspondence, value to morphological change. What are the values? Those conditions judged by the human mind to have value *are* values. Progress then is the series of evolutionary changes that have *human* value, and it is, somehow, a tendency towards good. It is an obscure feeling "clarified and put on a firm intellectual footing by biology." It is true that the problems of evil, of pain, of strife, of death, of insufficiency and of imperfection remain to perplex us, but nevertheless progress is an element "essential to an externally grounded conception of God," to be incorporated into the common theology of the future.

Finally, there is Sir Oliver Lodge's interpretation of evolution as an effort: a conception which is more fundamental than any other that is touched in this discussion. Why, in the physical sense, have changes, or reactions, or events occurred at all? The answer is clear. If, by any change, a system can lose free energy or dissipate its energy, or increase its entropy-value (roughly equivalent statements), then that change will occur *of itself*. When the free energy has become minimal, or the entropy maximal, changes in the system will cease altogether. Now the only system which, in strict logic, we can consider is the whole universe. When entropy has attained its maximum value, or when all energy has become universally dissipated, all changes in the universe, all events, or phenomena (from our human point of view) will have ceased.

The world-paradox is that the universe is still the locus of change. Given an unbounded past, complete and final dissipation, with cessation of change, ought *already* to have been attained. The passage of Nature is thus towards materiality, or inertia, or passivity, but the passage is not accomplished—though it ought to have been accomplished. The world can only be the locus of activity and change because something resists, has arrested, or at least has retarded the passage towards materiality. There is an effort against inertia and this is life—the only physical conception of life that appears to be possible. There is a spiritual as well as a material passage.

Now why are there separate personalities at all? On Sir Oliver Lodge's general line of argument it may be reasoned (by analogy) that personality itself ought to exhibit a passage, or ought to be dissipated or absorbed into the universal personality, which is God. Why are they not so absorbed? Something, then, resists the ultimate dissipation of personality, just as life resists universal energy-dissipation. This something is the "invaluable but rather terrible and fearfully responsible grant" of Free Will, against which even Deity itself strives. J. J.

Sanderson of Oundle School.

Sanderson of Oundle. Pp. vii + 366 + 16 plates. (London: Chatto and Windus, 1923.) 12*s.* 6*d.* net.

FEW schools have passed through a more interesting development in modern times than Oundle. It is an old foundation and it has had periods of distinction in its long history, but its real rise to importance began in 1892 when Frederick William Sanderson went there from Dulwich to take charge. It was no light undertaking. There had been an unsuccessful period: the numbers of boys had gone down, and what was worse, the standard of work was low. Sanderson put all his tremendous energy and enthusiasm into the task and never paused till he had raised the school to its present high position. Then came his tragic death last June with the sudden break of all his plans for future development.

Some of Sanderson's colleagues welcomed the happy idea of writing down while still fresh in their minds what they knew of his methods and ideals, and these impressions have been brought together and interpreted in this book under the simple and sufficient title of "Sanderson of Oundle." The purpose was not so much to praise and honour Sanderson; it was the much more important one of saving all that could be saved of him for the world.

The task has been well done, and no man could wish for a nobler memorial. We see Sanderson entering Oundle as a young man of thirty-five—a very downright, uncompromising, and resolute personality—with perfectly definite ideas of what he wished to do and a perfectly definite intention of doing it. The development of the boy was his purpose, not the fostering of pure scholarship: if the classical method would not serve some other means must be found. To him no boy was in the first instance stupid or beyond training, though he might be made so by a wooden educational system or a stupid teacher: every boy, even the reputedly dullest, had in him a desire to make or do something—some creative instinct—and if only this could be reached the boy could be trained. So Sanderson sought to discover each boy's bent; for the ordinary boy it was used as a means of developing his mental powers; for the really clever boys full opportunities were provided for the study of their special subjects. He set up shops for wood and iron work, where real things were made (he always disliked instructional futilities), engineering, chemical and physical laboratories, biological departments, an experimental farm and an art room; he developed music. He had always the latest big thing in science on show or at work; a motor-car engine and chassis which the boys could dismantle and reassemble, an aeroplane engine for the same purpose, a big wireless set with which they could transmit their concerts, and a score of other things to awaken the boys' interest and enthusiasm.

To the purist in education it all seemed very upsetting—the multiplicity of forms, the rapid changes in books and subjects, the refined and delicate apparatus entrusted to only partly trained schoolboys. But there was method in it all. Sanderson looked on all his subjects—shops, laboratories, and sides—as so many resonators by which to test each individual boy. If he had enough resonators he could find the one to which each boy responded; and so he never hesitated to start some new side or to drop it when it no longer served a useful end. Once he found a way in to the real boy the training became easy.

But Sanderson was more than a trainer of the mind. He loved life and he wished that all might have more of it. Many of his boys were to become captains of industry in the large industrial towns. It was not enough for him that they should understand and be interested in their future work: he saw that the surest way to the enriching of their lives was to uplift it all. To him the meanest tasks of daily life had in them something divine so long as they were honourable and ministered to some need of the community, and he set himself to find this. He therefore made his workshops and laboratories serve a higher purpose than the awakening of strivings for knowledge. "I want not so much to teach engineering," he once said to me, "as to find the divineness of it." So he would never recognise the supposed conflict between science and religion or the limitations usually imposed on scripture lessons. The Bible was to him a handbook for daily life, not merely an exercise for Sundays, and he always regretted that people knew so little of it; his scripture lessons covered the whole range of human activities. He was always on the look-out for copy for them. One might be telling him of some recent development in science and he would listen with deep interest; suddenly his eyes would twinkle and he would pull out an envelope and jot down on the back some note for his next scripture lesson. He would go up to a boy working in a workshop or laboratory and ask him his views on some new thing—his own views, for all Sanderson's efforts in library, laboratory, and study were directed to the development of the boy's powers of thinking for himself. It might be relativity, the possibilities of "wireless," or something else; he would listen and encourage the boy to talk. He would then give some wider turn—probably sociological—to the conversation; for it was always his aim to train leaders of men rather than mere scholars, and he knew that no one can lead if he lacks wide sympathies.

Of late years the social or community interest became uppermost with him and he believed that the schools could do much to repair the wreckage of the War; he emphasised always the need for co-operation and pulling one's weight, for choosing the high path, for steadfast devotion to duties and leaving rights to take care of themselves.

The last evening of Sanderson's life was spent with the present writer. He had attended the Rothamsted annual function and had obviously enjoyed it. After the visitors had gone we sat talking and, as always, he soon came to his plans for the future. He was delighted that his long-desired Chapel was to be built. It was to be the centre of the school life and as beautiful and dignified as he could make it; not only with the beauty of stone: it was to be also in a wonderful garden—a miniature Kew, as he said. In the windows were to be the great calls to a high and noble life. Most of all he was delighted with Lady Scott's statue of the bright-eyed, eager-hearted, expectant boy—"Here am I, send me"—the type he wanted to send out to remake a broken world. It was the man himself speaking of his hopes and ideals, as few would care to do to another man—ideals of fulness and richness of life based on beauty and nobleness of living. For these we wished our boys to strive and so we had entrusted them to him.

Sanderson had thoroughly enjoyed life. He early found what most men desire—a great cause on which to spend himself, and to which he could give once and give all. As the years passed they had but mellowed him, bringing out his kindliness and his rich rare gift of keeping touch with youth. When the news of his death was told to the school there fell a great silence. It had been the homage given him in life when he rose to speak; it was given him now. But their abiding feeling was one of thankfulness for the life which had so truly moulded theirs, and of certainty that this was not the end. The triumphant song "Let joy and praise to Heaven rise" can rarely have been more wonderfully sung than by the boys of Oundle when he was carried from their midst.

E. J. Russell.

Civil Engineering Geology.

Elements of Engineering Geology. By Prof. H. Ries and Prof. T. L. Watson. Pp. v+365. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1921.) 22*s.* net.

The call for a smaller engineering geology than the large work issued by Prof. Ries and Prof. Watson in 1914, has led those authors to prepare an abridgment entitled "The Elements of Engineering Geology." The volume includes an account of the general principles of geology and petrology, apparently with the intention that the book should suffice for the geological needs of engineering students. It, however, includes no sections on stratigraphy or palæontology, some acquaintance with which is generally regarded as essential to a geological course in engineering. Knowledge of these subjects would be necessary to the student who would benefit by the long chapter on ore deposits.

The book may be highly recommended to British students of civil engineering owing to its clear treatment of many important problems and its instructive series of maps and illustrations, though its value to them is inevitably lessened by the fact that most of its illustrations are taken from American example and literature. The nomenclature is also American in such cases, such as "gumbo," and the use of "diabase" instead of "dolerite." The attribution of all China clay to weathering is a conclusion which is emphatically rejected in Europe. The statement on p. 90 that an oil shale to be of value should yield from 30 to 60 gallons of oil per ton in addition to ammonia, is not in accordance with experience in Scotland, where shales containing 20 gallons or even less have been profitably worked. Melting snow is said rarely to affect large streams; this is certainly not true of some large rivers in Europe and Asia, where the spring floods are due to this cause.

The authors use the unlucky term "corrasion" for mechanical excavation by rivers and "corrosion" for solution. The American use of distinct terms for the basal and lateral wear of the streams had much to commend it; but "corrasion" as in the line "wealth corraded by corruption" means to "scrape together," and corrasion was first used in the sense of corrosion apparently by a misprint. In regard to nomenclature it is also to be regretted that the authors in a book on economic geology use the term "mineral" in the sense of "mineral species" or "simple mineral" and thus exclude coal, slate, most ores, oil shale and mineral oil from the category of minerals.

The chapter devoted to the coastal topography of the United States is particularly interesting and well illustrated; the difference of the problems from those which have to be dealt with by the British coastal engineer is shown by the absence in the book of any reference to groynes. In spite, however, of the book being mainly adapted for American colleges it may be warmly recommended to British civil engineering students.

(6) *Atomic Form: with Special Reference to the Configuration of the Carbon Atom.* By E. E. Price. Pp. iv+140+viii. (London: Longmans, Green and Co., 1922.) 5*s.* net.

(1) THE Faraday Society's general discussion on "Catalysis with Special Reference to Newer Theories of Chemical Action" was apparently arranged in view of the simultaneous presence in England of Prof. Perrin, Dr. Irving Langmuir, and Prof. Arrhenius. The first session of the discussion dealt with the radiation theory of chemical action and the second session with heterogeneous reactions, and these form Parts I. and II. of the report. The discussion on the radiation theory (which postulates that chemical action is due to radiation and that its velocity is proportional to the prevailing radiation-density) was characterised by two dramatic incidents. Prof. Lindemann pointed out that, if the original form of the radiation theory were correct, the inversion of cane sugar must be determined by the density of radiation of wave-length 1·05 μ; on this basis, the inversion should proceed 50 billion (5×10^{13} times more rapidly in sunlight than in the dark), whereas actually the acceleration is almost negligible. Following up this criticism, Dr. Langmuir said that the radiation theory "has all the characteristics of the typical unsuccessful hypothesis," since it has been made progressively more complicated, as successive attempts at verification have failed. Probably no theory has ever been put forward in which discrepancies of such magnitude have appeared, and it is at least a sign of courageous optimism that the authors should still hope to bring it into line with facts.

The discussion on heterogeneous reactions was opened by a paper in which Dr. Langmuir discussed the function of the solid surface, with special reference to the occlusion of oxygen on the surface of a tungsten filament. This takes place at a temperature of 1500° K. or more, even when the pressure is so low as 10^{-6} atmospheres, or when hydrogen, ammonia, or methane is present, as well as oxygen, showing that the film of occluded oxygen is extremely tenacious. It was suggested that the stable film is of monomolecular thickness, and that the film can only be dissipated in the form of the oxide WO_3. In the same way the tenacity with which a trace of carbon monoxide will cling to the surface of platinum, acting as a powerful poison as regards its catalytic activity towards hydrogen and oxygen, is attributed to the formation of a monomolecular film of carbonic oxide united chemically with the molecules of platinum. Carbon dioxide does not behave in this way, and does not act as a poison to the catalyst. On the other hand, the normal action of the catalyst in the presence of oxygen is attributed to the formation of a film of chemically bound oxygen of higher activity than the free gas.

Experimental work on the catalytic action of platinum in the oxidation of carbon monoxide and of hydrogen formed the subject of the second paper; and the discussion which followed is reported in full, together with a number of written communications on the same subject.

(2) Prof. Stewart has added another to the series of books, in which he has summarised, mainly perhaps for the benefit of the candidate for a degree in honours, some of the results of recent chemical research. The method of handling the material in such a volume is fairly familiar, and criticism may be limited to the question as to whether the work has been well done. On the whole, the answer may be given in the affirmative, but in more than one instance the reader who is familiar with current research will feel disappointed, because some of the sections appear to have been written so long ago that they are out of sympathy with current thought, even although later work may be included either in the same or some other part of the volume. Thus to many it would appear futile to discuss the theory of the colloidal state without including any reference to the work of McBain on colloidal electrolytes, which has now been going on for something like ten years; again it is merely tedious to read through a discussion as to whether hydrogen should be placed in Group 1 or Group 8 of Mendeléeff's classification, when modern theory makes it quite

clear that this element stands in a class by itself, and need not be forced into association either with the alkali metals or with the halogens. The final chapter, on atomic structure, is remarkable in that it begins with a recapitulation of some of the fantastic ideas of atomic structure that preceded the discovery of the electron, while it concludes by dismissing Bohr's atom as "considerably overrated," and setting up in its place "Stewart's atom" as possessing merits which are not possessed by the atoms of other workers.

The various chapters of the book do, however, provide useful summaries of work which must otherwise be studied either in separate monographs or in original literature, and to those who prefer this method of assimilating knowledge the book may be commended.

(3) Prof. Smits, whose monograph on allotropy has been translated from the German, deals with a very interesting subject, namely, the application of the phase rule to those cases in which at least one of the components is capable of existing in more than one form, so that the familiar phenomena of phase-equilibrium are complicated by the occurrence of a reversible isomeric or polymeric change in this component. When the change is sufficiently rapid, the component in question counts as one molecular species; but when the change is slow, each separate form must be treated as a separate species.

There can be little doubt that if the editor of these text-books had entrusted to Prof. Findlay the work of expounding the application of the phase rule to these fascinating cases, he would have been able to tell the story in simple language, and in such a way as to interest and attract the type of student for whom these monographs are written. It is, however, certain that, while a translation of the monograph into English is a real advantage as eliminating one of the most formidable difficulties of the student, who usually finds German not an easy language to read, even the translation gives the impression that the author has deliberately made the subject as difficult as possible. One must assume that in his own teaching the author discusses these phenomena at the close of a rigorous course of training, and that those who have followed his lectures may perhaps find in the theory of allotropy a puzzle worthy of their highly developed skill; but to the student who has not gone through this training, no mercy whatever is shown, and he might well be excused for forming the opinion that Prof. Smits, like one of the old alchemists, was trying to disguise his knowledge, instead of to diffuse it, by using a bewildering system of symbols and diagrams. Almost any one of these might "hold up" the reader for many minutes, if not indeed for hours, while he was trying to discover what meaning he must attach to symbols decorated with a positive cascade of superscript and subscript signs, and thus to find out the inner meaning of the diagram. By way of further punishment, the author omits to write down the chemical formulæ of the organic compounds with which he deals, so that the student must refer to the original literature if he wishes to know what formulæ have been assigned to the two forms of benzoylcamphor, or to the various modifications of milk sugar. In this case it would appear that the author is so concerned with the mathematical dissection of these compounds in their various phases that he has no interest whatever in their chemical composition; and this view is supported by the attitude which he adopts in similar cases throughout the volume.

In conclusion, it may be said that if a keen student wishes to test his abilities by means of a volume which might well bear the sub-title, "The Phase Rule made Difficult," the book might perhaps be commended. On the other hand, the average student will probably prefer to wait for an interpreter before he attempts to study the work of an author whose desire for complexity leads him to postulate the existence of half a dozen molecular species in the simple and orderly space-lattice of a metal.

(4) Prof. Pauli's monograph on the colloid chemistry of the proteins possesses nearly all the merits that are lacking in Prof. Smits' book. Although dealing with a much more difficult subject, it has the merit of being not only brief, but also as simple as any treatise on colloids that has yet appeared. Not only those who are specially interested in colloid chemistry, but also chemical students generally, would find both pleasure and profit in reading the book, and on these grounds it can be heartily commended. It is, indeed, a particularly easy task to review a book on which none but favourable comments are possible.

(5) Prof. Holmes, at the request of the Colloid Committee of the National Research Council, has written a "Laboratory Manual of Colloid Chemistry." The total number of experiments described in the book is 186, and most of these have been tested in the laboratory over a period of six years. It is an indication of the importance that now attaches to the study of colloids that a book dealing with laboratory experiments only should be called for, and Prof. Holmes has produced a volume which every teacher of physical chemistry will find it necessary to possess. It will also be welcomed by many other workers who are not responsible for the organisation of laboratory classes in physical chemistry.

(6) Mr. Price has invented a tetrahedral model of the carbon atom which has an equilateral triangle

as section on two of its planes of symmetry, while its faces are isosceles triangles. He claims that this figure lends itself better than the regular tetrahedron to the construction of models representing the structure of organic compounds. The close packing of polyhedral figures is an important factor in crystallographic research, but, when it is not correlated in any way with crystallographic data, it cannot be regarded as of any value in the investigation of molecular structure. The author proceeds as if the carbon atoms were actually tetrahedral in shape, with real poles at the corners, whereas in fact, the tetrahedron merely serves as a convenient means of showing the directions in which the valencies radiate. It is, however, interesting to notice that the figure which Lewis obtained by concentrating four duplets on the centres of four *edges* of a cube is actually a tetrahedron of the shape described by the author, although obviously the duplets in marsh gas must occupy the alternate *corners* of a cube, since all the evidence points to the fact that methane has the full symmetry of a regular tetrahedron.

The Trend of Evolution.

The Evolution of Man: a Series of Lectures delivered before the Yale Chapter of the Sigma Xi during the Academic Year 1921–1922, by Richard Swann Lull, Harry Burr Ferris, George Howard Parker, James Rowland Angell, Albert Galloway Keller, Edwin Grant Conklin. Edited by George Alfred Baitsell. Pp. x+202. (New Haven: Yale University Press; London: Oxford University Press, 1922.) 15*s*. net.

In the chapter entitled "The Natural History of Man" Prof. Ferris gives a very lucid summary of the most elementary facts of embryology and anatomy, which suggests to the uninitiated reviewer that the Society of the Sigma Xi, for whom the lectures in this book were prepared, is a lay body unfamiliar with biological teaching. As a means of interesting such an audience in some of the manifold aspects of biology and sociology these lectures no doubt served a useful purpose, but why call the volume "The Evolution of Man"? One would imagine that in a series of six lectures with such a title some one would have discussed seriously the problems of man's pedigree, and have attempted to explain how and why the human family acquired those distinctive attributes of brain and mind which conferred the rank of mankind upon it. But there nothing of the kind is to be found in the book.

Prof. Parker gives an excellent account of his investigations on the nervous system of sponges and other animals, but the title "The Evolution of the Nervous System of Man" raises hopes that are not fulfilled; and the same remark applies to the address by the president of Yale on "The Evolution of Intelligence," as well as to Prof. Keller's "Societal Evolution." The criticism one is impelled to make of all these addresses is that, while they are interesting and illuminating, both their own titles as well as that of the book are irrelevant.

In Prof. Conklin's essay, the title of which the reviewer has adopted as the label for this notice, is a sane discussion of the trends of civilised mankind under post-War conditions and an earnest plea for education, and better education, as the remedy for the ills of society and the means of averting the downfall of the best types of mankind.

Our Bookshelf.

Department of Agriculture and Technical Instruction for Ireland. Memoirs of the Geological Survey of Ireland. Mineral Resources. Memoir and Map of Localities of Minerals of Economic Importance and Metalliferous Mines in Ireland. By Prof. G. A. J. Cole. Pp. 155. (Dublin: Stationery Office, 1922). 7*s*. 6*d*. net.

It is much to be regretted that this volume must be looked upon as the swan-song of the old regime in Ireland rather than as the first effort of the new authorities. Information as to the mineral resources of Ireland has never before been collected into any authoritative memoir, but had to be sought for piecemeal among a number of miscellaneous geological and mining publications, for, as the author of the present work correctly observes, Sir Robert Kane's book on the industrial resources of Ireland is now far too old to be of any real value under the economic conditions of the present day.

Prof. Cole has done his work extremely well; he has arranged the various minerals that Ireland produces in alphabetical order, commencing with antimony and ending with zinc. It is perhaps characteristic of an Irish publication that the most important of all mineral products, namely coal, is not even mentioned. The author states specifically that he excludes sands, clay, and marble, and devotes his attention to "minerals of economic importance"; surely coal should be included under this head. The other minerals of economic importance are very fully and clearly dealt with; the list of localities is very complete and carefully drawn up, and all the more important occurrences are briefly described. If it does nothing else, the present work will serve to dispel some of the wild statements that are occasionally heard as to the immense mineral resources of Ireland, which have been neglected or, it is even sometimes hinted, deliberately concealed, by jealous Englishmen. Among the more persistent of such legends is that of the immense resources of iron ore in the Arigna valley; the present work shows that two persevering attempts were made to found an iron industry there, at the end of the eighteenth and again in the first half of the nineteenth century, and that both ended in failure; at what appears to have been the last attempt, only 300 tons of iron were produced in seven years at a cost of 50,000*l*. A study of the entire book shows that at the moment barytes is practically the only mineral of serious economic importance that Ireland is capable of producing. Apart, however, from the strictly commercial aspect of the subject, Prof. Cole's work is of great value to the student of mineral deposits, inasmuch as it supplies authentic information concerning the mineral resources of the country.

Overzicht van de theorie en de toepassingen van gassen, waarin de onderlinge botsingen der moleculen kunnen verwaarloosd worden. Door Dr. Jos. ter Heerdt. Pp. vii + 324. (Utrecht and Nijmegen: N. V. Dekker & Van de Vegt en J. W. van Leeuwen, 1923.) 6.50 florins.

SINCE the classic researches of Maxwell on the internal friction of gases and those of Crookes on radiometer theory, no investigations have been so important in connexion with the kinetic theory of gases as the work of Martin Knudsen on the properties of highly rarefied gases, in which the mutual collisions of the molecules may be neglected. Dr. Jos. ter Heerdt has produced a very clear monograph in which the work of Knudsen and that of some other investigators, Soddy and Berry, Gaede, Langmuir, Weber, etc. (scattered in many periodicals), is brought together and critically discussed.

After a short historical introduction and some general considerations regarding the kinetic theory of gases, (Chap. I.), the author deals in the following chapters with molecular flow through narrow capillaries and small holes in plates, with molecular flow through tubes with a temperature gradient (pressure equilibrium between two reservoirs at different temperatures, connected by a capillary tube), with the molecular conduction of heat and the coefficient of accommodation. The treatment of the problem of accommodation, as given in Chap. VI., is new and throws a new light on the question. Nevertheless no general solution is given of this very complicated problem. Chap. V. deals with the radiometer force and with the formula which Knudsen has deduced for it. In Chap. VII. a full and detailed description is given of modern high vacuum pumps, based on the principles of the kinetic theory of rarefied gases (Gaede, Langmuir) and of different kinds of high vacuum manometers. The book ends with a very complete bibliography.

The volume forms a readable and clearly written monograph on a subject not covered by any existing work and may be highly recommended to all who are interested in this subject. It is to be hoped that the book, which is published in Dutch, will be translated into English, French or German in order that it may reach a wider circle of readers. C. A. CROMMELIN.

Hawaiki: the Original Home of the Maori. With a Sketch of Polynesian History. By S. Percy Smith. Fourth edition. Pp. 288 + 20 plates. (Auckland, Melbourne and London: Whitcombe and Tombs, Ltd., 1921.) 12*s*. 6*d*.

IT is most fortunate that Mr. Percy Smith was able to publish the fourth and authoritative edition of this book before his death, as it contains a considerable amount of new material and of revised conclusions. It represents the gleaning of a long life spent in amassing new data, and laboriously sifting and collating existing information. All students of oceanic ethnology owe a great debt to this painstaking, kindly, and learned pioneer. Mr. Smith entirely justifies his reliance on the general accuracy of tradition, and he has been able to give approximate dates to events in unwritten history, and also to trace three main migrations into the Pacific from Indonesia, and numerous migrations within the Polynesian area. Constructive work of this kind on imperfect material is necessarily open to criticism, but Mr. Smith courageously attempts to interpret hints and obscure words, and by imagination, controlled by intimate knowledge of Polynesian ethnology, he has made a plausible connected story, which, in his concluding words, "will in the meantime serve the purpose of a summary of the history of the people, on which others may build."

The Indian dates on p. 85 require revision. The Sâka entered the Panjab about 75 B.C., not 950 B.C.; the great colonisations of Java from India are also placed much too early; according to Havell they were due to the final collapse of the Sâka power at the beginning of the fifth century. It is important to have correct dates for events in India, as Mr. Smith uses them in the development of his thesis. The view that the Polynesians may have been in part a branch of the "ancient Gangetic race" has much to recommend it, but by terming them "Proto-Aryan" he raises very grave difficulties, but, perhaps, Pre-Aryan is what he meant to express.

This little book is invaluable to all those who take an interest in the history of the most intrepid explorers of the Pacific. A. C. HADDON.

Expressionism in Art: Its Psychological and Biological Basis. By Dr. Oskar Pfister. Authorised translation by Barbara Low and Dr. M. A. Mugge. Pp. viii + 272. (London: Kegan Paul and Co., Ltd., 1922.) 6*s*. 6*d*. net.

DR. PFISTER'S work is a study by psycho-analytic methods of a French artist suffering from depression, who came to the author for psychological treatment. In addition to the analysis of his dreams, the artist was asked to draw whatever he liked, and these drawings, usually of an extremely unconventional character, were treated in the same way as the dreams. The results are very interesting, both from the insight obtained into the personality of the artist and also from the light thrown on that type of art generally known as expressionism.

The first part of the book is a study from a psychological point of view of the artist; the second part discusses the psychological and biological background of expressionism. The author shows how excellent for diagnostic purposes were the pictures which invariably represented the artist's psychical state. From a study of the pictures of other expressionists, he concludes that all expressionists carry into their work a number of infantile characteristics. Instead of attempting to understand the external world, they turn away and represent their own internal conflicts in phantasy form, their pictures thus being in reality self-portraits. If pushed to its logical extremes, expressionism would result in an absolute rejection of the empirical world, and hence in many it tends to become pathological. The relationship between the various neurotic types and expressionists is discussed.

It is a very interesting study, both of a particular man and of an art movement; but the method of writing is discursive, and the book might with advantage be considerably condensed.

The Races of England and Wales: a Survey of Recent Research. By Prof. H. J. Fleure. Pp. 118. (London: Benn Bros., Ltd., 1923.) 5*s*. net.

PROF. FLEURE's modest claim to have given in this work a survey of recent research is an understatement which may give a misleading idea of its very real importance as a contribution to the ethnology of England and Wales—an idea which the brevity of the book does nothing to remove. It summarises in a fair and judicial spirit the results of the observations of anthropologists on the physical characters of the peoples of England and Wales, both in prehistoric and in recent times, to which Prof. Fleure himself has contributed in no small degree; but it does far more than this. It reviews these results in the light of certain general conclusions on the question of the development of racial type at which Prof. Fleure has arrived. The inferences which he has drawn in consequence cannot fail to have a profound influence on the future discussion of British ethnology as well as to stimulate observation in certain directions in the future in support or refutation of his views. Of these, perhaps the most important is that the intermediate type, which forms a common element in the population of Britain, and is usually taken to be a combination of Nordic and Mediterranean, represents in reality an independent "descent with modification" within this country from a palæolithic type.

Cryptography. By André Langie. Translated from the French by J. C. H. Macbeth. Pp. viii+192. (London, Bombay and Sydney: Constable and Co., Ltd., 1922.) 9*s*. net.

As there is no manual of cryptography in English, this book, which is translated from the French, will be welcomed by all who wish to make a serious study of the subject, either for practical purposes or as an intellectual exercise. The author deals with his subject under three heads. Under the first he gives a brief history of the methods of conveying information secretly, beginning with the Greeks, Egyptians, and Romans; under the second he gives examples of cryptographical writings of which he himself has found the solution, for the most part, during the War; and under the third he gives lists and tables of frequency of single letters, bigrams, and other combinations in English and other languages. This section will naturally be one of the most frequently consulted in the book, as a knowledge of the relative frequency of occurrence of the different letters and combinations is essential in all decipherment. The translator adds a supplementary chapter dealing with methods of conveying information secretly, such as the use of sympathetic inks, tramps' signs, the marking of cards by cardsharpers, and the like, and describes the Playfair cipher, a substitution system extensively used for military purposes, Commander W. W. Smith, United States Navy, adding a note on its solution.

Botulism and Food Preservation (The Loch Maree Tragedy). By Dr. Gerald Leighton. Pp. xiii+237. (London: W. Collins, Sons and Co., Ltd., 1923.) 10*s*. net.

DR. LEIGHTON's report on the outbreak of botulism at Loch Maree in 1922 has been already noticed in NATURE (March 24, p. 415) and some account has also been given of the comprehensive researches of Prof. K. F. Meyer, of the University of California, into the distribution and biology of the responsible microbe (January 20, p. 95). In the present volume Dr. Leighton has collected into a convenient form most of the available information about the disease as it occurs in man and animals. Originally most frequently associated with sausages and especially common in Würtemberg, most of the recent cases have been identified in America and more commonly with canned vegetables than meat products. "Limberneck" in poultry appears to be botulism, and "grass sickness" of horses is either this or a closely allied condition. Prevention is a question of the adequate sterilisation of preserved foods. The second part of the book recounts the details of the tragedy of the potted duck sandwiches and concludes with an ample bibliography.

The Annual Register: a Review of Public Events at Home and Abroad for the Year 1922. Edited by Dr. M. Epstein. Pp. xii+316+199. (London: Longmans, Green and Co., 1923.) 30*s*. net.

A WORK of reference that has reached its hundred and sixty-fourth volume requires no commendation. This annual review of the year has an established place among indispensable works of reference. English history, which appears to include Irish history, and foreign and colonial history occupy about two-thirds of the book, in a summary which is conspicuous for its impartiality and lucidity. A chronicle of events is less well-balanced but extremely useful. The year's obituary gives biographical sketches of about 300 eminent men and women of all countries. Literature of the year is dealt with in a forty-page summary, which is a comprehensive and, to a large extent, critical survey of the year's books. Science has to be content with a twelve-page summary, which, however, ranges over so wide a field that little, if anything, of notable value is omitted. A full index enhances the value of the book.

A Text-Book of Machine Construction and Drawing. By H. E. Merritt and M. Platt. Pp. x+197. (London: G. Bell and Sons, Ltd., 1922.) 7*s*. 6*d*. net.

TEACHERS of classes dealing with machine construction and drawing are frequently put to a great deal of trouble in seeking for modern examples to put before their students. Text-books on the subject go out-of-date, and on account of the great strides which have been made in recent years in the manufacture of engineering materials, and in their treatment in the machine shop, and consequently in design, details have shown an increasing tendency to become obsolete. The volume before us contains a large number of designs suitable for students, and all of these examples are up-to-date. The authors make use of the American system of projection, and there is sufficient practical geometry included for the purposes of the draughtsman.

Letters to the Editor.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, nor to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Dr. Kammerer's Alytes.

THOSE who have followed the discussion of Dr. Kammerer's claims will be aware that special interest has centred on the question whether he could produce for examination males of Alytes showing the modification alleged to occur in consequence of his treatment. Some of the circumstances which aroused scepticism are related in my letter to NATURE, July 3, 1919, p. 344. We were originally told (*Arch. Entwm.*, 1909) that nuptial callosities or *Brunftschwielen* appeared on the thumbs of males of the treated strain, and that in the 5th treated generation (Kammerer's F_4) *all* the males had these structures. They are a conspicuous feature in most Batrachia, and Alytes is one of the few forms in which they are not known to occur. Since normal Alytes mate on land and the treated animals were made to pair in the water, we were asked (1909, pp. 516-7) to see in these *Schwielen* a true functional adaptation. The rugosities were developed to give the males a better grip of the slimy females.

Dr. Kammerer remarks that any one who has compared the feel of a dry toad with that of a wet one will not question that rugosities on those parts of the limb which come into contact with the body of the female are a very necessary equipment for an aquatic embrace (p. 516). This theme was developed at considerable length. In *Arch. Entwm.*, 1919, the same argument reappears, and, various other hypotheses being discussed and set aside, it is argued that the most probable cause of the development of rugosities was to be found in the change of mating habits. The process of mating in the water takes twice or thrice as long and is far more laborious. If his interpretation is right, Dr. Kammerer continues, the development is to be regarded as a "*funktionelle Anpassung*: ihre nachweisliche Erblichkeit würde hierdurch an theoretischer Tragweite gewinnen" (p. 339).

Up to 1919 nothing but vague diagrams (1909, Figs. 26 and 26*a*) had been offered us to show what these new organs looked like, and no detailed description had appeared. Dr. Kammerer in that year published the long paper mentioned above, making some new statements which I will consider presently. In illustration a photograph of the whole animal (F_5 in 1913) was given. This picture was rather like those handed about a few years ago as "spirit-photographs," and for demonstrational purposes was worthless. There were also several drawings, and a photograph, representing sections through the skin of a supposed *Schwiele*. At about that time Dr. Przibram was good enough to send me a slide with six similar sections labelled "F_3," which I have shown to numerous colleagues. As regards the sections and representations of sections, I do not question that they may have been taken through real incipient rugosities, but the development is slight and ambiguous.

The description of 1919 amplifies that of ten years before. The rugosities were originally described as in the proper place, namely, on the upper (sc. dorsal) and radial surface of the thumb; and as more males of F_4 and F_5 came into breeding condition, rugosities appeared not simply on the bases of the thumbs but extended in various degrees and with individual differences up the inside of the forearm. Inasmuch as various Batrachians have rugosities in that region (showing also individual differences and asymmetries), and since in the embrace of Alytes the parts named are in contact with the female, the new account raised no fresh improbability—rather the contrary. Many modified males are said to have been under Dr. Kammerer's observation during three years after he had (1910) been challenged to produce one, but a photograph of a single specimen—and that absolutely non-committal—was all that had been published to show the structures in position. We are told that the 1913-hatched brood failed to breed, and the last male (F_6) died in 1914 (1919, p. 328).

But one specimen (presumably that photographed) was known to be preserved in Vienna. It had been examined by visitors to the Versuchsanstalt, who reported verbally and variously as to what they had seen. A few weeks ago the announcement was made that this Alytes would be shown in Cambridge, and I received an invitation to attend a meeting at which it would be exhibited. Knowing that Dr. Kammerer had abstained from appearing at the Congress of geneticists which met at Vienna in September last, I inferred that he had no new evidence to produce, and I therefore excused myself from attendance, not wishing to enter deliberately into what was likely to prove a profitless altercation. When, however, an exhibition before the Linnean Society was arranged, I naturally attended as a fellow of the Society to see what I could. I expected to see a dark mark on the thumb or other fingers extending perhaps more or less over the wrist or up the forearm; and whether this was to be interpreted as a nuptial rugosity or not, would, I imagined, be more or less a matter of opinion.

What I did see was something altogether different. The animal was fastened with its back against an opaque plate in a cylindrical museum glass, with the ventral surface exposed. The right hand showed nothing special, but *across the palm* of the left hand was a broad dark mark. It looked like a piece of thickened, blackish-brown skin. Examining it with a good lens I could see no papillary or thorny structure, though considering the minuteness of the alleged spines, I scarcely expected to make them out very distinctly. But the appearance was quite unlike that of any natural *Brunftschwielen*. In them, even in *Rana agilis* which has them developed very slightly, one sees with a lens characteristic grey specks, not a dark uniform surface as in the creature exhibited. I do not mean that there was no break in the pad as a whole, about which my memory is doubtful, but that the surface was uniform and the colour continuous in tone, without the dotting or stippling so obvious in true *Brunftschwielen*. That there was no development on the right hand was explained. The skin had been snipped off during life to furnish sections.

A photograph of the palm of a hand was thrown on the screen. This palm was pointed to as showing rugosities, but I saw none. In the specimen exhibited, the backs of the digits were not visible, nor were we shown any photograph of them.

I direct attention first to the fact that the structure shown did not look like a real *Brunftschwiele*. Next I lay stress on its extraordinary position *It was in the wrong place*. Commenting on the evidence, I pointed this out. In the embrace of Batrachians the palms of the hands of the male are not in contact with the female. Those who looked at the specimen naturally concluded that they must be. One speaker confidently told me in the discussion that I was wrong, and that in the common toad the rugosities *are* on the palmar surface! To show how the hands are placed I send a photograph (Fig. 1) of a pair of *Rana agilis* killed and preserved while coupled. The lower digits of the male's hands are the thumbs.

Clearly the rugosities, to be effective, must be on the backs and radial sides of the digits, round the base of the thumb, as in our common frog, on the inner sides of the forearms, or in certain other positions, but not on the palms of the hands. There are,

Fig. 1.

of course, minor variations, in correspondence with which the positions of the rugosities differ. The clasp of Alytes, for example, is first inguinal and afterwards round the base of the head (Boulenger). Minute thorns may be formed on the back of Bombinator and perhaps in other places on the skins of Batrachians, where they cannot serve as *Brunftschwielen*; but on the palm of Alytes they would be as unexpected as a growth of hair on the palm of a man.

Dr. Kammerer's own reply was on different lines from that of the speaker I have mentioned, but curious and, as I thought, significant. He asked us to note that in his lecture he had refrained from using the word "Adaptation"—a defence sound perhaps, though surely disquieting to his disciples.

The discoveries claimed by Dr. Kammerer are many and extensive. To geneticists that regarding heredity and segregation in Alytes (*Verh. naturf. Ver.* Brünn, 1911) which I called in question at the Linnean meeting is the most astounding. But what I then heard and saw strengthens me in the opinion expressed in 1913, that until his alleged observations of *Brunftschwielen* in Alytes have been clearly demonstrated and confirmed, we are absolved from basing broad conclusions on his testimony.

The Light Elements and the Whole Number Rule.

I have recently developed a method of generating anode rays of high velocity which is much more suitable to mass-spectrum analysis than the hot anode method previously applied. By means of this device it is possible to obtain the mass-lines of the metals of the lithium and beryllium groups at the same time as those of such elements as carbon and chlorine, the masses of which are known.

The masses of Li^6, Li^7, Be^9, Na^{23}, Mg^{24}, K^{39}, K^{41}, Ca^{40} have all been determined, and the divergence from whole numbers is in no case so great as one-tenth per cent. of the mass measured. The masses of the isotopes of lithium are most probably about 0·005 of a unit high, but naturally this figure does not have much significance with the present apparatus.

The effects with magnesium and calcium are too weak to show their fainter components, but the integral relations between these and the principal lines have already been demonstrated by Dempster. (Phys. Rev. xviii, xx.)

This work completes the determinations of the masses of the more important isotopes of all the first twenty elements on the mass-spectrograph, and, with the obvious exception of hydrogen, each obeys the whole number rule to the accuracy of experiment, one part in a thousand.

It is of particular interest that no difference in mass is detectable between the isobaric atoms Ca^{40} and A^{40}, for general considerations might lead one to expect a radical difference in their nuclear structure owing to the presence of the two additional nuclear electrons in the latter.

Microphonic Flames.

[A few weeks ago it was reported in the daily Press that Dr. Lee de Forest had used a flame for the direct production of telephonic currents by sound waves In response to a request for details of his device, Dr de Forest writes as follows.—Ed. Nature.]

I have as yet prepared no paper on the subject of the "microphonic flame." For a long time I had puzzled over the problem of turning sound waves *directly* into electric telephonic currents. I recognised that sound waves passed through flames in the air; also that a flame was, to a certain degree, conducting electrically. Hence, I reasoned that if one passed a current through a flame, its conductivity *must* vary, more or less, with the alternate waves of compression and rarefaction, which constitute sound.

Setting out to verify my deductions, I succeeded almost at once. I employed first a "bat-wing" gas-flame, enriched this with potassium salts, used two platinum wire electrodes across a dry cell battery of 100 to 200 volts, in series with a high-resistance (radio) telephone receiver. By carefully adjusting the electrodes in the flame (especially the *cathode*—the position of the anode is not important; it can even be located a short distance *outside* the flame) I obtained in the telephone receiver a faint but *very perfect* reproduction of the music of a gramophone played 3 ft. from the flame. The adjustment of the gas pressure, using this type of flame, is critical. If too strong, the flame roars in the telephone receiver. If too low, the conductivity and sensitiveness of the flame falls off.

I next employed a type of Welsbach burner and mantle, using as electrodes platinum gauze "imbedded" in the mantle and directly inside the mantle. Also, an oxy-acetylene flame, employing for electrodes platinum wire *encased* in quartz, which, of course, becomes conducting in this flame. This arrangement gives an exceedingly perfect reproduction of the sound—voice or music—far better than any carbon microphone.

A small alcohol burner and flame can be employed. In this case I recommend as cathode a Nernst glower as supplying the necessary electrons. Or enrich the blue flame by potassium or sodium salts fed up through the wick, with the alcohol.

Audion amplifiers must, of course, be employed if one wishes to use the "flame microphone" for broadcasting, radio-phone, or "phonofilm" purposes.

The sensitiveness increases in general with the impressed P.D. across the electrodes—up to a limit.

Care must be taken to guard against: (1) hissing due to too high voltage discharge; (2) flame noises; (3) air fluctuations; (4) depositing of carbon upon the electrodes.

I have not had time yet to make a careful scientific study of this phenomenon, but am persuaded it is chiefly a *pressure* effect, controlling ionisation and the ionised conductivity of the flame.

LEE DE FOREST.

Molecular and Crystal Symmetry.

MR. T. V. BARKER has discussed in NATURE of May 12 the theory advanced by Fedorov and Shearer with reference to the relations between molecular and crystal symmetry. According to this hypothesis the symmetry of the crystal includes the symmetry of the molecule with such additional symmetry as is afforded by the arrangement of the molecules, if there be more than one, in the unit parallelepipedon or cell of the structure.

At the reading of Mr. Shearer's paper I mentioned some considerations which required to be taken into account in applying this principle (Proc. Phys. Soc., vol. 35, p. 99, 1923), and I propose to restate them here in somewhat more detail.

In many cases there is reason to believe that molecules have no existence in the structure of a crystal. In others they appear to maintain their identity. It does not, however, follow that they retain the full symmetry they possess when in the free state in a fluid; for the whole or a part of the symmetry may be destroyed by close packing in the crystal structure. Nor is it probable that the symmetry actually possessed by the unit cell formed of one or more molecules is always identical with that of the structure of which it forms part.

In the first place, a number of primary cells with different but similar orientation (including in this expression a symmetrical relation between enantiomorphic forms) may be combined by what may be termed cell-twinning to form a greater cell with higher symmetry. These greater cells may of course be regarded for crystallographical purposes as unit or elementary cells; but it is improbable that they would always be recognised as such by means of the X-rays, which would in many cases not permit of discrimination between the differently orientated primary cells. The same crystallographic characters would also result from ultra-microscopic twinning on a larger scale, involving groups of differently orientated cells instead of individual cells. Repeated ultra-microscopic twinning of this character is believed to take place with the triclinic mineral microcline, so as to give rise to the monoclinic mineral orthoclase.

Apart, however, from regular twinning, one would expect cells of low symmetry to build up in many instances structures of higher symmetry, but usually belonging to the same system. Perfect identity in cells is not necessary in the building up of a structure. A plagioclase crystal is formed of cells both of albite and of anorthite, with quite distinct atomic composition, and even to a limited extent of orthoclase which differs both in system and in molecular volume. Where, therefore, the outward forms of cells of the same substance in different orientations (in the wide sense employed above) closely resemble each other but do not show absolute identity, it may be expected that the crystal structure will be built up indiscriminately of cells with similar but not identical orientation. The result will be that the special features characteristic of a lower symmetry will be eliminated and only the highest symmetry of the system will remain. This is probably the reason why crystals possessing the symmetry of one of the lower classes of a system are comparatively rare, and in some instances are not known to occur.

These principles are well illustrated by the facts disclosed in a paper on the "Relation between the Crystal Structure and the Constitution of Carbon Compounds, Part I., Compounds of the Type CX_4" (Journ. Chem. Soc., vol. 123, pp. 71-79, 1923), by Miss Knaggs, of the Imperial and Bedford Colleges. She shows that in substances of the CX_4 type, where X is an element, the crystal usually belongs to the cubic system. Those of the type CX_3Y, where X and Y are elements, are as a rule trigonal or hexagonal, unless X is hydrogen, the atoms of which appear to be too small to determine a trigonal symmetry. Those of the form $C(CX_3)_4$ are usually cubic, as the trigonal character of the CX_3 group enables all four trigonal axes of the cubic system to be preserved. Finally, substances of the form $C(CX_2Y)_4$ are in general tetragonal. In every case in which the symmetry of the crystal shows it to belong to the same system as that of the molecule, it must be referred to a higher class, usually that with the highest symmetry in the system. For example, the molecules CX_4 and $C(CX_3)_4$, which are cubic, have no axial planes of symmetry, but wherever there is any definite crystalline form, the crystals possess such axial planes. In some cases, however, the cubic system is only recognised by the isotropic character of the crystals. Again it can be easily shown that the molecule $C(CH_2Y)_4$ belongs to a class of the tetragonal system with only a contra-directional or inverse tetragonal axis, but the crystals have all a co-directional or simple tetragonal axis, such as is found in the higher classes of the tetragonal system.

In many cases, on the other hand, there are isomorphic forms with lower symmetry, formed usually at lower temperatures. In these the atoms are apparently more tightly packed, and the molecules have either been distorted or have lost their identity altogether.

JOHN W. EVANS.

Imperial College of Science and Technology,
South Kensington, S.W.7,
May 15.

IN a recent letter to NATURE (May 12, p. 632) Mr. T. V. Barker takes exception to statements made by the writers in respect to the relation between the symmetry of a crystal and that of its components (G. Shearer, Proc. Phys. Soc., 1923, vol. 35, p. 81, and W. T. Astbury, Proc. Royal Soc., 1923, vol. 102, p. 506). It appears to us that his criticisms are based on certain misapprehensions.

Fedorov tried to prove (*Zeits. Kryst.*, 1912, Vol. 52, p. 22) that if n is the symmetry number of the structural unit of the crystal, or, briefly, the crystal unit, or, in other words, is the number of identical or enantiomorphously related asymmetric parts into which it is subdivisible, if m is the number of molecules it contains and p the symmetry number of each molecule, then $n = mp$. Mr. Barker believes that Fedorov failed to prove his case, that the first paper referred to above contains an unconscious repetition of Fedorov's argument, which, though new evidence is brought forward, is still unconvincing, and that the suggested structure for tartaric acid is against the principle and not, as we have said, in its favour.

In the first place, Fedorov's statement was surely unexceptionable in the form in which he made it. If one of the molecules, or groups of molecules into which the unit is divided, possesses a plane of symmetry, this can mean only that it has similar relations with its neighbours on either side of the plane and through them with the rest of the crystal. That is to say, the plane of symmetry of the molecule is also a plane of symmetry of the crystal. On the other hand, we must be ready to allow, as Sir William Bragg has pointed out, that a molecule as built into a crystal may not have the same form as the freer molecule of a liquid or a gas. Such a difference seems to occur in the case of tartaric acid, on which account the crystal and its solution differ in their optical properties. The molecule may have a plane of symmetry in one case and not in the other. It is a task of the future to correlate the forms and the symmetries of the molecule in its different conditions. It is by no means improbable that the differences are small (Journ. Chem. Soc., 1922, vol. 121, p. 2766). Fedorov was quite aware of this possibility himself. If Fedorov's statement is taken to refer to the molecule as built into the crystal, it seems to require no further defence.

In the next place, the rules or principles set out in the first of the two papers referred to do contain Fedorov's statement, no doubt. If the author had been aware of the paper he would have referred to it. But the essence of the statement which is criticised is not an enunciation of a law of crystal symmetry which could not have been and was not overlooked by the searching examination of the crystallographers. It was an attempt to codify certain results of X-ray analysis. Fedorov could say, rightly as we think, that a crystal of the monoclinic prismatic class could be formed of four groups, A, B, C, and D: of which B was obtained from A by reflection across a plane, C by digonal rotation about an axis, and D by inversion through a centre of symmetry. He had no direct evidence to carry him further. The X-rays do go further: they show that in the crystal unit of benzoic acid, for example, there really are four groups so related to one another, and they give their relative positions. Moreover, they show that each of these groups is, in substance at least, the chemical molecule. This is new knowledge, which could not be proved by Fedorov. If it had been in his power to do so, the crystallographic tables would have contained the dimensions of the unit cell of each crystal; and not merely, as they do now, the topical ratios.

We may point out that Mr. Barker is in error also in supposing that nothing can be said about the symmetry of the molecule until the position of every atom in it is accurately determined. The X-rays show that the molecules of benzoic acid, for example, are divisible into two groups, which present exactly the same aspect when viewed along the axis of the crystal and different aspects when viewed in any other direction. This is in agreement with the hypothesis that the two are the reflections of each other across the plane of symmetry, and that each is by itself asymmetric with respect to that plane.

Lastly, Mr. Barker refers to the structure of tartaric acid, described in the second of the two papers, as an infringement of the principles set out in the first, because, as he says, it has an "unobtrusive dyad axis," which does not coincide with the axis of the crystal. The only answer is that it has not, as may be seen from Figs. 8, 12, 14, 15 of the paper, or more easily from the model itself. There is no such axis, and, therefore, no infringement.

The Mechanism of the Cochlea.

In Mr. Wilkinson's letter in Nature of May 12, p. 636, three points are raised upon which I wish to comment.

For the sake of simplicity I described the mechanical conditions occurring when sound waves reach the cochlea in the normal manner by the chain of ossicles. In the case of bone conduction the mechanism of analysis ought to be the same as under other conditions. Bone conduction is the response to a continuous series of uniform waves from a tuning-fork which would produce a corresponding series of vibrations in a resonating system. I cannot agree that the movement "originates *at the basilar membrane*," because the movement depends on the whole resonating mechanism, including the inertia and friction of the fluids.

Damping is the decrease in amplitude due to resistance, and I believe that by using that term Mr. Wilkinson intends to deny any influence due to liquid friction in affecting the note to which the system resonates. In White's "Handbook of Physics" (Methuen and Co., first edition, p. 305), I find "partly closing the mouth [of a resonator] lowers the note." This is an example of friction in a gas affecting the frequency of resonance, which is also seen in the well-known method of tuning organ-pipes. If such an effect is shown with a gas, surely it must be much greater with a liquid in such narrow tubes as those of the cochlea.

With reference to the spiral ligament, I think that the point is unimportant. I merely pointed out the danger of deducing from the size of the ligament the tension on the membrane at rest. To make the point clearer I would suggest the analogy of the size of a pair of hooks supporting a cable. The size of the hooks may not be designed with reference to the tautness of the cable. The cable may be slack, so that the only pull may be that due to its weight; but large hooks may be used, because the cable may have to sustain heavy weights from time to time. I am quite willing to believe that the fibres of the basilar membrane near the *fenestra ovalis* may be more tightly stretched than those near the apex of the cochlea, but that does not necessarily follow from the dimensions of the spiral ligament.

Finally, I wish to emphasise that this correspondence arose in relation to the dimensions of the cochlea and the possibility of such a small structure acting as a resonating mechanism. The point that I wished to bring out was that, on account of its small size, liquid friction will be very great and that this friction may be *one* of the factors in the analysis.

An Einstein Paradox.

THE following, with amplified details to help discussion, is, I trust, a fair statement of the problem in Einstein's "Relativity" (Methuen). K, K_1 are together, each provided with a clock. The clocks agree at noon when K_1 starts moving in a straight line with uniform speed v (*estimated in K's units*).

Some time later, a light signal is flashed from a point L on the line, ahead of K_1, and is seen by K, K_1 at times t, t' on their respective clocks; $KL=x$ of K's units of space and $K_1L=x'$ of K_1's. Then, according to Einstein,

$$(1)\ \ldots\ x'=(x-vt)/\sqrt{1-v^2/c^2},$$
$$(2)\ \ldots\ t'=(t-vx/c^2)/\sqrt{1-v^2/c^2},$$

where c = vel. of light *in vacuo*.

Since (1) does not contain t' we shall avoid the comparison of clocks by considering that equation only.

Now let us take the case of $x'=0$; *i.e. let the light signal be made exactly when K_1 reaches L.*

Then by (1), $t=x/v$.

But x/v is the time on K's clock when K_1 reaches L; to this must be added the time for light to come from L.

Therefore true value of $t=x/v+x/c$.

Hence (1) appears to be fallacious.

In that case, also, $x^2-c^2t^2$ is not equal to $x'^2-c^2t'^2$.

It is remarkable that Einstein actually considered the case of $x'=0$, but overlooked the interpretation of it.

It may be interesting, possibly instructive, to consider how a "Newtonian philosopher" would deal with the above problem as soon as he became aware that the velocity of light was not negligible. There are three cases.

1. As above—the signal *ahead of* K and K_1, then

$$t=\frac{x-x'}{v}+\frac{x}{c}=\frac{(c+v)x-cx'}{cv},$$
$$t'=\frac{x-x'}{v}+\frac{x'}{c+v}=\frac{(c+v)x-cx'}{v(c+v)};$$

whence

$$t'=\frac{c}{c+v}t \quad \text{and} \quad x'=(1+v/c)x.$$

2. The signal *from behind* K, K_1, so that x, x' are negative:

$$t=\frac{x-x'}{v}+\frac{(-x)}{c}=\frac{(c-v)x-cx'}{cv},$$
$$t'=\frac{x-x'}{v}+\frac{(-x')}{c-v}=\frac{(c-v)x-cx'}{v(c-v)},$$

equations which, as might be expected, are deducible from the previous pair by writing $(-c)$ for c.

3. The signal *from between* K, K_1; or x positive, x' negative:

$$t=\frac{x-x'}{v}+\frac{x}{c},$$
$$t'=\frac{x-x'}{v}+\frac{(-x')}{c-v},$$

whence no neat results.

It seems reasonable to conclude that *no single pair* of equations, such as the Lorenz transformation, can meet all the cases!

Longevity in a Fern.

I WONDER what is known of the duration of life in common herbaceous plants, other than annuals and biennials? The following instance may serve as a contribution to the lore of the subject.

About the year 1872 I found on the Mendip Hills a mature specimen of that curious sport of the hart's-tongue known as *Scolopendrium vulgare* var. *perafcrum-cornutum*, in which the mid-rib and the lamina part company at the apex of the frond, the mid-rib projecting as a horn, and the lamina forming a frilled pocket on the anterior surface. I transferred it to my father's garden in the same neighbourhood, where it has flourished ever since, retaining its peculiar character.

In 1917, as it was in danger of being choked by the growth of surrounding shrubs, I transplanted it. The stock had twice divided dichotomously, forming three crowns, of which one was dead. I placed the living ones where they had room to grow, and now they are as vigorous, and as young in appearance, as the original plant fifty years ago. As the plant was of unknown age when found, and looks no older after fifty years, its capacity for life seems indefinite.

The Recording Ultramicrometer.

THE recording ultramicrometer was first very briefly described before the Royal Dublin Society (Royal Dublin Society, xvi. p. 185, March 1921; *cf.* also NATURE, June 23, 1921, vol. 107, p. 523). Since its exhibition at the Edinburgh meeting of the British Association many short accounts of it have appeared in England and abroad. Many correspondents have requested further information, and, as some time may elapse before a full account of my investigations in this connexion are published, I take this opportunity of giving some practical hints to enable others to set up the apparatus.

In Fig. 1 the three-electrode valve is connected to

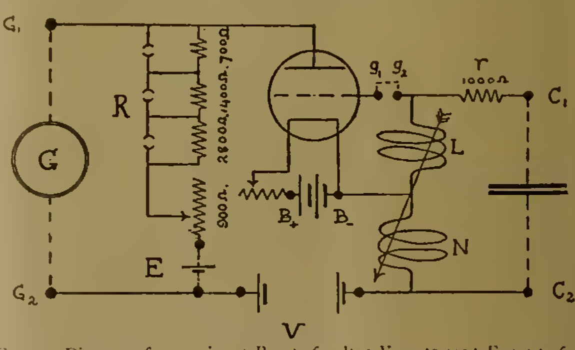

FIG. 1.—Diagram of connexions: B, 4 to 6 volts; V, 30 to 100; E, 1.5 to 6. L, N, about 10 cm., flat, 150 turns. G, aperiodic galvanometer, 10^{-8} amp. per div.

an oscillation circuit of the "Hartley" type, and in the anode circuit a sensitive galvanometer is introduced, its terminals being shunted by the "zero-shunt" E, R. The condenser C_1 C_2 of the oscillation circuit is formed by two parallel metal discs (say 5 cm. diameter). One of these may conveniently be adjustable by a fine micrometer screw, so that the capacity can be altered by turning the latter. As the plates are screwed together, increasing the capacity, it will generally be found that, from a certain point, the anode current increases, reaches a maximum, and finally rapidly recedes to its original value.

This sequence of changes takes place only when the circuit can oscillate. To follow the complete sequence it is necessary either to shunt the galvanometer heavily or to substitute for it a milliamperemeter.

A set of observations so obtained is given in Fig. 2, which represents the apparatus in the best adjustment for our purpose. To obtain this linear form of curve

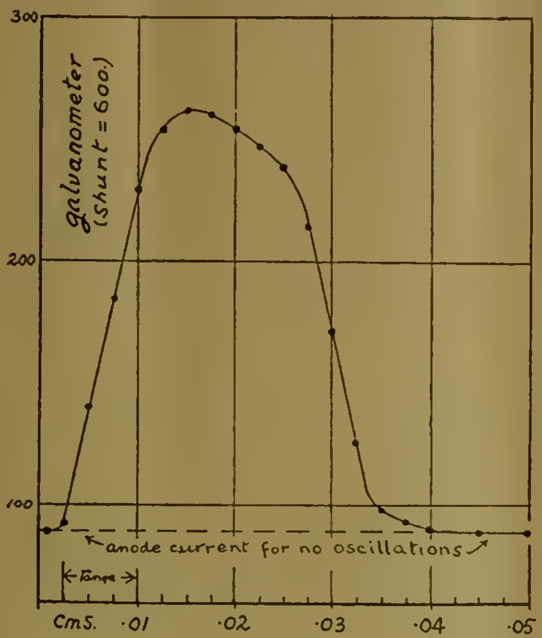

Fig. 2.

the relative positions (" coupling ") of the coils must be altered, and the most suitable plate voltages (V) ascertained by trial. With some valves it may be necessary to apply a negative potential to the grid between the points g_1 g_2, Fig. 1. I have used several common makes of " R Type," hard valves, and have never found any difficulty in obtaining the condition shown.

The function of the " zero-shunt " is to by-pass an amount E/R of the anode current j, so that, if R is large compared with the resistance of the galvanometer, the current through the latter is approximately j – E/R. When E and R are chosen so as to make this difference small, a sensitive galvanometer can be employed, unshunted, which will then give large deflexions, when the plates of the condenser suffer minute displacements. In view of the *linear* form of the curve (Fig. 2), it will be clear that the galvanometer reading is proportional to the plate displacement. Also, calibration is readily obtainable by shunting the galvanometer, say ten times, and then observing the deflexion obtained when the micrometer screw is turned through, say 1/1000 cm.

A resistance r up to 1000 ohms may be introduced into the oscillation circuit to reduce the sensitivity and widen the range of the plate movement. This resistance also renders it easier to obtain the linear adjustment. The large black dots in Fig. 1 represent the terminals on the case of the instrument; the batteries, galvanometer, and condenser plates are external and are connected to these terminals. The actual resistances, coils, etc., are mounted beneath the ebonite top of a small box, about one foot square and a few inches deep. Rigid connexions are employed to eliminate vibrational effects.

In the use of the apparatus for recording small displacements, movements, etc., one of the condenser plates is caused to partake of the movement to be measured by direct attachment, if possible, to the moving member. The other plate may be mounted, as already described, on a micrometer screw device to facilitate calibration. For steady working, at all times great care must be taken to employ batteries that are in perfect condition, and have an adequate current capacity. It is advisable to use cells of the same type for E as for V. Temperature changes must naturally be avoided in view of expansion and other effects. For " super " sensitivities (above 10^{-7} cm.) screening and other precautions become necessary.

A Permanent Image on Clear Glass.

The interesting observation described by Mr. Eric Robinson in Nature of April 28, p. 569, and commented upon in the same issue by Dr. J. W. French, is an excellent example of the ease with which the surface of glass may suffer modification and retain it over a long period of time. The present writer has studied a number of phenomena connected with " breath figures," and an account of the work will be found in the *Philosophical Magazine* for October last.

If the tip of a small blowpipe-flame is drawn rapidly across a sheet of glass it can be shown in various ways that the surface of the glass along the flame-track has been considerably modified. Flames of coal-gas, carbon monoxide, and hydrogen produce identical results. When moisture from breath condenses on the glass it is in the form of a misty deposit of minute hemispherical droplets, except along the flame-track, where it collects as a continuous transparent film. The contrast between the two types of condensation is most marked and constitutes a " breath figure." These flame-tracks are revealed when silver is chemically deposited upon the glass and they can also be traced by the greatly increased friction which manifests itself when a chemically cleaned watch-glass, which is being dragged across the plate, encounters one of the tracks. The insulation of the glass surface is also less along a flame-track than it is on those parts which have not been exposed to the action of the flame.

It is not possible in the space available to give the evidence in favour of the conclusion reached by me that at least two causes operate in producing the modification of the glass surface which leads to a " breath figure." One of these is that the flame removes the extremely thin film of contamination which certainly covers all glass which has not been subjected to a rigorous chemical cleansing process, and the other is probably a physical change in the surface of the glass itself. The latter is very persistent and can be detected for many months after the passage of the flame across the glass. I am inclined to attribute Mr. Robinson's effect to a physical change in the glass surface. Is it not possible that the gelatin of a photographic print which has been squeegeed upon glass may, when dry, exercise a considerable force on the surface in contact with it and that this force may have different local values depending upon the density of the photographic image? Such local differences in tension may impress upon the glass corresponding differences in surface structure which would then be capable of detection as a " breath figure " or by deposition of silver.

The Transmission of Speech by Light.[1]

By Prof. A. O. RANKINE.

IN 1880 Graham Bell devised a system of using light for transmitting sounds, including speech, and called his instrument the "photophone." This system afterwards experienced a chequered career, having attracted only occasionally the attention of other investigators, with the result that, although considerable improvements have been made, it has until quite recently remained a novelty. It is beginning, however, to enter upon the phase of practical use, more particularly in connexion with some of its applications in which the distance over which the light acts as the vehicle plays no essential part. In these circumstances it is, perhaps, desirable to introduce some modification of nomenclature. There is little doubt that Graham Bell's original idea was to transmit speech by means of a beam of light which travelled over as great a distance as possible. It is true that the maximum range he records having attained is 700 feet. The modesty of this achievement perhaps prevented him from introducing the notion of distance into the name he gave to the apparatus. Now, however, the name "photo-telephony" would appear to be appropriate for the improved system which, with its increased efficiency, and with the aid of modern amplifying devices, has a range of transmission of several miles and the immediate prospect of such extension that the earth's curvature will prove in practice to be the limiting factor. The adoption of this name for telephony by light would have the additional advantage that it would leave us free to retain the equally appropriate term "photophone" for those special modifications, already mentioned, in which distance is an unimportant consideration.

If we wish to use light for the transmission of sounds it is clear that we must impose on the light features which are characteristic of the sounds in question. The plan generally adopted is to modulate the intensity of the light in accordance with the vibrations constituting the sounds. How this is done will be considered later. For the moment the question is by what means these fluctuations of intensity can be made to reproduce audibly the original vibrations. This reproduction is possible because we have at our disposal certain substances, of which suitably prepared selenium is the best-known example, capable of acting as electric valves operated by variations of illumination. Selenium is not ideal for the purpose. Indeed, having regard to its many defects, it is surprising that it functions so well as it does. Shelford Bidwell, in a Friday evening discourse at the Royal Institution in 1881, spoke of the "capricious behaviour" of selenium, and it has to be admitted that this is still a fair description, even though many improvements of design and efficiency have been introduced by various makers of so-called selenium cells. There are, for example, obscure changes of conductivity, occurring slowly, which have defeated all attempts to use the electrical conduction of selenium as a basis in photometry.

Fortunately, these relatively slow changes are not of appreciable importance in connexion with the photophone, for in that case the fluctuations of light intensity are very rapid, corresponding, as they do, to audible frequencies. A more objectionable feature is that there is displayed a considerable lag in the electrical valve action, which prevents its operation being at all efficient, especially when the selenium is called upon to respond, as in the photophone, many times a second. If a suitable substitute free from this inertia-like effect could be found it would very soon displace selenium cells and the similar devices at present in use. Of the latter a notable example is the "thalofide" cell of T. W. Case, which is quicker than selenium in its response, but is sensitive to infra-red radiation rather than to visible light, and cannot be exposed to bright light without suffering deterioration in its photo-electric properties.

It is not proposed here to describe in detail the transmitting and receiving devices employed in speech transmission by light. The writer has, in a previous issue of NATURE,[2] already given some indication of the lines of development. With regard to the modulation of the light by speech two general plans have been adopted, namely (1) to cause the speech vibrations to control the actual candle-power of an artificial source of light, and (2) to use the voice to actuate a mechanism which interrupts in the appropriate manner a beam of light after it has left a constant source. Graham Bell's transmitter was of the latter type, and, although until recently the tendency, particularly on the continent, has been to employ the former plan by superimposing on the current in an electric arc or suitable filament lamp the microphonic currents arising from speech sounds, it is now fairly generally recognised that greater efficiency can be attained by improved forms of the interruption method. This method has also the advantage that it can be applied to any source of light, and thus brings into our service sunlight, which is the brightest of all.

The simplest form of the receiving device is a circuit consisting of a selenium cell, an electric battery, and a telephone receiver. On exposure of the selenium to constant illumination, a constant, or, at any rate, a very slowly varying current passes. If, however, the illumination is of a fluctuating character—if, in particular, the variations are those due to modulation by speech vibrations—the selenium is able, in spite of its lag, to control the current in a closely corresponding manner, so that the diaphragm in the telephone receiver, through which this current flows, is set in vibration, and emits sounds resembling with a remarkable degree of accuracy the original sounds used in modulating the light. The speech currents in this simple circuit can be transformed into other circuits if desired, and they can be amplified in the usual way by means of thermionic valves. It only has to be borne in mind that selenium cells are usually of very high resistance, and that, therefore, methods of transformation appropriate to such cases should be employed.

It is easy to arrange the optical system of the transmitter so that the light projected is confined to a very narrow angle and directed upon any small chosen

[1] From two lectures delivered at the Royal Institution on April 12 and 19.

[2] NATURE, vol. 104, p. 604 (1920).

area in the distance. The amount of light received by the selenium, placed, as it is, near the focus of a lens or mirror of definite aperture, diminishes, of course, as the distance is increased. Several factors determine the range of efficient transmission—the intrinsic brilliancy of the light source, the dimensions of the optical parts, the sensitivity of the selenium, and the number of stages of amplification which are used. No very conclusive tests of the maximum range of the photo-telephone have yet been carried out; it may, nevertheless, be asserted with some confidence that, given sunlight and modern amplifying devices, it is probably the earth's curvature which would impose a limit on the range of an instrument of quite reasonably small dimensions.

It is of interest to compare the photo-telephone with the system of wireless telephony now so commonly used in broadcasting. In both, waves in the ether constitute the fundamental basis; the medium is the same and the speed of propagation is the same. In both, speech vibrations modulate the intensity of the energy transmitted, and in both the results are made audible by changes of current in the receiving apparatus. The details are, of course, dissimilar. The radio-frequency waves are produced artificially, and are under control as regards wave-length; the luminous waves are taken as we find them emitted from the source. The detectors—the valve or crystal on one hand, and the selenium cell on the other—are not strictly comparable. But the only really important difference lies in the lengths of the waves. Roughly, the radio-frequency waves commonly employed are one thousand million times as long as those operative in photo-telephony. This difference is of great importance in relation to the mode of propagation. Wireless waves at present in use are so long that they turn readily round corners, so that not only does the earth's curvature impose no serious limitation of range, but broadcasting in all directions is possible and, indeed, inevitable. Light waves, on the other hand, are for practical purposes propagated rectilinearly; consequently photo-telephony can never be expected to attain a very great range. It has, however, the compensating feature that by its directiveness it implies not only secrecy of communication but non-interference by simultaneous transmissions, without the necessity of tuning as in radio-telephony. It is true that selenium is more sensitive to red light than to other colours, and is therefore somewhat selective as regards frequency, but the suppression of the other colours is not called for, and would, in fact, be a disadvantage.

The photophone, as distinct from the photo-telephone, has several other applications. Two may be briefly indicated. The modulated light from the transmitter can be focussed into a narrow line upon a uniformly moving kinematograph film upon which, after development, there appears a band of varying opacity corresponding to the light fluctuations, and, therefore, to the speech or other sounds used for modulating purposes. The same film, on being run at the same speed between a source of light and a selenium cell with a suitable optical arrangement, gives a reasonably good reproduction of the original sounds. With sufficient amplification the results can be heard proceeding from a loud-speaking telephone. The application of this form of gramophone to the problem of synchronised pictures and sounds is obvious, and has been described in an earlier article.[3] Many workers in various countries are now concentrating their attention upon perfecting a system of this kind, and there is no reason to suppose that realisation will be long delayed.

The speech currents controlled by selenium under the action of the modulated light from a photophone transmitter compare favourably in accuracy of form with those obtained by means of a carbon microphone. The photophone as a whole—*i.e.* the transmitter and receiver together regarded as one unit—can thus be used as a substitute for the microphone in cases where stricter accuracy in electrical sound transmission is desired. This necessity has arisen in acute form in connexion with radio-telephony, in which the radio-frequency oscillations have to be modulated in the transmitting valve as nearly as possible in accordance with the sounds it is desired to transmit. A photophone has been used successfully at the Manchester broadcasting station for this purpose, and for some months those who listen to this station have been receiving the results of what can quite fairly be described as a remarkable sequence of occurrences. A singer sings, and the aerial vibrations thus created fall upon a diaphragm. This is forced also into vibration and imparts its motion to a small mirror, which in turn deflects a beam of light so that more or less of it reaches a selenium cell. By its photo-electric property the cell controls an electric current so feeble that it has to be amplified by thermionic valves in several successive stages before it is intense enough to modulate efficiently the radio-frequency oscillations in the transmitting valve. Thence the modulated wave travels through the ether to the receiving aerial; here, perhaps, it undergoes one or more high-frequency magnifications, and then the modulations are detected by a crystal or valve. Then there may be several low-frequency amplifications before, eventually, the fluctuating current actuates a telephone diaphragm causing it to re-create those aerial vibrations which we hear. When we bear all this in mind our attitude is not that of criticism of the defects of reproduction, but rather that of amazement that it so closely resembles the original.

[3] NATURE, vol. 108, p. 276 (1921).

Recent Experiments in Aerial Surveying by Vertical Photographs.[1]

By Prof. B. MELVILL JONES and Major J. C. GRIFFITHS.

II.

COMPILATION OF THE MOSAICS.

THE compilation of the mosaics presents considerable difficulties unless approached in a systematic manner, for, although individual prints fit well together, there are always some slight errors which tend to accumulate, unless special precautions are taken to prevent this occurring.

We begin the compilation by laying out each strip of photographic prints separately, paying special attention to the joins between successive prints. Slight

[1] Continued from p. 709.

changes of height, either in the aeroplane or the ground, will cause slight changes in scale between successive strips, and slight persistent tilts, either in the camera or the ground, will cause the strips, as fitted in the first place, to show fictitious curvatures due to differences being represented to a larger scale on one side of the strip than on the other.

To make a good fit between successive strips, these fictitious curvatures and differences of scale must, so far as possible, be eliminated by distributing errors between all the joins of the individual prints. We do this by securing to the back of the strips lengths of stretched elastic, fixed to each print in one spot by dabs of seccotine, and, when all the strips have been so treated, we lay them side by side upon a table and stretch and bend them systematically, until we have got the best general fit that can be obtained, without detail handling of the separate prints.

FIG. 1.—Photographic map of $7\frac{1}{2}$ by 15 miles, showing the elastic bands used in the compilation. In the finished map the prints would be properly trimmed and the elastic bands removed.

Provided that the strips were originally taken in fairly straight lines, this process of systematic adjustment appears to eliminate the fictitious curvature almost entirely and to adjust the relative positions, even of points that are far apart, with remarkable accuracy. A final adjustment is then made, in which attention is given to each print separately, but no print is moved far from the position that it has taken up in the systematic adjustment. Fig. 1 shows a mosaic laid out in this way. Notice the straightness of the strips due to the gyroscopic control, which was used in this case.

ACCURACY OF THE MAPS.

Two mosaics of $7\frac{1}{2}$ by 15 miles have been compiled in this way, without any reference whatever to existing maps. Some 40 points were selected on each of these, and their positions on the mosaic plotted on transparent paper. A plotting of these same points was then taken from the Ordnance map and enlarged until the best possible fit could be obtained with the points from the mosaic. The two plottings were then slid over each other until the best fit was obtained, and thus the remaining discrepancies give a measure of the distortion of the mosaics, without regard to scale.

The first of these mosaics was made without the gyro control on the rudder; it contains an area of 10 miles by 5 in which no point is displaced by more than 100 yards, but outside this area, towards the ends, there are points displaced by as much as 250 yards.

In the second mosaic, which is the one illustrated in Fig. 1, the gyro rudder control was used, and in this mosaic there is no distortion greater than 100 yards in any part. The increased accuracy is due, mainly, to the greater straightness of the runs, and to the pilot having been able to give more attention to maintaining height and speed constant.

The average scale of both mosaics came out to 1/19,800 as against 1/20,000 intended. The difference of 1 per cent. may be due either to the aeroplane having been about 100 feet too low, or to errors introduced during the systematic adjustment.

COMPILING TO CONTROL POINTS.

Our next experiment was to start again with new prints and to compile these two days' work together into a single 15-mile square. But this time, instead of fastening the ends of the elastics down to the table, we fastened them to laths on the edges of the table. (See Fig. 2.) The object of this was to enable us to apply systematic strains to the mosaic as a whole, after the first systematic adjustment, to cause it to fit control points.

We chose four control points, forming a rough 10-mile square, and, assuming their positions to be independently known (in this case from the Ordnance map), constructed a template to fit them, upon a scale that would most nearly fit the corresponding points upon the mosaic, after its first adjustment. We then applied this template to the mosaic and found that, owing to the distortion of the latter, displacements of about 150 yards were necessary at each control point to obtain an exact fit. These displacements were given to the mosaic by moving the laths as a whole, so that the adjustments were distributed over all the joins. The mosaic was then given a final adjustment in detail and the prints stuck down in place after removing all the elastics. When this work had been completed, some 40 points, distributed over the surface of the mosaic, were measured up and compared with the Ordnance map, and it was found that there were no errors of more than 60 yards, except on the extreme northern edge of the part of the mosaic that was made without gyro control on the rudder. In this region errors up to 130 yards were recorded.

The scale to which the template had to be constructed came out at 1/19,930. The difference between this scale and that of the separate mosaics compiled from the same photos was possibly introduced during the systematic adjustments.

a good measure of control between very widely spaced ground-surveyed points. If, for example, the photos in these flights be taken at exactly equal time intervals and the positions of the ends of the strips be known, the centre of each intermediate photo could be determined with considerable accuracy.

We have in hand experiments upon a scheme for using these indication strips, together with a few long strips at right angles, to control the positions of the 10-mile square units. We estimate, on good but not yet conclusive evidence, that, representing these preliminary strips by elastic bands and stretching the frame so formed to fit control points, we could so distribute the errors that the 100 square mile units mosaics could be located in position within ¼ to ½ a mile, even when the control points are spaced as much as 50 miles apart. It will be noted that this method of locating position is unaffected by the presence of hills.

FIG. 2. Showing method of compiling the 15-mile square photographic map to fit four control points. The prints are hidden by the weights used to hold them in place after their final adjustment, but the white elastic bands to which the prints are fastened are clearly shown. The black elastic bands were added to facilitate systematic straining at right angles to the direction of the strips.

VARIATIONS OF HEIGHT.

The country of which this map was made contains local differences of level up to 300 feet in several places and on the extreme southern edge rises to 500 feet above the lowest part.

NAVIGATIONAL CONTROL.

In some types of country, control points even of 10-mile spacing may not be economically obtainable. The complete absence of control points would not, as we have seen, seriously affect the accuracy of the individual mosaics as regards distortion, but it may leave their average scale in some doubt. There may, therefore, be some difficulty, in these circumstances, in fitting the mosaics together and in controlling their relative positions. It will be remembered, however, that it was necessary, for the identification of the starting points of the mosaic strips, to begin a survey by laying down identification strips spaced 10 miles apart. The most economical way to do this, when mapping over large areas, would be to commence by laying down a series of long parallel strips 10 miles apart having a convenient length of, say, fifty miles. If care is taken to fly these indication strips very straight and at a constant speed, it may be possible to use them to give quite

We do not recommend using control points so widely spaced as this, but we are concerned to show that the mosaics could be located with moderate accuracy even when the control points are so far apart.

The methods upon which experiments are in progress would not be limited to use with control points forming any particular pattern; they could be used with any form of triangulation. If, however, triangulation is impracticable, as it may be in flat wooded country, we are informed that astronomical methods, carried out on the ground, with the help of wireless time signals, can be used to locate position within 100 to 200 yards. If this method could be employed, therefore, in conjunction with aerial methods, it would be possible to push accurate mapping into unsurveyed country in which the ordinary ground-surveying methods, based on triangulation, are impracticable.

TRAINING AND EQUIPMENT.

The methods that we have described require considerable skill and special training on the part of the pilot and observer. If they are not adequately trained the probabilities are that the strips of photographs that they produce will be badly curved and leave gaps between them, while the individual photos will be tilted up to about 6 degrees and taken from varying heights. In such circumstances accurate compilation is almost impossible unless a map already exists, and, even then, re-section and re-projection of individual photos will be necessary if anything but the roughest results are to be obtained. The gaps that have been left between strips will, moreover, have to be filled up; and, as this is not an easy operation, several additional flights may be necessary for a satisfactory completion of the mosaic.

We are, for these reasons, definitely of the opinion that to employ crews that are not specially practised in the work is to court certain failure; at least in the earlier stages, before experience has been gained.

Special equipment, such as gyro rudder controls, etc., is, in our opinion, necessary for continuous successful work at the rate we have indicated, namely 100 square miles a day. Should the gyros break down in the field, it would be possible to carry on for a time in the absence of any gyroscopical aid, but the strain on the pilot would be so greatly increased that his work would deteriorate seriously unless he confined himself to considerably less work than we have indicated for a single flight.

It is also important to use a stable aeroplane, having adequate accommodation for the observer and his camera and for the pilot's special instruments. We have ourselves used a tractor (D.H. 9a), but we consider that a pusher would be far more satisfactory on account of the better view downwards, sideways, and forwards.

Summary.

We have shown that it is possible to carry out aerial surveying by vertical photographs at the rate of 100 sq. miles to the day's flying. When working in moderately flat country the results so obtained can be worked up into 100 square mile mosaics which, when reduced to a suitable scale, will fit a true map within 100 yards at all points. If so desired these maps can be adjusted to fit any number of control points with very little extra labour. If these control points are spaced about 10 miles apart, the absolute error of any point on the mosaic should be less than 100 yards, but, if more closely spaced control points are available, the errors can be reduced, reaching a limit of something less than 20 yards, when the spacing is reduced to one mile.

If the available control points are spaced more widely than 10 miles apart, a measure of control can be provided from the air by navigational methods. We estimate that, even when the control points are spaced so far apart as 50 miles, we could in this way control the position of the 100 square mile units within $\frac{1}{4}$ to $\frac{1}{2}$ mile. We are working on this problem at present.

The maps can be made throughout from contact prints off original negatives, no re-projection of individual photos being necessary.

Triangulated points, forming any convenient pattern, can be used as control points; *e.g.* previously existing primary, or secondary, triangulations could be used.

The methods are dependent on there being sufficient detail visible on the photos to allow them to be joined correctly; they would not be practicable on absolutely featureless deserts or prairies.

Specially trained, picked crews using suitable aeroplanes, specially equipped, are necessary for success.

Obituary.

Col. G. F. Pearson.

On April 25, Col. George Falconer Pearson died at Kington, Herefordshire, aged ninety-six years. He was one of the last, if not the very last, of devoted servants of the Crown who joined the Indian service some time before the Mutiny, and became a distinguished pioneer of systematic conservancy of the Indian forests.

Pearson commenced his service in the 33rd Regiment of the Madras Light Infantry in 1846, in which he became adjutant, and he also acted for some time as A.D.C. to Sir Herbert Maddock. He happened to be on leave at home when the Mutiny broke out, but returned at once to India and joined his regiment in the Central Provinces, where he was employed in the chase of Tipoo Sahib and other rebels. After the Mutiny he raised a force of military police, 600 strong, with which he put down general lawlessness in the province.

Having thus become well acquainted with the extensive forests and the various tribes living in and around them, Mr. Temple, the Chief Commissioner, appointed Pearson the first Conservator of Forests of the Central Provinces in 1860. Pearson, being endowed with an iron constitution and great energy, devoted the next eight years to the organisation and administration of the 20,000 square miles of Government forests in the province, selecting and demarcating reserves, introducing a system of regulated utilisation, starting a successful method of protecting the forests against the annually recurring forest fires, and regulating shifting cultivation; in other words, substituting a regular system of management for the method of reckless devastation of the past. His success brought him the special thanks of the Government of India for his valuable services.

In 1868 Pearson was transferred to the charge of the forests in the North-west Provinces, where he reorganised the department, estimated the yield capacity of the forests, and opened out the hill forests by the construction of roads, bridges, and timber slides, by which large quantities of timber were brought down to the plains for railway construction. In 1871 he was appointed to act for Dr. Brandis as Inspector-General of Forests, and in 1872 he left India to take up the appointment of director of studies to the British forest probationers at Nancy, a post which he held until 1884. On his final retirement he settled at Kington, where he lived for thirty-nine years, being a J.P. and the friend of all classes of the inhabitants.

Pearson, though not specially educated as a forester, energetically absorbed and utilised the leading principles of rational forest conservancy, and took a great part in the introduction of a system of rational forest management in India. He recorded his experiences and ideas in numerous reports, and he published a book on his "Reminiscences" of his activity in the Central Provinces. He was a great judge of character, and he succeeded in becoming the friend of those who served under him, while stimulating them to energetic action similar to his own. While at Nancy, he overcame in a short time the difficulties which had sprung up before his arrival, and his influence upon the students was highly beneficial; in return they loved and admired him. His younger son is a distinguished member of the Dehra Dun Research Institute.

Capt. C. H. Ryder.

News has come from Copenhagen of the death of Capt. Carl Hartvig Ryder, director of the Danish Meteorological Service, on May 3. He had been known to be suffering from rheumatism for some years and lately to find the cares of his official duty onerous; but, to us, the news of his death has come quite unexpectedly.

The Danish Meteorological Office is justly famous for the early production of Daily Weather Charts of the Atlantic Ocean, 1873 to 1876, by Capt. Hoffmeyer, sometime director, a work which was continued by the Danish Meteorological Office and Deutsche Seewarte jointly from 1881 until 1911, with the interval of August 1882 to August 1883, which was covered by the maps of the London Meteorological Office. In 1921 the International Committee expressed the desire for the charts to be brought up-to-date and Capt. Ryder had promised his aid. Further, with its relations to Greenland and Iceland, Denmark is one of the guardians of the farthest North, and for many years the Danish Meteorological Office has compiled all available information about ice in northern waters and published with great promptitude year by year reports thereupon.

Capt. Ryder, a naval officer, was appointed director in 1907 on the death of Paulsen. He became a member of the International Meteorological Committee in 1910 and was an indefatigable and most helpful member of that body, especially in regard to weather telegrams from Iceland. By nature he was disposed to work out meteorological progress on conservative lines: he realised that there was still much to be done in improving the data without which there are no adequate means of testing theories. His presence at future international meetings will be sadly missed by his colleagues.

Napier Shaw.

We regret to announce the following deaths:

Dr. D. Duncan, formerly director of Public Instruction in India and principal of Presidency College, Madras, and biographer of Mr. Herbert Spencer, on May 18, aged eighty-three.

Dr. Hans Goldschmidt, the originator of the process for the preparation of chromium known by his name and of thermite, a mixture of aluminium and oxide of iron, used for welding iron and steel, and also in incendiary bombs, on May 20, aged sixty-two.

Prof. G. L. Goodale, professor of botany at Harvard University from 1878 until his retirement as emeritus professor in 1909, and president of the American Association in 1890, on April 12, aged eighty-three.

Prof. Immelmann, general secretary of the German Röntgen Society, in Berlin, on April 1, aged fifty-six.

Dr. A. Looss, formerly professor of parasitology in the School of Medicine, Cairo, a distinguished helminthologist, on May 4, aged sixty-two.

Mr. M. de C. S. Salter, superintendent of the British Rainfall Organisation, on May 21, aged forty-two.

Prof. A. G. Webster, professor of physics, Clark University, Worcester, Mass., known for his work on acoustics, aged fifty-nine.

Current Topics and Events.

We learn from the Paris correspondent of the *Times* that the celebrations of the centenary of the birth of Pasteur commenced on May 24 with a reception by the French President at the Elysée. On the following day the principal ceremony was held at the Sorbonne, where a plaque was unveiled which bears an inscription recording the meeting between Pasteur and Lister in the Sorbonne on December 27, 1892. This tribute was arranged by the Association France-Grande Bretagne. A visit was paid by the President and the Minister of Education to Pasteur's birthplace at Dôle on May 26. M. and Mme. Vallery-Radot, descendants of Pasteur, have presented a bust of Pasteur, which was unveiled in the Galerie des Glaces at the Palace of Versailles on May 28, and the French President is to unveil the Pasteur monument at Strasbourg on May 31. A kinematograph film tracing the principal events in the life of Pasteur and giving a general idea of his scientific work was exhibited on May 24 to more than 3000 school-children in Paris, and considerable sums in aid of French laboratories have been collected by the sale of Pasteur badges in the streets. A new French 10-centimes postage stamp bearing the effigy of Pasteur engraved by Prud'homme has been issued to mark the occasion of the centenary. We hope to publish later an account of the celebrations by one of the British delegates.

As recorded in our columns, the late Arthur William Bacot, entomologist to the Lister Institute of Preventive Medicine, one of the most brilliant and original investigators in the field of medical entomology, lost his life a little more than a year ago in the course of an experimental inquiry into the rôle of the louse in the transmission of typhus. Several of Mr. Bacot's friends and colleagues have thought that some memorial of him ought to be established in the village where he resided and, before his appointment to the staff of the Lister Institute, carried out important medico-entomological researches. Mr. Bacot entered the ranks of specialist investigators from those of amateur naturalists and Nature students, and always attached the greatest importance to the teaching of Nature study in the elementary schools. His colleagues and friends believe that the form of recognition which would have been most congenial to his feelings would be the provision of assistance to the authorities of the Council schools in his home (Loughton) in furthering the study of natural history. With that object, a fund has been opened—the Bacot Memorial fund. It is proposed that the interest on any money received—to be invested in the name of trustees chosen by the subscribers—should be devoted to the purchase of such pieces of simple apparatus such as collecting boxes, specimen cabinets, etc., necessary for the development of Nature study in a school. It is well known that in the present state of public finances it is difficult to obtain grants for such purposes from educational authorities, and that the availability of even a very small income makes a great difference to an enthusiastic teacher. Should any of Mr. Bacot's friends or admirers of his work who feel in sympathy with the proposal care to subscribe to the fund, subscriptions will be gratefully acknowledged either by the hon. treasurer, Mr. Hubert Baines, Bryn Mawr, Church Hill, Loughton, Essex, or by Dr. Major Greenwood, National Institute of Medical Research, Hampstead, N.W.3.

THE Jonas Laboratory for the mechanical testing of metals and the Edgar Allen Laboratory for magnetic investigations at the University of Sheffield were formally opened on May 3 by Sir Oliver Lodge. These laboratories have been equipped by means of two gifts of 5000*l*. each from the late Mr. Joseph Jonas and the late Mr. Edgar Allen respectively, accommodation being found in the existing buildings of the Applied Science Department of the University of Sheffield. The equipment of the Jonas Laboratory includes Armstrong-Whitworth machines of 85 and 50 tons capacity, with oil-pump and accumulator and a variety of extensometers, an Izod machine, and a new instrument for the detection of early slip in metals by electrical means. Special equipment for the study of fatigue has been provided, including a Haigh machine for alternating tension and compression, a modified Stromeyer machine for alternating torsion, and a modified Wöhler machine, the latter two having been designed and constructed in the department, and provided with optical devices for short-period tests. The instruments for the measurement of hardness include the ordinary Brinell machines, the small Brinell machine for tests with balls of small diameter, a scleroscope, sclerometers, and the Herbert pendulum instrument. There is also a series of instruments, optical and other, for determining the accuracy of standard gauges. The Edgar Allen Laboratory is specially equipped for investigations on the magnetic properties of steels and other alloys, and has been designed and arranged by Dr. T. F. Wall. Current of various voltages, direct and alternating, is supplied by cables to distributing boards around the room, and a special generating set has been installed for obtaining alternating currents of variable high frequencies. A powerful electro-magnet, capable of producing very intense fields, has been constructed in the department. The electrical instruments include a Duddell oscillograph, a variety of measuring instruments, vacuum thermo-junctions for small alternating currents, standard condensers and resistances, and magnetic instruments (Epstein square, fluxmeter, etc.). The equipment of this laboratory is exceptionally complete. On the occasion of the opening, a number of visitors inspected the laboratories, and Sir Oliver Lodge delivered an address on the value of research work in industry.

To commemorate the fiftieth anniversary of the foundation of the Institution of Electrical Engineers (under the name of the Society of Telegraph Engineers), the Council decided in 1921 to establish a Faraday medal in bronze to be awarded not more than once a year for "notable scientific or industrial achievement in Electrical Engineering, or for conspicuous services rendered to the advancement of Electrical Science, without restriction as regards nationality, country of residence, or membership of the Institution." The Council selected for the first award of the medal Mr. Oliver Heaviside, who, unfortunately, owing to ill-health, was unable to attend a meeting of the Institution to receive the medal, which was personally presented to him by the then president, Mr. J. S. Highfield, at Torquay on September 9, 1922. The second award of the medal was made by the Council to the Hon. Sir Charles Parsons, at the ordinary meeting of the Institution held on Thursday, May 10. Mr. Highfield, past-president, said that the name of Sir Charles Parsons stood first in the engineering world of to-day, and that there was, he thought, no one who did not know what a mighty work Sir Charles had done for the engineering of the last thirty or forty years. His name would be remembered in connexion with the design and development of that great engine for the production of power which we know to-day, the turbine. After Dr. S. Z. de Ferranti had also spoken of the work and of the great benefits that had come to the world as the result of Sir Charles Parsons's invention, the president, Mr. F. Gill, presented the Faraday medal to Sir Charles. In making the presentation, the president expressed the wish that Sir Charles would live many years in which to enjoy the very special position of regard and affection of all members of the Institution.

SUMMER time commenced in France on Saturday last, May 26, at 11 P.M.

SIR ARTHUR KEITH will deliver the twelfth biennial Huxley lecture at the Charing Cross Hospital Medical School on Wednesday, June 27, at 3 o'clock. The subject will be "Recent Advances in Science and their bearing on Medicine and Surgery." No tickets of admission will be necessary.

PROF. W. D. BANCROFT, professor of physical chemistry in Cornell University, New York, will deliver an address entitled "A Plea for Research" at the house of the Royal Photographic Society, 35 Russell Square, W.C.1, on June 5 at 8 o'clock.

BY the will of Sir James Dewar, who died on March 27, the University of Cambridge is to receive all his scientific apparatus in the chemical laboratory of the

University, and, similarly, the Royal Institution will receive all his apparatus in the Institution and the laboratory attached to it.

ON Wednesday, June 6, the Anglo-Batavian Society will entertain Dr. H. A. Lorentz, professor of physics in the University of Leyden, at dinner at the Langham Hotel, London, W., when Sir Walter Townley, chairman of the council of the Society, will preside. Among the guests who have accepted invitations for the dinner are Lord Haldane, Sir Frank Dyson, and Sir William Bragg.

EXAMINATION of candidates for the Associateship of the Institute of Physics will be held in London at the latter end of September next. Applications for entry must be received before June 30. Forms of application and copies of the papers set in 1922 can be obtained from the secretary, 10 Essex Street, London, W.C.2.

IT is stated in the *Times* that a wireless station is to be erected on Novaya Zemlya Island by the Russian authorities. The station will be situated by Matochkin Strait and will be in communication with North Russian and Siberian stations. The personnel will include, in addition to the wireless experts and meteorologists, a geologist and a zoologist.

THE seventy-ninth general meeting of the Institution of Mining Engineers will be held at Glasgow on June 12-14, and among the papers to be presented are "Coal-dust as an Explosive Agent," by Mr. G. H. Rice, and "The Recent Search for Oil in Great Britain," by Mr. H. P. Giffard. A summary will be submitted of the research work carried out for the committee on the control of atmospheric conditions in hot and deep mines. Excursions to collieries and works in the neighbourhood of Glasgow have been arranged.

AT the April meeting of the Franklin Institute, Philadelphia, the Howard N. Potts gold medal was presented to Dr. Albert W. Hull of the Research Laboratory, General Electric Company, Schenectady, New York, for his paper on "The Crystal Structure of the Common Elements," and the Edward Longstreth medal was presented to a representative of the Société Genevoise d'Instruments de Physique of Geneva, Switzerland, for the universal measuring machine produced by the company.

THE Association of Economic Biologists will hold its annual field meeting at Cambridge on Friday, June 15. The programme includes visits to the School of Agriculture, where investigations on animal nutrition and physiology will be demonstrated; to the National Institute of Agricultural Botany, where will be shown the field trials of agricultural crops, and to the University Farm and Plant Breeding Institute to see the investigations in progress on cereal hybridisation.

THE trustees of the Ramsay Memorial Fellowships for Chemical Research are prepared to consider, at the end of June, application for not more than two fellowships, one restricted to candidates educated in Glasgow. The fellowships, which are each of the annual value of 250*l*., plus a grant of not more than 50*l*. yearly for expenses, are tenable normally for two years, but they may be extended to three years. Applications must be sent by, at latest, June 15, to Dr. W. W. Seton, University College, Gower Street, W.C.1.

AT the annual general meeting of the Linnean Society held on May 24, the following officers were elected: *President*: Dr. A. B. Rendle; *Treasurer*: Mr. H. W. Monckton; *Secretaries*: Dr. B. Daydon Jackson, Dr. W. T. Calman, and Capt. J. Ramsbottom; *Other Members of Council*: Dr. W. Bateson, Dr. G. P. Bidder, Mr. R. H. Burne, Prof. F. E. Fritch, Prof. E. S. Goodrich, Dame Helen Gwynne-Vaughan, Sir Sidney F. Harmer, Dr. A. W. Hill, Mr. L. V. Lester-Garland, Baron Rothschild, Dr. E. J. Salisbury, Mr. R. J. Tabor, Mr. T. A. Sprague, Prof. F. E. Weiss, and Dr. A. Smith Woodward.

IT is stated in the *British Medical Journal* that the Ontario Legislature has established a research chair for Dr. Banting, the originator of the idea that diabetes might be controlled by extracts of the islands of Langerhans, for which the name "insulin" had been suggested by Sir Edward Schafer a good many years ago, and under which it has now become a commercial product. The income of the chair, to which Dr. Best will act as assistant, will be 10,000 dollars a year. Dr. Banting intends to be present at the discussion on diabetes in the Section of Medicine at the annual meeting of the British Medical Association in Portsmouth.

THE first attempt to broadcast a picture by wireless telephony was made on May 24 at the London Station of the British Broadcasting Co. The experiment was made by Dr. Fournier d'Albe, who used a special code method adapted to a juvenile audience of "listeners-in." It being Empire Day, the picture chosen for broadcasting was a portrait of King George V. The picture was coded by dividing it into thirty horizontal strips and splitting up each strip into twenty squares. A letter was assigned to each square to indicate its average shading, and these letters were written out in thirty lines of twenty letters each. Each line was divided into four groups of five letters, and each group was dictated into the microphone in turn. The lines were numbered, so that mistakes could be easily avoided. The total time of transmission, with instructions, was twenty-two minutes, but it was found that the code message itself could be taken down in eight minutes. The picture was reproduced either by graduated dots on squared paper or on an ordinary typewriter, using letters of graduated size and making the line space equal to the letter space. Recognisable reproductions were made in from twenty to twenty-five minutes. In the complete method a special typewriter or "dot-writer" is to be employed.

NEWS has reached Copenhagen of the progress of Mr. Lange Koch's expedition to north-west Greenland. The *Times* reports that Mr. Koch wintered at Upernivik on Baffin Bay and in March 1922 left for

Cape York, where his survey began. He continued his work to about lat. 82° N., but was forced to abandon his project of charting Peary Land. A large tractor proved very useful for transport, and easily pulled over snow a sledge loaded with food supplies and ten barrels of petroleum. After several hundred miles it broke down and had to be abandoned. Progress then became difficult. A bad epidemic of influenza in the Cape York district has caused such heavy mortality among the Eskimo that it is impossible at present to start any expedition from that base. Mr. Koch intends to return to Denmark in the course of the present summer.

The arrangements for the International Air Congress to be held in London at the Institution of Civil Engineers, Great George Street, London, S.W.1, on June 25-30, are now approaching completion. The papers to be presented cover every field of aeronautical development, and are thoroughly international in character, as contributions have been received from America, Belgium, Denmark, France, Holland, Italy, Spain, and Sweden, among other countries, in addition to Great Britain. Applications for membership of the Congress will be accepted up to Saturday June 9. A number of visits to various Government experimental and research establishments and Royal Air Force Stations have been arranged, and several of the leading aircraft and engineering firms have expressed their readiness to receive members of the Congress at their works. Communications regarding the Congress should be made to the International Air Congress, London, 1923, at 7 Albemarle Street, London, W.1.

Bulletin 54 S issued by Messrs. Watson and Sons (Electro-Medical), Ltd., Sunic House, 43 Parker Street, Kingsway, London, W.C.2, is a descriptive list of second-hand X-ray and electro-medical apparatus which the firm has for sale. Complete units for X-ray work are offered, in addition to numerous accessories, such as induction coils, Coolidge filament transformers, mercury interrupters, X-ray tubes, screens, and so on.

The Medical Supply Association, Ltd., of Gray's Inn Road, London, now supply "Radio-Wave" receiving apparatus of all kinds, from a "junior" crystal set, up to a "Radio-Wave Plutocrat" receiver with a range of 300 miles. Modern radio sets are now so simple that no special education or skill is required to work them. Some of the sets also can receive the roughest usage without damage. The receivers made by the Association are of the approved type and the valve apparatus supplied is fully licensed. The lengthy list given of radio parts in their catalogue will be welcomed by amateurs.

Messrs. Longmans and Co. have in the press, for appearance in their series of "Manuals of Telegraph and Telephone Engineering," "The Inspection and Testing of Materials, Apparatus, and Lines," by F. L. Henley, which will describe the methods employed in the British Post Office in the inspection and testing of supplies of the various materials used in line construction, cables, telephone and Morse telegraph instruments, and furnish the inspector with a basis of sound information upon which to form a judgment in those cases where electrical, mechanical, or chemical tests are either not available or are not conclusive. In the same publishers' "Rothamsted Monographs on Agricultural Science" will appear "Manuring of Grasslands for Hay," by Dr. Winifred E. Brenchley of the Rothamsted Experimental Station.

Our Astronomical Column.

The Diameters of Saturn's Satellites.—Major P. H. Hepburn contributes a paper on this subject to B.A.A. Journ. for March. The only one that is large enough to measure with a micrometer is Titan, for which Barnard and Lowell agreed in finding a diameter of some 2600 miles, say 0·7″ in arc. Major Levin found 3500 miles by the eclipse of Rhea by Titan, April 8, 1921; probably the truth lies between the two. For the other satellites estimates can be made (1) from the masses determined by H. Struve, combined with assumed densities, and (2) from the stellar magnitudes of the satellites determined by Guthnick and at Harvard, combined with assumed albedoes. In practice each method was found to help the other; it was established that all the smaller satellites must have small densities, not much greater than that of Saturn itself, which is $\frac{1}{8}$ of the earth's density, or 0·7 of water. In particular, Mimas must have both low density and high albedo, and Major Hepburn suggested, half seriously, that it might be a gigantic snowball; he had in a former paper suggested that the Ring might be composed of ice crystals. The values of the diameters considered most probable are: Mimas, 300 miles; Enceladus, 450; Tethys, 700; Dione, 800; Rhea, 1000. Data are lacking for trustworthy estimates of Hyperion and Iapetus. As Jupiter's satellites have also low densities, some colour is given to the old suggestion that the outer parts of the solar system are built of less dense materials than the inner parts. It will be remembered that the inner satellites of Saturn are much the smallest bodies the masses of which have been determined gravitationally, hence determination of their densities throws new light on our knowledge of that of small bodies generally. Bodies that have never been in a molten state might well have interstices between their particles which would be filled up in a molten condition.

Annuaire de l'Observatoire Royal de Belgique, 1924.—Publication of this well-known Annual was suspended during the War, but the present volume is a very successful effort to make up for the lost years. It begins with the ordinary calendar, astronomical, and tidal information for the year, all given in great detail, and then follows a full summary of astronomical progress since 1915; thus Wolfer's monthly sunspot numbers are given for six years; they show a clearly defined maximum in the middle of 1917. The stages in the dissolution of the great eclipse prominence of May 1919 are fully illustrated. A full account is also given of work on the polarity of sunspots, the magnetic field of the sun, and Einstein's theory, and the discussions to which it has led. There are, in addition, tables and detailed accounts of planetary, cometary, and stellar work during the six years dealt with. The volume is thus very useful as an index and guide to contemporary astronomical progress.

Research Items.

DATING THE HEBREW EXODUS FROM EGYPT.—In the April issue of the *Fortnightly Review* Dr. H. R. Hall attempts to estimate the value of the recent startling discoveries in Egypt, but he defers a full appreciation until next winter's work and an examination, which must be protracted, of the objects in the tomb. More definite conclusions are reached by Mr. Arthur Weigall in the *Empire Review* for May. He identifies the 80,000 "unclean" people, whom Manetho says that one of the Pharaohs deported to the east bank of the Nile, with the heretic Aton-worshippers. Thus arises the question of the Hebrew exodus, which tradition has associated with Rameses the Great, the best known of the Pharaohs. But it more probably occurred in the reign of Tutankhamen, 1358–1350 B.C., and this is corroborated by the Karnak inscription, which states that he was employing Asiatic slaves in his great work of rebuilding the temples ruined by Akhnaton, a result which raises the question of the connexion of Hebrew monotheism with the earliest known monotheism of the Egyptians. It is also interesting to note that Tutankhamen in the same inscription speaks of Egypt as being plague-ridden in his reign.

FLINTS IN MALTA.—In the May issue of *Man* Miss M. A. Murray describes the results of excavations at a group of megalithic ruins of Borg en Nadur, overlooking the little harbour of Fort St. George, which forms part of the great bay of Marsa Scirocco on the south-east of Malta. During the excavation of this site last summer about thirty stone implements were found under the pavement west of the dolmen. They include three specimens the appearance of which suggests that they are part of an apparatus for producing fire. Throughout Malta flints of this kind, generally recognisable by the fact that they contain no cutting edges and have a characteristic semi-circular hollow on one side, where the stone had been struck by the steel, are often found. Until the last fifty years or so, flint was imported into Malta from Sicily for fire-producing purposes, and during the War, when there was a shortage of matches, these flints came into use again, and were sought for in the fields where they had been thrown away. The flints found at Borg en Nadur may have formed part of such a consignment.

CIVILISATION AND PRIMITIVE PEOPLES.—Mr. H. Balfour in his presidential address delivered before the Folklore Society, published in *Folk-Lore*, vol. xxxiv. No. 1, discusses the results of the expedition to the Naga Hills, Assam, whence he has returned with a rich store of material for the Pitt-Rivers Museum. In his address, he discusses the danger of interfering with the institutions and customs of primitive tribes. "To root up old-established indigenous trees and plant in their place alien substitutes to which the soil is unsuited is a useless and unproductive work; and equally futile and unprofitable is it to abolish ruthlessly old-established beliefs and practices, and to endeavour to replace them with imported doctrines and customs, which have developed under totally different conditions, and which merely puzzle the natives without enlightening them." In the districts most exposed to foreign influence—that of Christian missionaries and that of the Bengalis—he noticed "marked evidence of a comparative lack of that virility, alertness, and zest which I had observed in the more eastern districts, and the partial atrophy of these qualities is certainly correlated with the loosening of the grip upon traditional customs and ritual. I firmly believe that the comparative inertness is mainly the outcome of change of habit consequent upon contact with alien peoples and alien cultures." These conclusions, arrived at by a singularly competent and sympathetic observer, demand the attention of all British officers placed in control of primitive races.

RED SEA-WATER DUE TO A DINOFLAGELLATE.—Another instance of discoloration of the sea by a Dinoflagellate is recorded by K. Hirasaka (*Annot. Zool. Japon.*, x., Art. 15, Dec. 1922). In December 1921 discoloration of the water in Gokasho Bay, Japan, was observed and was found to increase until by January 10, 1922, the entire bay presented "a deep bloody or a chocolate colour," which continued to the end of February, when it began to diminish, and by the middle of March had disappeared. The depth to which the discoloration extended was from three or four to six feet. The organism, a new species of Dinoflagellate of the genus Gymnodinium, seemed to migrate diurnally according to the temperature and intensity of light, the colour of the water being deepest in the afternoon. The author states that the discoloured sea water was highly luminous.

JAPANESE MARINE TRICLADS.—T. Kabouraki (Journ. Coll. Sci. Imp. Univ. Tokyo, xliv., Art. 3, Sept. 1922) gives an account of the anatomy of the three marine triclads known from Japan, namely, *Procerodes lactea*, *Stummeria trigonocephala*, and *Ectoplana limuli*. The former two live beneath stones, but the last named occurs abundantly on the cephalothoracic appendages and on the gill-books of *Limulus longispina*, is 4 to 6 mm. long and about 1 mm. broad, and usually milky white. The author concludes a brief discussion of the integument with his opinion that the turbellarian epidermis is homologous with the cuticle of the trematodes, and he regards the rhabdites as the equivalent of gland secretions, and as being of use to the worm in securing food as well as in offence and defence. He states that all three worms are very sensitive and they usually move to a dark place, and that even on a slight shock they stop instantly, contract, and remain immovable. Ectoplana is not a parasite, and causes no injury to the Limulus on which it occurs; it lives on the fragments of food left over by the Limulus, and hence is a commensal. It lays its eggs on the gill lamellæ. Appended is a note on the classification of the marine triclads and a key to the genera.

SOME ANTARCTIC CRUSTACEA.—The latest in the series of reports on the British Antarctic (*Terra Nova*) Expedition (Zoology, vol. iii. No. 10), published by the British Museum (Natural History), is by Prof. W. M. Tattersall and deals with the Crustacea of the order Mysidacea. The usual but indefensible grouping of these with the very different Euphausiacea under the name "Schizopoda" is here abandoned. In addition to the purely antarctic collections, the report deals with a large amount of material obtained during the winter cruises of the *Terra Nova* off the north of New Zealand. A review is given of all the known antarctic Mysidacea, and it is pointed out that they were all taken in deep water and form part of the cold water fauna which is found in the depths of all the oceans. The littoral antarctic species, if any exist, are still unknown. So far as the evidence goes, however, the distribution of the group supports Regan's delimitation of the Antarctic Zone. From New Zealand only three adequately described species of Mysidacea have hitherto been known. In this report the number is increased to fifteen, of which eight are described for the first time. Seven of the new species belong to the genus Tenagomysis, to which only two species had previously been referred. This genus is only known from New Zealand and the

Auckland Islands. The *Terra Nova* also collected a few species in the Atlantic, of which one, obtained off Rio de Janeiro, is especially interesting. It is referred to Dana's long-forgotten genus Promysis, with which Hansen's Uromysis is identified. The other two species of the genus are from the East Indian Archipelago, but the seeming discontinuity in the distribution may be obliterated by further research.

Botany at the Carnegie Research Stations.—The Carnegie Institution maintains two special research laboratories, at Tucson, Arizona, and Carmel, California, where desert and coastal vegetation are readily studied, but in addition, as Year Book No. 21 of the Carnegie Institution of Washington shows, its workers are far more widely spread. In the Department of Botanical Research, under the general direction of Dr. W. T. MacDougal, fundamental researches by H. A. Spoehr and his collaborators are being carried out upon photosynthesis and respiration. Some of this work has been published in full since the issue of the Year Book, as Carnegie Publication No. 325 (Studies in Plant Respiration and Photosynthesis, Washington, February 1923). Space only permits the mention of the following points from the brief summary in the Year Book, which is packed with interesting facts and views: lævulose is not found to be so readily used in respiration as glucose: an explanation of the increased diastatic activity of leaves kept in darkness is found in the increased production of amino-acids and their effect on diastatic action: respiration and photosynthesis are found to be strikingly inter-dependent and affected alike by changes in various external factors. Chemists as well as botanists will be interested in the methods developed by Dr. F. A. Cajaro for the quantitative estimation of small amounts of the separate sugars in mixtures of glucose, lævulose, sucrose, and maltose; these methods depend upon oxidation under standardised conditions and upon estimation of cupric reducing power. Dr. W. T. MacDougal's work upon permeability leads him to consider lipins and pentosans as important constituents of the plasma membrane; the effect of different kations upon permeability is being considered from this point of view, with many new experiments in progress to elucidate the puzzling phenomena of "antagonism." Many ecological investigations by Forrest Shreve are in progress, and W. Cannon has been studying the evaporating power of the air and of the plant in South Africa. Dr. F. E. Clements directs another group of researches. One notes studies of the water cycle of the plant, of vascular conductivity by Prof. J. B. Farmer's method, and the effect of sap movement upon bud development; this work has supplied no evidence for the once very popular assumption of an inhibiting factor released by actively growing buds.

New Fossil Turtle from Arizona.—Attention was recently directed (Nature, March 31, pp. 443-4) to the remarkable assemblage of vertebrate remains collected by Dr. J. W. Gidley in the Pliocene of Arizona, and to the promise of further information concerning the reptiles. C. W. Gilmore now supplies the description and numerous figures of a new fossil turtle from that district (Proc. U.S. Nat. Mus., vol. lxii., art. 5). *Kinosternon arizonense*, n.sp., the first extinct representative of the genus in America, is most nearly allied to the recent *K. flavescens* (Agassiz), which, with one other of the eight living American examples, is said to range into Arizona.

Meteorological Stations in High Latitudes.—The U.S. *Monthly Weather Review* for January contains an article by Sir Frederick Stupart, director of the Meteorological Service of Canada, on the above subject, which formed a presidential address, given before the American Meteorological Society at Boston, Mass., on December 30, 1922. The author, while acknowledging the furthering of meteorology when aiding commerce and finance, suggests that difficulties arise in granting funds for the equipment of an out-of-the-way Arctic station, although the latter may materially improve weather forecasting. In the early days of forecasting in Canada and the United States the weather services were handicapped by the lack of data from the North. This great want has more recently led to the establishment of stations in Iceland and Spitsbergen, and still later in Jan Mayen Island. The Alaskan stations are said to have been of the greatest use for forecasters in the United States and Canada. Reference is made to the influence of radiation during the winter months over the land areas of Siberia and northern America, which leads to the formation of high pressure and intense cold, while in some winters the low pressure of the North Pacific tends greatly to modify the pressure distribution in northern America, and in these cases mild winters may be looked for. In some winters the Siberian high pressures extend across as one system into America, and great cold waves sweep southwards. The study of the dominant anticyclonic and cyclonic conditions seem so full of promise that the author emphasises augmenting the number of stations in the Arctic zone. The study of the conditions in high latitudes would help also to a better understanding of the severe storms along the Atlantic steamship routes.

History of an Oil-Well.—Probably few individual oil-wells are of sufficient technical, apart from commercial, importance to warrant their being the subjects of communications to learned societies. Yet the paper read by Mr. A. E. Chambers to the Institution of Petroleum Technologists on April 10, dealing with one of the earliest, largest, and most celebrated wells in Mexico, namely, Potrero No. 4, constituted not only an interesting but also a valuable dissertation on a matter of more than mere local importance. Mexico, in regard to oil-production, is a country of surprises; its wells, even if not always big producers, at least provide plenty of variety both in behaviour and in the problems they present during development and production. Not the least of these problems is that connected with salt-water, a particularly formidable one at the present time. The well under discussion was no exception. Situated in Vera Cruz State, 50 kilometres N.W. of Tuxpam, it was brought in as a gusher at the end of 1910 and not got under proper control till March 1911. Thenceforward it produced oil until 1914 when, after developing extensive seepage areas in its vicinity, it caught fire, owing to lightning, in August of that year. This fire was not finally extinguished until early in April of the following year, when the well started producing again and continued till the end of 1918. Emulsification set in in 1919, and this closed the history of the well. During this chequered career it produced no less than one hundred million barrels of oil, and the technical difficulties which had to be overcome in connexion with its control were of no mean magnitude, considering the fact that drilling methods in those days were somewhat crude compared with present-day practice. The oil originally produced was of an asphaltic base, s.g. 0·931 at 60° F. The pressure (closed well) amounted to 825 lbs. per square inch. Its ultimate appearance in the storage tanks was as an emulsion having a s.g. of 0·979 and containing 54 per cent. of salt water. In this departure it unfortunately foreshadowed the behaviour of many more recent wells in Mexico, a feature the significance of which has latterly been so widely debated.

The Rockefeller Foundation's Gift of the Institute of Anatomy to University College, London.

THE erection of the new building for the Department of Anatomy, which also provides an extension for the Department of Physiology of University College, London, completes the scheme for the development of the building for the Faculty of Medical Sciences which had long been contemplated. The proposal was first definitely formulated in 1907 on the initiative of Prof. E. H. Starling, who took an active part in collecting the money for the erection in 1908 of the Department of Physiology, which was opened in 1909 by the Right Hon. R. B. (now Viscount) Haldane. The generosity of the late Mr. Andrew Carnegie made it possible in 1912 to add to the eastern end of the Institute of Physiology a building to house the Department of Pharmacology, which was formally opened on December 4 of that year by Sir Thomas Barlow, president of the Royal College of Physicians. When the War seemed to have destroyed all hope of any immediate completion of the original scheme by the addition at the western end of a building to house the Department of Anatomy, the Rockefeller Foundation became aware of the difficulty and offered to provide the means for completing a scheme which harmonised with its ideals in medical education. It was eager to give some striking expression of American friendship to the British Empire, and was also anxious to enlist the help of the British medical schools in its great schemes for "the promotion of the well-being of mankind throughout the world."

The Rockefeller Foundation has long recognised how much the well-being of mankind is dependent on the advancement of medical knowledge and on the training of men who can spread the benefits of this knowledge among their fellow creatures, and to this end has spent large sums, not only in the United States, but also in South America and China, for the establishment of medical schools in which research and the education of medical men should go hand in hand.

At the end of 1919 two representatives of the Rockefeller Foundation, Dr. Wickliffe Rose, general director of the International Health Board, and Dr. Richard M. Pearce, adviser in medical education to the Foundation, came to Europe to inquire into the methods, problems, and needs of medical education in this country and on the Continent. While in London they were informed of the new developments in medical education which had taken place there under the stimulus and with the financial help of the Board of Education. This development consisted in the establishment at several of the medical schools of clinical "units" in medicine, surgery, and gynæcology, which were staffed by whole-time teachers, so that these subjects could be treated like the cognate scientific subjects, the professor being able to devote all his working hours to teaching and research without being obliged to undertake private practice. This innovation especially excited the interest of the representatives of the Rockefeller Foundation, since the Foundation had already played a large part in the encouragement and endowment of this system of medical education in America.

FIG. 1.—Institute of Anatomy, University College, London.

The essential feature of the system is the close co-operation between all departments concerned in the medical curriculum. It is recognised that medicine and surgery cannot advance except in association with other departments hitherto regarded as more purely scientific—in particular, pathology, anatomy, physiology, and bio-chemistry.

At University College, Drs. Rose and Pearce found a hospital which had been founded for the express purpose of medical education. They found also active and well-equipped institutes for the study of some branches of medical science and definite plans for the completion of the whole scheme of medical education as soon as the necessary funds were available. Thus in the College there was fair provision for physiology, pharmacology, and bio-chemistry, but no proper facilities for teaching and research in anatomy, embryology, and histology. In the clinical subjects of the curriculum, while medicine and surgery were represented by the whole-time professors at University College Hospital, there was a lack of beds devoted entirely to the work of these units, and the accommodation for research into the chemistry of disease was deficient; there was no provision at all for scientific investigation and teaching in midwifery and the diseases of women. Plans for remedying these gaps in the scheme were ready; the only thing necessary for the realisation of the scheme was money. The representatives of the Rockefeller Foundation were impressed with the possibilities of the scheme for the creation of a complete and scientifically equipped School of Medicine which had been worked out by the College and Hospital Medical School, and reported favourably thereon to the Rockefeller Foundation. As a result of their report the Foundation decided not only to place at the disposal of University College sufficient funds for the realisation of the scheme formulated in 1907, but also to provide the additional endowment required to maintain the increase in staff which the scheme entailed. At the same time the Rockefeller Foundation made an even larger gift to University College Hospital Medical School for the promotion of the work of the clinical units.

The new building provides adequate accommodation and equipment for the study of anatomy and the prosecution of research. It also gives tangible expression to a wider conception of the scope of anatomy, which will now include histology, embryology, experimental embryology and neurology, the study of animal movements by cinematography, radiology, and anthropology, and in fact the study of man in the widest interpretation of the term, his evolution, structure, and the history of his movements.

The completion of the building for the three closely allied sciences of anatomy, physiology, and pharmacology represents far more than the mere provision of accommodation and equipment for teaching and research in anatomy and of an extension of the physiological laboratories. It is the expression of a far-reaching scheme of cöoperation, involving on one hand the closer correlation of teaching and research in anatomy, physiology, and pharmacology, and on the other the linking up of the work done in the Faculty of Medical Sciences in the College with that done in the Medical School of University College Hospital. Moreover, the new building is a permanent symbol of the bond of sympathy that unites British medicine in a common aim with the medical schools of America and with the Rockefeller Foundation.

By housing the departments of anatomy (with histology, embryology, and anthropology), physiology, bio-chemistry, and pharmacology in one Institute with a library and staff-room in common, the way has been prepared for a closer co-operation between teaching and research in these subjects than has been possible hitherto. The new anatomy building is linked by means of a tunnel passing under Gower Street with the Medical School of University College Hospital, and it is anticipated that this physical avenue of communication will facilitate a freer intercourse between the workers upon the two sides of Gower Street, to their mutual benefit.

The extension of the department of physiology affords ampler provision for teaching and research in experimental physiology, and makes it possible for Prof. Starling to remain in the College as Foulerton research professor of the Royal Society, even though he relinquishes the Jodrell chair of physiology and the directorship of the Institute which he created.

Of the five floors in the building, the lowest is devoted mainly to practical work in anatomy, that is, dissecting and radiography; the next floor to teaching accommodation and museums, as well as to anthropological investigation; the third and fourth to research in anatomy, histology, and embryology; and the top floor to teaching in microscopic anatomy. A basement contains the heating chambers, coke cellars, tank, and specimen rooms.

The building, designed by Prof. F. M. Simpson, faces Gower Street, and has a frontage of 154 feet exclusive of the end gateway, which gives access to the south quadrangle. At the back it joins the physiology building. On a level with the students' entrance from the south quadrangle are the large top-lighted dissecting room, with prosectorium and annexe, the X-ray rooms, injection room, workshop, and cloakrooms for men and women students.

The rooms for the X-ray examination of the living subject and for the study of X-ray plates are near at hand, so that the students may be able, when dissecting any region of the body, to correlate the X-ray appearance with what they see and handle in their dissections. The X-ray equipment, the chief features of which are mentioned later in this account, has been superintended by Major Charles E. S. Phillips, who has spared no trouble in devising the best possible means for teaching anatomy by radiography.

The main entrance from Gower Street is at the ground-floor level, and leads by an oak-panelled vestibule to the hall and central staircase which serves all floors. On the ground-floor are the museum and preparation room, lecture theatre, fitted with the latest Zeiss epidiascope, demonstration theatre, and rooms set apart for teaching and research in anthropology.

On the first floor are the medical sciences library and periodical room, oak-panelled, with a book-store adjoining the room for the lecturer in the history of medicine, the private room and laboratory for the professor of anatomy, the dean's office, and a series of research rooms, including a laboratory for comparative neurology. In the latter will be housed a collection of neurological preparations, the nucleus of which consists of sections made by the late Dr. Page May and Sir Victor Horsley, and others presented by the Central Institute for Brain Research in Amsterdam at the instance of Dr. Ariens Kappers.

On the second floor are located the research laboratories for the professor of embryology, and a lecture room seated for about ninety students, with an apparatus for the projection of histological preparations. Also on this floor are situated a small chemical laboratory, a laboratory for research in experimental embryology, and the micro-photographic and dark rooms, while two rooms provide accommodation for collections of preserved material and microscopical preparations. Prof. J. P. Hill has made a very rich collection of mammalian embryos, and aims at making as complete a series as possible of human embryos. For research in comparative embryology the Institute offers unique opportunities.

The main students' laboratory for microscopical anatomy is situated on the third floor. It affords accommodation for about ninety students. Adjacent to the laboratory are the preparation room, the research laboratory for the assistant in histology, modelling and aquarium rooms. Accommodation for keeping live animals is also provided on the third floor, and provision has been made of facilities for experimental embryology and for the study of degeneration effects in the nervous system.

In a room set aside for the cinematographic study of animal movements, there is to be installed a cinematographic apparatus (so-called ultra-cinema) designed by M. Nogues, of the Marey Institute of Paris, by means of which it is possible to take up to 300 photographs per second of moving objects. This is perhaps the best method of analysis of reflex movements and muscular adjustments, such as those of posture. In presentation such movements can be made to occupy ten to fifteen times their normal time. Heavy electric leads are carried to this room so that brilliant illumination by arc or mercury lamps may be employed; while the flat roof is admirably adapted to the purpose of cinematography in summer.

The X-ray department is equipped with the latest type of apparatus for radiography in all its medical branches. Facilities are provided for rapid work as well as for the study of movement and anatomical structure as revealed by the latest X-ray technique of the day. The power unit consists of a 10 kw. transformer X-ray set, which supplies energy to the X-ray tubes either when working from below or above the operating tables, or when used for fluoroscopy; and arrangements are made whereby the portable trolley control may be connected either at a position near the tables or at a separate wall plug adjacent to the fluorescent screening-stand at the far end of the room.

One of the X-ray operating tables is fitted with automatically moving plate carriers beneath the top, which itself is hinged so as to render the tube box and diaphragm mechanisms readily accessible. The other operating table is fitted with a Potter-Bucky grid, and is the second table of the kind that has come to this country from the United States. As well as a large screening apparatus, there is a heavy type tube stand for general use, and a number of minor accessories. Apparatus for the special radiography of the head is also provided.

The high-tension overhead leads are made of nickel-plated tubing of sufficient diameter to reduce the formation of corona to a minimum, and a high-tension switch actuated by strings serves to connect the transformer terminals with the set of leads required for each apparatus as desired. The protection of all engaged in the work of the department has been carefully provided for, and stray radiation prevented from entering adjacent rooms by a covering of lead six feet high upon the walls. The lead sheet carefully lapped at the joints is hidden beneath stout boarding which serves to absorb the soft component of any secondary radiation which may be produced from the lead by stray radiation. The floor is covered with rubber. An adjoining dark room and large viewing room, together with a plate store, completes the department.

The installation has been carried out by Messrs. Watson and Sons (Electro-Medical), Ltd., London, who not only did the work of equipping the X-ray rooms, but also gave Major Phillips the benefit of their experience in designing X-ray apparatus.

The Rockefeller Gift has also rendered it possible to effect certain much-needed alterations and extensions in the departments of bio-chemistry, pharmacology, and physiology. On the ground floor the general bio-chemical laboratory receives an extension behind the anatomy theatre, providing additional places for advanced students in bio-chemistry. The bio-chemical research laboratories are also enlarged by taking in the whole ground floor of the pharmacology building, providing in this way two additional research laboratories and a private room for the professor of bio-chemistry. In pharmacology further accommodation for research is provided by dividing the present pharmacology lecture theatre into two laboratories. The pharmacology lectures will be delivered in future in the physiology theatre. This department receives also two extra laboratories on the second floor of the physiology building in compensation for the ground-floor laboratories surrendered to bio-chemistry.

A large part of the first, second, and third floors of the building connecting the present Institute of Physiology with the Institute of Anatomy is used for increasing the laboratory accommodation for research in physiology.

Concerning the architecture, the Gower Street front is entirely in Portland stone; the back portions in Arlesey brick with stone dressings to match the existing physiology and pharmacology buildings. The floor of the dissecting room, annexe, and prosectorium is of white mosaic, and the walls of white glazed brick. On the corridors is a strip three feet wide of quarter-inch cork carpet, with margins of white terrazzo in the basement, and of oak or pitch pine on other floors. A dado of terrazzo with green panels and white frames runs up the whole of the staircase and along the sides of the principal corridors. The floors of most of the working-rooms are cement, covered with linoleum. The steps and landing of the staircase are oak on concrete, with iron balustrade; and the museum, library, periodical room, and entrance vestibule from Gower Street have oak floors.

A passenger lift runs from the basement to the top of the building, serving all floors, and hand-power lifts are provided from the injection room down to the tank room, and from the tank room up to the annexe of the dissecting room. The whole of the building is steel frame construction.

It is of interest that the house in which Charles Darwin began the compilation of the notebooks for his "Origin of Species" is only four doors away from the new building, and it is hoped that eventually upon this site will be built a Darwin Institute of Anthropology and Biology which will worthily commemorate the greatest of English biologists.

Applications of Physics to the Ceramic Industries.

THE ceramic industries formed the subject of the fourth of the series of lectures on "Physics in Industry" which are being given under the auspices of the Institute of Physics, and the lecture was given by Dr. J. W. Mellor on May 9 at the Institution of Electrical Engineers. Sir J. J. Thomson, president of the Institute, was in the chair. Eliminating such applications of physics as are common to other industries, Dr. Mellor dwelt only on specific applications of sound, light, heat, electricity and magnetism, and mechanical science in the manufacture of pottery and glassware. He made it clear that, while in these industries much has been done to utilise physical principles and knowledge, there remains a very wide field in which present practice is crude and unscientific, and where all the help which the physicist can give is needed to replace obsolete, rule-of-thumb procedure by methods which are exact, efficient, and trustworthy.

Up-to-date manufacturers are following with keen interest the various attempts now being made to produce a mode of illumination to imitate natural light, for the matching of coloured glazes under artificial light is usually difficult and sometimes impossible. In one example quoted where the colour of a nickel-blue tile had to be imitated, it appeared that the copy was green in gas-light and blue in daylight. Many chrome colours which appear green in daylight are crimson, pink, or purple in gas or electric light. During the War, blue lamp bulbs were needed, but they had to appear blue when illuminated by the glow of a red filament. Had absorption spectra of colouring oxides been available, much money and labour spent in fruitless experiments would have been saved.

It was due to the measurements made by physicists on the indices of refraction of small crystals that the two crystalline forms of silica were detected, and the knowledge of the transformations has placed the whole manufacture of silica bricks on a sound scientific foundation. Recent work on X-ray spectra promises shortly to do for the fire-brick manufacturer what a knowledge of indices of refraction has done for the silica-brick manufacture.

Applications of magnetism have been but partially explored. One problem that has been almost solved is the separation of particles of metallic iron from clay slip. A system of electromagnets made by the Rapid Magnetting Company is ingeniously arranged so that if the magnets cease to work, the dirty slip will not pass into the purified slip. Success, however, has not yet been attained in removing particles of cupriferous pyrites from fire-clays.

The physicist-engineer specialising in heat problems has an illimitable field for his knowledge and skill. Dr. Mellor estimates that in firing biscuit-ware only 2 per cent. of the fuel is usefully employed, although the processes of brick-firing are much more efficient. Another series of problems awaiting solution is connected with the drying of clays and clay-ware, where serious losses occur owing to the development of drying cracks unless an inordinately long time is allowed. It appears that little progress is possible until the physicist has worked out the distribution of water in the interior of a drying mass of clay, and he will obviously have to take into account the relation between the surface of the drying solid and the humidity of the surrounding atmosphere.

Dr. Mellor referred to the studies of the thermal strains in "ideal" kilns upon which Prof. Lees is engaged; later it is hoped to apply these results to actual kilns, and he expressed the wish that Prof. Lees would pass on to consider contraction strains set up during the uneven drying and firing of special shapes. The results of such an investigation will not only explain why some shapes fracture and others do not, but they will also indicate to the designer of chemical and sanitary apparatus, furnaces and coke ovens, the shapes to be avoided on account of the narrow margin of safety in manufacture and use. Numerous interesting problems relating to the grain of clay await solution. It appears, for example, that the particles can be oriented differently so that the drying and firing contractions are different in different directions. Then there is the plasticity of clays to be studied, and, indeed, the whole problem of the hydrostatics and dynamics of liquids with an indefinitely large number of particles in suspension. Akin to this are the colloidal problems—now ever with us—but for some unaccountable reason, which he ascribed to chance, Dr. Mellor preferred to label this branch of his subject as chemistry and not physics.

Electricity is usefully employed in high temperature testing work, and also for crucible furnaces, but a satisfactory electric furnace for firing pottery has not yet been evolved, and in any case the cost of power is here a paramount consideration. Dr. Mellor indicated the novel problems connected with the effects of convection currents of hot air that would have to be solved if electrically-heated furnaces or kilns came into use. The conditions are quite different from those in gas- or coal-fired furnaces.

In conclusion Dr. Mellor referred to the physical problems connected with the glazing of pottery. The governing condition here is that the thermal expansion of glaze and body should be the same. Data so far obtained have not taken sufficiently into consideration the complex adjustment of glaze and body; for example, there is the tensile strength of the glaze to be considered, as well as the rate at which the glaze attacks the body and the effect of solution of the body in the glaze and its coefficient of expansion.

The lecturer's statement of the case for much closer co-operation between the ceramist and the physicist than has hitherto obtained was forcible and convincing.

The Meteorology of Scott's Last Journey.

THE Halley lecture for 1923 was delivered at Oxford on May 17 by Dr. G. C. Simpson, the director of the Meteorological Office, who took for the subject of his lecture "The Meteorology of Scott's Last March."

The polar party left Hut Point on November 3, 1911, and first traversed the Barrier, where it experienced a remarkable daily variation of temperature. In spite of the fact that the sun was continually above the horizon, varying only from 10° above the southern horizon at midnight to about 30° above the northern horizon at mid-day, the regular daily temperature variation on cloudless days reached the enormous value of 20° F. This necessitated travelling by night and resting by day. Several serious blizzards were encountered.

It is now clear that the Barrier blizzard is extremely local, being confined to the western half of the Barrier. During ten months with simultaneous observation at Framheim—Amundsen's winter quarters in the east—and at Cape Evans in the west, winds of more than thirty miles an hour occurred during 30 per cent. of the time at Cape Evans, and only 2 per cent. at Framheim. This is due to the fact that when the pressure is higher over the Barrier than over the Ross Sea the air tends to flow from the Barrier northwards to the sea, but is deflected to the west by the earth's rotation. The edge of the western plateau extends like a wall 8000 feet high for more than a thousand miles along the west of the Barrier and of the Ross Sea. This prevents the air moving freely to the west, with the consequence that the air-flow from the whole of the Barrier is concentrated in the west, and moves northward with high velocity, giving rise to the familiar blizzard.

When the polar party was at the foot of the Beardmore Glacier it experienced a serious blizzard which gave the greatest snowfall ever recorded in high southern latitudes. The cause of this bad weather was the formation of a deep depression over the Ross Sea, which produced a great flow of warm air from the Ross Sea to the south of the Barrier.

On reaching the plateau, low temperatures were experienced. During the five weeks that Scott and his party were on the plateau the mean temperature was −19° F., with a maximum of −3° F., and a minimum of −30° F. As they descended from the plateau, the temperature at first rose in the normal way, but while the party was still on the glacier a great change in the weather occurred. From this date—February 11—until March 20, extremely abnormal conditions were experienced. There was little or no wind, the temperature fell rapidly to the neighbourhood of −40° F., and ice crystals were deposited from the cold air upon the surface which acted like sand on the runners of the sledge. These thirty-nine days were the deciding factor in the fate of the party. "We all associate Scott's disaster with the terrible Barrier blizzards, and in the end a blizzard did prove fatal, but at this time a blizzard, a succession of blizzards would have been the salvation of them all."

The temperatures experienced by Scott on the south of the Barrier were between 10° and 20° F. below the normal for the time of year. In these conditions the returning party struggled on, becoming weaker and more dispirited every day. On March 16, Oates made his heroic sacrifice in order to give his companions a chance of safety. Then at last—on March 20—the blizzard did come. But it came too late, and continued too long. When it commenced the party had food and fuel enough to reach the depôt at One Ton Camp only eleven miles away, but as the blizzard continued to rage day after day the fuel was used and food consumed.

"There is little doubt that this blizzard removed the cold stagnant air and the conditions over the Barrier became much better for sledge travelling. But it was too late; by the time the blizzard ceased, every man of the polar party had passed away, and in doing so had left a record and created a tradition of which every Englishman is, and always will be, proud."

Movements of the Earth's Crust.

PROF. HANS STILLE of Göttingen has issued, under the title of "Die Schrumpfung der Erde" (Berlin: Borntraeger; price 1s. 8*d*.), a "Festrede" given to his university, in which he aptly reviews old and new theories as to the effect of the earth's contraction on the features of the surface. He holds that the conception of a general contraction towards the interior is well founded; but there are many ways in which it may become manifest by wrinklings of the outer crust. He finds that what G. K. Gilbert styled "epeirogenic" (now written "epirogenetic") movements, the sinking or uplifting of the crust over wide areas, are more in need of explanation than the folding of mountain-ranges, which has been differentiated as "orogenetic." The rhythmic pulsation, however, that causes mountain-building to occur simultaneously and even catastrophically over the whole earth presents an unsolved problem. Prof. J. Joly has suggested in a recent lecture (NATURE, May 5, p. 603) that the heat generated by radioactive minerals accumulates at intervals of some millions of years and so causes a catastrophe. Cooling of the uplifted layers by their being brought into proximity with the overlying oceans starts a new era of quiescence.

We may ask, with an equal sense of adventurous speculation, if the pulsation may not be still more primordial and connected with the beating of the last heart of an undivided universe. Prof. Stille keeps us from any such rash imagining; but he points out that the facts of orogenetic episodes are opposed to the uniformitarian doctrines of von Hoff and Lyell, which are applicable only to the intervals between great crustal foldings. Epirogenetic movements occur during these intervals, and characterise the epoch in which we live. On the whole, the earth loses heat by radiation faster than it acquires it by contraction; in this remark we recognise an adherence to views that some geologists regard as quite old-fashioned.

Prof. Stille's ten pages of "Anmerkungen" are almost as readable as the text of the pamphlet, since he adds to a wide range of references critical observations on many of the opinions cited. He remarks that Wegener's epochs of continental drift do not coincide with those in which orogenetic movements actually occurred. In these notes the author writes, as others have lately done, "Thetys" for Suess's well-chosen name "Tēthys," possibly by a confusion of Thetis, daughter of Nereus, with the wife of Okeanos, lord of the great outer seas. A. Sander's review of diastrophism and earth-history (*Geol. Rundschau*, vol. 13, p. 217, November 1922) should be read in connexion with Stille's memoir. Its author concludes similarly in favour of the contraction-theory, but regards epirogenetic movements as not necessarily very slow. Like Stille, he points out that we are moving a little way back to the views of the catastrophists.

The Steel Works of Hadfields, Ltd.

VISIT OF H.R.H. THE PRINCE OF WALES.

MUCH scientific interest is attached to the visit paid by H.R.H. The Prince of Wales to the works of Messrs. Hadfields at Sheffield, on May 29, when he started up the new 28-in. rolling mill, which has been installed at the firm's East Hecla works. This marks an important phase in the transition from war to peace production of this great establishment, the head of which is Sir Robert Hadfield, whose discovery of manganese steel in 1882 may justly be said to have originated the development of modern alloy steels. The new reversing 28-in. blooming and finishing mill is unique in several respects, having been designed to deal satisfactorily with steels of special nature, and in particular it is equipped with all the necessary improvements and labour-saving devices to obtain the most economical production. The mill motor has a maximum rating of 11,600 horse-power, and is supplied with current from a fly-wheel motor generator set, the cast-steel fly-wheel of which is 11 ft. 6 in. in diameter and 30 tons in weight. The mill motor is capable of being reversed from full speed in one direction to full speed in the other direction in three or four seconds. The rolls are 28 in. in diameter, and from 6 ft. 6 in. to 7 ft. long, being manufactured by Messrs. Hadfields of their special forged steel, and the mill is capable of rolling 15-in. square ingots, weighing 25 cwt., and reducing them to 2½-in. square billets at one heat. It will also be used for rolling special alloy steels, and rails up to their heaviest sections and 55 ft. long in manganese steel. The rolling plant accessories are all of the most modern type, including the necessary appliances for special treatment of manganese steel. The whole works show that British engineering is quite capable of designing, manufacturing, and running rolling mills and other steel plants second to none in the world. In addition to the 28-in. mill, the rolling plant also includes 11-in. and 14-in. mills for rolling round and square bars of alloy and other special steels.

An interesting feature of the Prince of Wales's visit was that he cast his own portrait on a plaque or medallion 22 in. in diameter of Hadfield manganese steel. The medallion was designed by Mr. S. Nicholson Babb, who has several sculptures in this year's exhibition of the Royal Academy. In the course of his tour the Prince was shown a number of exhibits illustrating the scientific work of the Hadfield Research Department. These included a complete equipment for all branches of the mechanical testing of iron and steel, and the latest apparatus in use for iron, steel, and fuel analysis, and oil testing. The scientific instruments used in the exact control of the heat treatment of special steels were also shown, and it is of interest to note that at one time no less than 15,000 pyrometer readings per week were taken in the works in the various steel making and treating departments. A demonstration was also given of the effect of low temperature on the properties of steel. Other interesting research exhibits included furnaces and methods of testing refractories; also apparatus for testing the electrical and magnetic properties of steel and its micrographic structure. A visit was paid to the firm's experimental proof butt in which are developed the large calibre projectiles for which Messrs. Hadfields are notable. Exhibits of historical interest included old metallurgical books from the valuable collection of Sir Robert Hadfield, and a number of ancient iron specimens from Egypt, India, etc. The Prince was also shown the original small transformer made in 1903 of the low hysteresis steel invented by Sir Robert Hadfield, which material, on the authority of Dr. T. D. Yensen, has since saved the world a sum equal to the cost of the Panama Canal.

Technology and Schools.

THE Association of Teachers in Technical Institutions held its annual conference on May 21 at Leicester. The new president, Mr. W. R. Bower, of Huddersfield Technical College, delivered an address on the position of technical education, in the course of which, after quoting with approval the views on this subject expressed in the Board of Education's Draft Regulations of 1917 for Continuation, Technical, and Art Courses, he described the aim of technical teachers as "to blend education with the life and work of the people." The special characteristic of their method is to bring education by means of part-time courses, not only to the homes of the people, but also into their workshops and offices. Comparing their work with university work, he said, "Our principal function is to develop character and mentality by means of higher education amongst the many: the university should be more concerned with the individual and his fitness to become a specialist of the first order; their successes so far have been in letters, mathematics, and science rather than in technology, even if physicians and lawyers are included amongst the technologists." The principal problem of technical education is "the satisfaction of the ambition of the young adult as a scholar, a craftsman, and a citizen."

Among other matters touched on in the address were: the increase since 1859 of the number of students in technical institutions from 500 to nearly a million; and science courses in secondary schools. "Dabbling in technology" is strongly condemned, as is the planning of school science courses for direct connexion with possible university courses or advanced professional study. On the other hand, close correlation with the work of the local technical college is commended. Mr. Bower also referred to the imminent prospect of publication by the Burnham Committee of a list of technical qualifications of teachers to be deemed equal to degrees—a prospect regarded with mingled feelings by the teachers, who foresee excessive stress being laid on paper qualifications. It was stated that the source of supply of prospective technological teachers is to be found only in industrial districts. The admission of advanced technical students to share in post-graduate and research work in universities, even when they do not hold the ordinarily pre-requisite degrees, was mentioned, and it was maintained that this concession would be of considerable benefit to the universities.

A resolution was passed by the Conference pressing for a committee of inquiry with the view of correlating technical education with education generally.

University and Educational Intelligence.

Aberdeen.—Prof. Matthew Hay has resigned the position of Medical Officer of Health to the City of Aberdeen, which he has held for thirty-five years.

Cambridge.—Mr. S. M. Wadham, Christ's College, has been reappointed as senior demonstrator in botany. It is proposed to confer an honorary M.A. degree on Mr. H. F. Bird.

London.—A course of four free public lectures on "Tropical Hygiene" will be delivered by Dr. A. Balfour, of the Wellcome Bureau of Scientific Research, at St. Bartholomew's Hospital Medical College on June 12, 14, 19, and 21, at 5 o'clock.

Notice is given that the election of a Sharpey physiological scholar will shortly take place. The scholarship, which is of the value of 200*l.*, is for one year, but renewable, tenable in the department of physiology at University College. Applications, with particulars of academic training and list of publications, if any, must be sent by, at latest, June 23, to the Secretary of University College, Gower Street, W.C.1.

Manchester.—The Court of the University has approved of the institution of a special diploma in bacteriology. This is the first diploma in this subject instituted in this country, and the courses of instruction which candidates will be required to attend before presenting themselves for examination are designed to supply a thorough training in the general principles of the subject, together with advanced courses in one or more special branches. Graduates in medicine and in science of any approved university may enter for the course, and the syllabus has been designed to meet the requirements of medical graduates who wish to qualify for bacteriological posts or to obtain a special knowledge of medical bacteriology, and of graduates in science who desire to take up some branch of bacteriological work. The diploma will be awarded to candidates who, after graduation in science or in medicine, have attended the prescribed courses over at least one academic year, satisfied the examiners in the written and practical examinations, and presented a satisfactory thesis on an approved subject. It is hoped that the action of the University in instituting this new diploma will meet the needs of a considerable number of post-graduate students for whom no adequate provision has hitherto been made, and will help to supply efficiently trained bacteriologists for the numerous posts for which they are now required.

A number of research studentships are being offered to university graduates by the Empire Cotton Growing Corporation, and will be awarded in July next. The studentships, which are each of the annual value of 250*l.* plus certain extra allowances, are intended to provide opportunities for additional training in scientific research bearing on plant genetics and physiology, entomology, physics, etc., or for the study of those branches of tropical agriculture which may be of service in agricultural administration or in inspection in cotton-growing countries. A studentship is offered by the British Cotton Industry Research Association to candidates having special knowledge of physics, engineering, or technical technology. Accepted students must be prepared to spend the period of their studentship at the West Indian Agricultural College, Trinidad, or in some other institution abroad selected by the Corporation. Particulars of the studentships and forms of application (which must be returned by, at latest, June 18) may be obtained from the Secretary, The Empire Cotton Growing Corporation, Millbank House, Millbank, S.W.1.

THE annual report of the University of London University College Committee (1922–23) records important developments in several directions. The new Rockefeller building for anatomy, histology, and embryology, and the engineering building, including the Charles Hawksley hydraulics laboratory, begun in 1919, are nearing completion and will be ready for occupation in October. A new department of chemical engineering will shortly be established. The student enrolment, abnormally swollen during the three years following the War, showed a decrease of 4 per cent. in 1921–22, but has since then remained steady: on January 31, 1923, it was 2513. The proportion of post-graduate and research students (16 per cent.) is very high. The undergraduates were distributed in 1921–22 as follows: arts 58 per cent., science 19, medicine 13, engineering 8, law 2. The number of students from abroad—518—is very large. Of this number 100 were vacation course students, of whom 33 were from France, 15 from Holland, 12 from Scandinavia, and 10 from Switzerland. There were 108 students from India, 27 from the United States, 23 from S. Africa, 26 from Japan; 30 per cent. of post-graduate and research students were from abroad, including 54 from India. The evening work of the College, mainly of a post-graduate character, is steadily increasing, so that the buildings are now open five evenings a week. Free public lectures by the provost, 15 professors, and 20 other members of the college staff, and by 29 visitors, were attended by more than 6000 persons, the approximate aggregate number of attendances being 13,500.

"ONE of the most important events in the history of higher education in Belgium," according to the president of the administrative council of the University of Brussels, was the decision of the government last June to grant a subsidy of one million francs to each of the two "free" or non-state universities—Brussels and Louvain. He cites the recent grants by the British Treasury to Oxford and Cambridge as precedents justifying the acceptance of such patronage, and asserts that, far from being menaced, the independence of his university is remarkably strengthened—apparently because the ministers understand that a subsidy implies no title to exercise control over university teaching. In each of these two universities five chairs have recently been endowed for 15 years by Mr. Hoover's C.R.B. (Commission for Relief in Belgium) Educational Foundation. Thanks to this endowment, to a grant of 20 million francs from the City of Brussels, and to gifts of several millions from the heirs of Ernest Solvay and their relatives, the École Polytechnique of the University of Brussels is now excellently equipped for training in civil and electrical engineering. A subvention of 30 million francs from the Rockefeller Foundation has enabled the medical school to modernise its seven-years' medical curriculum, more comprehensive courses in physics and chemistry being included in the earlier part, the final year being reserved exclusively for clinical work. Of the 24 Americans studying in Belgium under the "Fondation Universitaire" (C.R.B.) bursary scheme 20 were last year at the University of Brussels, where also were 71 other foreign students including only one from Great Britain.

Societies and Academies.

LONDON.

Linnean Society, May 10.—Dr. A. Smith Woodward, president, in the chair.—Paul **Kammerer**: Breeding experiments on the inheritance of acquired characters (see NATURE, May 12, p. 637).

Physical Society, May 11.—Dr. Alexander Russell in the chair.—J. H. **Jeans**: The present position of the radiation problem. (Guthrie lecture.) Classical dynamics are in conflict with experience with respect to the radiation problem. The discrepancies suggest that the laws of Nature must be discontinuous. To explain the observed nature of black-body radiation Planck propounded the quantum theory; in the hands of Bohr it soon became apparent that the quantum theory contained also the clue to the line spectrum. Einstein's hypothesis of light quanta appeared to possess obvious advantages, but has had to give way before the destructive criticism of Lorentz and others, and the direct experimental test of G. I. Taylor. The different methods of interchange of energy between matter and ether, or radiation, may be classified as sub-atomic, atomic, and mass transfers. Typical of the first is the emission or absorption of radiation by a Bohr atom; of the second, the motion constituting heat in a solid; and of the third, the transmission of momentum occurring when a beam of radiation falls upon the surface of a perfect reflector. Physical and chemical transfers take place by quanta, while mechanical transfers take place according to the classical laws. Applying the general principles to a special problem, the case of the exchange of energy between a free electron e and a field of radiation X, it seems probable that no exchange of energy can occur. A conception in regard to this which was used by Einstein in 1917 appears difficult to interpret except on the view that electric forces are a manifestation of a sub-universe more fine-grained than anything we have yet imagined.

The Faraday Society, May 14.—Sir R. Robertson in the chair.—E. P. **Perman** and H. L. **Saunders**: The vapour pressures of concentrated cane-sugar solutions. Few measurements have been made in the case of concentrated solutions except at low temperatures. In the present observations the concentrations were from 10 per cent. to saturation and the temperatures 70°–90° C. The vapour pressure was measured directly, the actual pressure being balanced against a column of mercury. The pressure-concentration graph is not a straight line, as in previous determinations by a dynamic method, and the results are in harmony with Callendar's theory that definite hydrates are formed in solution. The results also show that Babo's law holds for sugar solutions.—E. W. J. **Mardles**: The elasticity of organogels of cellulose acetate. The phenomena of the strain, variable with time and partly reversible, and the persistence of deformation and optical anisotropy, have been ascribed to the formation with time, while under stress, of a metastable phase, due to the altered orientation of the molecules composing the complexes which have aggregated to form the gel structure. The relation between the modulus of elasticity and concentration for the organogels of cellulose acetate is expressed (approximately) by the expression $E = kC^n$, at higher concentrations over limited ranges; n decreases with fall in temperature. The relation between log E and temperature is approximately rectilinear over the range of temperature examined. Addition of substances to the gel mainly affects the modulus in proportion to the change in the number of particles which aggregate.—A. L. **Norbury**: Some experiments in the hardness and spontaneous annealing of lead. When Brinell hardness tests are made in lead the "time factor" is an important variable. The load, therefore, has to be applied and removed almost instantaneously and loads up to 300 kg. only can be used with a 10 mm. ball. Loads were maintained for varying lengths of time and the results are interpreted according to Meyer's formula $L = ad^n$, where L is the load, d the diameter of the impression, and a and n constants. It appears that the more annealed the lead the more the results are affected by the time factor. With cold-hammering, lead is spontaneously annealed at room temperature, and the rate of annealing increases with the amount of deformation, so that lead which has been severely hammered shows no increase in hardness.—D. **Stockdale**: An example of polymorphism in an intermetallic compound. A study of the liquidus of the copper rich aluminium-copper alloys shows that the compound Cu_2Al exists, but is unstable above 1015° C. The compound can probably exist in two polymorphic forms.—F. C. **Thompson** and E. **Whitehead**: Some notes on the etching properties of the α- and β-forms of carbide of iron. The transformation of iron carbide at 200° C. has been studied from the point of view of the etching properties. The effects, positive or negative, of numerous reagents are recorded. The best reagent for differentiating between the two forms of carbide was found to be potassium copper cyanide. Incidentally the self-tempering of samples of white iron quenched from below 300° C. was confirmed.

CAMBRIDGE.

Philosophical Society, May 7.—Mr. C. T. Heycock, president, in the chair.—G. D. **Liveing**: The recuperation of energy in the universe.—J. E. **Purvis**: (1) Infra-red spectra. (2) The absorption spectra of some organic and inorganic salts of didymium. (3) The absorption spectra of solutions of benzene and some of its derivates at various temperatures. (4) The absorption of the ultra-violet rays by phosphorus and some of its compounds.—E. C. **Stoner**: A note on the electromagnetic mass of the electron.—R. R. S. **Cox**: Chemical constants of diatomic molecules.

May 21.—P. A. **MacMahon**: (1) The partitions of infinity. (2) The prime numbers of measurement.—M. H. A. **Newman**: On approximate continuity.—J. P. **Gabbatt**: The pedal locus in hyperspace.—D. R. **Hartree**: On some approximate numerical applications of Bohr's theory of spectra.—A. G. **Thacker**: Some statistical aspects of geographical distribution.—J. **Walton**: On the structure of a middle Cambrian Alga from British Columbia (*Marpolia spissa*, Walcott).—F. T. **Brooks** and W. C. **Moore**: On the invasion of woody tissues by wound parasites.

DUBLIN.

Royal Irish Academy, April 23.—Prof. Sydney Young, president, in the chair.—W. McF. **Orr**: Solutions of systems of ordinary linear differential equations by contour integrals. The writer starts with the equation $\phi(D)x=f(t)$, where ϕ is a polynomial of degree r. The solution, subject to the conditions that initially x and its derivatives up to $(r-1)^{th}$ shall have given values, may be written

$$2\pi i x=\int_c \frac{e^{\lambda t}}{\phi(\lambda)}\left[\frac{\phi(D)-\phi(\lambda)}{D-\lambda}\right]_{t=0} d\lambda+\int_c \frac{d\lambda}{\phi(\lambda)}\int_0^t e^{\lambda(t-t')}f(t')dt',$$

where the integrals with respect to λ are taken round a contour which encloses all zeros of $\phi(\lambda)$. Not only is this solution verified, but it is also obtained from the original equation. This is done by changing the independent variable to t', multiplying across by $e^{\lambda(t-t')}dt'$, integrating from 0 to t, multiplying across by $d\lambda/\phi(\lambda)$, and integrating round an infinite contour. Simultaneous equations are solved similarly.

PARIS.

Academy of Sciences, May 7.—M. Albin Haller in the chair.—The president announced the death of Sir James Dewar, corresponding member of the general physics section.—Henri **Lebesgue**: The singularities of harmonic functions.—M. **Mesnager**: Observations on a communication by M. Sudria (April 23).—L. **Joubin**: The cruises proposed by the Office scientifique et technique des pêches during 1923. A programme of the work proposed for the coming season on the *Pourquoi Pas?* under M. Charcot and on *La Tanche*, under M. Rallier du Baty.—M. **d'Ocagne**: Equations with four variables representable both by simple and double alignment.—C. **Depéret** and L. **Mayet**: The phyletic branches of the elephants.—M. Marin Molliard was elected a member of the section of botany, in succession to the late M. Gaston Bonnier.—Pierre **Humbert**: Certain orthogonal polynomials.—Paul **Lévy**: The stable laws in the calculus of probabilities.—Bertrand **Gambier**: Systems of superabundant points in the plane: application to the study of certain surfaces.—Jean **Dufay**: The spectrum of the nocturnal sky. In the part of the spectrum studied (plate excludes the green and yellow) the light of the sky at night has qualitatively the same composition as sunlight. E. **Fichot**: The peculiarities of the amphidromic regime of open seas.—S. **Rabinovitch**: The geometrisation of electromagnetic forces.—Pierre **Auger** and A. **Dauvillier**: The existence of new lines, one a Sommerfeld doublet, excluded by the principle of selection, in the L series of the heavy elements.—Victor **Henri**: The ultra-violet absorption spectrum of the vapour of benzene chloride. A reproduction of the spectrum is given, together with a diagram showing its decomposition into groups and series. From the spectrum the molecule would appear to be asymmetrical.—Mlle. I. **Curie** and G. **Fournier**: The γ radiation of radium-D and radium-E. The results are in good agreement with those found by Rutherford and Richardson. In addition the existence of a penetrating radiation due to radium-E has been established and its coefficient of absorption determined.—Suzanne **Veil**: The evolution of the molecule of chromium hydroxide in water.—H. **Pélabon**: The thermoelectric power of alloys. For alloys not forming definite compounds the thermoelectric power usually lies between the values corresponding to those of the pure metals, but the thermoelectric power can never be calculated by the mixture rule. Results for lead-antimony alloys are given.—M. **Aubert** and G. **Dixmier**: The stability of alcohol-petrol mixtures in the presence of water. The results are summarised in two diagrams showing the effects of the gradual addition of water to alcohol-petrol mixtures, with special reference to the point at which separation into two layers takes place.—M. **Sauvageot** and H. **Delmas**: The possibility of tempering extra mild steel at a very high temperature. As the amount of carbon in steel diminishes, approaching pure iron, the critical tempering temperature rises rapidly, and coincides with the melting-point when the carbon is a little less than 0·09 per cent. (with manganese 0·33 per cent.).—Paul Mondain **Monval**: Eutectic points in saline solutions.—Robert **Stumper**: The corrosion of iron in the presence of iron sulphide. Experiments showing that iron in contact with sulphide of iron is more rapidly corroded than when the sulphide is absent. The action is electrolytic, since the presence of the sulphide in the same water was without effect unless the iron and the sulphide were in direct contact or connected by an iron wire.—Pierre **Jolibois** and Pierre **Lefebvre**: The dehydration of gypsum. Gypsum heated in a current of dry air at varying temperatures gives no indication of the formation of the semihydrate. On the other hand, if heated in steam at 160° C., the semihydrate $CaSO_4 . \frac{1}{2}H_2O$ is formed.—Mme. Pauline **Ramart** and J. **Blondeau**: The molecular transformations accompanying the dehydration of the primary α-α-disubstituted phenylethyl alcohols.—MM. **Chaumeil** and V. **Thomas**: Researches on picryl sulphide. Study of the binary picryl trinitroanisol sulphide.—Raymond **Delaby**: The action of the magnesium halides on the epibromhydrin of ethylglycerol.—MM. **Bordas** and **Touplain**: Specific characters of the heavy oils of beechwood creosote. The presence of cerulignol in these tars, giving a blue coloration in alcoholic solution with lime or baryta, suggests that these heavy oils may form a suitable ingredient in the mixture used for denaturing alcohol.—Maurice **Piettre**: The estimation of humic and fatty materials in the soil by means of pyridine. Pyridine is an excellent solvent for humus. Diluted with an equal volume of water, it can be used to extract and determine the fixed and free humus in soil.—Ch. **Mauguin**: The reflection of Röntgen rays on certain remarkable reticular planes of calcite. The experiments described form a new confirmation of the hypothesis of W. L. and W. H. Bragg on the structure of calcite.—L. **Cayeux**: The phenomenon of imprints in the Mesozoic iron minerals of France. So far as the oolitic iron minerals are concerned, the impressions may have been caused by pressure alone, or by solution with or without pressure effects.—Léon **Bertrand**: The rôle of the Provençal advance folds in the tectonic of the Maritime Alps.—Pierre **Bonnet**: The existence of the Coniacian in the Daralageoz massif (Southern Transcaucasia).—Americo **Garibaldi**: Thyroidectomy and immunity. A comparison of the results by various workers on this subject leads the author to modify the view put forward by him in 1920. The removal of the thyroid causes an increased sensibility towards substances foreign to their internal medium, but at the same time the defensive power of the organism undergoes a marked increase.—M. **Tiffeneau** and H. **Dorlencourt**: A new series of hypnotics, the aryldialkylglycols. These glycols, of which phenyldiethylglycol, $C_6H_5 . CH(OH) . C(OH)(C_2H_5)_2$, may be taken as the type, show marked hypnotic properties both towards mammals and fishes. These properties are due to the glycol group, and are strengthened by trisubstitution: they vary, between certain limits, with the number of carbon atoms in the molecule, and are modified by the relative positions of the substituting groups.—Raphaël **Dubois**: Gyratory antikinesis.—P. **Vignon**: The mimetism of the Pterochroza.—Louis **Roule**: The peculiarities of the Rhône basin with respect to its ichthyological fauna.

WASHINGTON.

National Academy of Sciences (Proc. Vol. 9, No. 3, March).—H. S. **Reed**: A note on the statistics of cyclic growth. The lateral shoots on a young apricot branch develop typically in three groups along the branch, and their size and number are greatest in the group nearest the proximal end of the branch. The mean lengths of corresponding lateral shoots are symmetrical about a mean for each group.—R. A. **Millikan**: Stokes' law of fall completely corrected. The form of Stokes' law proposed is

$$F = \frac{6\pi\eta av}{1 + A' l/a},$$

where F is the force acting, v the velocity produced, η the viscosity of the medium, l/a is the mean free path over the radius, and A' is a factor which varies theoretically from 0·7004 to 1·164 as, with decreasing density, l/a changes from very small to very large values and allowance is made for a percentage of specular reflection at the surface of the oil. The change in A' means physically a change from viscous resistance to resistance due to molecular impact. Experimental values of A' obtained by the oil-drop method in several gases at varying pressures vary from 0·864 to 1·154.—C. **Barus**: Gaseous viscosity measured by the interferometer U-tube. For air, a capillary tube is attached to the closed limb of the U-tube containing air at slightly more than atmospheric pressure. The displacement of the interference fringes decreases exponentially with time, and the decrease is timed over equidistant scale parts of an ocular micrometer. The value found for air in a heated room is 0·000180.—T. W. **Richards**: Compressibility, internal pressure, and atomic magnitudes. Internal pressure is defined as the pressure exerted by the force of affinity. Curves were obtained, partly by extrapolation, for the pressure-volume relations of sodium, potassium, chlorine, and bromine, reduced to a gram-atom basis, and the atomic diameters of these elements in the chloride and bromide of each metal were computed. The compressibility of the products calculated from these data is said to agree with the experimental values. The results are in accord with the theory that atoms are subject to different pressures in different chemical combinations, and their bulks depend on this and on the compressibility of the elements concerned.—J. **Kendall** and E. D. **Crittenden**: The separation of isotopes. As applied to chlorine, a solution of sodium chloride in agar-agar jelly is made the middle section of a tube used as an electrolytic cell built in three sections each three feet long. Between the anode and the chloride is a sodium hydroxide gel and solution, and separating it from the cathode is a sodium acetate gel and solution, the latter containing acetic acid. The boundary surfaces remain distinct because the chloride ion is preceded by a faster hydroxyl ion and followed by a slower acetate ion. The sections of the cell are renewed as the boundary surfaces move, so that the chloride ion eventually travels through about 100 feet of gel; 110 or 220 volt lighting circuit is suitable. The isotopes, if of different ionic mobilities, will appear at opposite end of the sodium chloride gel column. It is also suggested that since the discharge potentials of the isotopic chloride ions in any naturally occurring solution differ by 0·03 volt, it should be possible to effect electrolytic fractionation.—J. W. **Churchman**: The mechanism of selective bacteriostasis. Acid fuchsin at 45° C. appears to kill Gram-negative organisms, while Gram-positive organisms are unaffected; gentian violet has the reverse effect. A mixture of two similar dyes showing this selective bacteriostasis may prove better for the treatment of infection than either alone.—H. C. **Sherman**: An investigation of the chemical nature of two typical enzymes: pancreatic and malt amylases. Malt amylase appears to consist of a coagulable protein and a proteose or peptone. Deterioration is due to hydrolysis. Pancreatic amylase is similar though less stable in solution. With both substances, hydrolysis was checked by the addition of amino acids. There appear to be two stages in the enzyme activity of pancreatic amylase, the latter of which is promoted when lysine and tryptophane are added, indicating that these acids are closely bound in the enzyme molecule as in typical proteins.—A. J. **Lotka**: Note on the relative abundance of the elements in the earth's crust. Arranging the elements appearing in the lithosphere, hydrosphere, and atmosphere in the order of the percentage in which they occur according to Prof. Harkins's data, some curious arithmetical properties of the percentages and atomic numbers appear. The results suggest that the earth's crust may be the product of subatomic disintegration of the nucleus on which it rests.—S. **Lefschetz**: Continuous transformations of manifolds.—J. W. **Alexander**: A lemma on systems of knotted curves. Every 3-dimensional closed orientable manifold may be generated by rotation about an axis of a Riemann surface with a fixed number of simple branch points, such that no branch point ever crosses the axis or merges into another.—W. M. **Smallwood**: The nerve net in the earthworm (preliminary report). Structures considered to be nerve fibres pass round the cells in the circular and the longitudinal muscles of the body wall and each blood-vessel appears to have a nerve net. The nerve net in the layer covering all the internal organs is very extensive, originating apparently in the body wall. The nephridia appear to have a particularly good nerve supply.

Diary of Societies.

SATURDAY, JUNE 2.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Dr. A. W. Hill: The Vegetation of the Andes.

MONDAY, JUNE 4.

OIL CONFERENCE AT THE SIXTH INTERNATIONAL MINING EXHIBITION (at Royal Agricultural Hall, Islington), at 12 and 2.30.—E. H. Cunningham Craig: The Riddle of the Carpathians.—Dr. M. Kraus: Oil Deposits and the Tectonics of Vertical Pressure.—R. d'Andrimont: Note on the Genesis of Hydrocarbons and their Localisation in certain Zones of the Earth's Crust.

INSTITUTE OF ACTUARIES, at 5.—Annual General Meeting.

ROYAL INSTITUTION OF GREAT BRITAIN, at 5.—General Meeting.

ARISTOTELIAN SOCIETY (at University of London Club), at 8.—Sir Leslie Mackenzie: What does Dr. Whitehead mean by "Event"?

ROYAL SOCIETY OF CHEMICAL INDUSTRY (London Section) (at Chemical Society), at 8.—Dr. H. S. Hele-Shaw: The Stream-line Filter.

ROYAL GEOGRAPHICAL SOCIETY (at Æolian Hall), at 8.30.—F. Rodd: Journeys in Air.

TUESDAY, JUNE 5.

OIL CONFERENCE AT THE SIXTH INTERNATIONAL MINING EXHIBITION (at Royal Agricultural Hall, Islington), at 12.—A. Beeby Thompson: Oilfield Waste.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Prof. W. M. Flinders Petrie: Discoveries in Egypt (3).

ROYAL SOCIETY OF ARTS (Dominions and Colonies Section), at 4.30.—Sir Edward Davson: The Economic Conference and Crown Colony Development.

FELLOWSHIP OF MEDICINE (at Royal Society of Medicine), at 5.30.—R. A. Hendry: The Value of Antenatal Supervision

RÖNTGEN SOCIETY (at Institution of Electrical Engineers), at 8.15.—Prof. S. Russ: The Effects of X-rays of Different Wave-Lengths on Animal Tissue.—T. Thorne Baker: The Establishment of a Definite Relationship between Exposure and Density in an X-ray Plate.

WEDNESDAY, JUNE 6.

ROYAL SOCIETY OF MEDICINE (Surgery Section), at 5.30.—R. H. A. Whitelocke: The Treatment of Fractures of the Patella.—W. White: The Closure of the Supra-pubic Fistula following Prostatectomy: Observations on Sixty-eight Cases.

GEOLOGICAL SOCIETY OF LONDON, at 5.30.—Dr. H. Bolton: A new Blattoid Wing from the Harrow Hill Mine, Drybrook, Forest of Dean.—Dr. C. E. Tilley: Contact-Metamorphism in the Comrie Area of the Perthshire Highlands.

INSTITUTION OF ELECTRICAL ENGINEERS (Wireless Section), at 6.—C. E. Horton: Wireless Direction-finding in Steel Ships.

ENTOMOLOGICAL SOCIETY OF LONDON, at 8.

THURSDAY, JUNE 7.

OIL CONFERENCE AT THE SIXTH INTERNATIONAL MINING EXHIBITION (at Royal Agricultural Hall, Islington), at 12 and 2.30.—Prof. J. Voitesti: The Mode of Appearance of the Petroleum Deposits in the Carpathian Region, with general consideration on the Genesis of the Petroleum and the Source of the Actual Deposits.—Major J. A. Lautier: An Economic Study of Petroleum Mining by Underground Drainage.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Sir William M. Bayliss: The Nature of Enzyme Action (2).

ROYAL SOCIETY, at 4.30.—Sir Charles Sherrington and E. G. T. Liddell: Stimulus Rhythm in Reflex Tetanic Contraction.—K. N. Moss: Some Effects of High Air Temperatures and Muscular Exertion upon Colliers.—F. A. E. Crew: The Significance of an Achondroplasia-like Condition met with in Cattle.

LINNEAN SOCIETY OF LONDON, at 5.

ROYAL COLLEGE OF PHYSICIANS OF LONDON, at 5.—Prof. J. B. Leathes: The Rôle of Fats in Vital Phenomena. (Croonian Lectures (1).)

CHEMICAL SOCIETY, at 8.—H. Hunter: Investigations on the Dependence of Rotatory Power on Chemical Constitution. Part XX. The Rational Study of Optical Properties: Refraction a Constitutive Property.—A. E. Goddard: Researches on Indium. Part I. Diphenyl Indium Chloride and Phenyl Indium Oxide.—E. P. Perman and W. J. Howells: The Properties of Ammonium Nitrate. Part VI. The Reciprocal Salt Pair, Ammonium Nitrate and Potassium Sulphate.—E. W. Lanfear and J. F. Thorpe: Ring Chain Tautomerism. Part VI. The Mechanism of the Keto-cyclol Change in the Propane Series.—E. H. Usherwood: The Reversibility of Additive Reactions. Part I. The Aldol Reaction.—C. K. Ingold: Mechanism of the Pinacone-pinacoline and Wagner-Merrwein Transformations.—A. E. Goddard: Researches on Antimony. Part I. Tri-m-xylylstibine and its Derivatives.

ROYAL SOCIETY OF MEDICINE (Obstetrics and Gynæcology Section), at 8.—V. Bonney: Diurnal Incontinence of Urine in Women.—L. Phillips: The Treatment of Dysmenorrhœa, with Analysis of 100 Cases.

FRIDAY, JUNE 8.

OIL CONFERENCE AT THE SIXTH INTERNATIONAL MINING EXHIBITION (at Royal Agricultural Hall, Islington), at 12 and 2.30.—O. A. Young and S. D. Tuthill: The Standardisation Movement in America, and its Relation to and Application towards the Elimination of Waste in the Petroleum Industry.—G. Howell: The Caribbean Oil Region.

DIESEL ENGINE USERS' ASSOCIATION (at Institution of Electrical Engineers), at 2.30.—Eng.-Commdr. W. P. Sillince: Losses in Heat Engines and Means of Avoiding Them.

ROYAL ASTRONOMICAL SOCIETY, at 5.—W. S. Adams and G. Strömberg: Stellar Velocity and Absolute Magnitude: Note on a Paper by Prof. Eddington and Miss Douglas.—A. Buxton: Note on the Effect of Astigmatism on Star-Discs.

PHYSICAL SOCIETY OF LONDON (at Imperial College of Science and Technology), at 5.—Prof. J. G. Gray: A General Solution of the Problem of Finding the True Vertical for All Types of Marine and Aerial Craft, to be followed by a discussion.

MALACOLOGICAL SOCIETY OF LONDON (at Linnean Society), at 6.

ROYAL SOCIETY OF MEDICINE (Ophthalmology Section) (Annual General Meeting), at 8.30.—Miss Ida C. Mann: Some Suggestions on the Embryology of Congenital Crescents.—P. Doyne: The Tournée Reaction.

ROYAL INSTITUTION OF GREAT BRITAIN, at 9.—Miss Joan Evans: Jewels of the Renaissance.

SATURDAY, JUNE 9.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Dr. A. W. Hill: The New Zealand Flora.

PUBLIC LECTURES.

MONDAY, JUNE 4.

UNIVERSITY COLLEGE, at 5.30.—Prof. H. A. Lorentz: Problems in Relativity. (Succeeding Lectures on June 5 and 7.)

TUESDAY, JUNE 5.

KING'S COLLEGE, at 5.30.—Miss Hilda D. Oakeley: The Conflict within the Greek Moral Ideal. (Succeeding Lectures on June 12 and 19.)

WEDNESDAY, JUNE 6.

UNIVERSITY COLLEGE, at 5.—Prof. G. N. Lewis: The Structure and Behaviour of the Molecule. (Succeeding Lectures on June 8 and 12.)

THURSDAY, JUNE 7.

ST. MARY'S HOSPITAL (Institute of Pathology and Research), at 4.30.—Prof. F. G. Hopkins: An Oxidising Agent in Living Tissues.

NATURE

A WEEKLY ILLUSTRATED JOURNAL OF SCIENCE

"*To the solid ground*
Of Nature trusts the mind which builds for aye."—WORDSWORTH.

No. 2797, Vol. 111] SATURDAY, JUNE 9, 1923 [Price One Shilling

Registered as a Newspaper at the General Post Office.]

UNIVERSITY OF LONDON.

A Course of Four Advanced Lectures on "TROPICAL HYGIENE" will be given by DR. ANDREW BALFOUR (Director-in-Chief, Wellcome Bureau of Scientific Research) at ST. BARTHOLOMEW'S HOSPITAL MEDICAL COLLEGE (West Smithfield, E.C.1). on TUESDAY, June 12; THURSDAY, June 14; TUESDAY, June 19; and THURSDAY, June 21, at 5 P.M. At the first Lecture the Chair will be taken by The Right Hon. Lord STANMORE, C.V.O. ADMISSION FREE WITHOUT TICKET.

EDWIN DELLER, Academic Registrar.

THE UNIVERSITY OF MANCHESTER.

DEPARTMENT OF BACTERIOLOGY AND PREVENTIVE MEDICINE.

Diploma in Bacteriology.

The First Course of Instruction in connection with the above Diploma will commence in October 1923.

The course is open to Graduates in Medicine or in Science of any approved University, and extends over one Academic year. The first examination for the Diploma will be held in July 1924.

Intending Candidates should send their names to the INTERNAL REGISTRAR, from whom further particulars may be obtained.

IMPERIAL COLLEGE OF SCIENCE AND TECHNOLOGY.

HENRY GEORGE PLIMMER FELLOWSHIP IN PATHOLOGY.

Applications are invited from candidates qualified to pursue research in PATHOLOGY (including Morbid Anatomy, Histological Anatomy, Chemical Pathology, Protozoology, Bacteriology, and allied subjects in either Zoology or Medicine or Botany) for Election to a Fellowship for the year beginning September 1, 1923. Further particulars will be sent on application, in writing, to THE RECTOR, Imperial College of Science and Technology, South Kensington, S.W.7.

Applications must be received not later than June 25, 1923.

APPLICATIONS are invited by the Salters' Institute of Industrial Chemistry, Salters' Hall, St. Swithin's Lane, E.C.4, for a limited number of Fellowships for Post Graduates in Chemistry who are desirous of adopting an industrial career. The Fellowships are of the annual value of £250 to £300 and fall vacant in October next. Applications, with full particulars of training and experience, must reach the CLERK OF THE SALTERS' COMPANY before July 1.

EMPIRE COTTON GROWING CORPORATION.

THE BRITISH COTTON INDUSTRY RESEARCH ASSOCIATION.

RESEARCH STUDENTSHIPS.

SPECIAL STUDY STUDENTSHIPS.

Further Studentships (for University graduates only), about eight in number, are offered. They are of the value of £250 per annum each, with certain additional allowances and travelling expenses, and are tenable for one year. They will be awarded in July next.

These Studentships are intended to provide opportunities for additional training in scientific research bearing on plant genetics and physiology, entomology, physics, etc., or for the study of those branches of tropical agriculture which may be of service to men who may subsequently be engaged in agricultural administration or inspection in cotton-growing countries. One Studentship is offered by the British Cotton Industry Research Association for candidates having special knowledge of physics, engineering or textile technology with a view to its subsequent application on the industrial side.

The intention underlying the allocation of these Studentships is to increase the supply of workers with the necessary qualifications, who may later make use of the agricultural or industrial applications of their knowledge, and so find occupation in and be of service to cotton production and to the industry.

Applicants for a Studentship under the Empire Cotton Growing Corporation must be prepared to spend their Studentship year at the West Indian Agricultural College, Trinidad, or at some other Institution abroad, selected by the Corporation, and pass a medical examination.

Particulars of the conditions of tenure of the Studentships and Forms of Application may be obtained from the SECRETARY, The Empire Cotton Growing Corporation, Millbank House, Millbank, London, S.W.1. Forms of Application must be returned not later than June 18, 1923.

BIO-CHEMIST wanted for Marine Biological Station at Millport. Commencing Salary £350. Applications with three References to be forwarded on or before June 30 to A. LAWRIE BROWN, Writer, 88 Bath Street, Glasgow.

CHELSEA POLYTECHNIC,

CHELSEA, S.W.3.

Day and Evening Courses in Science under Recognised Teachers of London University.

I. INDUSTRIAL CHEMISTRY DEPARTMENT.
Technical Courses in Analytical and Manufacturing Chemistry, Pharmacy, Food and Drugs, A.I.C. Courses, Metallurgy, Assaying, Foundry Work, Research.

II. INDUSTRIAL PHYSICS DEPARTMENT.
Practical work in General Physics, Applications to Industries, Metrology, Calorimetry, Illumination, Acoustics, Electrical Measurement, Research.

III. BIOLOGICAL AND GEOLOGICAL DEPARTMENT.
Courses for B.Sc., etc., in Botany, Geology, Mineralogy, Zoology, Special Courses in Bio-chemistry, Bio-physics, Bacteriology, Physiology, Hygiene, Entomology, Plant Pathology. Course for Tropical Planters, Research.

SIDNEY SKINNER, M.A., Principal.

Telephone: Kensington 899.

BATTERSEA POLYTECHNIC.

LONDON, S.W.11.

Principal—ROBERT H. PICKARD, D.Sc., F.R.S.

COURSES FOR WOMEN.

Full-time day courses for women preparing to be teachers of Domestic Subjects.

Preparation for posts as Institutional Matrons and Housekeepers and for colonial and home life.

Full-time day courses of training for Women Health Visitors and Infant Welfare Workers.

Evening courses of training for Sanitary Inspectors, Health Visitors, Meat and Food Inspectors, Smoke Inspectors, etc.

Day and Evening courses in Art, Music, and Domestic Science.

Hostels for Women Students. Large Athletic Ground and numerous clubs and societies.

UNIVERSITY OF LIVERPOOL.

SESSION 1923-24.

The Autumn Term begins on October 4. Prospectuses and full particulars of the following may be obtained free (with the exception of the Calendar, price 2s. 6d., post free, 3s.) on application to the REGISTRAR:

FACULTIES OF ARTS, SCIENCE, MEDICINE, LAW, AND ENGINEERING.
SCHOOL OF ARCHITECTURE.
DEPARTMENT OF CIVIC DESIGN.
DEPARTMENT OF COMMERCE.
INSTITUTE OF ARCHÆOLOGY.
DEPARTMENT OF EDUCATION.
SCHOOL OF SOCIAL STUDIES.
SCHOOL OF LOCAL HISTORY AND RECORDS.
SCHOOL OF RUSSIAN STUDIES.
UNIVERSITY EXTENSION BOARD.
DEPARTMENT OF PUBLIC HEALTH.
SCHOOL OF TROPICAL MEDICINE.
SCHOOL OF VETERINARY SCIENCE.
SCHOOL OF DENTAL SURGERY.
DOCTORATE IN PHILOSOPHY.
FELLOWSHIPS, SCHOLARSHIPS, STUDENTSHIPS, EXHIBITIONS, SPECIAL GRANTS AND PRIZES.
HALLS OF RESIDENCE.
UNIVERSITY CALENDAR.
JOINT BOARD MATRICULATION EXAMINATION.
AWARD OF HIGHER SCHOOL CERTIFICATES.
AWARD OF SCHOOL CERTIFICATES.

CHESHIRE SCHOOL OF AGRICULTURE.

Applications are invited for the post of LECTURER in AGRICULTURAL CHEMISTRY. Salary £250, rising £300 by annual instalments of £25, with board residence.

Particulars and form of application, to be returned before June 16, 1923, from PRINCIPAL, Cheshire School of Agriculture, Reaseheath, Nantwich.

F. F. POTTER, Director of Education.

TO SCIENTISTS AND RESEARCH STUDENTS.

THE INTERNATIONAL BIBLIOGRAPHICAL SERVICE BUREAU,

employed by British Government Departments, University Professors, etc., supplies complete Continental and American bibliographies on any scientific, literary, or medical subject. Chemical work a speciality. Extracts made.

Headquarters: Vienna. English representative: "ALEXANDRIAN," 1A Longridge Road, Earl's Court, S.W.5.

SATURDAY, JUNE 9, 1923.

NO. 2797, VOL. 111]

Medical Education in England.

IN a memorandum of nearly two hundred pages, addressed to the Minister of Health, Sir George Newman has reviewed some of the recent advances in medical education in England.[1] The occasion is timely. Never before has there been such an urgency and expectation of reforms; never, as since the War, such general appreciation of the vast potentialities of medical science in determining the society of the future. There is no medical school in Britain but has felt reinvigorated by the general sense of change and movement forwards. Like the celestial shades, Benevolence and Gratitude, in Tourguenieff's amusing satire, Science and Practice have been made acquainted. Of all the heavenly company they alone did not know each other before. Congratulation is free and happy; it is part of the new atmosphere of hope and fresh resolve.

Since the publication of an earlier memorandum in 1918 "there have been significant developments in Medical Education" in England, and medical education in England was, on the whole, ahead of the rest of the world already. Probably this last is a fair summary of the facts as they are presented here, not by Sir George Newman alone, but by a host of industrious correspondents, in great wealth of detail, albeit from diverging points of view. Darwin and Huxley among the naturalists, Shakespeare, Keats, and Wordsworth among the poets, are requisitioned to point the moral of Sir Clifford Allbutt, who has said that "at this moment it is revealed to us that Medicine has come to a new birth. . . . What is then this new birth, this revolution in Medicine? It is nothing less than its enlargement from an art of observation and empiricism to an applied science founded upon research; from a craft of tradition and sagacity to an applied science of analysis and law; from a descriptive code of surface phenomena to the discovery of deeper affinities; from a set of rules and axioms of quality to measurements of quantity."

The new knowledge came in almost bewildering succession—cell changes, toxins, immunology, asepsis, internal secretion, cardiology. "The medical man may now be, if he will, master of his fate"; and we know that this jubilation is scarcely in excess or ill-founded. We know that chemistry and physics have served the physiologist nobly and untiringly; that an enlightened anatomy, liberated from the narrow specialism of the dead-house, is rising to its old command of all biological problems; that British physiology

[1] "Recent Advances in Medical Education in England." A Memorandum addressed to the Minister of Health by Sir George Newman, Chief Medical Officer of the Ministry of Health and of the Board of Education. (London: H.M. Stationery Office, 1923. 1s. 3*d.* net.)

adds still to unequalled conquests; that "integration" in medicine has at least begun.

Why, then, should we turn from Sir George Newman's remarkable document dissatisfied and oppressed? It is not primarily the wealth of medical knowledge that is Sir George Newman's theme, but the problem of student inheritance. It may be true that "the most after all that can be accomplished . . . is to provide him with the tools of learning in order that by experience he may become a reliable and effective workman." It is true, if by "tools of learning" is meant something which, though vague, is positively and certainly immeasurably short of his ultimate attainment as a representative physician or surgeon, or an efficient general practitioner. In the most that can be accomplished is room for widely divergent ideals and attitudes. "Science," writes Dr. Bateson, "is not a material to be bought round the corner by the dram, but the one permanent and indispensable light in which every action and every policy must be judged. . . . The splendid purpose which Science serves is the inculcation of principle and balance, not facts."

Is this sentiment, so ingrained in the outlook of the man of science who necessarily looks forwards and away from the already known, a safe approach to the discussion of the adventitious and the merely academic in the medical curriculum? Over and over again it is borne in upon us that the medical student is the veriest beast of intellectual burden. The biologist writes threateningly that "if the medical man is not a biologist, he is nothing," while it is admitted that "what is necessary is a widening of the basis, less imposition of details on the memory of the student, and an introduction to scientific thought and method." In chemistry "the amount of detail imposed upon the student in didactic lectures is still perhaps too great." Anatomy "has been robbed of its heritage and reduced to the routine and detailed analysis of a scrapped machine, and the only goal has all too frequently been the examination test." The past student of anatomy was "overburdened with a multiplicity of detail, wearied with bone classes and a hundred systematic lectures, and harassed by meticulous examinations for which he is driven to prepare himself by 'cramming.'" Even in medicine and surgery "the student is overfed for his size." He attempts to learn, merely for examination purposes, much that is of little value, yet fails completely to master the simpler knowledge and manipulations which may fall to his lot frequently. How could it be otherwise when the prestige of famous schools depends upon pass lists and distinction lists, and not by any means upon the "inculcation of principle and balance" which only life, "never overlooking a mistake or making the smallest allowance for ignorance," can test? Much as the fame of some of them deserves to be founded in the breadth and distinction and power to influence of their teachers, that is the case in scarcely one. "At present, in spite of the reasonableness, high competency and goodwill of the examiners, the system remains a shackle upon medical education."

Sir George Newman offers two remedies for this malady. The first is time and the natural order of events, a necessary element, doubtless, in every advancement. The second is the acquisition of a more practical outlook throughout the training of the student. His science should be applied science. We wonder whether the historical and, as it were, developmental setting in which Sir George Newman has cast his study has not misled him there. Is the progress of medicine really an orderly progress as of one body? The point is sharpened by Prof. Halliburton, to whose views the memorandum gives assent. "I venture to think," he says, "that not infrequently the fault lies not with the physiological teacher, but with the hospital physician. . . . The physician, after an inadequate study of the science of physiology in the remote past, may have lost all touch and sympathy with the science of to-day, may have sunk into an easy empiricism, and may be content to cloak his ignorance by sneers at the application of scientific methods to practice." Thoughtful students have themselves recognised (or suspected) that it was there the bottom fell out of their curriculum. They had been taught to expect too much from practice: had confused applied science with the application of scientific methods. Sir George Newman regards the antithesis between the practical man and the inquiring man as false. But it is not false. It lies at the root of all the present difficulties of medical education. The "clinical unit" system—a genuine device of integration—may do much to resolve it; but confusion of thought in regard to it will prove the most dangerous obstacle to that great reform in medicine which now opens before us so hopefully.

British Coal-Mining in the War Period.

The British Coal-Mining Industry during the War. By Sir R. A. S. Redmayne. (Economic and Social History of the World War, British Series. Published on behalf of the Carnegie Endowment for International Peace.) Pp. xv + 348. (Oxford: Clarendon Press; London: Oxford University Press, 1923.) 10*s.* 6*d.* net.

SIR RICHARD REDMAYNE is to be congratulated upon having produced a work of quite exceptional interest; the history of the means by which the British coal supply, upon which our chances of victory so greatly depended during the War, was maintained, must necessarily be interesting, but it becomes even more so when it is told by one who himself played a leading part in this strenuous work. In no other way would it have been possible for the public to gain even an insight into the elaborate and complex operations that were required in order to maintain the output of this indispensable fuel through the whole of that trying and anxious time.

The inception of the present book is somewhat curious; it is published under the auspices of the Carnegie Endowment for International Peace, in pursuance apparently of a theory that the best way to prevent wars in the future is to explain all the details necessary to carry them on successfully. Whatever may be thought of this proposition, it has certainly given occasion for the publication of matter of the highest interest. Sir Richard's narrative is chronological, the leading events of each year, so far as the subject of coal supply is concerned, being grouped together. For much of what he has written he is and must remain the sole authority, but it can fairly be said that the description sounds very straightforward, and leaves on the reader's mind a convincing impression of impartial accuracy. Coal control necessarily bulks very largely, and it need scarcely be said that Sir Richard writes of coal control from the point of view of one of the controllers; it would no doubt have been an immense advantage to have had a companion chapter written by one of the controlled. The harrow appears to be remarkably well pleased with itself, but it is just possible that the toad may not be quite so appreciative.

Sir Richard is of the opinion that upon the whole the coal control worked well; and although it has been severely criticised in many quarters, the subject is so complex that it is difficult to see how any system could have been devised that would not be liable to many grave objections. Sir Richard, indeed, almost hints at defects when he points out, as he does in more than one passage, that direct financial control of the collieries might well have been avoided had it not been for the turbulence, selfishness, and disloyalty of one section of the industry—the coal miners of South Wales; he seems to think that their attitude rendered direct control absolutely necessary.

In appointing the coal controller it was possibly right to select a man of business ability and the power of organisation and administration rather than one possessed of technical knowledge and experience in coal production; but even though this may have been sound policy, it was certainly wrong to have chosen for his subordinates, for the men with whom the colliery manager would come into direct contact, so many who were unacquainted with mining matters. When a colliery manager found that the representative of the coal control, to whom he had to state his case and to whom the decision even in matters of great importance appeared often to be left, was absolutely ignorant of the elements of the mining industry, he naturally lost faith in the Department, and the coal control fell into disfavour, which could have been largely avoided had the subordinate executive of the coal control known more about coal mining. It may possibly not be true that the colliery manager who asked for a new winding rope 300 fathoms long was informed that the Department could not grant him more than 150 fathoms, or that a request addressed to the coal control for washed nuts was referred to the food controller; but the mere fact that such stories were current shows well enough how little confidence the coal control department succeeded in inspiring into the coal trade.

Necessarily, the doings of the coal control and the various sub-departments into which it was divided make up the greater part of the book, but probably to many readers the final chapter, in which Sir Richard summarises the economic history of the coal industry and gives the conclusions which he himself draws from this review, will be the most interesting. At the present moment it is perhaps most important to point out that Sir Richard's views have matured since he gave his evidence before the Sankey Commission; he there carefully avoided expressing any decided views on the nationalisation of collieries, and went so far as to say that in his opinion no man can say whether mines would be as efficiently run if they are centralised and run as a national concern as they are under present conditions. Now he writes very differently: "Complete freedom of action for those engaged in the management is absolutely essential to the successful conduct of so highly organised and technical an industry as that of coal-mining. Where an industry has to be conducted under a great diversity of conditions the edicts of a central authority stand in constant need of modification as they are applied to particular cases. Otherwise work will be conducted wrong-headedly and in defiance of material facts. True as this is of all great industrial concerns, it is particularly so in the case of mining." "Whatever results may accrue from such a policy [*i.e.* nationalisation], from the record of observation I find great difficulty in believing that it would make for efficiency. . . . Even if nationalised control were not vetoed by the inherent physical difficulties of the case, it would still have the disadvantage of removing from the industry the great energising forces of personal responsibility and initiative."

If this book did nothing else than record in such unmistakable language Sir Richard's adhesion to the views that have been expressed by practically every one experienced in the technical administration of collieries, it would serve a most useful purpose at the present moment; but in addition it presents, as has been indicated, an inside view of one of the most complex of the various emergency administrations developed by the stress of war conditions, and forms a document which no student of industrial economics can afford to neglect. H. Louis.

The Structural Units of the Body.

Emil Fischer—Gesammelte Werke. Herausgegeben von M. Bergmann. *Untersuchungen über Aminosäuren, Polypeptide und Proteine II.* (1907–1919). Von Emil Fischer. Herausgegeben von M. Bergmann. Pp. ix + 922. (Berlin: Julius Springer, 1923.) 24*s.* 2*d.*

At the beginning of the twentieth century knowledge of the nitrogenous constituents of the body lagged far behind that of the fats and sugars, and the information available as to the composition and structure of the various forms of protein was of the scantiest. Within five years a complete change in this respect was effected as the result of the labours of Emil Fischer and his pupils—not only were the constituents of the proteins almost completely identified both qualitatively and quantitatively, but also the artificial synthesis of most of the individual units was effected, and the first steps taken towards their coupling together to form polypeptides.

Fischer's pioneer work on the amino acids, polypeptides, and proteins commenced just prior to his taking possession of the new laboratories in the Hessischestrasse, Berlin, about 1899, and during the next six years this was his main work: he republished his collected papers in 1906. Dr. Bergmann has now collected the further publications in this series up to 1916: they amount to a stately volume of 892 pages. During the last few years of his life Fischer worked in the main at problems in sugar chemistry, but he always spoke of his intention to return to investigations of the proteins.

The papers reprinted in the volume before us fall naturally into four classes—the investigation of the individual amino acids which form the units from which the proteins are built up, the synthesis of polypeptides of ever-increasing structural complexity from the amino acids, the investigation of the degradation products of protein hydrolysis, and the study of the remarkable so-called Walden rearrangement of groups attached to asymmetric carbon atoms, which takes place during a variety of relatively simple chemical reactions. The value of the collected papers as a work of reference is materially enhanced by a carefully prepared index.

Fischer's work in these fields is in many ways typical not only of the man himself but also of the German method. The problem was attacked thoroughly, methodically, and systematically, with all the resources of a great and newly-equipped laboratory; an adequate number of trained assistants were available, funds were not lacking, and the time of the professor himself was not too much occupied by routine and administrative work, which could be performed equally well by a less gifted individual. Publication was prompt, and could be secured without that friction with editorial committees which is so destructive of enthusiasm.

In all, nineteen amino acids have been separated as products of protein hydrolysis. Glycocoll was isolated so far back as 1820 by Braconnot, who obtained it from gelatin, together with leucine, which Proust had found two years earlier in cheese. Oldest of all is cystine, the only protein constituent containing sulphur in its molecule, which was discovered in 1810 by Wollaston. Fischer added proline and oxyproline to the list in 1901–2, and discovered the more complex diaminotrioxydodecanic acid in 1904. Hopkins and Cole isolated tryptophane in 1901. The amino acids typify all classes of acids: normal paraffins, aromatic analogues and their hydroxy derivatives, dicarboxylic acids, heterocyclic pyrrolidine compounds, imidazols, indols, and lastly diamino substances. They occur in the proteins as optically active forms, and have mostly been synthesised in this form.

Having fully characterised the amino acids, Fischer's next step was to devise methods of coupling them together, at first in pairs, to form what he named dipeptides, and afterwards in increasing numbers until a molecule approximating in complexity to the actual protein was obtained. It will be evident that the number of possible isomerides of such compounds obtained by altering the order in which the various amino acids are linked together is very large. Thus for an octadecapeptide synthesised by Fischer from 15 molecules of glycine and 3 molecules of lysine there are 816 possible different methods of arrangement. Judging from the results of the analysis of the products of the partial hydrolysis of the natural proteins, they never contain long chains of a single amino acid, but are highly complex, each following link in the chain being a different acid. In this respect there is a resemblance to the fats, the natural compounds being in the main mixed glycerides containing several fatty acid radicles. As a consequence the number of possible isomerides of a product having the structure of casein is enormous. When our methods are more refined, such minor variations may possibly serve to explain the differences between the caseins derived from the milk of various animals and the highly specific behaviour of various proteins in immunity tests. Of outstanding importance is the fact that the synthetic products are attacked by those enzymes which normally effect protein digestion. Material is thus afforded for the systematic study of the fermentative processes in the organism, and it may be claimed that the chemist has gone a long way to meet the physiologist on common ground.

The synthesis of the type protein may be said to have been accomplished by Fischer, but the synthesis of an actual protein is quite another matter, and least of all will it ever be possible economically to make synthetic protein at a price to compare with the product of the vegetable world. Alike with sugar, fat, and protein, it is the problem of man so to increase yield, and maybe quality as well as quantity, as to provide a sufficiency of cheap food for our needs. The application of chemical knowledge to agriculture and to horticulture in ever-increasing intensity is not the least important of our tasks.

At the moment of putting down this monumental work, with more than a pang of sorrow that its author has passed beyond, one cannot help the involuntary comparison with an entirely different type of chemist of our own race—Sir James Dewar. Fischer, the patient, untiring observer and investigator in the organic laboratory, never allowing himself to deviate from his plan. Dewar, all genius and impatience, full of daring, an artist above all both in his science and his spirit. E. F. ARMSTRONG.

Actuarial Mathematics.

(1) *Calculus and Probability for Actuarial Students.* By A. Henry. (Published by the Authority of and on Behalf of the Institute of Actuaries.) Pp. vii + 152. (London: C. and E. Layton, 1922.) 12s. 6d.

(2) *Life Contingencies.* By E. F. Spurgeon. (Published by the Authority and on Behalf of the Institute of Actuaries.) Pp. xxvii + 477. (London: C. and E. Layton, 1922.) 30s.

(1) MR. HENRY'S volume contains a course of differential and integral calculus, coupled with finite differences, designed primarily to meet the requirements of actuarial students. Stress is laid throughout on the numerical methods with which actuaries are mainly concerned. The treatment of the differential and integral calculus suffers from lack of rigour and would not satisfy a modern pure mathematician. It contains nothing, however, likely to mislead those whose main interest lies in the numerical applications.

The eight chapters on finite differences give all the most useful rules for interpolation, both direct and inverse. A numerical example, to evaluate $f(2{\cdot}33333)$, given $f(2{\cdot}30103)=200$, $f(2{\cdot}32222)=210$, $f(2{\cdot}34242)=220$, $f(2{\cdot}36173)=230$, is worked out by four methods which lead to the same result, 215·442. Such illustrations as this tend to increase the faith of a reader sceptical about the validity of the formulæ. The section on integral calculus contains a useful chapter on approximate numerical integration including the formulæ of Lubbock, Woolhouse, Simpson, Weddle, and G. F. Hardy. A chapter on probability and a collection of examples conclude the volume. Mr. Henry's book is one which can be strongly recommended, not only to actuarial students, but to all whose work lies in the numerical applications of the calculus and finite differences.

(2) The second volume before us is issued as the "official" text-book on life contingencies. It discusses mathematically such subjects as mortality tables and their statistical application, probabilities of life and death, and all the usual types of assurance and annuity. A mortality table, on which the calculation of assurance data rests, is necessarily constructed from experimental evidence: it gives the number of people, among N aged n years, who may be expected to attain the age of $n+x$ years. The usual tables are: (1) English life tables compiled from census returns and death registers, (2) tables compiled from the experience of British life offices, relating to the *select* class of lives with which the companies have dealt, and (3) such tables as Gompertz's and Makeham's, which are based on conjectured theoretical expressions for the functions occurring in a life-table.

Mr. Spurgeon's volume will now be accepted as the standard treatise, so far as the subjects with which it deals are concerned. A reader possessing a fair working knowledge of elementary mathematics, including the calculus and finite differences so far as they are contained in Mr. Henry's companion volume, should be sufficiently prepared to read most of it. The arguments throughout the book are clearly presented, and the theory is illustrated by many solved numerical examples—most of which involve using data supplied by the tables.

We cannot help thinking that the notation adopted for some of the actuarial functions is unfortunate. In certain types of mathematical work a multiple-suffix notation is helpful, but such symbols as

$$ {}_{t}V^{(m)}_{[x]\,\overline{n}|}, \qquad {}_{n|}A^{1}_{[x]\,\overline{m}|}, \qquad {}_{t+\frac{r}{m}}V^{(m)}_{[x]} $$

present considerable difficulties to both printer and

 Z 1

reader. It would certainly be desirable for such an intricate notation to be simplified.

The book ends with eighty pages of tables giving the numerical values of certain actuarial functions according to various laws of mortality.

Our Bookshelf.

Nutrition de la plante: utilisation des substances ternaires. Par Prof. M. Molliard. (*Encyclopédie Scientifique: Bibliothèque de Physiologie et de Pathologie végétales.*) Pp. 306. (Paris: Gaston Doin, 1923.) 15.40 francs.

In this volume the author has aimed at presenting, as a concrete whole, much of the scattered information with regard to the ultimate utilisation of the non-nitrogenous compounds produced by plants in the course of their metabolism. Dealing in the first place with the digestion and migration of reserve materials, chiefly sugars, starches, and oils, attention is directed to the function of the various diastases, and to the mechanism of diastatic action. It is concluded that diastatic reactions represent merely a particular case of the ordinary catalytic phenomena, the apparent discrepancies being explained by the colloidal nature of the catalyser and the physical properties of the products resulting from the reaction. Respiration, with its attendant phenomena of oxidation, is discussed in some detail with special reference to the function and mode of action of the oxydases. Other oxidation processes are exemplified by fermentations induced by some of the lower fungi and bacteria, as in the production of acetic acid by various bacteria and oxalic and citric acids by certain Mucedineæ. The final chapters deal with fermentations which do not result in the fixation of oxygen, particularly alcoholic fermentation and intramolecular respiration, together with the production of such substances as lactic and butyric acid by bacteria in the presence of the appropriate sugars. The book thus provides a useful résumé of the aspect of plant nutrition with which it deals.

Matter, Life, Mind, and God: Five Lectures on Contemporary Tendencies of Thought. By Prof. R. F. Alfred Hoernlé. Pp. xiii + 215. (London: Methuen and Co., Ltd., 1923.) 6*s*. net.

The five lectures in "Matter, Life, Mind, and God" present us with the main tendencies of philosophical thought in respect of the great problems of philosophy indicated by the title. Prof. Hoernlé's aim is to consider these questions synoptically, and he shows admirably how no one abstract point of view of a single science can be considered as having exhausted reality. His treatment of the relations of science, religion, and philosophy, of the tendency away from a materialistic outlook (he calls this chapter "The Revolt against 'Matter'"), of the order of Nature, of the nature and function of mind, and of religion and the meaning of "God," is fresh and stimulating. The book suffers from a certain diffuseness, which is perhaps inevitable considering the wide range of the tendencies of thought which are considered in it; and this fact is apt to mask the synoptic conclusions which the reader is expected to draw from it. There are excellent bibliographies appended to each chapter, with notes as to the relevancy of works cited to various positions stated in the text.

Memories of Travel. By Viscount Bryce. Pp. xiii + 300. (London: Macmillan and Co., Ltd., 1923.) 12*s*. 6*d*. net.

From many notes of travel, written in various parts of the world, these sketches have been selected for publication. They cover a wide range, Iceland, Poland, the Alps, Palestine, Siberia, North America, and the islands of the Pacific. Slight as most of the chapters are, they were well worth publication. Lord Bryce was a careful observer of Nature and had interests so wide and a taste in scenery so catholic that every land seems vivid before the reader's eye. His charm of style and ease of description make one overlook the occasional weakness in his geological explanations. The chapter on Iceland, written in 1872, gives a description of Icelandic scenery and peasant life that could scarcely be improved and yet it runs to less than fifty pages. Vivid pictures of Tahiti, of travel in the Altai mountains, or climbing in Europe are equally fresh and interesting. Even his "catalogue of the scenery of North America" is most attractive, although the whole continent is embraced in some two dozen pages. It is to be hoped that further sketches will be selected for publication from the wealth of material which Lord Bryce left. There is ample room among works of travel for these delightful sketches.

The Appearance of Mind. By James Clark M'Kerrow. Pp. xv + 120. (London: Longmans, Green and Co., 1923.) 6*s*. net.

This is a first book by a young author. It is a striking argument ably developed. It is almost a commonplace in philosophy to deny the reality, in the sense of substantial or causal unity, of the object of knowledge, and to reduce things to phenomena. Mr. M'Kerrow holds that the notion of mind is even more misleading and less justifiable. It must be desubjectified in a way which even Hume did not succeed in attaining. The immaterial principle which he would substitute for mind is "viable equilibrium." He denies that his theory is identical with behaviourism, which is equally anxious to disclaim mind, but he suggests that it may supply just what is wanting to behaviourism to make it work.

The Chemistry Tangle Unravelled: being Chemistry systematised on a New Plan based on the Works of Abegg, Kossel, and Langmuir. By Dr. Francis W. Gray. Pp. x + 148. (London: Longmans, Green and Co., 1923.) 6*s*. net.

This book is mainly an exposition of the work of Kossel. In spite of its title, it does not throw any new light on chemical problems, and the student would be well advised to read the original papers of Kossel, Lewis, and Langmuir rather than to attempt to absorb their theories in the less attractive form in which they are presented by Dr. Gray.

The Isotopes of Germanium.

Using the improved method of accelerated anode rays I have been successful in obtaining the mass-spectrum of germanium. The anode contained a fluorine compound made by the action of HF on a pure specimen of germanium oxide for which I am indebted to Prof. Dennis of Cornell University.

The effects are somewhat feeble, but satisfactory evidence of three isotopes has been obtained. Their mass-lines are at 70, 72, 74, and appear to be whole numbers though the accuracy of measurement is not so high as usual. The intensities are roughly in the proportion 2 : 4 : 5, which agrees reasonably well with the value 72·5 for the chemical atomic weight at present in use.

These values conform to the general rule connecting even atomic number with even atomic weight. It will be noticed that Ge^{70} is isobaric with the weakest and heaviest component of zinc discovered by Dempster, and Ge^{74} isobaric with the lightest and weakest isotopes of selenium announced in NATURE of November 18, 1922, p. 664.

Cambridge, May 23.

The Wave Theory and the Quantum Theory.

In a letter published in NATURE on December 23, 1922, I put forward a theory of dispersion which attempted to begin the reconciliation of the quantum theory with the wave theory. I have received several letters criticising my hypothesis, and it seemed to me that it would be well to acknowledge the justice of the criticism. By a small change it is possible to meet the objection, but this change carries certain important implications. In my former letter, in order to be concise, I had to get as quickly as possible to the positive results, but here I wish to set out the train of thought from which the hypothesis started, and to indicate some of its consequences. It is perhaps well at once to say that in its present shape the hypothesis is in rather severe difficulties over one phenomenon, but nevertheless the argument leads to a good many criticisms of existing theories which may be of interest.

It must be taken as absolutely certain that both the electromagnetic theory and the quantum theory are valid in their respective fields, and equally certain that the two descriptions are incompatible. We can only conclude that they are parts of an overriding system, which would give rise to mathematical formulæ identical with those of the present theories. It is true that from the present theories predictions can be made which are verified; this does not confirm the physical pictures associated with those theories, but only shows that the limits of their validity have not been reached. Now although the developments of the quantum theory in the past ten years have been enormous, and though there is no sign of their ceasing, yet these developments have not tended in the very smallest degree towards closing the gap which separates it from the wave theory. For this reason it seemed to me that the only hope of finding a reconciliation must lie in some other direction, and that it would be best deliberately to give up thinking of details and to go back to fundamentals.

In starting to modify existing theories it is obviously best to change as little as possible, and therefore we have at once to choose whether it shall be the wave theory or the quantum theory which shall serve as basis. On this question there will be a great diversity of opinion, but to me it seems that the wave theory is undoubtedly to be preferred. The chief reason for this is that, so far as we know, the classical theory gives correctly the observed results in the interference of light, no matter how high the frequency or how feeble the intensity; so that even if we could find a new language in which to describe interference, it would be possible exactly to transform the mathematics which expressed it into the present language of waves. In other words, the wave equations imply an infinite number of degrees of freedom and it can make no difference by what name these degrees are called. The main objection to the electromagnetic theory is that it claims to present a *complete* system of mechanics, and it is this completeness that is its fault; but the wave theory is only a part of the electromagnetic theory, and we can get a large latitude for modification by retaining only this part and altering the part which describes the interaction of waves with matter.

In the quantum theory it must be conceded that, for such things as resonance potentials or the hydrogen spectrum, it is extraordinarily difficult to conceive of any alternative explanation; but, even allowing for the danger of being over-critical of an avowedly incomplete theory, it is not too much to say that from first to last the associated physical picture is in great difficulties. In the first place frequency, which plays such a leading part in the theory, is not at all the same thing as it is in mechanics, and is not susceptible of any clear definition. Then there is the difficulty that the quantum conditions determining the permissible Bohr orbits can only be explained physically by attributing to the electrons a knowledge of the future. Again there is the extreme formalism of the Correspondence Principle, a most powerful method of advance, but one which even by itself would force one to believe in the inadequacy of the quantum picture. A great part of the success of the theory of spectra has lain in the demonstration that the properties of the atom can be described in terms of whole numbers, but the dynamical concepts associated with these numbers are chiefly derived from analogy with the case of hydrogen, and could be reinterpreted in conformity with any new interpretation that was found for hydrogen. For all these reasons it is natural to suppose that the complete picture will resemble the classical theory much more closely than it will the quantum theory.

In my former letter I brought up the point that there is no reason to believe in an exact conservation of energy, but only in a statistical balance. The point is not at all new, but from much discussion of the subject I think there is no doubt that many physicists consider a breach of the law of conservation as a serious objection to any theory. If we are to believe at all in the wave theory it is much more reasonable to maintain the exact opposite. The photoelectric effect is an impossibility in conjunction with the wave theory if energy is exactly conserved, but if only a statistical balance is required, then it becomes nothing more than one unexplained problem among others. Again there exist rigorous proofs that no system of differential equations can give the observed law for the partition of energy among a large number of degrees of freedom; but these proofs make use of exact conservation, and fail if it is denied; so the denial makes it far more possible to believe in the continuity of Nature. In the course of various discussions it has been suggested to me that it would be more satisfactory to suppose that energy was exactly conserved, but could become latent. It is difficult to see what advantages such an idea can have; but, at any rate, there is an essential difference in it, for it would imply that the total apparent energy of an enclosed system will fluctuate about a *fixed* average value, whereas in the case of a statistical balance it may slowly wander away from the initial value and will exhibit no tendency to return to it. Of course the wave equations possess an energy integral, and so acceptance of the wave theory implies conservation of energy in free space; it is for interaction with matter that it need not hold.

The principal point which I wish here to make is that a mere acceptance of the wave theory implies certain important consequences, which must follow no matter what is the nature of the reaction between waves and matter—consequences which have perhaps not always been fully appreciated. The starting-point is that when a light wave acts on matter there is certainly a reaction on the light and that it is inconceivable that this should be anything but a spherical wave issuing from the matter. Now consider what happens when light is absorbed. Evidently the molecules must give out waves of such a type that the transmitted light is reduced in intensity, and the diminution can only arise through the interference pattern composed by the plane and the spherical waves round about the produced direction of the incident beam. Moreover, the reduction is only possible if *there is some phase relation between the incident and the emitted light.* Examined from any other direction there will be no interference and the matter will appear to emit light—in other words, there must certainly be a scattered wave. It can be shown without more specific hypothesis that its magnitude is related to the optical constants of the matter in much the same way as it is in the classical theory. To any one accustomed to thinking only in terms of the electromagnetic theory there will be nothing remarkable in all this, though it is worth noting how much more general it is than the electromagnetic theory; but I have never seen the point mentioned in connexion with the quantum theory, and it appears to me that this scattered wave, having a phase relation with the incident and determining the balance of energy, is one of the most essential features to be watched in any attempt to work out a quantum theory of absorption.

In my former letter a similar argument led to the dispersion formula. Dispersion is more or less adequately described by the classical theory, provided that the electrons are supposed to be retained with such forces that in a free vibration they would emit light of frequency corresponding to some spectrum line. On the other hand, this line can only be described in terms of the quantum theory by the difference between the energies of two stationary states. Now the most striking merit of the Bohr theory was that it gave a simple physical meaning to the "terms" of the spectrum line, and the meaning ought also to apply for refraction. For this reason I tried the idea that an atom could only give out a standard type of wave, intending it to be the same wave as in a free emission, and was much surprised to find how easily this led to the ordinary dispersion formula. In a private letter Prof. Bohr pointed out to me an objection which makes it impossible to maintain the hypothesis in this simple form, because if the standard wave were as large as is indicated by the quantum theory, it would not explain the refraction of very faint lights. He has since published the same criticism in *Zs. f. Ph.*, vol. 13, 3, p. 117. I had overlooked this important point, but after writing the letter I came across another result which suggested the need for modification. This was that the intensity of scattering of hard γ-rays would be proportional not to the intensity, but to the amplitude of the incident rays. This seemed a very improbable result, but not quite inconceivable in view of the well-known difficulties about the scattering of γ-rays. In the course of a visit which I paid to Montreal, Dr. J. A. Gray, of McGill University, who is familiar with such work, very kindly agreed to examine the question experimentally, and has since informed me that he has verified that the scattered intensity is proportional to the incident intensity.[1] In the meanwhile it was evident that a simple modification of the hypothesis would meet the difficulty, and it also meets Prof. Bohr's objection. It was before assumed that the scattered light depended on the product of two factors. One of these was the probability of excitation, proportional to the rate of change of the incident electric force; this I called $A_n(\delta E/\delta t)dt$. The other was the amplitude α_n of the standard wave. It is only necessary to alter the assumptions by taking $A_n dt$ as the probability and $\alpha_n(\delta E/\delta t)$ as the amplitude of the scattered wave for both objections to disappear. The excited wave is still characteristic of the atom in frequency and phase, but its amplitude is proportional to the incident wave. This is the form of the theory with which I have since been working. But the failure of the standard wave is a very severe blow to accepted ideas of the quantum theory. It is not possible to suppose that the atom goes right into its upper quantum state; but instead we are forced to believe that the atom, so to speak, knows what the upper state is like without going there, and the exact opposite of this is one of the greatest merits of the Bohr theory. We must now believe (and the same conclusion can be drawn from the views of Bohr in the paper already cited) that the two stationary states associated with a spectrum line have a much more intimate connexion than is suggested by the theory of emission, a connexion of which their dynamical formulation gives no hint; and once this is admitted it becomes very questionable exactly what the physical nature of the states may be, and how much further we may depend on the simple ideas hitherto in vogue.

The necessary abandonment of the standard wave destroyed the strongest argument for my hypothesis, as it could no longer unite the classical theory with the simple form of the quantum theory. Nevertheless it seemed well worth while to follow it up, for it explains interference while departing very widely from the difficulties in which the classical theory is involved. In the course of later work it has appeared that all the ordinary phenomena of optics are given quite satisfactorily, including dispersion, metallic reflection, optical activity, X-ray reflection, and scattering as exemplified in the light of the sky. The theory gives a straightforward interpretation of one of the two effects recently discovered by Clark and Duane (Proc. Nat. Acad., vol. 9, p. 126 and p. 131). For the "X-peak" I know of no explanation, but the other effect strongly suggests that white X-rays can excite the characteristic radiations of the atoms of a crystal *in phase*. In this instance I think my hypothesis has very distinct advantages over the classical theory, but it would be premature to discuss

[1] The test consisted in varying the distance of the source—changing its amount would not have done.

the matter here. What may be called second order scattering does not work very well on the hypothesis, but neither does it on the classical theory. Rather perversely the phenomenon which causes almost insuperable difficulty is the one which is most satisfactory on either the classical or the quantum theory, and that is the phenomenon of resonance radiation, as exhibited in Wood's work with mercury vapour. On my hypothesis the vapour ought to be excitable by light of wave-lengths different from its own, instead of requiring a very exact adjustment in the incident light, as it in fact does. It seems possible that a satisfactory modification of the hypothesis might result from a study of this failure.

In connexion with resonance radiation it is worth raising the question of whether the resonant light has a phase relation with the incident. In the quantum theory it is always assumed that it does not, but there does not seem to be much direct evidence. As pointed out above, there must be some light scattered in the process of absorption, and this light must have a phase relation, but it would depend on the phase difference whether this is the observed light or only a much weaker emission of the same frequency. I suppose the balance of evidence is rather against the phase relation; on that side there is the fact that one line of the spectrum can excite the emission of others, and there is some indication of the existence of a considerable latent period. On the other side any form of the wave theory requires that at least a part of the scattered wave should be in phase, and there is also some support, though not very strong, in Wood's recent discovery that the light is nearly completely polarised. Perhaps the work of Clark and Duane may also be invoked on this side.

As general conclusion the argument shows that the physical picture associated with the present quantum theory can be valid only over a very limited field, and that the more satisfactory parts of the electromagnetic theory can be taken over by a wave theory freed from many hampering restrictions.

The so-called "Baccy-juice" in the Waters of the Thames Oyster-beds.

DURING May or June the waters over the oyster-beds at various places in the Thames estuary become periodically brown-coloured. This brown coloration is called "baccy-juice" by the local fishermen, who have connected with it such important observations on fisheries that its nature is worth recording. By the courtesy of Major A. Gardner and Mr. Louis French, I obtained on May 24 and May 28 tow-nettings and living samples of the "baccy-juice" from off Whitstable and off West Mersea, and find, as surmised, that the brown coloration is due almost entirely to the presence of great numbers of the spherical colonies of the brown flagellate Phæocystis. It is well known that Phæocystis occurs periodically in the English Channel and in the North Sea, and it is not surprising that it should occur in a similar way in the Thames estuary. The occurrence of "baccy-juice" in the Thames estuary is not welcomed by the fishermen (excluding oyster fishermen), who say that it is useless trawling for fish in the locality of this material, and also state that a cold spell of a few days is sufficient to cause it to disappear; these apparently good practical observations are well worth recording.

The Phæocystis from both sides of the Thames estuary, it is interesting to note, were carrying on each colony two or three individuals of a species of Acineta, closely allied to if not identical with *Acineta tuberosa*, var. *fraiponti*, which is taking advantage of the floating Phæocystis to adopt a planktonic and semi-parasitic habit.

A brown coloration of the water over oyster-beds in the riverine portion of estuaries is also very common in summer and autumn, but in the rivers Yealm and Helford and in the Hamoaze estuary this colour is due almost entirely to various peridinians, which constitute a very large proportion of the diet of oysters at this time. In an estuary more open to the influence of the sea, where high salinities probably occur, as at Padstow, a brown coloration in autumn was found to be due to enormous quantities of a species of Chætoceras. In July 1922 the slight brown coloration of the water over the oyster-beds in the West Mersea creeks of the River Blackwater was due to a variety of diatoms, among which *Leptocylindrus danicus*,[1] Cleve, was the most common; but at the same time the diatom, *Nitzschia closterium*, was the dominant and almost the only floating form in those stagnant or semi-stagnant oyster-pits which had mud on the bottom.

The Relation of the Critical Constants and the True Specific Heat of Ferromagnetic Substances.

A MAGNET should have, like a fluid, three critical constants—a critical temperature, a critical intensity of magnetisation, and a critical field. The critical temperature and the critical intensity may be experimentally determined; the critical field is more difficult to find by experiment, but it may be calculated from the other two critical constants. When this is done for iron, cobalt, nickel, and magnetite it is found that the critical fields are very simply related to one another, being almost exactly in proportion to the numbers 1·0 (1·5), 2·0, and 3·0 respectively.

Further, these numbers are inversely as the true specific heats of these substances at their critical temperatures, and the product of the critical field and the true specific heat must therefore be a constant. For iron this constant is 0·0225, for cobalt 0·0230, and for nickel 0·0225; for magnetite it is 0·0691, but if this is divided by 3, the number of atoms of iron in the molecule, the result again is the number 0·0230.

The critical field is calculated as $\theta/8I_0$, where θ is the absolute critical temperature, and I_0 the maximum intensity of magnetisation; and hence the true specific heat multiplied by the ratio θ/I_0 is $0{\cdot}0225 \times 8$, that is, 0·18. Now this number is, to a close approximation, five times the energy per unit of temperature for one degree of freedom calculated from R, the gas constant, and the atomic weights of the ferromagnetic metals, and this points to the specific heat at the critical temperature as that corresponding to five degrees of freedom. As there are three degrees of freedom in the calculation of the specific heat at air temperature, there must be an acquisition of two degrees of freedom at the critical temperature, a conclusion which has been reached by a different method, and was the subject of a letter printed in NATURE of July 1, 1922 (vol. 110, p. 10).

The result stated above may be put in another way by saying that the thermal energy at the critical temperature and the maximum intensity of magnetisation of the ferromagnetic substances are proportional to one another.

[1] I am indebted to Dr. M. V. Lebour for this identification.

Some relation of this kind was surmised by Faraday, who wrote: "My impression has been that there was a certain temperature for each body (well known in the case of iron) beneath which it was magnetic, but above which it lost all power; and further, there was some relation between this *point* of temperature and the *intensity* of magnetic force which the body when reduced beneath it could acquire" (*Phil. Mag.*, 1836, vol. iii. p. 177).

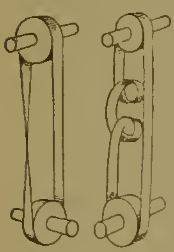
A Puzzle Paper Band.

SOME thirty or forty years ago geometricians were much interested in the endless band of paper to which one half twist had been given before joining the ends. This gave the figure having only one surface and one edge. At that time those who studied this figure were so obsessed with the consequence of cutting down the middle line of such a band or of a band with two or more half twists that I believe no one noticed the result which I wish now to describe. It is the doubling up in a proper manner of an endless band to which four half twists have been given so as to produce the endless band first described but of double thickness. The first band is shown at A, as an endless belt connecting two crossed shafts for which, as is well known, it is exactly fitted. B shows the band with the four half twists all on one side in the form of two complete loops, and to be uniform with the other it is shown as an open band connecting two parallel shafts. The only object of putting in the shafts and pulleys is to assist the perspective. They are not wanted in making the experiment. Now if B, which appears sufficiently uncompromising, is folded up properly it becomes A but of double thickness.



A B

I used this doubled A for a time as a record sheet for my recording calorimeter, for, having a head-room to work in of four feet and a movement of paper of six inches a day, I was able in this way to obtain a continuous record for 32 days on one side of the paper only. This is superseded now by a more convenient arrangement.

It may be worth while to add that while lying awake one night I visualised A in two thicknesses and saw it to be what I wanted, and the next day I found it all right. What I did not visualise was the puzzle that it is to fold up B into an A of double thickness, and that it makes a first-class parlour puzzle game. It has this further advantage that a number may be made, some with right-hand and some with left-hand twists, so that any preliminary success gained on one may make the other seem the more difficult. The band should be not less than 50 times as long as it is wide.

Of the four half twists two are easily seen in the finished double thickness band, for each thickness has one half twist; it is amusing to find out where the other two have gone. C. V. BOYS.

The Viscosity of Liquids.

IN NATURE for May 5, p. 600, Prof. C. V. Raman writes: "I have suggested that the viscosity of liquids and its variation with temperature may be explained on the hypothesis that the liquid state of aggregation is composite in character; that is, is composed in part of molecules 'rigidly' attached to each other as in a solid, and in part of molecules which are relatively mobile as in the gaseous state (NATURE, April 21, p. 532)."

The above hypothesis was suggested by me in a paper which appeared in the *Phil. Mag.* for Feb. 1888, p. 156. In solids the atoms or molecules, in normal conditions, are, in the majority of instances, adhering to each other, and if, owing to vibratory movements within the mass, the adhesion should be broken anywhere, the *same bond* is quickly restored if the mass be only moderately strained. If, however, the mass should be in a state of considerable strain, broken bonds may make new attachments, and the solid be permanently deformed. In the case of liquids, although the majority of the molecules are bonded by chemical forces, a number, depending upon the temperature, etc., are continually breaking bond, even in the absence of strain. but, instead of again remaking the original bonds, they may form *fresh bonds*. In the paper already quoted, p. 160, I remark: "Gravity may, therefore, give rise to a slow but continuous change of form in an elastic substance in the interior of which liquefaction and resolidification are constantly going on." The theory, particularly as regards ice, was afterwards developed in some detail, and I should like to invite attention to a paper on "The Viscosity of Ice," Proc. Roy. Soc. A, vol. 81, 1908, p. 250.

Irving Langmuir (Jour. Amer. Chem. Soc., vol. xxxix., Sept. 1917, p. 1858) also advances the same idea. He remarks: "The mobility of a liquid is thus due to a shifting of the relative positions of atoms which are all chemically combined with each other."

Perseid Meteors in July 1592.

IN NATURE of November 18, 1922 (vol. 110, p. 667), there appeared a letter from Mr. H. Beveridge, directing attention to a statement by Abūl Fazl that "on the 27th day of Tir O.S., which might correspond to about July 28, 1592, three hundred little stars or pieces of stars (*sitāracha*) were seen traversing the heavens from west to east." The date, Tir 27, belongs to the Târîkh-i Ilâhî, or Divine Era, which was used by Abūl Fazl, and must not be confounded with other calendars in which the same month names occur.

In a study assisted by Mr. Beveridge's courtesy I have examined a large number of dates belonging to this era, and I find that each year was made to begin at the sunset following the vernal equinox, and, so far as the dates can be tested by the days of the week or by an astronomical phenomenon, each month would appear to have been made to begin at the sunset following the entrance of the sun into a sign of the zodiac. There is one instance, however, where a month is made to begin one day earlier than it should according to this rule. According to this rule Tir 27 should begin at the twenty-seventh sunset after the summer solstice, which in the year 1592 would be on July 7 of the Julian calendar or July 17 of the Gregorian calendar, and I infer that the meteors were observed on the night of July 17-18 of the Gregorian calendar. There is no reason to suspect an error of more than one day in this date. In his translation of Abūl Fazl's Akbarnāma Mr. Beveridge identified Tir 24 of that year with July 4 of the Julian calendar, and I take it that July 28 in his letter to NATURE was a *lapsus calami*.

In the *Observatory* for May 1923, p. 169, Mr. W. F.

Denning examines the dates of abundant showers of Perseids and finds that a large proportion of them can be satisfied by a period of 11·75 years. This period would give an abundant shower for the year 1592, and Mr. Denning has included that year, apparently on Mr. Beveridge's authority, in the list of years of observed maxima. A list of Perseid showers, or at least of showers at the time of year when Perseids are expected, is to be found in Arago, "Astronomie populaire," iv. p. 296-8, and is extracted from Biot's "Catalogue général des étoiles filantes . . . observés en Chine," published in *Mémoires présentés à l'Academie, sciences math. et phys.*, x., p. 129, etc. To these Chinese observations it is possible to add one from Matthew Paris of the date 1243 July 26. The complete series then becomes: 714 July 15, 784 July 10, 830 July 22, 833 July 23, 835 July 22, 841 July 21, 865 Aug. 1, 924 July 21-23, 925 July 22, 23, 926 July 22, 933 July 20-25, 1243 July 26, 1451 July 27, all Julian dates.

An analysis of the dates of the medieval observations shows that the date of maximum intensity of the Perseid shower has not shifted its position in the sidereal year since the year 830 at latest. The date corresponds to a solar longitude of 138 reduced to the equinox of 1900. A few of the showers recorded in history fall a little before or after that date, and in two instances (784 and 865) the difference is as much as ten days on either side of the normal maximum. In 1592, on the other hand, the recorded shower falls nineteen days earlier than the normal maximum, and this raises a doubt whether it was really a Perseid shower at all or some otherwise unknown shower which happened to fall in a year when an abundant Perseid shower was due. The Measurement of Overvoltage.

IN general, the term overvoltage refers to the difference between the potential required to discharge an ion at a particular electrode and the calculated reversible value, in the same electrolyte. Strictly speaking, therefore, overvoltage only exists while the current is flowing, and hence measurements should be made under these conditions. Some workers, however, state that the "transfer resistance" of a gas film at the electrode causes the measured potential to be in excess of the true value; consequently, an alternative method has been adopted in which a rotating commutator rapidly interrupts the polarising current and connects the experimental electrode with the potentiometer system. In this way disturbing influences due to transfer resistance are said to be eliminated, since the potential of the electrode is measured when the current is not flowing. This method gives lower results than the direct method for the following reasons: (1) When the polarising circuit is broken, an extremely rapid fall of potential occurs, which is appreciable even in the small interval that elapses between the periods when current flows; (2) since the current only flows intermittently through the experimental cell, current density and time effects are not comparable with those obtained when the current flows continuously; (3) the continual make and break of the circuit by the commutator sets up alternating induced currents, and it is well known that electrical discharges of such a nature tend to lower the potential of a polarised electrode.

In some recent work, hitherto unpublished, the magnitude of the effects due to these induced currents has been investigated. The lowering of potential was found to depend upon the particular electrode examined, and was usually of the order of 0·3 volt, and in some cases as much as 0·5 volt. The value of the induced current, and consequently its effect on the potential, will depend on the frequency of the intermittent current, and upon the resistance and self-inductance of the circuit; but it seems fairly certain that the lowering of potential, due to induced currents in the commutator method for measuring overvoltage, is considerable.

In order to eliminate as many sources of error as possible, the following method for the measurement of overvoltage is being tested. The commutator method is being used, but a "choking coil" of high self-inductance is placed in the circuit in order to reduce the induced current to a negligible amount. Further, instead of the polarising and potentiometer circuits being made for equal intervals of time, the latter will only be complete for about 10° in each revolution. Thus for about 97 per cent. of the time the polarising current will flow through the cell, and, if the commutator revolves 3000 times per minute, only 0·0007 seconds will elapse between opening and closing the current circuit. To ascertain the magnitude of the fall of potential during this period, further experiments will be made, either by varying the speed of the commutator, or by increasing the period per revolution in which the experimental electrode is connected with the potentiometer system. By extrapolation, it should be possible to determine the potential of the electrode at the instant of breaking the current, and the results compared with those obtained while current is still flowing, in order to determine the effect of the so-called "transfer resistance." A New Phototropic Compound of Mercury.

IN an attempt to prepare the phototropic compound, dimercuric-diiodo-disulphide, described by Dr. Ray (Jour. Chem. Soc. 1917, T, 101-109), we accidentally discovered a new phototropic mercury compound of the formula $Hg\langle^{HS}_{CNS}$ through a mistake of the laboratory attendant in supplying us with potassium nitrate in the place of the nitrite. The compound is prepared by the interaction of a mercuric salt with ammonium sulphocyanide and thio-urea in a solution of acetic acid in the presence of an oxidising agent. The compound is also prepared by the action of hydrogen sulphide on mercuric sulphocyanide. This gives us a clue to the constitution of the yellow mercuric compound.

The compound is very phototropic, inasmuch as it is effected by strong sunlight in less than 1/60th of a second and by diffused daylight in a few seconds. It appears, therefore, to be the most phototropic compound as yet known. In researches on this compound we have prepared a red variety of mercuric sulphide by precipitation methods. Again, by the decomposition of the yellow mercuric compound, we have prepared a yellow variety of mercuric sulphide which shows interesting thermotropic properties. By the action of free iodine on the new phototropic compound, an iodine compound of mercury which is also phototropic has been prepared. Further work is in progress. Y. VENKATARAMAIAH.

Ancient Egyptian Chronology.

By Dr. H. R. HALL.

WHEN one is told that Tutankhamen, the Egyptian king, the discovery of whose tomb, followed by the tragedy of Lord Carnarvon's death, has aroused such widespread interest in ancient Egypt, reigned roughly between the years 1360 and 1350 B.C., it is naturally asked by many how this is known with such certainty? The Egyptians had no regular era. They merely spoke of such-and-such a year of King X. The Assyrian, however, possessed a continuous era, of which each year was noted by the name of an eponymous official. The definite fixing of this Assyrian era has been due to the help of astronomy. In a certain eponymy of the eighth century B.C., an eclipse of the sun is recorded as having taken place in the month Sivan (May-June). This has been reckoned astronomically to have taken place in 763 B.C. All other evidence of the kind fits in with and confirms this: the eponym-dates are certain to the actual year so far back as 893 B.C., when the later Assyrian series began, and are also now certain to within a few years at a much earlier period. So far back as the ninth century, at least, then, we can fix Egyptian dates with the aid of Assyrian synchronisms, and we find that Shishak I., the conqueror of Jerusalem, must have reigned about 930 B.C., which is not so different from the old traditional biblical date of 975 B.C.

Besides having no era, the Egyptians took no notice of eclipses. They did, however, possess an "epoch" which was based on astronomical observation: the "Sothic cycle." At an early period, apparently in the year 4241 or 4238 B.C., the Egyptian calendar was fixed to begin with the first day of the first month on the day of the heliacal rising of Sothis or Sirius. The year consisted of 360 ordinary days + 5 epagomenal. The necessity of intercalating a day every fourth year was not noticed. Hence, as time went on, the months lost all relation to the seasons, and the heliacal rising of Sirius would not correspond again with the first day of the year until a whole cycle of 1460 years had been completed. This cycle was recorded, but only used for calendrical purposes, never for dating events.

We know from classical sources that a new "æon" or cycle began in A.D. 139 or 143. The Alexandrian mathematician, Theon, called the beginning of the preceding cycle, which began in 1321 or 1317 B.C., the "era of Menophres." Now we know from synchronisms with Babylonian and Assyrian history, as well as from dead reckoning of the length of reigns, checked by the statements of Manetho (the Egyptian historiographer who lived in the third century B.C.), that roughly about 1321–1317 B.C. must have fallen the short period between the Egyptian kings Harmais (Harmhab) and Seti I., the end of the XVIIIth and the beginning of the XIXth Dynasty of Manetho; and between them reigned Rameses I., whose second name was Menpehre. Evidently he is Menophres, and the beginning of the era and the date of either 1321 or 1317 B.C. must have fallen in his reign. With this conclusion all the other evidence agrees.

Reckoning back from this date, we find that the dates of certain new-year festivals that are recorded on certain days of the month in certain years in the reigns of Thutmases (Tethmosis or Thothmes) III., and Amenhatpe (Amenophis) I., predecessors of Menophres, can be fixed to the years 1474 or 1470, and 1550 or 1546 B.C. The date for Thutmases III. is confirmed by the identification of two new-moon festivals recorded on certain days of the month in two stated years of his reign as those of May 15, 1479, and February 23, 1477 B.C. Our very full knowledge of the history of this time (the XVIIIth Dynasty) enables us to say definitely that these dates correspond to what a dead reckoning of the kings' reigns back from Menophres would demand. Also they fit in absolutely with the dates, based ultimately on the eponym-lists, demanded for Babylonian and Assyrian history at this time, when synchronisms with Egypt were frequent. Computing further back from the reign of Amenhatpe I. we find that I'ahmases (A'ahmes or Amosis) I., his predecessor, and the founder of the dynasty, must have ascended the throne within a few years either way of 1580 B.C.

So we know that Tutankhamen reigned about 1360–1350 B.C. He preceded Menophres by about thirty-five years, most of which was occupied by the reign of Harmais or Harmhab. The heretical king Akhnaten, the monotheistic worshipper of the god of the sun's disk, of whom there has been so much talk lately, and his father the great Amenhatpe or Amenophis III (Nibmare, the Mimmuriya of the contemporary Babylonians and Memnon of later Greek legend) will have reigned *circa* 1410–1360 B.C., the date also demanded by the synchronisms with Babylonia.

I have implied that no Egyptian dates earlier than 1580 B.C. are so certain as these. Of course there are the exceptions of the era-dates of 2781 (2778) and 4241 (4238) B.C. But we do not know what kings were reigning at these dates. Amosis, I imply, is the first king of whose date we can be certain; but this view is not universally held by Egyptologists. Some would go further back, to at least 2000 B.C. for certain dates, which are again deduced from the Sothic reckoning, on the following grounds.

In a papyrus of the XIIth Dynasty it is stated that Sothis rose heliacally on a certain day of a certain month in the seventh year of King Senusret III. German investigators have computed this date at 1882 (1878) or 1876 (1872) B.C.; but from the same data a British computer, Mr. Nicklin, has arrived at the date 1945 B.C. There is, therefore, evidently some room for doubt in the matter.

The German date is, however, generally received, and the XIIth Dynasty therefore currently ascribed to the period 2000–1788 B.C. But, apart from the fact of Mr. Nicklin's varying computation this date has seemed to several, including myself, to be open to serious objection, because it does not allow sufficient time for the XIIIth Dynasty and the period of the Hyksos kings. We have an Egyptian record of the kings, the Turin Papyrus, which gives a long list of the monarchs of this period, though without dates. Manetho, the Ptolemaic historiographer (or his commentators) assigns a lengthy period of time to this age. Yet the evidence from Crete is in favour of a short period, and would not disagree with the German dates. That of Egyptian archæology and art is also in favour of the shorter dates, yet scarcely for so short a period as a bare two hundred years. We have, too, so many contemporary records of kings of this time (apart from the evidence of the Turin Papyrus) that we cannot suppose that only two hundred years elapsed between the end of the XIIth and the beginning of the XVIIIth Dynasty. The Hyksos period alone can, one would think, scarcely have occupied less than two centuries.

So impressed is Prof. Flinders Petrie by these arguments (and others) that he boldly supposes that we must put the XIIth Dynasty back a whole Sothic period in time, and make Senusret III. reign about 3300 instead of about 1900 B.C. He has not been followed in this cutting of the Gordian knot, for few will believe that 1600 years can have elapsed between the two great dynasties, which on the ancient monumental lists of kings at Abydos and Sakkarah are immediately coterminous, the Hyksos and their predecessors being regarded either as usurpers or of no account. Prof. Capart is the only Egyptologist who seems inclined to go somewhat in the direction of supporting Prof. Petrie, but he must do so at the expense of abandoning the astronomical calculation, which Prof. Petrie accepts.

Personally, being unable to believe either that so few as 200 or so many as 1600 years separated the two dynasties, I can only suspend judgment until the astronomers have examined the question and the evidence anew and have recalculated the date indicated by the observation in Senusret's reign. Until then I can only suppose that some mistake either in ancient observation or modern calculation has occurred, and adopt provisionally the very round date of *circa* 2000 B.C. for the end of the XIIth Dynasty, which would satisfy most historical, archæological, and artistic demands.

This date would give the Middle Kingdom (XIth–XVIth Dynasty) the date *circa* 2350–2000 B.C. We know the lengths of the reigns of the kings of the XIIth Dynasty accurately from contemporary monuments, and Manetho combined with the monuments gives us an adequate idea of the XIth.

Now the Turin Papyrus becomes important. Its regnal years for the Old Kingdom (Dyns. I.–VII.) are often useful, in conjunction with Manetho and the monuments, and it gives the definite sum-total of the reigns of this period as 955 years. Allowing about 150 or 200 years for the IXth and Xth Dynasties (so far as they were not contemporary with the VIIIth and XIth) and for the period of interregnum in art and civilisation which certainly elapsed between the VIth and the XIth, we can roughly date the Old Kingdom to the round date *circa* 3500–2500 B.C. The three conquerors of the North, the Scorpion, Narmerza, and 'Ahai, who seem to have become conflate in later Egyptian legend as Meni or Menes, the first king of all Egypt and founder of the Ist Dynasty, will then have reigned about 3600 or 3500 B.C.

This date is about two centuries earlier than that maintained by the Germans, who are followed by Prof. Breasted. Prof. Petrie, of course, in accordance with his theory, goes much further back, returning to the remote date of more than 5000 B.C. which used to be credited twenty or thirty years ago. Capart moves in the same direction, too far in my opinion, and relying somewhat on an interpretation of the evidence of the fragments of the Palermo Stone (an ancient contemporary monumental chronicle of the time of the Vth Dynasty) put forward by Borchardt, which has been shown to be misconceived and untrustworthy by Prof. Peet.

The predynastic period, when there existed two independent kingdoms, if not three, in Egypt, which had arisen out of neolithic primitiveness, will then date to any length of time before 3500 B.C. that one may be inclined to credit. The institution of the fixed calendar in 4241 or 4238 B.C. will have been the first important sign of civilisation in Egypt.

Such, explained as succinctly as possible consistently with intelligibility, is the evidence on the subject of ancient Egyptian chronology. If the astronomers will turn their attention to the Kahun date and recompute it, and also tell us whether any ancient mistake is possible and of what kind, we shall all be better able to make up our minds on the subject of the dates before 1580 B.C.

That there is room for a recomputation is shown by the divergence of the calculations of Mr. Nicklin and of the Germans. That doubts of the necessary validity of all astronomical calculations of this kind are not altogether mistaken seems to be shown by the fact that the astronomical fixation of certain early Mesopotamian dates by Kugler, which has been accepted for several years past, is now discredited by many Assyriologists on the authority of the newly-discovered Assyrian king-lists and on account of the fact that Kugler's calculations, I understand, place the harvest season at an impossible time of the year. These doubters would bring the epoch of Hammurabi down again to nearly the date originally advocated by the late Prof. King before he accepted Kugler's results.

The 800th Anniversary of the Foundation of St. Bartholomew's Hospital.

In the long history of St. Bartholomew's Hospital, now extending over eight hundred years, during which the gates have never been closed or the wards entirely empty, many men have served the Charity well and faithfully. The exacting nature of the duties required of those attending upon the sick do not leave much time for speculative science, but the staff of the hospital has always been foremost in advancing the art of physic. The hospital was founded in 1123; and the celebration of its eight hundredth anniversary is being held this week. It was founded upon a religious basis and was placed in charge of a master, eight brethren and four sisters of the Augustinian Order. They had no science, but the scanty records of the treatment adopted shows that common sense prevailed and the experience gained was sufficient to build up a great tradition of practice and nursing.

The religious foundation lasted uninterruptedly for four hundred years until the Reformation led to a reconstruction. The enlightened policy of the citizens of London prevented spoliation and wholesale destruction, so that the Charity as it exists to-day still retains some of its original archaic characteristics. A succession of great surgeons—Vicary, Gale, Clowes, and Woodall—held office in the hospital under the later Tudor sovereigns. They were men who had gained their experience in the foreign wars and had served so far afield as Poland and Russia. Rough, practical surgeons, they concerned themselves with the sick and hurt and in an abortive attempt to raise their own professional status. Of science they knew nothing. It was slightly better, perhaps, on the medical side. Dr. Timothy Bright did some service when he invented his system of shorthand, but the discoveries of William Gilbert in magnetism seem to have been entirely unknown to them, although as members of the same profession and of the same college, living together in a small town, they must have been constantly in association with him. The governors of the hospital would indeed have done themselves great honour had they chosen him as their first physician under the new foundation instead of electing one who was afterwards hanged, drawn, and quartered for conspiring to poison Elizabeth.

The real scientific history of the hospital begins with William Harvey, appointed physician in 1609, who announced his discovery of the circulation of the blood in the Lumleian lectures at the College of Physicians in 1616. The discovery revolutionised the practice of medicine and made possible an experimental physiology. The very simplicity of the proofs were a stumbling-block to his contemporaries, but the teaching was eagerly accepted by the younger generation, those founders of the Royal Society who formed so wonderful a band at Oxford and in London just after the Restoration.

When Harvey died, the mantle of science in the hospital fell sometimes on the medical and sometimes on the surgical side of the house. Percivall Pott began to teach surgery systematically, and his lectures were attended by John Hunter, the founder of scientific surgery in England. The pupils of Pott followed each other in a long succession as surgeons to the hospital and *quasi cursores* handed on the Hunterian teaching to our own day. Earle and Abernethy, Lawrence, Savory, and Butlin bridged the interval between the death of Hunter and the dawn of Lister. But, as in the time of Harvey, the older teaching had become so ingrained in the school that it was found difficult to accept the doctrine of the germ theory of disease and the revelations of antiseptic surgery. It was not until a new generation came into its own that men like C. B. Lockwood entered whole-heartedly into the promised land of Listerism, and Klein, Kanthack, and Andrewes advanced the great science of bacteriology.

Until 1836 the teaching of chemistry was in the hands of the physicians to the hospital, but from that time onwards it became specialised and the school was fortunate in obtaining a regular succession of first-rate teachers; Brand, Stenhouse, Frankland, Abel, Odling, Russell, and Chattaway followed each other, the students were well taught, and some opportunities were afforded for original work. In like manner, Sir Lauder Brunton, before he became physician to the hospital, was a pioneer in experimental pharmacology, and in that branch of knowledge which has since developed into bio-chemistry. Between 1882 and 1912 Steavenson and Lewis Jones by their work at the hospital raised medical electricity from a scientific empiricism to its position as a recognised branch of medicine. Lewis Jones, indeed, in his all too short life fairly earned the title of "the Father of Medical Electricity."

A great hospital leads to advances in many departments of science. New problems are constantly presented; the permutations and combinations arising in the complex structure of the human body are endless and the chemist and physicist are often able to give material help in placing medicine upon a firm basis of fact.

The Complete Gasification of Coal.

By Dr. J. S. G. THOMAS.

IT is well known that the percentage thermal efficiency of gas production from coal can be increased by gasifying the coke resulting from the high temperature carbonising process, and various processes and plants for effecting this conversion have long been available. Shortage of fuel supplies during the years of the War, and afterwards, resulted in the Board of Trade issuing instructions to gas companies to "stretch" their supplies of gas. The "stretching" process intended was to consist of a reduction of calorific power of the gas supply, accomplished by dilution of straight coal gas with either blue or carburetted water gas. The attention of the industry in all countries was, at the time, naturally directed towards increasing the efficiency of production of water gas and its efficient utilisation admixed with coal gas in a towns' gas supply. In England considerable work on these lines was done by George Helps, the "big noise" of Nuneaton.

Much publicity has recently been given to a plant designed by C. B. Tully, and operated at Bedford, for the complete gasification of coal. Altogether, since 1919, about two hundred such plants have been erected in this country, the largest being installed at Halifax, which is capable of producing about 7000 therms per day. The installation at Bedford comprises two sets, each capable of producing about 2500 therms per twenty-four hours. The average percentage composition of the gas is approximately CO_2, 5; N_2, 5; O_2, 0·5; CO, 36; H_2, 45; CH_4, 8; C_nH_m, 0·5, and the calorific power is about 350 B.Th.U. per cubic foot. Bedford is supplied with a mixture of straight coal gas with about 51 per cent. of this gas, the resulting calorific power being about 460 B.Th.U. per cubic foot. Manufacturing costs in the case of the Tully plant are stated to amount to about 2·74*d.* per therm and the capital manufacturing charges to about 0·08*d.* per therm. The desirability or otherwise of the manufacture and distribution of this gas in any definite case must be determined by a variety of factors, among others by the size of the undertaking, local conditions as regards supplies of raw coal, characteristics of the demand for gas, storage capacity, and size of the distributing system. Increased costs must be incurred in the distribution of the gas compared with those incurred in the case of straight coal gas.

On one matter to which public attention has recently been directed we would remark that the possibility of converting the comparatively large percentage of carbon monoxide in water gas into carbon dioxide or methane is by no means a novel proposition either from the scientific or industrial point of view. Sabatier and his co-workers showed, many years ago, that in the presence of nickel, cobalt, or palladium, carbon monoxide and hydrogen at 230-400° C. react to form methane and water, thus: $CO + 3H_2 = CH_4 + H_2O$. This hydrogenation is subject to the important objection from the technical point of view that while hydrogen must be present in excess, an equal volume of hydrogen must be added to water gas to provide the mixture theoretically necessary. This hydrogen can be derived from water gas, and the net result is that the yield of methane is only about 15 per cent. of the total water gas employed. Sabatier pointed out that by passing water gas over nickel at 400-500° C. the following reaction occurred; $3CO + 3H_2 = CH_4 + H_2O + C + CO_2$. The carbon deposited on the catalyst may, at the same temperature, be caused to react with steam to form a mixture of hydrogen, methane, and carbon dioxide, whereby the catalyst is regenerated for use in the first phase of the process. Sabatier further suggested that both phases might be combined by passing water-gas and steam over a nickel catalyst at 400-500° C., when the following reaction occurs: $5CO + 5H_2 + H_2O = 2CH_4 + 2H_2 + 3CO_2$.

These various reactions are summarised in a recent paper by Drs. E. F. Armstrong and T. P. Hilditch, read before the Royal Society (see NATURE, February 3, p. 168), in which they direct attention to a reaction between carbon monoxide and hydrogen which has hitherto apparently escaped notice. They find that the action between equal volumes of carbon monoxide and hydrogen in the presence of nickel or a similar catalyst at temperatures below 300° is in the main represented by $2CO + 2H_2 = CO_2 + CH_4$. It will be noticed that the gases carbon monoxide and hydrogen participate in the reaction very approximately in the relative proportions in which they are present in blue water gas, (43 per cent. CO, 48 per cent. H_2). The reaction, though never complete, proceeds to a very considerable extent, and the authors consider the process may be of value in gas practice as the proportion of methane is 25 per cent. of the water gas decomposed, whereas by any of the other processes referred to the maximum possible yield is only 20 per cent.

The idea of the technical utilisation of the first reaction referred to above for the production of methane, and the application of the reversible reaction $CO + H_2O = CO_2 + H_2$ for the production of hydrogen has recently been revived in connexion with the Tully plants. It must be realised that little if any actual large-scale operations of this nature have hitherto been carried out. Considerable experience is necessary for the successful operation of catalytic plants operated at relatively high temperatures and dealing with the huge volume constituting a day's make of towns' gas in the case of even one of the smaller gas companies. It is contemplated that the plant required would be of the same nature as that designed for the catalytic purification of gas from sulphur compounds which is in successful operation in the works of the South Metropolitan Gas Company. Operating charges would possibly amount to about ½*d*. per therm. It is questionable whether it would be technically feasible to remove the carbon dioxide produced. A suitable catalyst has been prepared, and small-scale operations in a plant capable of treating 200 cubic feet of gas per hour have been carried out. Large-scale operations constitute a much more difficult proposition.

Obituary.

MR. F. W. HARMER.

BY the death on April 24 of Mr. Frederic William Harmer, within a few days of the completion of his eighty-eighth year, the county of Norfolk loses one of its most distinguished sons and East Anglia the penultimate survivor of a band of amateur and professional geologists to whom science is under deep obligations, not merely for the elucidation of local problems, but for the establishment of principles and of methods of research of European or even wider application.

Mr. Harmer, descended from a stock the most ancient in Norfolk, was early imbued with a love of science, especially of geology, and the fortunate chance of a meeting in 1864 with Searles V. Wood the younger directed his enthusiasm and energy along lines of research that, with one significant break, he followed to the end of his long and useful life. The two friends embarked upon the study of the records of the Ice Age, and, in pursuance of Wood's conviction that accurate mapping of the glacial deposits was essential to the decipherment of their story, the task—never before attempted—was undertaken, and in the course of a few years an area of 2000 square miles was mapped on the scale of one inch to the mile. Harmer's share was the county of Norfolk and the northern parts of Suffolk.

Wood told the present writer that the young officers of the Geological Survey with whom he was often in conflict ought to be grateful to him and his friend because their demonstration of the practicability of mapping drift deposits had compelled the Survey to increase its staff. Copies of the map, claimed by its authors to be the first of its kind ever produced, have been deposited in the library of the Geological Society and in the Museums at Norwich and Ipswich, and a lithographed reduction of the eastern portion was appended by Wood to one of the supplements to his father's great monograph of the Crag Mollusca.

The period of his association with Wood, of whom Mr. Harmer always spoke with touching reverence and affection, was brought to a premature close by the complete breakdown of Wood's health ending with his death in the early 'eighties. The loss of his friend and master acted as an effective damper upon Mr. Harmer's geological activities, and for more than a decade he threw his energies into business and the multifarious duties of municipal life.

The meeting of the British Association at Ipswich in 1895 was marked by the reappearance of Mr. Harmer, to the great surprise of a generation that had come to regard his work as finished. He presented two important papers upon the Coralline and Red Crags, which were received with great interest and attention by newcomers in the field of Pliocene geology and also by distinguished workers from France and Belgium present at the meeting.

From this time until the end of his life Mr. Harmer's interest and activity never flagged. He again took to the field and contributed many important papers to the Geological Society and other bodies. In Pliocene geology his achievements were many and valuable. The discovery of a deposit of Red Crag at Little Oakley, which yielded to his minute and pertinacious investigation a fauna of unparalleled richness, led him to a general review of the Pliocene geology of East Anglia, giving definiteness to the opinion long held by workers in that field that the deposits of Red Crag age marked successive stages in the withdrawal of the North Sea from south to north.

A discussion of the fragmentary Upper Tertiary patches of Lenham gave occasion for the correlation of the British Pliocenes with those of Belgium and Holland. His achievements in this field of study have the enthusiastic recognition of the geologists of Holland, Belgium, and France.

The remarkable contrast presented by the contemporary Pliocene deposits of the two sides of the North Sea in regard to the abundance of shells led to investigations of great moment. Premising that shells are cast up in profusion on the Dutch coast by the prevalence of onshore winds, Mr. Harmer showed that in Pliocene times the western shores received the shelly beaches. He proceeded from this to an elaborate discussion of the meteorology of the Pliocene and Glacial Periods, the first attempt by any man of science to apply the methods and results of modern meteorology to the solution of geological problems. This pioneer work has been followed up by many writers, notably in the recent book "The Evolution of Climate" by Mr. C. E. P. Brooks, to whom Harmer's work was apparently unknown.

The many additions to the Molluscan fauna of the Upper Tertiaries rendered necessary the resumption of the work of description interrupted by the death of the elder Searles Wood. Mr. Harmer undertook the task, and it is gratifying to know that shortly before the accident by which his death was accelerated he had revised the final proofs of the last of a series of supplements to the monograph on the Crag Mollusca published by the Palæontographical Society.

The great value of Mr. Harmer's work was recognised by his geological brethren; from the Geological Society he received the Murchison medal; he was elected successively Membre Associé Étranger and Membre Honoraire of the Belgian Geological Society; and the University of Cambridge conferred upon him the honorary degree of M.A.

Two of Mr. Harmer's sons adopted a scientific career, in which they have attained very high distinction; the elder, Sir Sidney F. Harmer, is well known as the director of the Natural History Department of the British Museum; the other, Mr. William Douglas Harmer, called at a very early age to the position of warden of St. Bartholomew's Hospital—always regarded as a presage of future distinction—is now the senior surgeon in the throat department of the hospital.

Percy F. Kendall.

Mr. M. de C. S. Salter.

The death on May 21, after a short illness, of Mr. Mortyn de Carle Sowerby Salter, at the early age of forty-two, removes from the scientific world an extremely able worker just at the moment when the mastery he had attained in his special field of study had brought him in sight of important achievements. The son of Mr. M. J. Salter, he was educated at Bancroft's school, and passed directly, at the age of sixteen years, to an assistantship in the British Rainfall Organisation under its founder Mr. G. J. Symons. Here he developed an aptitude for statistics and a patience with detailed routine which enabled him later to grasp the scientific principles underlying the distribution of rain and develop an enthusiasm for research combined with sagacity in the practical application of his knowledge.

Mr. Salter became my chief assistant at Camden Square in 1907, and from 1912 onwards relieved me of the whole responsibility for the accuracy of the annual rainfall tables in "British Rainfall." In 1914 he was appointed assistant-director and in 1918 joint-director of the Organisation, and on the transfer to the Meteorological Office of the Air Ministry in 1919 he became the first superintendent-in-charge, and was thus able to make the transition from private to official management easy for the five thousand voluntary observers.

Mr. Salter's health was always precarious, but he was nevertheless an indefatigable worker, and to the fact that no Medical Board would pass him for any form of military service is probably due the survival of the long-established system of rainfall investigation throughout the years of the War.

Mr. Salter served on the council of the Royal Meteorological Society and as a vice-president for many years; and he was an active member of the Institution of Water Engineers. He contributed numerous papers to these societies and to the *Meteorological Magazine*, of which he was joint-editor since 1913. He took a considerable part in the compilation of annual rainfall maps of the British Isles and of large-scale rainfall maps of many counties and other areas in co-operation with me, and after my retirement he carried the rainfall mapping of the country far towards completion. His little book "The Rainfall of the British Isles," published in 1921, gives an excellent account of the existing state of knowledge on the subject. In a paper on the fluctuations of annual rainfall considered cartographically, in collaboration with Mr. J. Glasspoole, read to the Royal Meteorological Society during his last illness, Mr. Salter gave an important discussion of the regional relations of rainfall and atmospheric pressure full of promise for future development.

For twenty-three years I found Mr. Salter a loyal fellow-worker and faithful friend, keenly intelligent, absolutely trustworthy, full of sympathy and consideration. I have pictured him writing my obituary notice; I never thought the natural order would be reversed. Hugh Robert Mill.

Prof. E. Hagen.

The issue of the *Physikalische Zeitschrift* for April 1 contains the account of the life and work of the late Prof. E. Hagen given by Prof. E. Gümlich at the meeting of the German Physical Society on March 9. Prof. Hagen was born at Königsberg on January 31, 1851, and losing his mother, who was the youngest daughter of Bessel the astronomer, in 1856, was brought up by a stepmother for whom he had a lifelong affection. On the removal of his father to Berlin he became a pupil at the local Gymnasium and in 1871 entered the University. After two years there he went to Heidelberg, where he graduated in 1875, having in the meantime acted as assistant to Bunsen. The next two years he spent at Dresden as assistant to Toepler and a further six as assistant to Helmholtz at Berlin.

In 1883 Hagen became a lecturer in the University of Berlin, and next year extra professor of applied physics at the Dresden Polytechnic. In 1887 he became physicist to the Navy and, removing to Kiel, acted also as extra professor at the University. In 1893 he became director of the technical section of the Reichsanstalt at Charlottenburg. He married in 1896 the daughter of Von Bezold the meteorologist, and in 1904 joined the staff of the German Museum at Munich. He died of inflammation of the knee on January 15. He was best known in this country for his work in conjunction with Rubens on the connexion between the electrical conductivity and the radiating and reflecting powers of metals.

It is with much regret that we record the death of Dr. Elizabeth Acton, on Sunday, May 13, after a prolonged illness. Dr. Acton was a distinguished student of the late Prof. G. S. West in the botanical department of the University of Birmingham. In 1908 she took her Bachelor of Science degree with honours, and in the following year received the M.Sc. for research work in botany. After that time she was almost continuously engaged in botanical research, and in 1916 was awarded the degree of D.Sc. (Birmingham). Her contributions to the study of fresh-water algæ are of outstanding value, and her work throughout was marked by great thoroughness and painstaking accuracy. Her early death has removed a devoted worker from the sphere of botanical research. Dr. Acton's activities outside her scientific work were necessarily limited, owing partly to her continuous ill-health and partly to her retiring disposition. She was a loyal friend, and her uncompromising honesty was one of her chief characteristics. J. S. B. E.
E. M. P.

We regret to announce the following deaths:

Prof. J. Chiene, emeritus professor of surgery in the University of Edinburgh and a friend and disciple of Lord Lister, on May 29, aged eighty.

Canon W. W. Fowler, president in 1901–2 of the Entomological Society, and author of "The Coleoptera of the British Islands," on June 3, aged seventy-four.

Prof. Franz Neger, professor of botany in the Dresden Technical College and director of the Botanical Gardens there, who worked with Baeyer for several years and published a thesis on dehydracetic acid, aged fifty-four.

Current Topics and Events.

The immense progress which has been made in the elucidation of crystal structure by means of X-rays, since the first discovery of von Laue at Munich in 1912, and especially the quantitative development which has afforded the absolute distances separating the atoms, their actual sizes, and the dimensions of the space-lattice cells, is largely due to the invention of the ionising X-ray spectrometer by Sir William Bragg. The brilliant use made of that instrument at University College, London, and latterly also by an increasing number of other workers in various parts of the world, has been the means of accumulating a surprising amount of knowledge of the structure and structural dimensions of a large number of substances, many of the more recently studied of which are no longer of the simplicity of those first submitted to investigation. It must prove of interest, therefore, to our readers that we are able to present, as a supplement to the present issue, a revised form of an admirable lecture which was recently delivered by Sir William Bragg to the Royal Society of Arts. The most noteworthy fact which emerges from the accumulated results, including those derived from the photographic method of Laue and the powder methods of Debye, Scherrer, and Hull, is that the conclusions of crystallographers, based on the most accurate crystal measurement and on the perfected geometrical theory of crystal structure, are proved to be correct, both as regards the nature of that structure, and its relative unit-cell dimensions in those few cases in which it had been possible to determine them. These relative dimensions are now converted into absolute values by the X-ray spectrometric measurements. The recent venture into the more difficult field of organic substances is adding a further chapter of exceptional interest, and is of immense importance both to chemistry and to optics. The results have already had the happy effect of restoring the molecule to its proper place in the solid state, from which only a misreading of the first few results with the simplest inorganic compounds had temporarily displaced it. Moreover, they have rendered it clear that the number, nature, and arrangement of the external electrons of the atom itself are involved in cementing together the parts of the crystal structure, so that further work is bound to throw light on atomic structure, and possibly to decide between, or combine the correct portions of, the rival theories concerning it.

Circular No. 137, issued by the Bureau of Standards, U.S.A., is the fourth of a series of circulars describing very simple radio receiving sets which were originally prepared for use by the Boys' and

Girls' Radio Clubs of the States Relations Service, Department of Agriculture. In Circular No. 120 it was shown how a single circuit and in Circular No. 121 how a double circuit crystal-detector set could be made out of ordinary domestic materials. It is now shown how the operation of either set can be improved by the use of a very simple and cheap condenser connected across the telephone receivers and a similar one connected in series with the antenna. Clear instructions are also given for constructing a simple loading coil so that longer waves can be received. The condenser in series with the antenna makes it easy to tune to wave lengths of less than 300 metres, whilst the condenser across the telephone receivers increases the intensity of the signals. The loading coil enables time signals, etc., to be received from high power stations. The parts for the auxiliary condensers cost about 80 cents, and the parts for the loading coli about 3 dollars.

Messrs. W. Heffer and Sons, Ltd., Cambridge, have just circulated a very full and useful catalogue (No. 224) of scientific books and serials numbering upwards of 2000 titles and classified under the headings of agriculture, husbandry, and farriery; anthropology and ethnology; botany; chemistry, chemical technology, and metallurgy; geology, mineralogy, and palæontology; zoology and biology; physiology, anatomy, and medicine; psychology and psycho-analysis portraits of men of science; and mathematics, physics, and engineering. The list is especially interesting from the fact that many of the works are from the library of the late Sir William Ramsay. We note that Messrs. Heffer are offering for sale in one lot a large collection of books, pamphlets, and serials dealing with aeronautics.

The cinematographic film, entitled "The Wonderland of Big Game," which Major A. R. Dugmore is showing at the Polytechnic Hall, Regent Street, London, is certainly one of the finest of its kind and deserves the attention of all interested in natural history. It is the result of a special expedition to East Africa made by Major Dugmore in 1922, and it is shown in connexion with a most charming and lucid explanatory lecture delivered by Major Dugmore himself. The outstanding merit of this film is its entire truthfulness and freedom from fake. It shows about thirty species, not only in their natural surroundings, but also under perfectly natural conditions, unharried by the big game hunter and usually unconscious of the presence of the harmless photographer. Save for occasional shots at lions, only one shot was fired at an animal during the expedition, and that was one intended merely to turn a rhinoceros from a headlong charge upon the camera. The animals are shown grazing at their ease upon the veldt, moving through the forest glades, or coming down to the water-holes to drink. The pictures of the common and Grevy's zebras, rhinoceros, elephant, buffalo, oryx and other antelopes, and, above all, of the reticulated giraffe are of very great interest; no one, with an experience wholly derived from Regent's Park, can imagine the grace of giraffes in free motion. The flashlight portraits of a lion and his mate also deserve special notice. Though perhaps less thrilling than some of the photographs of lions exhibited at other places recently, they are true to life, showing the animals as they normally behave, and not as they are when, infuriated by pain, they are held in a powerful trap, concealed by some convenient bush from the lens of the camera. Portions of the film will appeal also to those who are interested in anthropology, physical geography, and geology. Major Dugmore deserves success; and we hope that his lecture will draw large audiences for a long time to come.

The work that has been carried on by the British Science Guild since 1905, with the object of bringing about a better public appreciation of the value of science, is in many respects unique. There is no body that has done more to bridge the gap between the public and the man of science. Among various matters of general interest that are now engaging the attention of its various committees may be mentioned the adequate representation of science at the British Empire Exhibition and the question of a British Empire patent. The Catalogue of British Scientific and Technical Books has proved a valuable piece of work, and it is satisfactory to note that sales and contributions have brought in a sum which almost equals the cost of production. The publication of a new edition is now being taken in hand. An interesting step has been the issue of publicity leaflets summarising recent scientific developments in popular form. The first of the series, by Prof. J. C. McLennan, deals with "Helium and its Uses." The production in mass of this non-inflammable gas for use in airships is a fascinating story, and there is no more striking example of scientific achievement during the War. The second leaflet, by Prof. J. A. Fleming, on "The Thermionic Valve" is now in preparation. There is no doubt that this new departure will be of service in promoting the objects of the Guild. Naturally, however, such propaganda work cannot be conducted without the "sinews of war." At the special meeting at the Mansion House on February 27, and again at the annual dinner on May 30, reference was made to the appeal now being issued by the Guild for contributions to form a fund of 50,000*l.* to enable its programme to be energetically developed. It is to be hoped that this appeal, which has received most influential support, will meet with a generous response.

The second, or ladies', conversazione of the Royal Society this year will be held at Burlington House on Wednesday, June 20.

Dr. A. Bowman, senior naturalist on the staff of the Fishery Board for Scotland, has been appointed superintendent of scientific investigations under the Board.

Prof. C. Moureu, president of the Société Chimique de France, will deliver a lecture on "Les gaz rares des sources thermales, des grisous et autres gaz naturels" at the rooms of the Chemical Society, Burlington House, on Thursday, June 14, at 8.30 p.m.

H.R.H. THE PRINCE OF WALES has graciously accepted enrolment as an honorary member of the Institution of Mining Engineers and of the Institution of Mining and Metallurgy.

THE Board of Managers of the Royal Institution has elected Sir William Bragg to be Fullerian professor of chemistry, and director of the Laboratory and of the Davy Faraday Research Laboratory, in succession to Sir James Dewar.

THE list of honours conferred upon the occasion of the King's birthday includes the following names of men distinguished in scientific fields:—*Knights:* Mr. G. H. Knibbs, director of the Bureau of Science and Industry, Commonwealth of Australia; Prof. W. J. R. Simpson, professor of hygiene, King's College, London; and Dr. H. W. G. Mackenzie, senior censor, Royal College of Physicians. *Knight Companion of the Order of the Indian Empire* (*C.I.E.*), Mr. J. Evershed, director of the Kodaikanal and Madras Observatories. *Member of the Order of the British Empire* (*M.B.E.*), Mr. R. Ward, superintendent of the Botanic Gardens, British Guiana.

A limited number of fellowships for post-graduates in chemistry who are desirous of adopting an industrial career are being offered by the Salters' Institute of Industrial Chemistry to become operative in October next. The fellowships are of the annual value of from 250*l.* to 300*l.* each. Applications, with full particulars of training and experience, must reach the clerk of the Salters' Company, Salters' Hall, St. Swithin's Lane, E.C.4, before July 1.

UNDER the auspices of the Pontificia Accademia Romana dei Nuovi Lincei, a number of public lectures on subjects of scientific importance has been given recently in Rome. On April 26 and 27 Prof. C. J. de la Vallée Poussin, of the University of Louvain, lectured on functions of a real variable; on April 28, Prof. G. Gianfranceschi, of Rome, dealt with the structure of the atom; and on April 30, Prof. G. Boccardi, of the University of Turin, discussed the position of research on the variation of latitude. A lecture in commemoration of Louis Pasteur was delivered on May 2 by Prof. A. Anile, of the University of Naples, who dealt with the life and work of Pasteur. The addresses are to be printed and published by the Academy in due course.

THE Société Française de Physique, the headquarters of which are at 44 Rue de Rennes, Paris, was founded in 1873. There are now more than 1100 members, including 250 foreign members. Meetings are held twice monthly, and the transactions are published in a Bulletin. In addition to the Bulletin, members receive every month the *Journal de Physique et le Radium*, which publishes original communications, particularly on subjects dealt with at the meetings of the Society, and includes a review of a large number of French and foreign periodicals. Persons desirous of becoming members should send to the president a written application, supported by the recommendation of two members. The yearly subscription for foreign members is 65 francs, with an entrance fee of 10 francs.

IN connexion with the visit of H.R.H. the Prince of Wales to the East Hecla Works of Messrs. Hadfields, Ltd., to which reference was made last week, p. 759, we have received a description of the equipment of the works, including the research laboratories, which are provided with a very extensive range of instruments for the study and investigation of steels. In addition to the mechanical laboratories, in which alternating and impact tests are conducted as well as the older tests, there is a thorough equipment for the standardisation of pyrometers, whether thermo-electric, resistance, optical, or radiation. The apparatus in this section includes a Harker furnace for very high temperatures. Electrical and magnetic testing instruments are also included, in addition to the usual micrographic equipment. A feature of the department is the collection of specimens illustrating the researches which led to the discovery by Sir Robert Hadfield of manganese steel and of low hysteresis steel. Collections illustrating the early history of metallurgy were also exhibited on this occasion.

THE Board of Managers of the Washington Academy of Sciences has elected the following honorary foreign members in recognition of their prominence in their respective fields and their intimate connexion with scientific work in Washington: Prof. L. Manouvrier, Paris, for his work in anthropology; Dr. C. F. A. Christensen, director of Universitetets Botaniske Museum, Copenhagen, for his services to systematic botany, particularly his monographic studies of tropical American ferns of the tribe Dryopterideae; Dr. Paul Marchal, French Ministry of Agriculture, for his investigations in biological problems and their relation to agriculture, and especially for his research work in polyembryony; Mr. E. C. Andrews, Government geologist of New South Wales, for his work in geology, particularly in the fields of origin of coral reefs, physiography, origin of the Australian flora, mountain formation, and origin of metalliferous deposits; Sir Ernest Rutherford, for his distinguished work in chemistry; Prof. F. Omori, professor of seismology, Imperial University, Tokyo, for his outstanding work in seismology; Prof. G. Stefanini, Florence, for his investigations in palæontology and stratigraphy, especially the tertiary formations of Italy and echinoids in general; and Prof. Max Weber, University of Amsterdam, for his work in zoology.

IN the Journal of the Franklin Institute for May, General Squier describes a method of transmitting the telegraph alphabet which can be applied to radio communication, telegraph lines, and submarine cables. Owing to the rapid expansion of radio telephony and telegraphy the problem of interference, both natural and artificial, has become one the solution of which must shortly become imperative. As there are only a limited number of lanes through the ether their conservation is of international importance. Radio waves are used very widely in navigation and for radio beacons. In addition, we seem to be on the threshold of another great development—"photo-broadcasting," which will require and demand still more ether channels to serve the public of the near future. Radio telegraphy as conducted at present causes great disturbance. The power stations produce great explosions in the ether, the waves sent out having a wide range of frequencies which interfere with all forms of radio receiver. At present the radio engineer has utilised all the audio range of frequencies and several octaves of the radio frequency range. General Squier's plan is to utilise the infra audio range of frequencies, which are not used at present. An advantage of his system is that it cannot interfere with radio receiving. When applied to submarine telegraphy a modulating frequency of 10 per second corresponds to 75 words per minute, which is far higher than any form of sound reception.

AT a meeting of the Optical Society held on Thursday, May 24, Mr. R. S. Whipple, vice-president, in the chair, the sixth of the series of lectures on the evolution and development of optical instruments was delivered by Mr. David Baxandall, the subject being "Telescopes before the early part of the 19th century." The period from the time of Roger Bacon (d. 1292) to the beginning of the 17th century was dealt with at some length, particular attention being directed to William Bourne's description (1585) of a 12-inch perspective glass of about 15 feet focal length, which gave telescopic vision and magnified distant objects about twenty times. The invention of the telescope with concave eyelens by Hans Lippershey in 1608 was then dealt with and William Gascoigne's description of the way he arrived at the invention of telescopic sights quoted. The invention of the Gregorian and Newtonian reflecting telescopes was next referred to, and followed by a description of Hadley's reflector. The work of Chester Moor Hall, and the researches and work of John Dollond and Peter Dollond on the development of the achromatic lens, were also discussed. The lecture was illustrated by a number of pictures of old telescopes and by exhibits from the Science Museum, which included an early Italian telescope, and object-glasses or telescopes by various telescope-makers from the latter part of the 17th until the early part of the 19th century; the original glass negative made by Sir John Herschel in 1839; William Herschel's polishing machine, and the 7-foot reflector with which he discovered the planet Uranus. A number of these examples are from Mr. Thomas H. Court's collection in the Science Museum.

CAPT. R. AMUNDSEN hopes to undertake his projected flight across the North Pole about the end of June. After a visit to Nome, Capt. Amundsen returned to Wainwright, his winter quarters near Cape Barrow, the most northerly point of Alaska, in April last. The Norwegian Storthing has voted 60,000 kroner for an expedition to go to his support on the European side of the polar basin. In an article in the *Times* Mr. H. W. Sverdrup, second in command of the *Maud*, discusses the prospects of a successful flight to Spitsbergen or Cape Columbia in Grant Land. Capt. Amundsen has been provided by the United States Coast and Geodetic Survey with a Fischer sextant with an artificial horizon. This should allow him to measure the altitude of the sun with an exactness of 10′ to 20′ and possibly 1′ to 2′. If, however, the sun is obscured, Capt. Amundsen will require to fly by compass only. In this case he will have to change his course every now and then in order to follow a meridian from Point Barrow to the Pole, whereas from the Pole a constant course can be kept. If solar observations are impossible, there is only the actual flying time on which to calculate the position. Sixteen hours from Point Barrow should take the airman to the Pole, from which a compass course of N. 171° W. should land him on Spitsbergen. The difficulty will be to estimate leeway, etc. A contrary wind of about 10 metres a second would allow the aeroplane to reach only lat. 85° N. after sixteen hours' flight, and a course of N. 171° W. from there would take it to the New Siberia Islands. Mr. Sverdrup agrees that the prospects for a successful flight to Cape Columbia must be considered more favourable.

AT the annual meeting of the Illuminating Engineering Society on May 24, the report of the Council contained a summary of much varied and useful work. A joint committee, on which the Society and educational bodies will be represented, is to be appointed to consider courses of instruction in illuminating engineering, and the preparation of a suitable textbook for the use of students. Dr. J. F. Crowley presented a paper on "The Use of Synchronously Intermittent Light in Industry," which was illustrated by some striking experiments. The development of the neon lamp, which can be completely extinguished and lighted at a high frequency, has revolutionised methods and led to important industrial developments. By the aid of an oscilloscope utilising such lamps fed by an alternating current of regulated frequency, the motions of a high-speed machine can be apparently slowed down until they are almost stationary. Thus the movements of the mechanism of a sewing machine, illuminated by the intermittent light of a neon lamp, can be followed with perfect ease and any small irregularities observed at leisure. The method has been applied to many problems involved in textile machinery, where exact and regular speed-regulation is of great importance; and in other cases it is possible to detect and observe such phenomena as undue play at bearings, effects with whirling shafts, etc., which are quite unrecognisable by ordinary steady light. Mr. P. R. Ord also demonstrated the use of the Nutting-Hilger spectrophotometer for the comparison of natural and artificial daylight, an apparatus which affords valuable information on the colour-revealing qualities of such lighting units. A number of curves were shown to illustrate the departure from normal daylight and the extent of the variations in the spectrum of daylight at different times in the day.

MANY optical instruments, in the construction of which prisms form an essential part, are grouped together in a new catalogue which has just been issued by Mr. John Browning, of 37 Southampton

Street, Strand, London, W.C.2. A wide range of direct-vision pocket spectroscopes, some with and some without comparison prisms and micrometer scales, is included, together with larger portable sizes fitted with collimators. Among the table spectrometers manufactured by the firm is one of an auto-collimating type in which the telescope has an object-glass of 1 in. diameter and 9 in. focal length. The circle is 5 in. in diameter with two verniers reading to 1′. Other instruments described are stereoscopes, prismatic compasses, prismatic field and opera glasses, and there is also included a short, light-weight telescope having a Porro prism erecting system and fitted with a revolving adapter carrying two eyepieces giving magnifications of 10 and 15 respectively; this should prove useful to the tourist or naturalist. Simple explanatory notes describing the construction, use, and adjustment of the various instruments increase the usefulness of the catalogue.

THE latest catalogue (No. 444) of Mr. F. Edwards, 83 High Street, Marylebone, W.1, is devoted to biography and history. It contains a short list of lives of men of science, reasonably priced.

A TRANSLATION, by Jessie Elliot Ritchie and Dr. J. Ritchie, of Prof. H. Boule's "Les Hommes Fossiles" is to be published shortly by Messrs. Oliver and Boyd, Edinburgh, under the title of "Fossil Men: Elements of Human Palæontology." The work has been brought up-to-date by the addition of notes by the author.

As many of the works on natural history published by the Trustees of the British Museum (Natural History) are out-of-print and difficult to obtain, a list of the volumes on sale by Messrs. Wheldon and Wesley, Ltd., 2 Arthur Street, W.C.2, should be of interest to many readers of NATURE. The catalogue, classified according to subjects, is New Series, No. 7. It can be had upon application to the publishers.

THE Cambridge University Press is to publish this summer, under the title of "The Domain of Natural Science," the Gifford Lectures delivered by Prof. E. W. Hobson in the University of Aberdeen in 1921 and 1922. The work is an attempt to settle the relation of "that complex of knowledge and ideas which is denoted by the term natural science" to religion and philosophy at the present day. To attain this object the author has examined the historical development, aims, and true characteristics of the various departments of natural science. Vol. xviii., Q–S, of the Royal Society of London Catalogue of Scientific Papers, Fourth Series, will be issued by the same house immediately.

Our Astronomical Column.

JUNE METEORIC DISPLAYS.—Mr. W. F. Denning writes: "Sometimes a fair number of meteors are to be seen during the short nights of June, and there are many radiants visible, but they are so feeble that unless the observer maintains long vigils he will not gather sufficient paths to indicate the places of radiation accurately.

"Some of the chief radiants at midsummer are:

$213°+53°$	$245°+64°$	$252°-13°$	$252°-23°$
$260°-12°$	$260°-22°$	$261°+5°$	$280°-13°$
$272°+68°$	$282°-24°$	$354°+40°$	$355°+77°$

Considering that the twilight is strong and persistent during the whole of the night and that therefore the conditions are not favourable, the meteors are often more in evidence than would have been expected. The nights of June are also so agreeable for outdoor work that this particular time of the year is an attractive one to the student of meteors. It is true that what may be termed the real opening of the meteoric season occurs at the middle of July, but June anticipates a few of the advantages of the former month in a minor degree.

"The Perseids possibly commence to display the vanguard of their coming host at the end of June, and this question needs further attention. A few meteors exhibiting all the characteristics of the Perseids have been recorded so early as June 25-26 and with conformable directions, but it is just possible that other showers may have been responsible. To ascertain the truth two observations at distant stations are required, and observers should make special efforts to obtain them during the last week in June and first week in July. If this endeavour were thoroughly carried out we should soon acquire the necessary evidence and discover the opening date of the great Perseid shower. It is by far the finest annual display exhibited in the heavens and lasts for a longer period than any other stream, for late Perseids are seen until about September 5 and 6, when the radiant is at $90°+57°$ on the N.E. boundaries of Auriga."

THE CORONA OF 1908 AND SOLAR PROMINENCES.—In the Memoirs of the Kodaikánal Observatory (vol. 1, Pt. ii. p. 67) Mr. Evershed referred to the corona of 1908 as affording a test of the relationship of prominences to coronal streamers, because the Kodaikánal photographs of prominences showed considerable activity over the sun's south polar region and an almost complete absence over the north pole. In Mon. Not. R.A.S. vol. 83, p. 153, he returns to this subject because, as he says, "the corona, as drawn by the late Mr. Wesley from photographs obtained at Flint Island by Mr. McClean, shows the opposite distribution as regards the coronal streamers, which are more conspicuous over the north polar region than over the south, and thus the test in this instance appears to fail, although from previous eclipses there seemed to be a close correspondence between the coronal streamers and the principal zones of prominence activity." Mr. Evershed was therefore led to re-examine the orientation of the Flint Island photographs in relation to his own prominence photographs and Dr. Campbell's published photographs of the corona. He has now come to the conclusion that the north and south points on Mr. Wesley's drawings should be interchanged.

Mr. Evershed concludes that "Dr. Campbell's orientation is correct and that the corona of 1908 is not an exceptional case, but, on the contrary, adds weight to the evidence previously found for a close relationship between prominences and coronal streamers as advocated by Major Lockyer in his recent and also his earlier paper."

Research Items.

STEATOPYGOUS FIGURES FOUND IN FRANCE.—Female figures with that remarkable conformation known as steatopygous have been found in southern Europe from time to time, and have been connected with the peculiar build of Bushmen-Hottentot women. A figure of this kind discovered at Lespugue, Haute-Garonne, is described by Dr. René de Saint-Périer in *L'Anthropologie*, vol. xxxii. No. 5-6, with a useful list of references to other figures of the same kind.

BALKAN EMBROIDERY PATTERNS.—In the May issue of *Man* Miss Edith Durham publishes a series of interesting embroidery patterns from the Balkan Peninsula. Those worked in cross-stitch are generally used by the Slav-speaking peoples, those in chain-stitch by the Albanians. Up till very recent days embroidery was used lavishly on the garments of both men and women. The superiority of the Albanian as a designer is marked in this series. He is the artist of the Balkans, and the curvilinear patterns run through the inlaid metal work and carving, which is now fast dying out. He is usually his own silversmith, and the rough ornaments which he makes are extraordinarily like those found at Glasinatz, which include little doves pierced to wear as amulets.

"SHEEP-TRACKS" ON GRASSY SLOPES.—Close-set grassy ridges running parallel along the surface of a bank are familiar in many countries, and almost everywhere the popular explanation of their presence is that they are due to the traffic of sheep. Hilmar Ødum, of the Danish Geological Survey, has recently made a study of their appearance and development in the Færöe Isles and in Denmark, and finally disposes of the myth of their zoological origin (*Danmarks geolog. Undersøg.*, Ræk. iv. Bd. 1). He finds that the formation of the ridges, which he names "terracettes," originates in a settling of the loose earth on an unstable slope into a position of greater stability. At first a series of horizontal cracks appears in the turf covering a steep slope, then the narrow turf section between two cracks sinks slightly, turning at the same time about a horizontal axis, so that its surface comes to rest at an inclination rather less steep than that of the slope as a whole. The ridges, once begun, increase in definiteness, owing to the filtering out by the grassy coating and final settling of soil particles washed down by rain. The whole process is of a superficial character and is entirely a geological phenomenon.

THE POPULATION OF INDIA.—In anticipation of the report on the Indian Census of 1921, Mr. J. T. Marten, Census Commissioner, gave an interesting review of the results in a lecture delivered before the Royal Society of Arts and published in the Society's Journal of April 6. The economical conditions of the country suffered naturally from the effects of the War, and the difficulties attending the enumeration were increased by the failure of discipline among the people resulting from political unrest. The most interesting departure on this occasion was the attempt to extend the census of industries, but the weakness of the Industrial Department has made the result somewhat disappointing. Mr. Marten remarks: "We have a population with very considerable natural capabilities of increase. That increase is checked by ignorance of and indifference to maternal and infant welfare, by occasional famines and by epidemics, such as malaria, plague, and influenza. We endeavour year by year to minimise the effect of these checks. What if our endeavour should be successful? Can India support a considerable increase of population in the future under any conditions that seem likely to arise? If not, which is to lead the way to economy, the birth-rate or the death-rate, and will the other follow? In this connexion we have made some tentative efforts to collect in some provinces, where circumstances seemed most suitable, on special schedules, some statistics of the size and sex constitution of families in different social strata, with a view to obtaining information as to the normal fertility of married couples. The attempt is beset with difficulties."

CHROMOSOMES IN MAN.—The number of chromosomes in man has long been uncertain. In 1914 von Winiwarter published the most trustworthy account, finding 47 chromosomes in male germ cells and inferring 48 in the female. Other investigators found 24, and at one time it appeared that this half number was characteristic of the negro. Dr. T. S. Painter (*Journ. Exptl. Zool.* vol. 37, p. 29) has recently published a paper which probably settles the matter. He finds 48 chromosomes in both the white man and the negro. The reports of 24 were probably due to clumping of the chromosome pairs before fixation. Dr. Painter finds that the 48 chromosomes include an X-Y pair of sex-chromosomes. The Y-chromosome is very small and was probably overlooked by von Winiwarter. Painter also finds giant spermatogonial cells with larger nuclei and twice as many chromosomes (approximately 96). The occurrence of giant spermatozoa has long been known. If they are functional then triploid individuals might arise, and it is pointed out that some of these with new combinations of sex-chromosomes might be intersexes or hermaphrodites, such as have been shown to occur in a similar way in Drosophila.

MINERAL CONSTITUTION OF SOIL-TYPES.—James Hendrick and George Newlands (*Journ. Agric. Science*, 1923, p. 1) have examined the mineral particles constituting the more sandy grades separated from the "fine earth" of a number of British soils, dealing with the material finer than 3 mm. in diameter. They find that the separation of different minerals is practically impossible for grades below the "fine sand" of English workers—that is, finer than 0·04 mm., a figure that should have been stated. The coarser grades, however, can be divided mechanically, magnetically, and microscopically, into an "orthoclase group," including all the felspars, a "quartz group," and a "ferrosilicate group." A number of minerals, such as zircon, garnet, and tourmaline, that are "accessory" in the parent rocks appear in "surprising amount" in the soils, owing to their resistance to abrasion and decay. A greater surprise is the constant record of granular hæmatite, side by side with scaly yellow limonite. The authors hope that such investigations may be of service as showing the reserve of bases present in the silicate particles. The fresh state, however, of many of the felspars suggests that the agriculturist has little to gain from the coarser grades, apart from their influence on soil-texture, unless, as is quite possible, chemical exchanges take place on the surfaces of the grains. It is well, indeed, that the study of adsorptive reactions should not be entirely restricted to the colloidal field.

LAND MOLLUSCA OF THE SOUTH-WESTERN UNITED STATES.—In the year 1905 Dr. H. A. Pilsbry published the first of a series of memoirs on the "Mollusca of the South-western States." Later instalments were mostly written in collaboration with J. H. Ferris, and now the eleventh part by these two well-known American malacologists has just come to hand (Proc. Acad. Nat. Sci. Philad., vol. lxxv.). It is as admirable both in descriptions and figures as its predecessors, and deals principally with those members of the Helix family that inhabit the desert lands of Arizona. The genus Sonorella dwells in colonies in the interstices of the screes and tumbled talus of the volcanic rocks forming the hills of that arid and sparsely inhabited region, seldom coming to the surface save in very wet weather. Their collection is therefore an arduous matter only to be undertaken by a properly equipped expedition. The prospective interest lies in the fact that each group of hills seems to have largely its own species, or variety of snail, and that when the whole area has been surveyed important deductions as to the physical geography of the past may be built up on the evidence of the distribution, past and present, of these molluscan forms.

DORSAL EYES OF THE SEA SLUG.—K. Hirasaka (*Annot. Zool. Japon.* x., Art. 17, Dec. 1922) gives an account of the dorsal eyes of the amphibious sea-slug *Onchidium verruculatum*, which occurs abundantly near the Marine Biological Station at Misaki. The dorsal surface of the slug bears numerous papillæ of varying size, some of which are provided with eyes, one to seven in number. In the posterior third of the body some of the papillæ are of large size and branched, forming the respiratory "gill-trees." Semper stated that the eyes decrease in number as the slug grows, and he put forward the view that the eyes were in course of degeneration; but the present author shows that Semper was mistaken in his belief that the eyes disappear as growth proceeds. The cornea of each eye consists of modified epidermal cells, below which is a fibrillar connective tissue forming a circular sheet containing in its peripheral parts circular and radial muscle fibres. The lens is composed of a large distal cell and a small proximal group of cells, the former differentiated into a distal, spherical, more or less homogeneous body, and a basal cup-shaped part containing the nucleus. Early in development this cell exhibits a nerve issuing from its base, but the nerve becomes atrophied in the fully developed eye. The proximal lens cells form a group of usually three or four nucleated cells. Lining the proximal two-thirds of the pigmented cup which envelops the eye is the retina—a single layer of cells loosely packed together, and imbedded in connective tissue. In the basal part of each cell is a large lumen filled with a coagulable substance, and proximally the cell tapers into a nerve fibre which enters one of the nerves passing to the pleural ganglia.

MINERAL FERTILISERS.—As a result of three years' residence on the island, Launcelot Owen (Quart. Journ. Geol. Soc., vol. lxxix. p. 1, 1923) describes the deposits of tricalcium phosphate that are exploited in Ocean Isl., a member of the Gilbert group. These have originated in guano, which gathered in the hollows of a "karrenfeld," worn out of upraised coral-limestone. The fantastic features of this old surface of erosion have been well illustrated by G. S. Robertson in his work on "Basic Slags and Rock Phosphates" (1922), where views of the similar surface of Nauru Isl. are also given. L. Owen states that the loose friable phosphate is in no sense alluvial, but results from the aggregation of concretions. The coral-rock, including the pinnacles, became dolomitised, and was then permeated by the phosphate down to a depth of fully fifty feet. A level exists where the percentage of tricalcium phosphate sinks from its normal 88 to 79 per cent., and below this no phosphate deposits of any extent are found. The author (p. 13) rejects the idea of the occurrence of compounds such as dahllite and apatite, and is apparently unaware that the rock of Sombrero, once regarded as pure tricalcium phosphate, is now proved to consist of dahllite. He notes (p. 6) the occurrence of a translucent isotropic and amorphous phosphate, which he regards as colloidal. This is possibly the substance for which A. F. Rogers revived the name collophane in 1922. As a contribution to our knowledge of potassic fertilisers, the U.S. Geological Survey (Bull. 727, 1922) has published G. R. Mansfield's investigation of "Potash in the Greensands of New Jersey," with maps showing the distribution of the sands and marls. The general characters of glauconite as a fertiliser are now well known; its application to the land is beneficial, though it may not equal in effect the recently described "potash shales" of Illinois (Illinois Univ. Agric. Station, Bull. 232, 1921.)

SYNTHETIC MARBLE.—The generally accepted theory of the igneous formation of marble rests on crude experiments made by Hall (1801–3), in which chalk was heated in a closed gun-barrel. In the April number of the Journal of the Chemical Society Dr. M. Copisarow describes some interesting experiments, which tend to support an aqueous origin of marble. When solid calcium chloride and hydrated sodium carbonate, or a paste of precipitated chalk and sodium chloride solution were heated in an autoclave at 300° at a pressure of 24 atmospheres for 8 hours, a compact mass of marble, capable of taking a high polish, was formed. The salts present facilitated the solution of the chalk or other form of calcium carbonate and the high pressure conditioned crystallisation. When sodium sulphate was used with calcium chloride a compact mass of alabaster was formed.

SEA-LEVEL CHANGES IN DENMARK.—An investigation of a submerged peat-bog in the harbour of Rungsted, Denmark, by Dr. Knud Jessen, of the Danish Geological Survey, has revealed considerable changes in relative levels of sea and land in the neighbourhood of Copenhagen during the late-glacial period (*Danmarks geolog. Undersøg.* Ræk. iv. Bd. 1). About 260 metres off the coast, and at a depth beneath the surface of the sea of some 20 metres, was found a fresh-water clay—"Dryas-clay"—containing land plants, and this was overlaid first by deposits containing, among other things, bones of a vole and of a wild pig; secondly, by peat containing oak, alder, hazel, etc.; and, finally, by sea-mud with cockle shells and recent sea-sand. The indications seem to be that, at the beginning of the late-glacial period, the sea was 18 metres higher at Copenhagen than now, and that elevation of the land took place later, so that at the end of the late-glacial period it stood at least 24 metres above its present level relative to the sea; this elevation persisted from the younger Dryas-period till the Littorina submergence, which finally broke the land-connexion between Seeland and Scania.

VERTICAL MOVEMENTS OF THE ATMOSPHERE.—Mr. I. I. Kassatkine, in his monograph of the above title which has been published in the Bulletin of the Imperial Society of Naturalists in Moscow, 1915, puts forward a theory of rain formation. According to this theory, upward currents of air, on reaching the cloud level, cause still further separation of moisture by raising the clouds. The drops thereupon coalesce to form larger ones, which will eventually attain a size such that they can fall against the direction of the upward current, instead of being carried up still higher. Whether these drops reach the earth's surface or not will depend on the nature of the layers of air through which they must pass. If the latter are dry, and the upward current strong, they will have evaporated away before reaching the earth. If the height of the clouds is h_s, and the height to which they are lifted is h_b, then, before any rain can reach the earth, the ratio h_s/h_b must attain a limiting value a, which for Moscow has a value which varies from 2·5 to 3·5; when its value falls below this, irrespective of the degree of cloudiness, no rain can fall. The anomalously low rainfall of Swakopmund is explained, on this basis, to be due to the presence of a pronounced inversion caused by the sea-breeze, below the average cloud level, which inhibits the development of upward currents. Farther inland, where this factor does not exist, the rainfall is much greater.

PROJECTION FOR AERONAUTICAL MAPS.—In 1919 the International Aeronautical Conference decided to adopt the Mercator projection for the general small-scale air map. In the Geophysical Supplement (vol. i. No. 3) of the Monthly Notices of the Royal Astronomical Society, Col. E. M. Jack and Capt. G. T. McCaw contribute a paper on the value of Mercator in this connexion, answering criticisms that have been made regarding its adoption. The substance of the paper was read to the British Association at Hull. The essential value of these small-scale maps is for aerial navigation; that is, for the direction of the course of the aeroplane from one point to another. In consequence it applies not to local large-scale maps but to maps on a scale of 1 : 2,000,000 or 1 : 3,000,000. In most criticisms of Mercator, the use of the polyconic has been advocated. The authors reply to these arguments by pointing out that the disadvantages of the polyconic are threefold—the sheets do not fit together, the measurement of bearings is less simple and direct than in Mercator, and, with a single exception, no straight line represents anything in Nature save as an approximation. On the other hand, a good case is made for the use of Mercator, even if that projection, in common with all others, has some obvious defects. The authors answer the criticisms at length, but point to the essential quality that Mercator possesses, of representing a line of constant bearing as a straight line, as being of prime importance to the navigator. The varying scale does not trouble the aviator, but the bearing line enters into almost every problem with which he has to deal. Mercator enables him to solve these problems by simple graphic means, and, as a result, he prefers it to any other projection. At the same time the authors admit that, if flying beyond lat. 70° becomes common, some other projection will need to be used for polar regions, but this does not affect the problem at present.

FREE-AIR PRESSURE MAPS FOR THE UNITED STATES.—Supplement No. 21 to the U.S. *Monthly Weather Review* is a discussion on "the preparation and significance of free-air pressure maps for the central and eastern United States," by Mr. C. Le Roy Meisinger. The aim of the author is to develop barometric maps of free-air levels which shall have a direct and important bearing upon accurate forecasting for aviation. The discussion opens with "the history and problems of American barometry," and an explanation is given of the relations involved in the reduction of pressure from one level to another, temperature introducing a considerable difficulty. The author, referring to practical experience being required to demonstrate the value of free-air pressure maps, and stating that the United States does not possess this experience, mentions that in Japan daily maps of the 3-kilometre level have been drawn for several years and are of great service to Japanese forecasters. Details are given of Dr. R. Sekiguchi's experience in forecasting from these maps in Japan. Cyclonic centres in the Far East show better agreement with the trend of the isobars on the 3-kilometre maps than with that at sea-level. Various interesting examples are given, and probably valuable information may be gained from these for other parts of the globe. A large number of specimen maps are shown for sea level, 1-kilometre level, and 2-kilometre level, while details are given of each series. The work is of considerable importance to aviation, and the upper-air charts show what the winds are doing aloft when it is often impossible to gain the information from the sea-level charts. It is claimed that the discussion affords a glimpse of the physical processes at work, and may help to lift us from empiricism a little nearer to that ultimate goal toward which students of weather forecasting are striving.

ENDURANCE LIMIT OF STEELS. — Engineering Bulletin No. 136 of the University of Illinois contains an account of further experiments on the fatigue of metals, conducted by H. F. Moore and T. M. Jasper. The new results, which have been obtained by similar methods to those described in a former Bulletin, confirm the existence of a true endurance limit for steels of different compositions. For moderately hard steels, this limit may be found by rapid tests in which the rise of temperature is measured. Only a few preliminary tests have been made by Gough's method of determining the increase of deflexion as the range of stress is increased. A fairly close correlation is found to exist between the endurance limit and the ultimate tensile strength or the Brinell hardness, and a much less close connexion between the endurance limit and the yield point and limit of proportionality, there being no correlation with the impact or repeated impact values. It should be remarked, however, that the range of materials studied was not very wide, and the authors did not examine defective materials. A formula for the effects of cycles of stress not involving complete reversal is proposed, the results not being in agreement with Goodman's diagram.

A NEW FILAMENT ELECTROMETER.—In the issue of the *Physikalische Zeitschrift* for April 15, Dr. C. W. Lutz, of the Geophysics Observatory, Munich, describes an improved form of filament electrometer, which has been constructed by the firm of Edelmann, for use in the observatory. The filament is of platinum, and its lower part is attached to one end of a diameter of a circular loop of quartz fibre; the other end of the diameter of the loop being attached to the sliding frame by means of which the whole may be removed from the instrument for replacement of the filament. The deflectors between which the filament is placed are adjustable by means of screw heads outside the metal cover of the instrument. The filament is observed through a microscope magnifying 285 times, and, for distances of the deflectors from the filament exceeding 4 mm., the deflexions are proportional to the applied volts over the whole of the scale of the ocular of the microscope, which is graduated from a central zero to 50 on each side. The insulation throughout is amber. The sensitivity of the instrument may be varied by the usual methods from 0·001 to 2 volts per division of the scale.

The Royal Observatory, Greenwich.

ANNUAL VISITATION.

THE visitation of the Royal Observatory took place on Saturday afternoon, June 2. In addition to members of the Board of Visitors a large number of guests interested in astronomy were present, and took part in the inspection of the observatory and instruments.

The astrographic equatorial has been remounted on its return from Christmas Island, and the instruments left in Russia in 1914 have just arrived safely after an absence of nearly nine years. The Astronomer Royal in his report expresses his regret at the failure of the Christmas Island expedition; he notes, however, that the close verification of the Einstein shift by the Lick Observatory expedition renders it unnecessary to send an expedition from Greenwich to observe the Californian eclipse next September.

The exchange of wireless signals has reopened the question of the small differences of time-determinations at different observatories. Examination of the bearings of the transit circle showed that the western pivot was bearing only on its eastern edge; this was remedied by a slight lowering of the bearing. The test was made by placing some rouge on the bearings, then lowering and rotating the instrument; the presence or absence of rouge on the pivot showed where it was in contact with the bearing.

The results of the wireless time comparisons for the year are given; the annual means are Paris +0·10 sec.; Bordeaux +0·14 sec.; Nauen 0·00 sec.; Annapolis (August to December only) +0·03 sec. The plus sign means that the other station is late on Greenwich. In the case of Annapolis, the discordance is wholly explicable by the time of transmission; 0·06 sec. of the Paris and Bordeaux discordances is due to the fact that Leverrier's Tables of the Sun, used in France, differ by this amount from those of Newcomb. In the long run these differences will probably give excellent determinations of longitude.

Observations of the moon are dealt with in special detail in the present report, on account of the fact that Hansen's tables, used in the "Nautical Almanac" from 1862 to the end of 1922, have now been superseded by those of Brown. This was, therefore, selected as a suitable occasion for collecting all the Greenwich observations of the moon made since the time of Bradley, and reducing them to Brown's system (modified by using Fotheringham's secular acceleration, which is 4·79″ in excess of Brown's). It was then found that the residuals could be represented by two empirical terms, one with amplitude 3″ and period 70 years, the other with amplitude $1\frac{1}{2}''$ and period 59 years. The two terms are now in unison, producing a large oscillation, but in Bradley's time they tended to neutralise each other. A full comparison is given between Brown's Tables and observation for the first quarter of 1923; there is a nearly constant error in longitude of −7·8″, about half of which is due to Brown's use of too small an acceleration.

Observations with the Cookson floating telescope, lent by Cambridge Observatory, are being continued. Mr. Jones has revised his determinations of latitude variation with this instrument; and they are in satisfactory accord with those made elsewhere. One of the seven-year maxima of latitude variation is due about 1923. The 28-inch equatorial is being used for observation of close and difficult pairs; 66 pairs with separation less than 0·5″, and 105 between 0·5″ and 1·0″ have been observed during the year. Mr. Jackson is continuing to deduce hypothetical parallaxes for these and other stars.

The 26-inch refractor is being used for photographic determinations of stellar parallax; 49 parallaxes have been determined during the year, making a total of 195 with the instrument. The 30-inch reflector is being used for photography of stellar spectra with a combination of prism and grating. A principal spectrum is thus obtained, bordered by diffraction spectra of known relative intensities, thus determining the density gradient of the plate for all wave-lengths. With the astrographic equatorial some of the fields photographed about twenty years ago are being re-photographed through the glass, so that superposition on the earlier plates, film to film, enables proper motions to be deduced. The work has begun with zone 65° N. Declination, and will gradually approach the pole.

Sunspot activity continues to decline. There was, however, a considerable group of spots visible from December 22 until January 4 in latitude 6° N. A high-latitude spot in 41° S. was photographed on November 14 and 15.

The following are the provisional magnetic elements deduced for 1922:

Declination 13° 46·6′ W., Dip 66° 51·9′, Hor. Force 0·18449, Vert. Force 0·43181 (the last two being in C.G.S. units).

The weather report is for the twelve months ending April 30, 1923. The mean temperature was 49·8° F., being 0·2° above the average. On two days, both in May, the temperature reached 90° F. It fell to freezing-point on 21 days. There were 1404 hours of bright sunshine, 31·5 per cent. of the possible amount.

The Astronomer Royal naturally refers to the severe loss which the Observatory has sustained in the death of Mr. W. W. Bryant, noting his enthusiasm in former years as a meridian and double-star observer, and the zeal and energy with which he afterwards carried on the work of the Magnetic and Meteorological Department. Allusion is also made to the astronomers who have visited the observatory for special purposes during the year; they include Mr. Dodwell, director of Adelaide Observatory, Messrs. Comrie and Greaves from Cambridge, and Mr. S. Gaythorpe, who came to study the Horrocks MSS. in connexion with a biography of Horrocks which he is preparing.

A. C. D. C.

Royal Visit to University College and Hospital, London.

ON Thursday, May 31, the King, who was accompanied by the Queen, opened the new Institute of Anatomy at University College, London, and laid the foundation-stone of the new Obstetric Hospital. Her Majesty laid the foundation-stone of a Nurses' Home which is to be erected on an adjacent site in connexion with University College Hospital.

Before a gathering as brilliantly representative of the science and practice of medicine as of philanthropy and affairs, his Majesty said there could be but few instances on record in which any foundation had received 1,200,000*l*. from a single benefactor in a single gift. The magnificent generosity of the Rockefeller Trustees is the more impressive since it was bestowed by a citizen of the United States of America upon a college and hospital in London, and thus upon the people of Great Britain and the Empire. The declared purpose of the trustees is "to promote the well-being of mankind throughout the world." That they should have selected the University of

London to receive this princely endowment is not merely a high and well-deserved compliment and the creation of yet another tie of sympathy and friendship linking us to the United States; but it is also the evidence and declaration of their conviction that the progress of science and the welfare of mankind are not delimited by national or racial boundaries, and that work done in London for the relief of human suffering, the improvement of medical education and the advance of science, is a service to the whole world. The advance of knowledge and the ever-rising standard of medical education necessitate reorganisation which would give an impetus to the more effective training and equipment of the British practitioner. The underlying principle is as old as Ecclesiasticus: "The wisdom of a learned man cometh by opportunity of leisure, and he that hath little business shall become wise." Its specific application to medical teaching and research is new.

Continuing, the King referred to her Majesty's particular satisfaction on learning that the care of maternity and infant life, in which the Queen has always been actively interested, is part of the scheme, and that the claims of the nursing service have not been overlooked. The privilege of accepting the munificent gift of the Rockefeller Trustees imposes obligations upon the staff to fulfil the ideals which it represented, and upon the public to furnish necessary support. It is inconceivable that Englishmen should decline to welcome this generous challenge from our kinsmen across the Atlantic to a friendly rivalry in medical skill, devotion, and beneficence. His Majesty cordially wished Godspeed to this great enterprise.

The address was followed with responsive attention, and when the stones were laid their Majesties proceeded to the library of the Medical School and thence to the new building of the Institute of Anatomy. A tour of the building was made, their Majesties being particularly interested in the brilliantly-lighted dissecting-room and the equipment of the X-ray rooms, where the director of the Institute, Prof. G. Elliot Smith, demonstrated various radiographic and anatomical exhibits, among them plates taken twenty years ago of the mummy Thothmes IV., and whole specimens made transparent by the Spalteholz method to facilitate comparison with X-ray plates by students of anatomy. Both their Majesties were also keenly interested in radiographic plates and photographs shown by Mr. H. A. Harris revealing the effect of successive illnesses upon the growth of the long bones of a child.

The Mind of the Maori.

THE authorities of the Dominion Museum at Wellington, New Zealand, have published a series of monographs on the ancient institutions, mental and spiritual concepts, and ceremonies of the pre-European Maori, with an examination of the esoteric meaning underlying innumerable personifications and mytho-poetic allegories. They are written by Mr. Elsdon Best, who is regarded as the greatest living authority on Maori history and folklore.

In the first paper mentioned below,[1] stress is laid upon the two different phases of Maori religion. The ritual and teaching of the priests and men of superior rank were of a distinctly higher type than that of the common people. They formed the most intensely *tapu* portion of Maori esoteric lore and were so jealously guarded that for many years they were entirely unknown to Europeans.

Mr. Best's account of Maori myths is derived from the East Coast tribes. There is an elaborate cosmogony. Things celestial and terrestrial are spoken of as persons, and the processes of evolution are described in genealogical form. In the beginning was the vast unknown time of Po, before Rangi and Papa (sky and earth) appeared. From the union of these arose certain supernatural beings whose names are known throughout Polynesia—Tane, Tu, Rongo, Tangaroa, Tawhirimatea, and Whiro. These beings formed and arranged the present world. Mr. Best gives a highly poetical account of their varied exploits, and in some of the concepts finds a likeness to ancient beliefs in Chaldea, Egypt, India, China, and Japan. The cosmogonic genealogy of Rangi and Papa, which in one account consists of such names as Pu (root), More (extremity), Take (stump), Weu (fibre), is compared to the World-Tree of Scandinavian myth, and the three baskets of knowledge obtained from the heavens by Tane are likened to the three baskets or books of knowledge of the Indian Buddhists.

Mr. Best describes four classes of Maori gods. The first, alone, is Io, the supreme deity, then come the departmental and tribal gods, and lastly, the spirits of dead ancestors. The startling suggestion is made that the name Io may be a form of Jehovah. Several other gods are compared with those of Egypt and Assyria.

The Maori conception of the spiritual nature of man is concisely stated by Mr. Best in the following account from a native: "The conclusions he arrived at from what he considered clear evidence were—that man possesses a spiritual quality that leaves the body during dreams and quits it for ever at the death of the physical basis (this is the *wairua*); that death is marked by the passing, the extinction, of an invisible activity called the *manawa ora* (breath of life); that man also possesses a physical life-principle termed the *mauri*—one that cannot desert the living body but does so at death; that he possesses yet another life-principle called the *hau*, that can be affected by the arts of black magic; that man possesses several sources of mental and intellectual activity, and that the semblance of man, or of any entity, may be taken and employed as a medium in ceremonies believed to affect the originals."

The papers on astronomical knowledge and the division of time are remarkable examples of Mr. Best's intimate acquaintance with the lore of the Maori people. The Maori named the heavenly bodies and accounted for them in myths; they used them as time measurers and guides in navigation; and they personified them and worshipped them as benefactors and deities.

In these papers Mr. Best has given us a highly interesting and in many places an intensely poetical account of the speculations and fancies of the Maori mind. The only weak points are the comparisons of Polynesian names with those of the ancient world. These entirely fail when the words are traced by strict phonetic law to their cognates in Indonesia and Melanesia.

The Promotion of Research in the University of Bristol.

IT is common knowledge that the universities of Great Britain are woefully lacking in funds specifically allocated to the furtherance of their main function, namely, research. Too much prominence cannot, therefore, be given to the activities of the Colston Research Society in the city of Bristol, the object of which is the promotion of research in its University. This Society, under a slightly different name, was originally founded in 1899 for the purpose of promoting the cause of a university at Bristol, and it played a most influential part in securing the foundation of the University ten years later. It then turned its attention to the assistance of a specific branch of university activity and chose that of the promotion of research.

The Society met for its annual dinner and collection on June 1 under the presidency of Mr. Claude B. Fry, with Prof. Flinders Petrie and Sir Richard Gregory as the principal guests. The collection, which amounted to 669*l*., brought the total sum collected since its inauguration twenty-three years ago up to nearly 12,000*l*.

The annual sum of about 600*l*., which is thus available for research, is allocated to the various departments of the University of Bristol by a joint committee of the Society and the University. It is interesting to note that, while the greater part of the funds collected is provided by local merchants and industrial firms, the Society accepts the term research in its widest sense and has recently made awards to the arts faculty, which will be continued so far as funds permit.

In addition to the collection, an important extension in the activities of the Society was made by the president for last year, Mr. Ernest Walls, which seems likely more and more as years go on to cement the relationship between the University and local industries. This act was the foundation of a number of annual Colston research fellowships. These fellowships are post-graduate in character and are earmarked to a particular faculty or branch of research, or to a particular research problem. In those cases in which the research problem is of an industrial character and carried out, with the consent of the supervising professor, at the wish of the firm, additional funds for apparatus and material are also available. The donor of a fellowship has access to the research work and receives the results of the work twelve months prior to publication. During last year fellowships were provided by the Imperial Tobacco Co. (botany), Messrs. J. S. Fry and Sons (engineering), Christopher Thomas Bros. (chemistry), Messrs. Packer and Sons (chemistry), Mr. Frank Cowlin (medicine), and Messrs. E. S. and A. Robinson (chemistry). That the scheme is an undoubted success is borne out by the fact that at the recent meeting of the Society it was stated that five of the above fellowships were being renewed for a second year and that two new fellowships had been promised, one from Messrs. Carsons, Ltd., and the other from Messrs. William Butler, both in chemistry.

To those conversant with the relations between universities and industry in a country like the United States, this may seem to be a very small organisation; but in the present depressed state of the finances of British universities, the existence of one Society rallying to the support of the most essential function of a university is exceedingly encouraging, and the scheme may be commended to the notice of other centres of learning.

Radiation Theory.

ON Monday, May 28, a lecture was delivered at the University of Edinburgh by Prof. H. A. Lorentz, of the University of Haarlem, on "Primary and Secondary Radiation." In the course of his remarks, Prof. Lorentz said that in former times the radiation of light was held to be due to the presence in the luminous source of small particles vibrating about positions of equilibrium; in the electromagnetic theory of light this idea became more definite, in that the oscillating particles were supposed to be electrically charged. The progress made in the last few years has shown that, in many cases at least, this explanation of radiation can no longer be maintained.

In Bohr's theory of spectral lines, the emission of light is due to the transition from one stationary state of an atom to another. The frequency of the emitted radiation is determined by the change in the energy of the atom, and is widely different from the frequency really existing in the atom, in which the electrons freely revolve around the nucleus. When light is emitted by a luminous body, and, in general, when we are concerned with the original production of waves, we can speak of a *primary* radiation, whereas the term *secondary* radiation can be applied to those cases in which particles that are struck by incident rays thereby become centres of emission.

There is perhaps but one case of primary radiation for which the old theory still holds, namely, the emission of electromagnetic waves by an antenna. If, as has been shown by the experiments of Tolman and Stewart, an electric current in a metallic wire consists of a motion of electrons, then this must also be true of the alternating currents in the antenna, so that here the oscillatory motion of the electrons is seen to produce waves.

As to the secondary radiation, this appears in many cases to conform to the classical laws. This can be illustrated by the consideration of (1) Huygens' principle and his construction for the progression of a wave front, (2) the propagation of light in a system of molecules, (3) the scattering of light by molecules (blue of the sky, Lord Rayleigh's formula), (4) the scattering of X-rays (Barkla's experiments), (5) the diffraction of X-rays by crystals, it being possible, as has been shown by W. L. Bragg and Bosanquet, to calculate in this case the intensity of the secondary beams by means of the old theory.

Even for the primary radiation of light, the classical theories need not wholly be abandoned.

Soil Acidity and Plant Distribution.

AN important series of studies on the hydrogen ion concentration of the soil and its relation to plant distribution has been published by Carsten Olsen (*Compt. rend. Lab. Carlsberg*, xv., 1923). These studies deal with the hydrogen ion concentrations of a series of Danish soils covered by natural vegetation, the observed range being from P_H 3·4 to 8·0. The composition of the vegetation is found to be very closely correlated with the hydrogen ion concentration of the soil, and the author considers that the distribution of the more important species may be largely determined by this factor. The number and density of species in a given place are also found to be greatest when the soil reaction approaches neutrality. Olsen further points out that the vegetation of alkaline soils poor in mineral nutrients bears no resemblance to that of very acid soils poor in nutrients. This section of the paper is very impressive in its wealth of data, and it includes exhaustive tables showing vegetation composition in relation to P_H and also a large number of partial soil analyses. Only those who have used the field methods employed by Olsen can really appreciate the extent and thoroughness of his investigations.

The author then deals with the growth of typical indicator species in water cultures. Species normally growing on acid soils are found to show best growth in nutrient solutions with a reaction of about P_H 4·0. On the other hand, plants normally growing on neutral or alkaline soils show most vigorous growth in culture media of about P_H 6 to 7. In these media the plants of acid soils do not thrive and become chlorotic. Olsen further examines the theory of Hartwell and Pember that soil acidity may be associated with the toxicity of aluminium ions. Though aluminium was found to be toxic to barley, the theory appeared not to be valid for plants of alkaline soils in general. Further, while his observations confirm the idea that acid soils as a whole produce ammonia rather than nitrates, Olsen's experiments show no evidence for the supposition that the plants normally growing on acid soils utilise ammonia and not nitrates, or that the plants of alkaline soils can only utilise nitrates. Both nitrates and ammonia appear to have the same value as sources of nitrogen in the cases examined, and, moreover, nitrification may be much more active in acid soils than is commonly supposed, as rapid nitrification existed in soils as acid as P_H 4·4.

This valuable paper should be in the hands of all those interested in soil acidity and plant growth.

University and Educational Intelligence.

BIRMINGHAM.—The late Elizabeth Kenway of Moseley has left to the University a legacy of 1000*l.*, free of duty, to be applied as the Council shall think fit.

We learn from the *Times* that the late Joseph Samuel Taylor, of the firm of Taylor and Challen, engineers, has left the residue of his estate, after numerous bequests to local charities, to the University for research work in mechanical engineering, metallurgy, and chemistry.

CAMBRIDGE.—In connexion with the coming meeting of the International Union of Pure and Applied Chemistry, it is proposed to confer honorary degrees of Doctor of Science on M. A. Haller, president of the Academy of Sciences of the Institute of France, Prof. W. D. Bancroft, Cornell University, Prof. E. J. Cohen, University of Utrecht, Prof. C. Moureu, Collège de France, Prof. R. Nasini, University of Pisa, Prof. A. Pictet, University of Geneva, and Prof. F. Swarts, University of Ghent.

Mr. J. E. Littlewood, Trinity College, has been reappointed Cayley lecturer in mathematics; Mr. R. A. Herman, Trinity College, has been reappointed University lecturer in mathematics, and Mr. J. Gray, King's College, has been re-elected Balfour student.

It is recommended that a special grant of 25*l.* be made to the Marine Biological Station at Plymouth.

MANCHESTER.—The Sheridan Delépine research fellowship in preventive medicine, value 300*l.* for one year, will be awarded shortly. The elected candidate will be required to register as a research student of the University, and to devote the whole of his time to research in the department of bacteriology and preventive medicine. Applications, together with particulars of the qualifications of the candidates and of the proposed subject of research, should reach the Internal Registrar on or before June 15.

ST. ANDREWS.—The Court has agreed to hold in trust a sum raised in recognition of Dr. David McEwan's services as professor of surgery in Dundee. The income from the fund is to be employed in providing an annual prize in surgery to be awarded to the best student in that subject in the Final M.B., Ch.B. Examination in the University.

It is expected that Mr. Rudyard Kipling, Rector of the University, will be installed and will deliver his rectorial address on Tuesday, October 9.

THE summer meeting of the Association of Women Science Teachers will be held at Reading, on Saturday, July 7.

NOTICE is given that applications for the Ramsay Memorial fellowships in chemical science, of the value of 300*l.* a year each, must be made not later than June 15 to Dr. Walter Seton, secretary of the Ramsay Memorial Fellowships Trust, at University College, London, W.C.1, from whom full particulars of the conditions governing the award can be obtained.

APPLICATIONS are invited from Edinburgh University medical women for the Dr. Jessie Macgregor prize of 50*l.* for the best piece of original work, published or unpublished, in the science of medicine. Competitors must lodge the record of their work, accompanied by a letter vouching that the work was done by the sender, and mentioning the place or places in which it was carried out, not later than June 30, with the Convener of the Trustees, Royal College of Physicians, Edinburgh.

THE University of Geneva is organising a summer school in which are included two attractive courses of botanical and geological field-work. The botanical course, opening on July 10 and closing on September 10, will be conducted by Prof. R. Chodat, director of the Alpine station at Bourg-St. Pierre in the Grand St. Bernard region, where the course is to be held, and studies will be made of Alpine flora, plant distribution, etc. The geological course will be in the charge of Prof. L. W. Collet, professor of geology in the University of Geneva, and the first portion, July 10-15, will be spent at the University. The remainder of the course, July 16-August 10, will be devoted to field-work on tectonics and glacial geology. Both courses provide opportunities for numerous expeditions. Further information about the courses can be obtained from the Secretary of the University of Geneva, or in Great Britain, from the Economic Division, Swiss Legation, 32 Queen Anne Street, London, W.1.

A STUDY of Dental Education was undertaken early in 1921 on behalf of the Carnegie Foundation for the Advancement of Teaching by Dr. William J. Gies, of Columbia University. Each of the Dental Schools of the United States (47) and Canada (5) has been visited, its equipment thoroughly inspected, and its relationships with other educational institutions ascertained. The investigation has been carried on with the active co-operation of the Dental Educational Council of America and the Canadian Association of Dental Faculties and of the local faculties. The recently published annual report of the Carnegie Foundation announces that Dr. Gies's report will shortly be ready for issue. There being no national board of dental examiners, the examinations for licence to practise in the several States are dissimilar, and the dental laws differ in many of their requirements where uniformity would have obvious advantages. A compilation of these laws, which have not hitherto been easily accessible for comparative study, has been prepared and will shortly be issued with comments on their main educational features. Custom blinds us to the anomaly of the isolation of dentistry as compared with ophthalmology, aural surgery, laryngology, and other specialties of medicine —of putting teeth and jaws in an elaborately insulated compartment by themselves—and a reconsideration of fundamentals such as is likely to be involved in and entailed by Dr. Gies's study may have beneficial results.

Societies and Academies.

London.

Royal Society, May 31.—E. **Griffiths** and G. W. C. **Kaye**: The measurement of thermal conductivity, No. 1. Three types of apparatus of the "plate" type are described for the rapid precision determination of the thermal conductivities of materials at low conductivity. Energy was supplied by electrical means and temperatures were measured by thermocouples. An average time for the attainment of the "steady state" was 30 minutes or less, and the average accuracy of measurement of the conductivity was about 1 per cent. Among the topics discussed was the thermal resistance at the bounding faces of a material, the effect of superimposing layers of compressible material, the measurement of the thickness of compressible material, the dependence of the conductivity of timber on structure and moisture-content and the variation of the conductivity of rubber with mineral content.—G. W. C. **Kaye** and J. K. **Roberts**: The thermal conductivities of metal crystals. I.—Bismuth. A "plate" apparatus measuring thermal conductivities as high as 0·02 C.G.S. with an accuracy of about 1 per cent., using specimens 2 cms. by 1 cm. in area and about 1 or 2 mm. in thickness was used. The conductivities of single crystals of metallic bismuth in directions parallel and perpendicular to the trigonal axis at 18° C. are, in C.G.S. units, 0·0159 and 0·0221. The ratio of conductivities is 1·39. The mean value 0·0191 agrees well with the figure 0·0193 obtained on bars by Jaeger and Diesselhorst in 1899. Thus in the case of bismuth metal in the aggregate, the distribution of the constituent small crystals is random, and the effect on the thermal conductivity of any inter-crystalline layers is not appreciable.—C. V. **Drysdale** and S. **Butterworth**: The distribution of the magnetic field and return current round a submarine cable carrying alternating current. Pt. I. (By C. V. Drysdale.) An exact knowledge of the magnetic field distribution in the neighbourhood of a submarine cable is of great importance in connexion with leader gear and the propagation of radio signals between submerged stations. Investigations have been carried out since 1918 at the Admiralty Experimental Stations at Parkeston Quay and Shandon, with the object of determining the magnitude and phase of the magnetic field in and above the surface, and of the return current in the water, as well as the velocity of propagation and attenuation of the electro-magnetic waves in the water and the shielding effect of the cable armouring. Measurements were made with an alternating current potentiometer on horizontal and vertical search coils above and below the surface and on electrodes in the water at frequencies from 50 to 500 periods per second. Pt. II. (By S. Butterworth.) Expressions for the distribution of electric force due to a long cable carrying alternating currents and immersed in a sea of uniform depth have been obtained in the form of Fourier integrals and formulæ have been developed which cover the following cases: (1) The field above the surface of the sea when the depth of the water is small; (2) the field above the sea at large distances from the cable, there being no restriction in regard to depth; (3) the field below the surface of the sea for points vertically above the cable; and (4) the field below the surface of the sea at large distances from the cable when the depth of the sea is great. The results for points above the surface of the sea have been verified by tests in which the sea is replaced by a sheet of lead. The formulæ are in substantial agreement with actual sea observations.—S. **Russ**: The effect of X-rays of different wavelengths upon some animal tissues. Two regions in the X-ray spectrum were selected, and it was arranged that equal doses of X-ray energy were absorbed in their passage through the tissues. In these circumstances more profound effects were produced by the longer wave-lengths (0·45-0·30 Å.U.) than by the shorter wave-lengths (about 0·168 Å.U.), both upon the normal skin of the rat and upon Jensen's rat sarcoma. The degree of this differential action is more pronounced in the case of the skin than it is for the tumour, the numerical values being 6 and 2·6 respectively. These numbers are termed "therapeutic factors."—E. F. **Armstrong** and T. P. **Hilditch**: A study of catalytic actions at solid surfaces. Pt. XI.—The action of alumina and certain other oxides in promoting the activity of nickel catalyst. In the absence of any carrier for the nickel, the presence of a small proportion (up to 5 per cent.) of an oxide, such as that of aluminium or magnesium, increases the catalytic activity of the reduced metal. When the nickel oxide is deposited on a support, *e.g.* kieselguhr from which the metallic constituents have been extracted, the catalyst is inferior to that on natural kieselguhr. Its activity is restored if about 20 per cent. of alumina is precipitated with the hydroxide of the nickel. If this proportion of alumina is first deposited on the acid-extracted kieselguhr and the nickel hydroxide or carbonate then precipitated on to this preparation, the catalytic activity of the product generally exceeds that of nickel on the natural kieselguhr. It seems that the action of the non-reducible oxide is mainly mechanical and connected with increase or diminution of the surface area of the exposed nickel.—N. K. **Adam**: The structure of thin films. Pt. IV.—Benzene derivatives.—A condition of stability in monomolecular films. Derivatives of benzene, such as hexadecyl phenol, containing one long chain and one polar group in the para position, orient on water surfaces like fatty acids, the phenol group forming the head of the molecule in contact with the water. Compounds such as cetyl palmitate, palmitic anilide, etc., which contain one polar group placed between two chains or one chain and a ring, do not adhere to a water surface well enough to give measurable condensed films. The para sulphonic acids in hexadecyl and octadecyl benzene give soap-like solutions in water. Pt. V. Bromine in the α position, in the bromo-acids and esters, increases the cross-section of the molecules in the films. The bromine atom increases the solubility of films of the higher fatty acids. It also lowers the temperature of change from condensed to expanded films; but it does not appreciably affect the properties of the films, when expanded. The double linkage in the α β position relative to the $COOC_2H_5$ group increases the cross-section of the molecule in the films, as it does in iso-oleic acid.—W. B. **Rimmer**: The spectrum of ammonia. Of the three bands which are associated with the spectrum of ammonia, the ultra-violet band has already been investigated in detail by Fowler and Gregory, and is represented in the solar spectrum. The "Schuster bands" λ 5635 and λ 5670, have given no sign of resolution under high dispersion, and it is probable that they do not occur in the solar spectrum. The "α band" of Eder and Valenta is of great complexity, consisting of about 3000 lines; there is no conclusive evidence that this band occurs either in the solar spectrum or in the spectrum of sunspots. The Schuster bands seem to have their origin in the normal ammonia molecule and the ultra-violet band is probably due to emission from a more stable combination of nitrogen and hydrogen. The α band appears to be associated with a combination of nitrogen and hydrogen of intermediate stability. The occurrence of the ultra-violet band alone in the solar spectrum indicates that only the most stable combination of nitrogen and hydrogen can exist under the conditions that obtain in the reversing layer.

Royal Microscopical Society, May 16.—E. J. Sheppard, vice-president, in the chair.—W. M. **Ames**: Applications of the microscope in the manufacture of rubber. This work falls into two divisions, examination of pigments and examination of microsections of rubber, both of which involve special methods. For work on pigments, particularly when investigating particle size, slides should be prepared by the method of Green so as to ensure uniform distribution of the pigment in one plane. The microscope enables relative particle sizes to be determined with certainty. Owing to the great resiliency of rubber, the preparation of sections sufficiently thin to be examined by transmitted light is difficult. Inorganic pigments if present can be identified, and their distribution studied. Certain organic materials such as fibre, reclaimed rubber, glue, and rubber substitute can also be identified. The behaviour of the sulphur formations in the rubber can be observed as the rubber perishes, and a comparison made between natural and artificial (heat) ageing. The variation, with temperature, of the solubility of sulphur in vulcanised and unvulcanised rubber can also be observed. When rubber under strain is examined, vacua are found between the separate units of sulphur formations, and at the poles of crystalline pigments, but have not been detected in the case of gas-black or zinc oxide. Permanent internal deformation is visible in the rubber after retraction.

Geological Society, May 16.—Prof. W. W. Watts, vice-president, in the chair.—W. B. R. **King**: The Upper Ordovician rocks of the South-Western Berwyn Hills. The district described lies in the south-eastern corner of the 1-inch Ordnance Survey Map, Sheet 136 (Bala). The area is one where the beds strike in a north-easterly and south-westerly direction, with dips nearly vertical. The black graptolitic shale-group is of shallow-water, probably lagoon, origin. The area appears to have been one of shallow water throughout Upper Ordovician times, and actually became land at the end of that period. The gap in the succession occasioned by this uplift was greatest in the south-east, near Welshpool; while the areas on the north (Glyn Ceiriog) and west (Bala) remained under the sea. The shallowing of the water in these areas is, however, manifested by the deposition of either gritty beds or oolitic limestones. A new species of Calymene is described from the upper part of the Ashgillian, where it is taken as a local index-fossil.—W. J. **Pugh**: The geology of the district around Corris and Aberllefenni (Merioneth). The succession and structure of an area of about 25 square miles, lying south-east of Cader Idris, are described. The area has been surveyed on the scale of 6 inches to the mile. The rocks are partly Lower Silurian and partly Upper Ordovician in age. The Valentian succession is similar to that described at Machynlleth (O. T. Jones and W. J. Pugh, Q.J.G.S. vol. lxxi. (1915–16), p. 343), and the same classification is retained. It is considered to rest conformably upon the Bala series. The general strike, from south-west to north-east, is determined by the fact that the area lies on the south-eastern flank of the Harlech Dome; but the district is crossed by important folds transverse to the normal strike. These structures have been correlated with those described farther south at Machynlleth.

Aristotelian Society, May 28.—Prof. A. N. Whitehead, president, in the chair.—C. Delisle **Burns**: The contact of minds. The word "mind" is taken to mean mental process or percipient event, and thus to refer to all such facts as thinking, feeling, and the sensation which accompanies or is part of thinking. It is generally admitted that mental processes are grouped so that they "belong to" distinct persons or selves; but there is also a connexion between these groups of mental processes in co-operation or communication or intercourse between persons. In communication "I" am aware that "you" are thinking, that is to say, I am aware that you are or have a mind; or it may be said that I am aware that an "other" mind exists. The problem to be considered, then, is *how* I come to know that an other mind exists. The traditional view is that "I" come to know that other minds exist by a process of inference, based upon a comparison of my "body" with other bodies. This traditional view has already been attacked by Lossky and others. It seems false, first, because it implies a very unlikely description of psychological development. Secondly, at any stage in life the differences between my own body and other bodies in my contemplation are so great that the likeness can scarcely be a valid logical ground for the belief that other minds exist. As an alternative to the traditional view, therefore, it is suggested that Prof. Alexander's term "enjoyment" may provide an explanation of the way in which "other" minds come to be known. But enjoyment must then be taken *not* to imply any process peculiar to "my" thinking or feeling. That is to say, there must be enjoyment of co-operation or communication. As objects are given in contemplation, so other minds are given in another form of awareness. There is, then, direct contact of minds, not "through" bodies or across any bridge which is non-mental. This, however, does not mean that mind is not bodily; since mental process is probably the name for a relation, the terms of which are bodily. We need not assume that mental process is explicable in terms of "body" or that "body" is explicable in terms of mental process: but the contact of minds occurs in one area of reality and the contact of bodies in another, and the two are inseparable, as the force called gravitation is inseparable from "mass."

DUBLIN.

Royal Irish Academy, May 14.—Prof. Sydney Young, president, in the chair.—J. J. **Nolan** and J. **Enright**: Experiments on large ions in air. The effects of such substances as sulphur dioxide and ammonia on the development of large ions were investigated. The effect of temperature on the large ions was examined. The large ion is unaffected up to 100° C., but at that temperature begins to break up. The coefficient of recombination between large and small ions was determined. The conditions under which multiple charges on the large ion can occur were investigated. The large ion in the atmosphere has probably a single electronic charge.

EDINBURGH.

Royal Society, May 7.—Prof. F. O. Bower, president, in the chair.—Miss A. V. **Douglas**: The sizes of particles in certain pelagic deposits. Samples of sea bottom brought back by the *Quest* from the South Atlantic bottoms were examined for the distribution of sizes of particles. The estimation is made by allowing continuous deposit of the particles from suspension in water upon one pan of a balance and thence ascertaining the rate of deposit and estimating the associated sizes, employing Stokes's law. The result is a measure of relative numbers of particles of each equivalent spherical radius. Six samples are treated, three of diatomaceous ooze, and three of globigerina ooze. The features of the curves showing proportionate distribution of sizes confirm the characters formed by Sven Odén from the *Challenger* specimens.—R. A. **Houstoun** and W. H. **Manson**: Note on a new method of investigating colour blindness. In a previous paper Dr. Houstoun investigated 23 cases of congenital colour blindness and exhibited the results by contour lines on the colour triangle. The same method has been applied to 14 cases of colour blindness induced by disease. The results show that there is no difference in kind between the two classes of cases, and that here also trichromasy passes into monochromasy directly without passing through dichromasy as an intermediate case. W. **Peddie**: The mechanism behind relativity. The Lorentzian equations of transformation from one reference frame to another were introduced in order that Maxwell's equations of propagation of electromagnetic action should be invariant in form under the transformation. Besides this explicit assumption, there is, further, the implicit postulate of a single unique luminiferous ether through which action is propagated at a constant (or approximately constant) speed. The theory of relativity was originated by the latter postulate as much as by the former. The compulsion to adopt Lorentzian relativity disappears if we postulate instead that each atom of matter is associated with a strain form (in an underlying ether) through which alone it receives light, and that it emits light into the similar strain forms of other atoms. The Michelson-Morley result, the aberrational effect, the Fresnel dragging coefficient, and the Doppler effect, all follow; and only the Newtonian relativity is employed, for light is propagated independently to each observer.—R. A. **Sampson**: On Lorentz's equations and the concepts of motion. This paper is a mathematical examination of the foundations of Lorentz's equations, with special reference to the time paradoxes which it is well known that they imply. As a result a group or family of similar equations emerges, among which Lorentz's form occupies a peculiar place. Other members of the family introduce no paradoxes and are equally competent to explain all the known critical experiments.—J. **Marshall**: The interior and exterior space-time forms of the Poincaré electron in Weyl's geometry. Forms for ds^2 are obtained from Weyl's gauging equation. Assuming $g_{11}=0$, the value of $\phi\mu$ is obtained, and arising from the ds^2 form, a pressure is shown to act inwards on the electron.

PARIS.

Academy of Sciences, May 14.—M. Albin Haller in the chair.—C. **Guichard**: The triple orthogonal systems of M. Bianchi. Application to a problem on reciprocal polars with respect to a sphere.—M. de **Sparre**: Concerning hammering in return mains.—J. L. **Walsh**: A theorem of algebra.—René **Garnier**: Uniform functions of two independent variables defined by the inversion of an algebraic system to total differentials of the fourth order.—Georges **Bouligand**: The singularities of harmonic functions.—H. G. Evans and H. E. **Bray**: Poisson's formula and the problem of Dirichlet.—J. **Haag**: The resolution of certain equations of Fredholm by means of an integral series.—Max **Morand**: The electromagnetic origin of inert mass and heavy mass.—Maurice **Nuyens**: Gravific field due to a massic sphere taking into account the cosmic constant.—Pierre **Steiner**: The ultra-violet absorption spectra of the alkaloids of the isoquinoline group: narceine. The ultra-violet absorption curve of narceine resembles generally that of narcotine and of opianic acid. The curve of hydrocotarnine is different from the preceding. So little as 0·05 milligrams of narceine in 2 c.c. of solvent can be detected spectrographically.—A. **Dauvillier**: High frequency spectrographic researches in the group of the rare earths. The results of a detailed examination of the L series of cerium, neodymium, samarium, europium, and gadolinium.—M. S. **Lambert**: Stereoradioscopy.—F. **Wolfers**: An appearance of reflection of X-rays at the surface of bodies.—Hector **Pécheux**: The magnetism of steels. An account of measurements made with three steels of varying carbon content. For forged annealed steels the permeability decreases with increase of carbon.—G. **Athanasiu**: The sensibility of photographic plates containing mercury salts. Of the mercury salts studied, the plates with mercuric iodide were the most sensitive, with a maximum in the green, the sensibility decreasing rapidly and uniformly with the wave-length. Curves are given showing the relation between the sensibility and the wave-length for mercuric and mercurous iodides, mercurous bromide, and chloride.—P. **Laffitte**: The formation of the explosive wave. A study of the explosion of carbon bisulphide and oxygen, utilising the photographic method of Mallard and Le Chatelier.—Alfred **Marx** and Jean **Rozières**: The purification of liquids by the simultaneous action of centrifugal force and the electric field. The removal of colloidal matters in suspension from liquids has been attempted by centrifugal force and by electrical fields, but neither method has completely solved the problem on the industrial scale. The use of an electro-centrifugal separator (2700 turns per minute, voltage gradient 4000 volts per centimetre), has proved successful with dirty transformer oil, the breaking down voltage being increased from 19,000 to 31,000 volts. This material remained practically unchanged when rotated at the same speed without an electrical field; the latter, without rotation, also proved ineffective.—Paul **Pascal**: The preparation of sodium metaphosphate at a low temperature. By the interaction of sodium ethylate and ethyl metaphosphate, sodium metaphosphate is produced at a temperature between 35° and 40° C. Its cryoscopic behaviour proves this salt to have the formula $NaPO_3$, differing from the polymers previously known. The salt may be heated to 800° C. without polymerisation.—**Pastureau** and H. **Bernard**: Tetramethylglycerol. The chlorhydrin $(CH_3)_2 . C(OH) . CHCl . C(OH)(CH_3)_2$, the mode of preparation of which has already been described by the authors, on treatment with an aqueous solution of potassium carbonate gives tetramethylglycerol.—Alfred **Gillet**: A verification of the antioxygen power of the polyphenols: relation between the fastness to light of dyes on the fibre and the presence in their molecule of the diphenol function (ortho- or para-). With the exception of pyrazolone dyes and cotton fabrics dyed with a copper mordant, great stability of dyes on fibre is closely related to the presence in the molecule of an *o*- or *p*- diphenol group.—Ph. **Schereschewsky** and Ph. **Wehrle**: The study of clouds by synoptic photography (the cloud week).—J. **Houdas**: The preservation of seeds in inert gases. Certain seeds (such as *Geubera Jamesoni*) lose their germinating power after exposure to air for a few weeks. In sealed tubes in an inert gas (hydrogen or carbon dioxide) the germinating power of seeds of this plant has been proved to be unchanged after eleven years. The seeds of other plants have given similar results.—L. J. **Simon**: The determination of carbon in arable soil. The method of wet combustion with silver bichromate is recommended.—J. M. **Lahy**: The graphical study of the stroke in typewriting. The speed of typewriting is a function of the alternation of the hands. No general rule can be given as to the number of fingers to be used; the touch is personal, and the most favourable mode of working can only be obtained by study of the individual.—Auguste **Lumière**: The toxicity of autolysates and of tissue extracts.—J. **Lopez-Lomba**: Changes in weight of the organs of the pigeon in the course of B-avitaminosis. The changes of weight in ten isolated organs of the pigeon fed with a diet deficient in B-vitamins are shown graphically.—**Samec** and V. **Isajevič**: The composition of glycogen. A comparison of the properties of starch and glycogen. There are various points of difference, the most marked being the higher proportion of phosphorus in the glycogen.—J. **Voicu**: The effect of humus in small and larger doses on the fixation of nitrogen by *Azobacter chroococcum*.—Alphonse **Labbé**: The influence of the increasing P_H of sea-water on the rapidity of segmentation of the eggs of Halosydna and Sabellaria.—Robert **Dollfus**: The trematode of mother-of-pearl in Provence mussels.—Foveau de **Courmelles**: The similitude of forms of shock in medicine, their dangerous but avoidable superposition. A discussion of anaphylactic shock produced by X-ray treatment, and means of avoiding it.

CAPE TOWN.

Royal Society of South Africa, April 18.—Dr. A. Ogg, president, in the chair.—C. von **Bonde**: Note on the Heterosomata (flat-fishes) of South Africa. Some abnormalities are discussed which are occasionally found in pigmentation, scales, etc., of flat-fish generally, and in particular in some new species described.—T. **Stewart**: Some notes on the drought of 1922–23 on Table Mountain. The first rainfall observations on Table Mountain were begun in January, 1881, when a gauge was placed at a spot called Disa Head, the elevation of which, above the sea-level, is about 2500 feet. Additional gauges were fixed, until by the year 1900 there were eleven in all. The average rainfall for 30 years on the highest portion of the mountain is about 75 inches. The average for the same gauges for 1922 was about 66¼ inches, and there were ten years of the 30 when the average was lower. On no previous dry season has the precipitation at Waai Kopje (elevation 3100 feet)—which gives results for 42 years—been so low as it has been for the seven months, September-March, 1923. If the Disa Head station is taken as indicating the conditions at the 2500 feet level, the dry seasons of 1883–84, 1919–20, and 1920–21 were drier than the last one.—J. S. **Thomas**: The sulphide and hydrosulphide of ammonium. By the action of hydrogen sulphide on alcoholic solutions of ammonia at 0° C., solutions were obtained in which the ratio $[NH_3]/[H_2S]$ approximated to 1; *i.e.* the solution consisted mainly of ammonium hydrosulphide. Ammonia reacts with ammonium hydrosulphide suspended in ether extremely slowly, but on the addition of a small quantity of alcohol a rapid reaction takes place and a heavy yellow oil separates, having the composition $(NH_4)_2S_2NH_3$. This substance is very unstable, and is extremely toxic. When this oil is allowed to stand, transparent cubic crystals separate for which the ratio $[NH_3]/[H_2S]$ was found to be 2. This substance appears to be anhydrous ammonium monosulphide.

Official Publications Received.

The Organisation of Research in India.

THE remarkable results that have been achieved in recent years in India by scientific plant-breeding are strikingly illustrated by a table contained in "A Review of Agricultural Operations in India," recently published by the Government of India (Calcutta: Superintendent of Government Printing, 1923).

In the season 1921-22 the area under new and improved varieties of crops was returned at nearly $3\frac{1}{2}$ million acres. To this should be added a large area (particularly of wheat and cotton) laid down with seed obtained from other sources than official Seed Depots. Of the above-mentioned area, no less than approximately $1\frac{1}{4}$ million acres were under improved cottons, yielding in some cases an increased profit to the cultivators of 20*s.* per acre. But in regard to this crop, Indian administrators are still not satisfied with the progress made. An Indian Central Cotton Committee was appointed to examine the whole problem of cotton growing and marketing. This Committee reported in August last, and already the Indian Government has adopted one of its recommendations and passed an Act authorising the levy of a cess of 4d. per bale of cotton exported and consumed in mills, the money so raised to be used to create a Central Fund for Cotton Research.

It is estimated that this cess will produce about 45,000*l.* per annum (or one-and-a-half times the total amount originally set aside for agricultural research in Great Britain by the Development Commission). The greater portion of this sum will be devoted to the creation of a Cotton Breeding and Seed Distribution Institute, to be established, probably at Indore, in Central India. In addition, a definite scheme for research in technological problems has been formulated. An experimental spinning plant will be provided for this purpose. Further, an information bureau has been started for the collection and distribution of trade and agricultural information. It is probable that the central breeding station at Indore will be placed under the direction of Mr. and Mrs. Howard, whose successful work at Pusa in wheat-breeding is well known in Great Britain.

The Central Cotton Committee has also been instrumental in securing the enactment of measures designed to cope with the difficulties peculiar to the improvement of the cotton crop. Cotton being a plant which, usually, is cross-fertilised, an improved variety cannot be handled in a small way. Consequently, an Act has been passed which gives the Government power to notify a particular area (generally 2000 square miles) for protection, and so prevent, over a large region, the sowing of any variety other than that which it is desired to introduce. The official regulation of cotton "gins" and presses is also likely to be introduced.

All these measures are an example of energetic and purposeful action taken by Government, under the inspiration of results achieved by research in the interests of agriculture. The progress already made has, no doubt, been favoured by the great field which the Indian crops provide for plant improvement. (There is no space to tell of the achievements in the breeding of sugar-cane, but the distressed agriculturists of Great Britain will read with envy of a crop of an improved variety of sugar-cane yielding 60 tons of raw cane per acre, as against a normal 20 tons, worth at a moderate estimate 60*l*.) But when favourable conditions are allowed for, there remains the fact that the Government appreciates, and has been quick to develop economically, the results of scientific work. It was not content to let these results rest at the laboratory stage.

What could be accomplished by similar methods in Great Britain it is difficult to say; some remnants of enlightened despotism still linger in India, and can be used quickly and effectively in the interests of progress; but it might be worth considering whether in the present sorry plight of agriculture some measure of action similar to that followed in India could not be taken. In particular, the idea of creating a research fund by the levy of a cess on the product that it is desired to improve may be worthy of consideration. Bacon, cheese, butter, wool, flax are examples of products that are imported into Britain in large quantities, to the detriment of the home producer. Is organised research powerless to help? There can be no doubt as to the answer, but our politicians, while ready to give lip-service to the value of "education and research," and even grants of money in aid of experimental work, have failed to show an adequate appreciation of the need of *following up* the achievements of research by administrative action, such as that so effectively taken by the Government of India.

Shield Tunnelling.

Shield and Compressed Air Tunnelling. By B. H. M. Hewett and S. Johannesson. Pp. x+465. (New York and London: McGraw-Hill Book Co. Inc., 1922.) 25*s*.

OF late years engineers have been driven more and more to find a location for railways, roadways, and large water-mains below the surface of the ground. In cities, by going underground the cost of acquiring valuable property is escaped. In crossing rivers, a tunnel may be less expensive than a bridge. A method has been devised for tunnelling in soft or water-bearing ground in which the miners work in a shield and an inrush of water is prevented by compressed air. In this method rings of cast-iron segments are erected in the shield, forming a water-tight lining, and as each section is completed the shield is driven forward by hydraulic jacks, leaving the lining to support the rock or earth. The more difficult the ground the greater is the advantage of this method of working. The number of tunnels which have been so driven in different countries is now large, but though the method is simple in principle the difficulties and dangers met with in carrying it out are among the most serious which tax the skill and experience of the engineer and contractor.

Information about shield tunnelling is scattered in the proceedings of professional societies, and the treatise of Messrs. Hewett and Johannesson is one of the first in which the data of past experience are gathered together and the attempt is made to formulate principles and rules of practice. It is an excellent treatise, full of information, well illustrated, and competently discussed.

Brunel patented the first shield, and by its help overcame the very great difficulties of driving the first tunnel under the Thames (1825–1843). In 1869, Barlow promoted the construction of the Tower Subway for foot passengers under the Thames. When contractors feared to undertake the work, a young engineer, Greathead, designed a new form of shield and completed the tunnel in a year. This was in dry London clay. Then, when such difficulty was experienced in driving the two Hudson River tunnels in water-bearing silt at New York that the work was temporarily abandoned, Greathead and Baker carried it on for 2000 feet by a shield and compressed air. Stopped again by want of capital, the tunnels were completed in 1904 by Jacobs. Later the Blackwall and Rotherhithe tunnels under the Thames and others abroad were successfully constructed by the same method. Descriptions of these and a full bibliography are given in this treatise.

The cast-iron lining for shield-driven tunnels is now in general use. The space between the lining and ground is filled by cement grout, forced by compressed air through holes in the lining, and the interior is made fair by brick or concrete. The joints of the lining are caulked with rust cement. There is a bulkhead behind the shield through which the compressed air is forced, and it contains airlocks for men and materials. The shield is driven forward by hydraulic jacks, working with pressures up to 6000 pounds per sq. in. and exerting a total force amounting to 6000 tons in some cases. Usually in the shield is a hydraulic erector for lifting and placing the cast-iron segments and mechanical excavators for removing the soil at the face. It may give an idea of the complex arrangements necessary if it is stated that among the equipment required are a low-pressure plant for supplying air to keep back the water; a high-pressure plant to supply compressed air for working rock drills and other tools; a service water supply for grouting and washing; an electric light and power supply; and transportation plant. A useful chapter is one on the working force needed, the rate of progress in different cases, and the cost.

The authors give a theory of the stresses in the tunnel lining, a subject hitherto far too much neglected, designs having followed rule-of-thumb methods. This is not a suitable occasion for discussing a mathematical theory. The mode of treatment is unusual, but the results are interesting. The authors seem to underrate the erection stresses due to the weight. The most important external load is the earth pressure. The theory of earth pressure of Rankine is adopted, in which c depending on the angle of repose is the ratio of the "active" horizontal pressure to the vertical pressure and $1/c$ the ratio of the "passive" resistance of the earth, if the structure presses against it and is on the point of displacing it. But the statements (p. 76) that if the active horizontal pressures are not sufficiently large in relation to the vertical pressures the tunnel will have a tendency to deflect horizontally, and (p. 53) that if k lies between c and $1/c$ the tunnel lining will not be subject to a moment, require more justification.

An interesting chapter is that on compressed-air illness and the precautions to prevent it. The cause is the absorption of an excess of nitrogen by the blood—disengaged if the pressure is reduced. The cure is careful limitation of the period of work and slow decompression. If in spite of precautions cases of illness occur, the remedy is to recompress and decompress more slowly. For this a hospital lock is provided.

W. C. U.

Colour Vision and Colour Vision Theories.

(1) *Colour Vision: A Discussion of the Leading Phenomena and their Physical Laws.* By Prof. W. Peddie. Pp. xii+208. (London: E. Arnold and Co., 1922.) 12*s.* 6*d.* net.

(2) *Colour and Methods of Colour Reproduction.* By Dr. L. C. Martin. With Chapters on Colour Printing and Colour Photography, by William Gamble. Pp. xiii+187. (London, Glasgow and Bombay: Blackie and Sons, Ltd., 1923.) 12*s.* 6*d.* net.

THERE are no subjects on which discussion and demonstration are more needed than those of vision and colour vision. The trichromatic theory as presented by Helmholtz was the best theory in relation to the facts known at the time, but the difficulties of the theory were thoroughly recognised by him. That it was a theory and not a fact was stated by Helmholtz. That all colours can be matched by a mixture of three selected simple colours is a fact, but the statement that there is an underlying trichromatic basis is not only not a fact, but it is also not supported by any fact which cannot be explained in another way, and there is the most conclusive evidence that this is not the case, while another explanation is completely consistent with the facts. The state of chaos existing in many minds with regard to colour vision is due to the assumption that the trichromatic theory is a fact. If the theory be denied there is no evidence for it, and this was known to Helmholtz.

(1) Prof. Peddie's book is an uncompromising acceptance of the theory as a fact. The book is an admirable exposition of the functions of three variables, but no attempt is made to answer any of the objections to the theory or to show how the theory is consistent with known facts. In this respect the author differs from other writers, who admit that something more is required. If we regard colour perception as developed secondarily to light perception, as it undoubtedly was, we can form a series from total colour blindness to super-normal colour perception. The colours differing most physically in wave-length being first discriminated, these gradually approached each other until green was discriminated in the centre as a new colour, then yellow, then blue, then orange, and lastly indigo. The explanation, therefore, why red and green make yellow when mixed is, that yellow having replaced the red-green of a previous state of development, the colour perception is not sufficiently developed to discriminate between a mixture of red and green and simple yellow.

No two accounts of the trichromatic theory agree, and the theory is loaded with subsidiary hypotheses, many of them quite inconsistent with each other; that is to say, one will explain one set of facts but not another set of facts for which a different arrangement is required. Space will not permit of more than a few of the very long list of objections to the trichromatic theory being given here. If a mixture of spectral lights red, green, and violet be made to match a simple white, on the trichromatic theory the internal physiological processes should be identical; but if the eyes be now fatigued with a red light containing that used in the mixture, about twice as much green will be required in the mixed white, the mixture appearing bright green to a normal person with unfatigued eyes. Again, if a spectrum be viewed with an eye fatigued by looking at burning sodium, the yellow will have disappeared from the spectrum and the red and green will appear to meet, but a feeble red at the end of the spectrum will be quite visible. If, however, after looking through a deep-red glass for the shortest possible time the terminal red be viewed, it will not be visible. On the trichromatic theory much greater fatigue of the red sensation process is obtained with the burning sodium.

When we come to colour blindness, which, according to Helmholtz, is the key of colour vision, the trichromatic theory fails completely to explain any case when it is fully and thoroughly examined. How, for example, does it explain that more than 50 per cent. of the dangerously colour blind can get through the wool test? How are the innumerable cases of dichromic vision to be explained? All see in the spectrum two simple colours and a neutral region, but one is only detected by very efficient tests, others by very rough tests: the latter are obviously much more colour blind than the first class. How are the trichromic, with their absence of the yellow sensation and wide monochromatic area in the yellow region—for example this may be from $\lambda 610\ \mu\mu$ to $\lambda 535\ \mu\mu$—to be explained? How is it that in so many cases the apex of the luminosity curve remains at the normal point and a normal white equation is made? Why, indeed, should a man who has three colour sensations be colour blind at all? As a matter of fact, there is considerable variation in colour perception without colour blindness; a man may make an anomalous white equation without being colour blind.

Finally, it can be clearly shown that, with a man having a defective terminal red, this is not due to a diminution of a hypothetical red sensation which is affected by rays corresponding to every part of the spectrum. For example, a man may have shortening of the red end of the spectrum; he may pass the wool test, or if the proper colours be there, put certain pinks and violets together as identical. Shown a bright red in the lantern corresponding to the shortened portion, he does not see it at all. It will be noticed that the pinks he puts with the violets are much lighter than the latter, but when viewed through a blue-green glass both appear identical in colour and shade to the normal-sighted. The blue-green glass has cut off the red rays. How, according to Prof. Peddie's construction, can a man with shortening of the red end of the spectrum pick out yellow at the normal point and have a luminosity curve with the normal apex?

The valuable work of Shelford Bidwell, which is so inimical to the trichromatic theory, is not mentioned. Bidwell showed that the phenomena of intermittent light are quite inconsistent with the compound character of the yellow sensation. If the image of a white object be formed suddenly on a portion of the retina which was previously occupied by the image of a black object, this image is surrounded by a red border. Bidwell states: "Though the image of the needle was colourless when the patch was illuminated by the greenish-yellow rays of the spectrum, it appeared red when the same hue was formed by combining red and green rays." The fact that the red border is not found with the pure greenish-yellow spectral light and is found with the compound light is strong evidence against the compound nature of the yellow sensation when caused by simple yellow light.

(2) The valuable book by Martin and Gamble should be read by all interested in colour. It is very well written, and gives an admirable account of the facts and views of different writers, without bias towards any particular theory. Dr. Martin states in the preface: "It is now more than ever necessary that the limitations of the trichromatic theory shall be explored, still by physically sound methods but by men who are fitted to understand the psychological and physiological view points. Furthermore, there is a great deal of work which needs the most careful verification and checking."

The book is divided into three sections. Part one deals with the nature of light and colour, colour analysis and synthesis, the colours of material objects, their nomenclature and measurement, colour in regard to illumination, colour in human experience, and colouring materials. This part is so clearly written that it can be easily understood by any one who has not much knowledge of physics and mathematics. Part two deals with the eye and its reactions to light, photometry, instruments for colour measurement, colour vision with an account of the principal theories, and colour blindness. Part three is written by Mr. Gamble, and deals with colour printing and photography in colours. A number of useful tables are given in an appendix.

Nature Knowledge and Pastime.

(1) *Great and Small Things.* By Sir Ray Lankester. Pp. xi + 246. (London: Methuen and Co., Ltd., 1923.) 7*s.* 6*d.* net.

(2) *The Badger: Afield and Underground.* By H. Mortimer Batten. Pp. 159 + 12 plates. (London: H. F. and G. Witherby, 1923.) 8*s.* 6*d.* net.

(3) *A Perthshire Naturalist: Charles Macintosh of Inver.* By H. Coates. With a chapter on Scottish Folk-music by H. Wiseman. Pp. xx + 244 + 32 plates. (London: T. Fisher Unwin, 1923.) 18*s.* net.

(4) *The Highlands with Rope and Rucksack.* By Dr. E. A. Baker. Pp. 253 + 19 plates. (London: H. F. and G. Witherby, 1923.) 12*s.* 6*d.* net.

(1) THE volume before us is the fifth, if we are not mistaken, in a series of volumes whereby Sir Ray Lankester has rendered notable service to those persons who, though debarred by circumstance from undertaking sustained research, deeply sympathise with advance in natural science, are eager for sound informa-

tion, and grateful to a competent showman, so to speak. In the present volume the author ranges wide—from the gorilla which, having spent its childhood in devoted attachment to a lady in Sloane Street, sickened and died when she was obliged to part with him, to the parasites of a pond snail and Metchnikoff's investigation of the means of making old age still older. The title of the book is well chosen, for it contains the conclusions of a trained intellect upon such great problems as the suffering inseparable from the existence of all animals, and upon such small ones as the relative advantage (or otherwise) of the different ways of using tobacco. Even those smokers who display little interest in chemical science, though rightly regarding nicotine as the chief toxic agent in tobacco, may feel relieved in learning that "it is a colourless volatile liquid, which is vaporised and carried along with the smoke," and not the malodorous oily juice that collects in the stem of a foul pipe or the stump of a cigar.

Elderly folk who were reared in the belief that they had to work their way through life equipped with only five senses—sight, hearing, smell, taste, and touch—may be surprised to learn that all the time they have been served by double that number. Increased knowledge of physiology has revealed the existence in the human frame of a distinct apparatus and separate nerve-threads for the perception of heat, cold, and pain, for muscular contraction and for the maintenance of equilibrium, all of which—except the last, which escaped consideration—were of old roughly assigned as functions of the sense of touch.

Sir Ray Lankester points out that the most salient anatomical difference between man and the gorilla is in the structure of the foot. In man the axial line of the posterior limb passes straight down the shin-bone to the hallux or great toe; whereas in plantigrades, such as bears and anthropoid apes, it is directed between the third and fourth digits, leaving the hallux to be deflected and developed into a powerful grasping organ. The importance of this difference consists in the absence of any trace of a form of foot intermediate between that of man and the ape.

This volume, like its predecessors in the series, is written with lucid fluency, is admirably illustrated, and many readers will pass a hearty vote of thanks to the author for having devoted his well-earned leisure to their profit.

(2) In his great work on British and Irish mammals, Mr. J. G. Millais apologised for having quoted at so great length from Sir Alfred Pease's treatise on the badger, which had rendered it scarcely possible to write anything new upon that subject. While Mr. Mortimer Batten can scarcely claim to have made fresh addition to our knowledge of the habits of this most cryptic creature, he has recorded in very readable form his own patient observation thereof, confirming much that has been written by other naturalists and giving his own views upon points whereon these have differed. He considers the badger to be "the most abused and misunderstood of British wild beasts," quoting the sickening treatment of the animal prescribed by Nicholas Cox in the sixteenth century before baiting it with terriers. "Cut away the nether jaw, but meddle not with the other, leaving the other to show the fury of the beast, although it can do no harm therewith." Drawing the badger, a so-called sport which it is to be feared is still in vogue as a clandestine pastime, was made illegal by the Act of 1850; but unfortunately there is no law against "trying" terriers on a captive badger.

Sir Alfred Pease stated that the badger had become rare in Scotland and had "entirely vanished" from the north-east of that country. Mr. Mortimer Batten, however, has satisfied himself that the race survives in far greater numbers than most people think, founding his opinions not only on the badgers which he has himself found, with his terriers, in cairns, but also on the great preponderance in some hill districts of the tracks of badgers in snow over those of foxes.

Naturalists have differed widely in estimating the period of the sow badger's gestation. Mr. Millais accepted fifteen months as possible, at least for a badger in captivity; Sir Alfred Pease put it at nine months, Tom Speedy at seven, Sir Harry Johnston at six; but Mr. Batten gives good grounds for agreeing with Capt. Salvin that the normal term is eleven or twelve months. He rejects the supposed analogy with the roe, which has been credited with the power of postponing parturition until circumstances are suitable for her.

"What really does happen in the case of the roe is this—the embryo does not develop, or at least develops very slowly, during the first four months of pregnancy, so that she carries her young close upon four months longer than is normal. This peculiarity of the roe is probably owing to a total change of environment—that is, the animal originated under semi-tropical conditions, and migration northward during [? after] the glacial age led to a postponement in the operation of parturition."

This may pass for speculation on an obscure problem; the value of Mr. Mortimer Batten's book consists in the convenient manner in which he has summarised all that is known of one of our larger wild animals, subject to critical light from his own observation, and has supplied excellent photographs and explanatory cuts.

(3) Charles Macintosh was of a type not infrequent among the Scottish peasantry—men self-taught in some branch of natural history; keen observers but ill-equipped with appliances and books of reference,

patiently accumulating facts until, in middle life or past it, some happy accident brings their work to the knowledge of those whose scientific standing enables them to advise and assist. Probably there are and have been many "mute, inglorious" Tyndalls and Huxleys to whom such chance never came; but just as the labours of Robert Dick of Thurso on the Old Red Sandstone were recognised and redeemed from oblivion by Hugh Miller and Sir Roderick Murchison, so when Dr. Buchanan White started in 1872 to investigate the mycology of Perthshire he found that Macintosh, a humble rural postman on a weekly wage of 12*s.*, had gone far to make a complete collection of the Basidiomycetæ, and straightway enlisted him as an auxiliary and correspondent of the Perthshire Society of Natural Science.

Charles Macintosh was born in 1839, the son of a handloom weaver in the village of Inver, near Dunkeld. When he was sixteen years old he obtained employment in a sawmill, and two years later met with an accident that deprived him of all the fingers and the thumb of his left hand. In 1858 he was appointed post-runner in the district between Dunkeld and Ballinluig—a sylvan and riparian region most congenial to one with his bent for botany and natural history. His daily round afoot was about 16 miles, enough, it might be thought, to abate inclination for serious work when off duty; but

"ingenium res
Adversae nudare solent,"

and Macintosh's appetite for knowledge was insatiable. With the aid of a very imperfect microscope and a few antiquated works on botany, by the time he became acquainted with Dr. Buchanan White in 1872 he had made a very extensive collection, not only of the flowering plants, but also of the ferns and other cryptogams of Strathtay. After that, having supplied himself out of his savings with better instruments and modern books, he contributed several additions to the flora of Perthshire, including seventeen species of fungus hitherto unrecorded in Britain, of which four were new to science, namely, *Curreyella aucupariæ*, *Melogramma elongatum*, *Ascobolus Carletoni*, and *Ombrophila megalospora*. He finished 32 years' service under the Post Office in 1890, and died in 1922.

Mr. Coates has done full justice to the subject of this memoir, which is very fully illustrated, the frontispiece being an exceptionally interesting photograph of Macintosh. We have noted very few slips: the great oak at Birnam may possibly be a survival of the primeval forest, but not so the sycamore (p. 60), for that is not an indigenous species. Both trees are well known to the present writer, and to estimate their age at one thousand years is to disregard what is obviously their vigorous prime. To describe a family bible as "a human document" (p. 11) is grievously to misapply a metaphorical phrase. Lastly, widely as the spurious adjective "phenomenal" has come into use in the sense of "extraordinary," to describe the Tay as having been reduced by drought to "almost phenomenally small proportions" (p. 221) is surely neither sense nor English!

(4) A certain German philosopher is credited with the doctrine that every object of interest should be inspected from its proper point of view—a church from the outside, a tavern from the inside, and a mountain from the bottom. Whatever may be Dr. Ernest Baker's opinion about churches and taverns, he holds emphatically that the worst aspect of a mountain is from the bottom. Its only legitimate purpose is to be climbed on its most difficult side. The first fifty pages of his treatise on "the excellent sport of rock-climbing" are applied to a denunciation of Highland landowners for putting difficulties in the way of tourists and trippers, but for which he is confident that the Scottish Highlands would attract as many holiday folk as Switzerland does.

Dr. Baker's own narrative testifies to the fact that the summer climate of the Highlands is scarcely so serene as that of Switzerland. In his adventures among the Highland hills he encountered many spells of dismal weather.

"We were awake betimes, but rain was falling, and for three long days the weather remained too bad for serious climbing. Stob Dearg was continuously swathed in mist; and the gullies, as we could see afar off by the tracks of white, were spouting water amain" (p. 78).

As for landowners, there are no doubt surly ones as well as others of milder mood; but the powers of both in preventing access to their estates are more strictly limited than Dr. Baker explains. They can only proceed against trespass by obtaining interdict against individuals. "Trespassers will be prosecuted" is *brutum fulmen* unless damage can be proved. It may be doubtful whether a judge would decide that damage had been done in the incident described as follows; but the immediate consequences might have been serious if the Highland glens had been as full of holiday-makers as the author would like to have them.

"As usual on a new climb, we found many splinters hanging in dangerous places, and the worst of them we cleared away. One big lump of porphyry, caught in unstable equipoise on the bevel-end of a ledge, gave rise to a memorable incident. I was held from above by the rope while I gave the rock a final shove that released it. Thirty feet below, a pinnacle stood out from the face, a squarish mass some twenty-five feet in height and about sixteen in girth. It is discernible in the photo taken near the foot of the climb, but its place knows it no more. . . . We calculated afterwards that it would weigh 80 or 90 tons. . . . The falling rock hit the top of it. The pinnacle shook in its socket, lurched forward, bowed majestically over, and, almost before we knew what was happening, went hurtling down the cliffs and gullies. It cleared some hundreds of feet at a leap; then striking a projection, bounded off, leaving an ugly scar behind, and thundered on down the crags, smashing off corners, crashing into the screes in the gullies and splashing up the snow like water. . . . The whole ridge vibrated like a bridge with a heavy express rushing over."

Pretty pastime! yet landowners are but human after all, and might not unreasonably demur to much of this kind of thing. There is no evidence that in his scrambles Dr. Baker took any notice of geology, botany, or anything except the opportunity for hazardous athletics. His book is illustrated with many good photographs of hill scenery.

Herbert Maxwell.

Psychotherapy.

Suggestion and Mental Analysis: An Outline of the Theory and Practice of Mind Cure. By Dr. William Brown. Third edition, with Index. Pp. 176. (London: University of London Press, Ltd., 1923.) 3*s*. 6*d*. net.

As implied by the title, Dr. Brown's "Suggestion and Mental Analysis" brings together the widely divergent views of the two principal schools of psychotherapy. It is an attempt to harmonise the theory and practice of the hypnotists, suggestionists, and autosuggestionists, on one hand, and of the psycho-analysts on the other. It is generally claimed by the partisans of each school that its method is exclusively the best suited for the treatment of those forms of psychoneuroses in which mental therapy is indicated. Indeed, as Dr. Brown points out, extremists of both schools agree in disclaiming any possibility of a synthesis of their methods. In practice, however, it not seldom works out that such disclaimers are ignored, even by the purists. Dr. Brown argues that the various methods of psychotherapy can be advantageously employed in combination. He bases his views upon a very large number of typical clinical cases which have passed through his hands both in civilian practice and as a result of the special conditions due to the War. With regard to the latter cases, Dr. Brown worked mainly by suggestion and hypnosis, and with marked success. He now advocates a judicious use of all the methods, some of which are more especially adapted to one type of case and some to others. He thus, on empirical grounds, declares himself to be an eclectic.

The book is elementary—even popular—but it touches upon most of the points which are treated at length in the large and continually growing literature of psychotherapy. The first chapters deal with generalities on suggestion and the subconscious, and sketch briefly the theories and methods of the analysts. Several interesting case-histories are given in some detail to illustrate the dissociation due to hysteria and hysterical epilepsy. Hypnosis is contrasted with suggestion, and is itself declared to be a form of dissociation; in consequence of which the conclusion is—rightly—drawn that frequent hypnotising of a patient is dangerous. Nevertheless, hypnosis is a valuable procedure to employ in certain cases. Indeed, all proved methods are valuable. This is the general conclusion of the book, in which such divergent views as those of Charcot, Bernheim, Freud, Jung, Coué, and others are considered.

The more scientific and therapeutic part of the volume is supplemented by three chapters on the "philosophical background," which consist of a summary exposition and criticism of the philosophy of M. Bergson. It is true, as Dr. Brown remarks, that "every revolution in scientific theory synchronises closely with the development of new ideas, and even new systems, within the domain of philosophy"; and no doubt Bergson's philosophy synchronises to some extent with the rise and growth of recent psychotherapeutic theory and practice. There are obvious similarities in both. But it is not obvious why these chapters should have been included in a book on psychotherapy; and their inclusion makes it appear rather overweighted with speculation. The present is the third edition of the book; and it is clear that this excellent elementary presentation of the theory and practice of "mind cure" meets the good reception it deserves at the hands of the public. There is a good index.

Our Bookshelf.

Cements and Artificial Stone: a Descriptive Catalogue of the Specimens in the Sedgwick Museum, Cambridge. By the late John Watson. Edited by Dr. R. H. Rastall. Pp. xii+131. (Cambridge: W. Heffer and Sons, Ltd.; London: Simpkin, Marshall and Co., Ltd., 1922.) 6*s*. net.

The collections brought together by the zealous care of Mr. Watson in the Sedgwick Museum have been of great service in technical geology. Probably much may still be added to the samples of cement and artificial stone described in the present volume, as these materials become still more favoured by architects and engineers. The labour and art of the mason may decline, but the production of durable cements for covering walls, the colouring of them until they surpass in brilliance the painted surfaces of Roman times, and the imparting of increased delicacy to moulded work in stucco, are alike honourable and artistic occupations. The materials of artificial slabs are largely natural rock, brecciated or pulverised, but otherwise untreated, and the pride of their makers lies in the production of monolithic blocks of more uniform texture and more free from cracks than can be obtained from ordinary quarries. Mr. Watson (p. 76) gives an impressive account of the hollow blocks of reinforced concrete, each weighing 2464 tons, and measuring 66 by 53 by 50 feet, used in harbour-construction at Valparaiso in 1917. It seems as if a house of considerable size, with staircases and passage-ways, could now be moulded round a light steel framework as a single piece, and transported by flotation to any quarter of the globe.

The author shows (p. 94) how well-known building-stones, with their pleasing colours, are already successfully imitated, and how a great field lies open before the manufacturer of light roofing-tiles that may compete in our towns with the monotonous grey tints of slate. Nothing is likely to oust polished granite from its supreme place as a decorative stone for towns; but those who would decry the use of artificial stone must remember that the glories of Verona, the Hansa Towns, and Hampton Court are largely due to the manipulation and moulding of detrital clay. Mr. Watson gives a long and interesting history of the Portland cement industry, which his specimens fully illustrate. He directs attention (pp. 101 and 114) to the good acoustic properties of selenitic cement for lining walls; but we cannot find a mention of the remarkable cement now formed from magnesite and used for floors. The early use of the Italian *pozzolana* (which even the "Encyclopædia Britannica" spells in places *pozzuolana*) is well mentioned; but we doubt if (p. 2) Puteoli was also known to the Romans as "Putevolano." G. A. J. C.

Special Steels: a Concise Treatise on the Constitution, Manufacture, Working, Heat Treatment, and Applications of Alloy Steels, for Students, Operators, and Users of Special Steels. Chiefly founded on the Researches regarding Alloy Steels of Sir Robert Hadfield. By Thos. H. Burnham. (Pitman's Technical Primers Series.) Pp. xxii + 194. (London: Sir Isaac Pitman and Sons, Ltd., 1923.) 5*s*. net.

THIS small volume is a welcome addition to the literature dealing with special steels, as it contains a large amount of useful information compressed into a small compass. The necessity for economy in the use of iron ore is clearly indicated both by Sir Robert A. Hadfield and the author, who show that, by the use of special steels, the amount of iron necessary for most purposes is greatly reduced.

Considerable information is given relating to the constitution and manufacture of special steels and to their later heat or other treatment. Much useful work has been done during the past twenty years in connexion with the heat treatment of ordinary carbon steel, but this treatment, in the case of large masses, is always unsatisfactory on account of the impossibility of bringing about uniform structural changes. If, however, carbon steel is alloyed with other elements a considerably greater range of mechanical and other properties is available. These considerations are dealt with in this small book. Accounts are given of various classes of special steels, while under "chromium steel" details are given relating to rustless steel, such as its composition, mechanical and heat treatment, mechanical properties, resistance to corrosion, and its applications. A chapter each is devoted to silicon, manganese, and tungsten steels, while some details are given respecting the manufacture, properties, and uses of other types of special steel. The final chapter (xii.) points out the general trend of progress, and there are four appendices which deal respectively with: (1) carbon steels; (2) a classified list of papers by Sir Robert A. Hadfield; (3) a list of symposia of the Faraday Society; and (4) the relation between hardness number and shock qualities, tensile strength and compression strength of various types of steel.

The book provides the student and the practical man with a handy survey of the subject, and should find a place in all technical libraries. W. H. M.

(1) *Animal Nutrition: Foods and Feeding.* By E. T. Halnan. Pp. 52. 2*s*. net. (2) *Farm Costing and Accounts.* By C. S. Orwin. Pp. 31. 1*s*. 6*d*. net. (3) *Insect Pests and Fungous Diseases of Farm Crops.* By A. Roebuck. Pp. 55. 2*s*. net. (4) *Poultry Keeping on the Farm.* By Edward Brown. Pp. 54. (London: Benn Bros., Ltd., 1923.) 2*s*. net.

THE four little books under notice belong to the "Successful Farming Series," the purpose of which is "to raise the standard of British Farming in all its branches."

Even in this small compass Mr. E. T. Halnan (1) has developed the subject of animal nutrition from the fundamental scientific facts to the practical deductions drawn therefrom. The exposition is lucid, and the book should not only interest farmers who have no scientific knowledge, but it should also be of real use to them in their daily work.

(2) In "Farm Costing and Accounts," by Prof. C. S. Orwin, simple methods are given for keeping financial accounts suited to the needs of almost any farmer—and incidentally sufficient for purposes of reclaiming excess income tax—and an outline of the methods of keeping the more intricate costing accounts.

(3) "Insect Pests and Fungous Diseases of Farm Crops," by Mr. A. Roebuck, contains descriptions of the common insect pests and the appearances of plants attacked by them or by various fungi. The writer suggests prophylactic measures such as balanced manures, and the avoidance of harbouring places for pests such as are found on untidy and ill-kept farms and buildings.

(4) In "Poultry Keeping on the Farm," Mr. Edward Brown emphasises the possibility of increasing very greatly the number of poultry kept in this country. In his opinion this increase can take place most profitably on farms, where the birds could find much of their food; but he maintains that there are also big openings for specialised poultry keeping, more especially in the vicinity of large towns, and for selective breeding.

The Elementary Principles of Lighting and Photometry. By J. W. T. Walsh. Pp. xvi + 220. (London: Methuen and Co., Ltd., 1923.) 10*s*. 6*d*. net.

MR. WALSH's book may be regarded as a useful supplement to pre-War works on illumination. The text may be conveniently divided into four main sections. We have first an account of the effect of light on the eye, followed by an explanation of terms and elementary principles. Next there are chapters dealing with various aspects of photometry, leading to a discussion on calculations of illumination. Finally we have, in the second half of the book, a general discussion of practical lighting problems. Consideration of the human eye forms a natural starting-point, and in general a logical sequence of subjects is adopted. One may question, however, whether the separation of heterochromatic photometry and the flicker-photometer in the penultimate chapter is desirable. Surely this might more fitly have been included in the earlier section of the book dealing with photometry in general? Mr. Walsh's experience at the National Physical Laboratory has stood him in good stead in dealing with this phase of the subject. The hints on laboratory practice are sound, and there is a useful description of the chief forms of illumination-photometers. It is interesting to note that, with proper precautions, an accuracy of 2-3 per cent. is considered possible with this class of instrument. The chapter on industrial lighting contains a useful survey of the work of the Home Office Departmental Committee on Lighting in Factories and Workshops, and the contents of various American codes. One is glad to note the inclusion of a chapter on daylight illumination, which is now being studied in a more scientific manner than in the past.

The final chapters on colour and light-projection include a variety of special applications of light such as motor-car headlights, searchlights, flood-lighting, and artificial daylight. (In the calculation of flood-lighting on p. 189 a slip appears to have been made.) The book is concluded by a series of definitions of the chief photometric quantities, a bibliography, and an adequate index.

L'Arc électrique. Par Maurice Leblanc fils. (Recueil des Conférences-Rapports de Documentation sur la Physique. Vol. 3, 1re Série, Conférences 7, 8. Édité par la Société *Journal de Physique*.) Pp. 131. (Paris: Les Presses Universitaires de France, 1922.) 10 francs.

THE first chapter of the work under notice contains the more important formulæ obtained by modern physicists in connexion with the electric arc. A drawback to the use of these formulæ is that it is difficult to find out where theory ends and empiricism begins. If we accept the formulæ we have to abandon the theory of dimensions as applied to equations. In the second chapter Mrs. Ayrton's work is well described. It is stated that Blondel was the first to prove that there was no appreciable counter electromotive force in the arc. If E denotes the potential difference across the arc and I the current through it, then dE/dI is called the resistance of the arc, and it is pointed out that it is a negative quantity. A good description is given of magnetic and mercury vapour lamps. The phenomena shown by the so-called "non-arcing" metals, such as phosphor-bronze, aluminium-bronze, aluminium and zinc, are attributed to a metallic oxide covering the electrodes with an insulating layer or to the vapour being difficult to ionise. It is pointed out that although the current and voltage vanish instantaneously in alternating current arcs, yet their power factor is not unity. This is stated to be due to the fact that they do not both follow the sine law. As a matter of fact, provided that the ordinate of the current wave is always proportional to the ordinate of the voltage wave, and they vanish instantaneously, the power factor would be unity whatever the shape of the voltage wave. The third chapter gives the technical applications of the electric arc to searchlights, furnaces, electric welding, for producing high-frequency waves, and in electric "safety valves" for protection against lightning.

A. R.

Machine-Shop Mathematics. By G. Wentworth, D. E. Smith, and H. D. Harper. (Wentworth-Smith Mathematical Series.) Pp. v+162. (London: Ginn and Co., 1922.) 5s. 6d. net.

THE presentation, in most cases without proof, of a hundred and twenty formulæ in as many pages can scarcely lay claim to the title of mathematics, but this book forms nevertheless a clearly worded and practical introduction to machine-shop calculations. Its scope is confessedly limited to the needs of those who hope to become expert machinists with little or no mathematical grounding, and throughout the book more attention is paid to the explanation of technological details than to the development of method. The use of measuring instruments and calculations affecting cutting speeds, taper turning, screw cutting, indexing and gear cutting are clearly described, generally with the aid of excellent diagrams. The number of formulæ is large, and a judicious reduction in this respect would bring emphasis on to the more important without prejudice to the range of the book. Illustrative problems are worked out in the text, and examples throughout are numerous and well chosen. Their value to the self-dependent student would, however, be greatly enhanced if answers were given. Calculations are in most cases made to cover British as well as American practice, but reference tables at the end give American standards only.

H. W. S.

An Introduction to the Psychology of Religion. By R. H. Thouless. Pp. vi+286. (Cambridge: At the University Press, 1923.) 7s. 6d. net.

THERE is an undoubted movement of thought towards a restatement of religion and religious problems along the lines of recent psychological achievement. This has already taken the place, to a large extent, of the apologetic defence of religion on the plane of the sciences of Nature. Mr. Thouless writes for those who wish to make a study of the problems of religion from a psychological point of view without any prior knowledge of psychological terminology. The most interesting parts of his book are those in which he relates religion to certain of the instinctive tendencies of man, while defending it from the charge of being no more than a subjective experience of gregariousness or sex; and his chapter on the phenomena of mysticism, for which he goes in the main to the mystics of the Roman Catholic Church. He treats this subject with great insight and exactness, and interprets it sympathetically in the light of recent psychoanalytical theory. The book, while avowedly "popular," will be of interest to students both of religion and of psychology.

Letters to the Editor.

Gravitation and Light-pressure in Nebulæ.

DOES not Prof. Lindemann's theory of spiral nebulæ (discussed by Sir Oliver Lodge in NATURE of May 26, p. 702) fail through disregarding the absorption or reflection of radiation which must necessarily accompany any mechanical action of light-pressure? Prof. Lindemann's typical nebula has a mass of about 0·1 gram per sq. cm. of area, which is probably something like the true value; but to get this value, Prof. Lindemann's assumed particles of diameters 10^{-4} or 10^{-5} cm. must lie behind one another some thousands deep. The particles in the outermost layer are, no doubt, acted on by light-pressure in the way supposed, but not so those in the inner layers; these are shielded from light-pressure but not from gravitation—and here the whole theory seems to fail. Incidentally, a nebula formed of solid particles lying thousands deep would surely be too opaque for novæ formed in its interior to be seen as novæ.

The whole question seems to be governed by a calculation much simpler than any given by Prof. Lindemann. If a star or group of stars emit radiant energy E per unit time, the flow of momentum through any cross-section of a cone of solid angle ω will be $E\omega/4\pi C$ per unit time. Thus the maximum mass m which light-pressure can possibly support (or repel) in this cone at a distance r from the light is given by

$$\frac{\gamma m M}{r^2} = \frac{E\omega}{4\pi C},$$

where γ is the gravitation constant, and M the mass of the star or stars. Thus the maximum mass per unit area, $m/\omega r^2$, is

$$\frac{1}{4\pi\gamma C}\frac{E}{M}.$$

This is of course independent of r, because gravitation and light pressure both fall off as $1/r^2$; it does not depend on the number of stars at work, since E and M are each proportional to that number. For the aggregate of matter in the universe we may perhaps put E/M equal to unity, this being about half its value for our sun. The maximum mass per unit area which light-pressure can support or repel is now $1/4\pi\gamma C$, or about one gram per 25,000 sq. cm., whereas the spiral nebulæ, on Prof. Lindemann's own estimate, have one gram per 10 sq. cm. No doubt it may be argued that the nebulæ in the past were more tenuous than now, but the nebulæ reduced to a surface-density of one gram per 25,000 sq. cm. would cover the heavens many times over at any reasonable distance.

I have long wondered whether a true example of suspension in equilibrium between gravitation and light-pressure may not possibly be found in the shells which constitute the outer surfaces of the planetary nebulæ. That there is suspension in equilibrium seems scarcely open to question; the hypothesis that gravitation and light-pressure are the equilibrating agencies satisfies all the numerical tests I have been able to apply. But it is necessary for stability that the matter should be gaseous, as is in fact spectroscopically found to be the case. A hollow shell of solid particles can be suspended in equilibrium, but this equilibrium cannot be stable for radial displacements. Press the shell closer in to the star and its particles shield one another more from light-pressure, so that gravitation becomes relatively more potent than light-pressure and the shell falls in. But a hollow shell of gas may be stable if its temperature is such that its degrees of dissociation and ionisation are sufficiently sensitive to changes of temperature. Press such a shell closer in to the star and its constituents break up more; assuming that this increases its opacity, light-pressure becomes relatively more potent and the shell is driven back. Draw the shell out to a radius greater than the equilibrium radius and the converse occurs: the equilibrium is stable.

J. H. JEANS.

May 28.

IN the issue of NATURE for May 26, p. 702, there is an interesting letter by Sir Oliver Lodge about a suggestion I had put forward on the nature of the spiral nebulæ. Sir Oliver Lodge suggests that the recombination of electrons ejected photoelectrically might well be more important as a source of light than simple reflection. This does not seem to me probable. In spite of many efforts to improve photoelectric cells, the best type only gives an efficiency of about 2 per cent. Even if the spirals were equally efficient, therefore, only this fraction of the incident energy could be emitted in the form of light on recombination of the electrons. It is probable that any material of which spirals may be composed has a reflection coefficient of at least 20 per cent. and very likely 50 per cent., so that ordinary reflection must be at least ten times and is probably some hundreds of times as effective as the process imagined by Sir Oliver Lodge.

Selection and Segregation.

I THINK by "recent discussions in the columns of NATURE" Prof. Arthur Willey (NATURE, May 5, p. 602) alludes to discussions started by me. I gather that he believes that evolution is founded on mutations the inheritance of which is Mendelian, and, therefore, that natural selection preserves but does not create racial change. Experiment furnishes him with justification, but not with proof. On the same evidence, and a great deal more, divergent opinions have been founded. Crucial tests are required—tests which, from the nature of the case, experiment cannot furnish, but which may be found in abundance among facts that are within common knowledge and are not disputed. So far as I am able to judge, they do not support Mendelian theory, and to them I invite Prof. Willey's attention. If I be mistaken, it should be easy to indicate my errors. If I be right (I am not alluding to Prof. Willey), is it worth while to ignore evidence which is common property and on which attention is more or less riveted, or to hint that I am ignorant of the latest work of the truest biologists—and then to scuttle from my challenge? In spite of Mendelians, the Mendelian facts are so illuminating that they are sure, when linked with the rest of our knowledge, to influence immensely our conceptions of, and control of, life. They can be so linked only by means of crucial instances. May I, therefore, iterate a few of the latter? I have some morals to draw or imply. Can a flaw of fact or reasoning be found in the following?

1. Our powers of observing are proportionate to our familiarity with the objects of study. In all Nature, we are, for purposes of observing fluctuations and natural selection, sufficiently intimate with only one species—our own (see NATURE, January 13, p. 50). Either we must derive our evidence from the lives and deaths of men, or else our thinking is mere guessing. Examining the evidence, we find (*a*) that stringent natural selection is in full swing all the world over; (*b*) that fluctuations, not mutations, are chosen; and (*c*) that the result is always adaptive evolution. If that be the case with men, whom naturalists describe as having "escaped from selection," is it not, to say the least, likely to be the case with other types?

2. Human races never differentiate while there is interbreeding, but invariably diverge when separated by time and space. So far as clear evidence goes, this is true of all natural types. Have we not here proof that offspring blend parental differences, and therefore that natural racial change is based on fluctuations?

3. It has been said very truly, "The fact that the gametes of the cross transmit each member of the pair pure, is as strong an indication as can be desired of the discontinuity between them." The converse must be true also; if the members of the cross blend, we have proof that the unlikeness between them was built up of fluctuations. Now, all human races, and so far as I know all natural races, blend when crossed, except in characters linked with sex.

4. There is massive evidence, not disputed by Mendelians, that male is undeveloped female, and *vice versa*. Here we have alternate patency and latency, alternate *reproduction*, *not* alternate *inheritance*. Male and female characters, belonging to different sets, do not blend; but, presumably, *the patent characters of the one sex blend with the latent characters of the other*. Sometimes, as in aphides, the patency and latency extends unaltered over many generations. But if, as is alleged, the *inheritance* of sex is Mendelian and segregation occurs, how is the prolonged latency of the male traits conceivable? Theoretically males, as well as females, should appear in the first parthenogenetic generation, after which, since the males cannot reproduce, and the females have become pure dominants, males should never again appear.

5. If a mutant crosses with the normal, we have, admittedly, in the impure dominant, exactly such patency and latency as is found in sexual characters. Mendelians insist that afterwards there is segregation, and, therefore, that in following generations pure dominants and recessives occur. How, then, does it happen that "pure" dominants sometimes produce recessives, and recessives dominants? How does it happen that *purely* bred domesticated types (*e.g.* pigeons, poultry, and many plants) often "throw back"—reproduce the ancestral type which according to theory was eliminated perhaps hundreds, perhaps even thousands, of generations previously? Is this not clear evidence that Nature treats mutations like sexual traits, making their reproduction, not their inheritance, alternate?

6. Crossing often reveals long-lost ancestral traits among artificial varieties, but never among men or other natural types. Is this not clear proof that while man often chooses mutations, Nature selects among fluctuations? But man does not always choose mutations. Sometimes, though he cannot easily perceive fluctuations except among his own kind, he selects them. Thus speed in racehorses is due to a high average of excellence in a thousand co-ordinated structures. A thousand mutations occurring at once are out of the question. As might be expected, (*a*) racehorses tend, in lack of stringent selection, to retrogress with a speed which is proportionate to the antecedent progression, and (*b*) the offspring of a cross between race and ordinary horses blend the parental differences, as in hunters and hacks.

7. Apparently, then, the crossing of mutants with the normal results in alternate reproduction. Yet careful artificial breeding produces all the effects of alternate inheritance; for in this way undesired traits may be rendered almost permanently latent, as witness the narrow stripes revealed by the offspring of horses crossed with the broad-striped Burchell zebra, whence it appears that man never domesticated the horse as such, but began with an animal striped like the Somali zebra, the coloration of which he rendered latent by selecting mutations. Human mutations—idiocy, hare-lip, tumours, and so on—are common; but useful human mutations are unknown. Many of them, idiocy, for example, become yearly more common, and medical men, believing that they usually indicate the reappearance of latent ancestral traits, hope by preventing procreation to reduce their frequency. If, however, Mendelian theory be correct, they are new variations, and the position of humanity is hopeless. In that case the human species is "ever-mutating"; and, since human mutations are ever-injurious, there is no scope for selection. And yet the odd thing is that there is always selection, and the result is always improved adaptation.

8. I suppose my word "predisposition" (potentiality, diathesis) corresponds somewhat with the Mendelian word "gene." But I merely follow physiologists and pathologists who, assuming germinal predisposition, seek in each case to discover the nurture that causes development. If I have speculated, it is only to suppose, as others have done, that perhaps all the cells of the body are alike in nature, and differ only through nurture. "Gene," on the other hand, implies a knowledge more profound, or an assumption more daring. Itself a discrete unit, it is the representative of a unit character (one with Mendelian inheritance). Like the "physiological units," "gemmules," and "determinants" of our predecessors, it is a brick in the architecture of the germplasm. It is difficult to understand, however; for the multicellular individual, a cell-community, is compounded of characters; and a character may be a sub-community (*e.g.* rose-comb, extra digit, blacksmith's muscle), or a quality of the whole community (for example, size, shape, colour), or a quality of a character (for example, colour of a flower). As we have just seen, crossed natural varieties blend their characters: have they, then, no unit characters, and, therefore, no genes? I understand that characters, not their modifications, are represented by genes. Thus there is a gene (or genes) for normal but not for diseased skin, for skin-colour but not for sunburn, for normal but not for blacksmith's muscles. Unfortunately I know of no character that is not a modification of its antecedent self. Thus the muscles of the athlete were modified by nurture from those of the ordinary man, which were modified from those of the youth, and so on right back to the germ-cell. Which, then, is the character, and which its modifications? *Obviously* all characters are "fluctuations due to conditions of environment, to nutrition, correlation of organs, and the like. There is no indisputable evidence that they can be worked up and fixed as a specific character." But try to conceive a character which is not a product of some sort of nurture! It appears, then, that genes represent nothing conceivable, and that evolution is impossible. But the attempt to understand genes makes my head

ache. Intellectually unfit to grapple with these subtilties, I must return to the simple, if crude and ignorant, physiological conception that all characters are products of germinal predisposition and somatic nurture; and to the notion that, while there is always blending and sometimes alternate reproduction, there is never alternate inheritance.

Martini's Equations for the Epidemiology of Immunising Diseases.

THE differential equations constructed by Dr. Martini and quoted by Dr. Lotka in NATURE of May 12, p. 633, namely,

$$\frac{du}{dt}=\alpha u(1-i)-qu, \quad . \quad . \quad . \quad (1)$$

$$\frac{di}{dt}=\alpha u(1-i)-mu, \quad . \quad . \quad . \quad (2)$$

aroused my interest by the statement that they cannot be integrated in finite terms. I have noticed that in one particular case the integrals of the equations can be expressed in a moderately simple form, and that in this case Dr. Martini's second position of equilibrium, namely,

$$u=\frac{m(\alpha-q)}{\alpha q}, \quad i=\frac{\alpha-q}{\alpha},$$

is unattainable within a finite time unless it is permanent.

The particular case in question which has come to my notice is that in which $q=m$, that is to say, the fraction of the affected population which ceases to be so per unit time is equal to the fraction of the immune population which loses immunity or dies per unit time. In this case it is evident by subtraction that

$$\frac{du}{dt}-\frac{di}{dt}=-q(u-i),$$

so that $u-i=Aqe^{-qt}$, where A is the constant of integration. On substituting for i in (1) it is evident that

$$\frac{du}{dt}=(\alpha-q+\alpha Aqe^{-qt})u-\alpha u^2,$$

an equation reducible to the linear form (and so soluble by quadratures) by the substitution $v=1/u$.

The solution, which it will be sufficient to quote, is

$$\frac{1}{u}=\sum_{n=0}^{\infty}\frac{(-)^n\alpha^{n+1}A^n e^{-nqt}}{(\alpha-q)(\alpha-2q)\ .\ .\ .\ (\alpha-nq-q)}$$
$$+B\,exp\{(q-\alpha)t+\alpha Ae^{-qt}\},$$

where B is the second constant of integration.

It is easy to see that the second position of equilibrium is given in this case by

$$u=i=\frac{\alpha-q}{\alpha},$$

and if u and i have this value for a finite value of t, it is readily seen successively that $A=0$ and $B=0$, so that u and i have this value for all time. On the other hand, whatever be the values of A and B, the value $(\alpha-q)/\alpha$ is the limit to which both u and i tend as the time tends to infinity, provided that α exceeds q; if α does not exceed q, they tend to zero, unless $B=0$.

I imagine from Dr. Lotka's silence concerning these results that they have not been previously obtained, and, for all I know, the case $q=m$ may be of no practical importance. But the analysis which I have given seems to me to throw some light on what the behaviour of the solution might be expected to be in the general case.

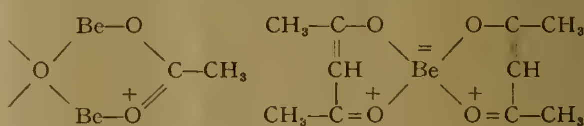
The Structure of Basic Beryllium Acetate.

THE remarkable compound $Be_4O(C_2H_3O_2)_6$, the crystal structure of which Sir William Bragg describes in his letter in NATURE of April 21, p. 532, can be given a chemical formula in complete accordance with its properties. Tanatar and Kurowski have described (Journ. Russ. Phys.-Chem. Ges. 39, 936, 1630; 40, 787; *Chem. Centr.* 1908, I. 102, 1523; II. 1409) a series of compounds (including the formate, acetate, propionate, and benzoate) of the general formula Be_4OA_6. These compounds have none of the characteristics of salts. They are volatile, they have low melting-points (some are liquid), they are soluble in organic solvents such as benzene, and they do not conduct electricity.

They resemble the non-ionised members of the "chelate" series of compounds, to which Prof. Morgan has directed attention. These are derived from substances containing such groupings as HO – C. . . . . C = O, which combine with an atom of a metal by replacement of the hydroxyl hydrogen, and at the same time also (as he has shown) through the carbonyl oxygen. The simplest example is the volatile beryllium acetylacetonate (formula I.). The carbonyl oxygens becoming trivalent must each lose an electron. These two electrons go to the beryllium, which already has two valency electrons, and thus give it the four required to constitute the four non-polar links in the resulting compound. Chelate compounds of this type, in which the group is attached through both oxygens to the same metallic atom, are not formed by the carboxyl group, obviously because this would lead to the formation of a 4-ring, which is unstable. But there is no reason why the carboxyl should not react in this way if the attachment is to two different metallic atoms, with the formation of a ring of 5 or 6 atoms.

This must happen with basic beryllium acetate. We have at the centre, as Sir William Bragg suggests, the oxygen atom attached to 4 beryllium atoms. The octet of the oxygen is made up of 4 electrons from the four beryllium atoms, and four from the oxygen. But the oxygen atom originally had six valency electrons, and so it must lose two. The attachment of the acetate group to two beryllium atoms is shown in formula II. It forms a 6-ring:—



II. I.

But in forming the ring each acetate group must lose an electron from its carbonyl oxygen, so that the six give up six electrons, in addition to the two given up by the central oxygen. We therefore have eight electrons, two of which go to each beryllium atom, increasing its valency electrons from 2 to 4. Thus each beryllium atom can form four non-polar links, these being (1) to the central oxygen, and (2, 3, 4) through three acetate groups to each of the other three beryllium atoms. One of these six chelate groups thus corresponds to each edge of the tetrahedron.

Mr. T. V. Barker has pointed out to me that if the double link in the carboxyl group remains permanently attached to one particular oxygen atom, the most symmetrical configuration of the molecule is one that exhibits a threefold axis of symmetry, and consequently is enantiomorphous; but if the double link oscillates between the two oxygens, then the symmetry is that of a regular tetrahedron.

Tanatar and Kurowski have described (*l.c.*) a compound $Zr_4O_5(OCO{\cdot}C_6H_5)_6$, which is soluble in benzene. Now zirconium can form 6 non-polar links, and in the group Zr:O two of these form the double link to the oxygen, which also absorbs two of the 4 zirconium valency electrons. Thus the group ZrO resembles a beryllium atom in having two free valency electrons, and also the power of forming four non-polar links. The zirconium compound can therefore be formulated as $(ZrO)_4O(OCO{\cdot}C_6H_5)_6$, with a structure exactly analogous to that of the beryllium compound. It would be interesting to know whether this zirconium benzoate has, as one would expect, a crystal structure similar to that of the basic beryllium acetate.

Biology of Man.

IN the review by J. S. H. of Mr. Wells's "Men Like Gods" (NATURE, May 5, p. 591) we are told that even domestic-minded leopards and tigers are not lightly to be dismissed after recent experiments on the *inheritance* of tameness and wildness in rats. Almost in the next paragraph we are further informed that the rôle of eugenics is to be reduced to a minimum, and its functions are to be replaced by education. Wildness in the lower animals is to be removed by selective breeding, wildness and brutality in man is to be cured by education, by environment, and that mysterious process a "change of heart." It is very strange how dominant is the wholly unwarranted belief that man is an animal for whom other laws hold than for his humbler mammalian kindred.

KARL PEARSON.

Galton Laboratory of National Eugenics,
University of London.

IN referring to the reduction of eugenics to a minimum I was quoting Mr. Wells, not putting forward my own views. Later on, in criticising Mr. Wells, I expressly referred to the possibility of the "control of heredity" in man as well as in lower organisms.

In the second part of his letter Prof. Pearson is ambiguous. He refers to "the wholly unwarranted belief that man is an animal for whom other laws hold than for his humbler mammalian kindred." In one sense of the word *other* this is of course wholly unwarranted—if, that is, we take it to mean "wholly different." If, however, we mean that, besides the laws applicable to lower organisms, there are "other" *additional* laws at work in the sphere of human evolution, then I venture to say that we are enunciating a truism. To take the simplest and most important example. No other organism can transmit tradition for more than one generation: man can. Or to take another example cognate to the "change of heart" (which need be no less important for being "mysterious"), you do not find cows or sheep or other of man's mammalian kindred stopping the business of their existence to look at the sunset or at a work of art; whereas man (or rather many men) do so.

One of the chief human characters of man is his greater modifiability (in the strict biological sense). This implies that alteration of environment, especially of social environment, must co-operate with eugenics if any human progress is to be achieved. J. S. H.

Official List of Fourteen Generic Names of Fishes.

THE Secretary of the International Commission on Zoological Nomenclature has the honour to notify zoologists, especially ichthyologists, that Prof. David Starr Jordan and the U.S. Fish Commission concur in recommending the adoption of the general principle that names now current are not to be discarded unless the data show this to be a clear-cut necessity. Under this general principle they propose that the following fourteen generic names of fishes, in regard to which a difference of opinion exists, shall be provisionally legitimised with the types indicated:

Aëtobatus Blainv., 1816 (type, *Raja narinari* Euphrasen); *Conger* Cuv., 1817 (*Muraena conger* L.); *Coregonus* Linn., 1758 (*Salmo lavaretus* L.); *Eleotris* Bloch and Schneider, 1801 (*gyrinus* Cuv. and Val.); *Epinephelus* Bloch, 1792 (*marginalis* Bloch); *Gymnothorax* Bloch, 1795 (*recticularis* Bloch); *Lampetra* Gray, 1851 (*Petromyzon fluviatilis* L.); *Malapterurus* Lacépède, 1803 (*Silurus electricus* L.); *Mustelus* Linck, 1790 (*Squalus mustelus* L. [= *Mustelus laevis*]); *Polynemus* Linn., 1758 (*paradisaeus* L.); *Sciaena* Linn., 1758 (*umbra* L. = *Cheilodipterus aquila* Lacép. as restr. by Cuvier, 1815); *Serranus* Cuv. (*Perca cabrilla* L.); *Stolephorus* Lacép., 1803 (*commersonianus* Lacép.); *Teuthis* Linn., 1766 (*javus* L.).

The Secretary of the Commission will delay the vote on this case until one year from date, in order to give to the profession ample opportunity to express concurrence or dissension as respects any or all of these names.

C. W. STILES,
Secretary to Commission.

Tertiary Brachiopods from Japan.

WITH reference to the notice of Ichirô Hayasaka's memoir on "Tertiary Brachiopods from Japan" in NATURE of May 12, p. 647, may I add my testimony as to the extreme importance of this work, and, at the same time, direct attention to one or two discrepancies? To do full justice to this memoir is beyond the scope of this letter, and one can only deal with the matter in the briefest possible way.

Mr. Hayasaka is to be congratulated upon having provided us with such an excellent list of Japanese Tertiary Brachiopoda, many of which seem to be correctly placed as to genus and species. There are some forms, however, which one is surprised to find included in the list, for example, *Hemithyris psittacea*, *Terebratulina caput-serpentis*, *T. septentrionalis*, *Magellania* (*Neothyris*) *lenticularis*, and *Magadina cumingi*.

With regard to *H. psittacea*, considering its wide circumpolar distribution, it might reasonably be expected to occur as an Upper Tertiary fossil in Japan; but the figures given by Hayasaka do not suggest this species to me. They show a much larger shell, without the characteristic beak.

Terebratulina caput-serpentis (now *retusa*) is North Atlantic in its distribution, and a variety (*v. emarginata*) inhabits the Mediterranean. It ranges from the Miocene in Europe.

Terebratulina septentrionalis is also a North Atlantic species, occurring on both the American and North European shores. The geological history of this species is not well known; but it is cited from the Pliocene. I am dealing with its supposed occurrence at the Cape in a forthcoming paper.

The presence of the essentially Austral forms, *Magellania lenticularis* and *Magadina cumingi*, in the Tertiary rocks of Japan, opens up a very wide question as to the former geographical distribution of these genera. With regard to the first species, I might point out that the figures accompanying the memoir do not suggest the New Zealand form; figure 17 especially being very unlike.

As to *Magadina cumingi*, the figures certainly present a general resemblance to the species occurring off the coasts of S.E. Australia and to certain New Zealand Miocene forms. But identity in outward appearance is not a safe criterion. It is found by experience that it is necessary to investigate the interiors before a species can be definitely referred to its proper genus. Forms having the same shape externally may possess quite different loop-stages. This feature is nowhere better displayed than in the forms possessing Bouchardiform beak characters, like the species in question.

In conclusion I should like to point out that Dall's generic name for *T. grayi* Reeve, namely, *Pereudesia*, 1920, is antedated by my *Coptothyris*, 1918 (replacing my *Thomsonia*, 1916, preoccupied). This fact has been pointed out in other papers. By the recognition of this form as a distinct genus there are now three finished types of northern genera in the Dallininæ.

The Ionising Potentials of Nitrogen and Hydrogen.

In a paper published last autumn (Proc. Roy. Soc. A, 102, pp. 283-293, 1922) I suggested a new mode of attack on some ionisation problems and described its application in experiments on mercury vapour. The object of the method is to give a direct means of studying the types of ion produced in a gas or vapour by the impact of electrons of known speed. The experimental principle involved is the combination of an ordinary ionising potential arrangement with a simple positive-ray analysis apparatus. The extension of the method to gases and some of the results obtained may be of interest.

For the production of ions the common arrangement of a tungsten filament, a grid and a plate is used. Electrons from the filament are accelerated to the grid by a field V_1 and then retarded by an opposing field V_2 which also serves to draw positive ions toward the plate. A narrow slit in this lets through a beam of positive ions which are then further accelerated by a large electric field, V_3. These ions are then bent in a semicircle by a magnetic field and detected electrically. Different values of V_3 bring ions of different m/e on to the detecting slit. By using two Langmuir pumps a sufficiently high vacuum is maintained in the positive ray box to prevent scattering, and very sharp peaks are obtained corresponding to different types of ion.

In nitrogen it was found that for values of V_1 slightly above the ionising potential of 16·9 volts, only molecular ions of $m/e=28$ were present. As V_1 was increased small numbers of N^{++} ions began to appear at 24·1 ± 1·0 volts, while N^+ ions were not present in appreciable numbers until V_1 passed 27·7 ± 1·0. These three critical potentials are interpreted as corresponding to the transitions $N_2 \rightarrow N_2^+ + e^-$, $N_2 \rightarrow N^{++} + N + 2e^-$ and $N_2 \rightarrow 2N^+ + 2e^-$. If this interpretation is correct, the first ionising potential of atomic nitrogen is about 11 volts and the second about 18 volts, assuming the heat of dissociation of nitrogen to be of the order of 140,000 calories, equivalent to six volts.

At a value of V_1 corresponding to the K-limit for nitrogen (375 volts) the proportion of atomic ions increased very sharply.

Preliminary results on hydrogen indicate that the ionisation of molecular hydrogen in the neighbourhood of 16·5 volts is not usually accompanied by dissociation as has been generally supposed. Whether there may be a small number of atomic ions produced at this point is not yet certain. Experiments are being continued.

Chromosome Numbers in Aegilops.

I have recently been investigating the cytology of species of Aegilops, and find the chromosome numbers as follows:—

	Haploid Number.
Aegilops cylindrica	= 7
A. ovata	= 14
A. ventricosa	= 14

On morphological and other grounds I expressed the view in my monograph on "The Wheat Plant" that one or both of the former species appear to be involved in the ancestry of the *vulgare* group of wheats. Later I hope to discuss the significance of these chromosome numbers in relation to this hypothesis.

Effect of Insulin upon Blood Sugar Concentration.

The injection of insulin into rabbits causes the blood sugar concentration to be lowered, as determined by micro methods. When a certain concentration is reached, 0·05 per cent. by Bang's method, the animal goes into convulsions. If the animal is then killed and the sugar extracted from a large quantity of blood, it is found that it is without copper-reducing value as determined by the Wood-Ost method. This method is not liable to estimate substances in blood other than reducing sugars.

There is, however, a considerable quantity of carbohydrate present, as indicated by the α-naphthol test. The substance is dextro-rotatory. We have not succeeded by acid hydrolysis in obtaining copper-reducing substances from it, though these can apparently be formed under certain conditions as a result of enzyme action *in vitro*.

Dudley and Marrian (Proc. Physiol. Soc., May 19, 1923) have shown that the glycogen content of the liver and muscles of animals is greatly diminished after insulin. We have obtained from the liver and muscles of rabbits after insulin a substance similar to that present in blood under this condition. Owing to its resistance to acid hydrolysis it would not be estimated by ordinary methods. The chemical nature of this sugar is being studied.

We noticed in the case of some solid preparations that the α-naphthol reaction gradually disappeared on drying. Mr. H. F. Holden suggested that this might be due to polymerisation, and that on hydrolysis with acid the α-naphthol reaction would reappear. We find that this happens. It seems possible that the carbohydrate content of the animal body may be not appreciably diminished after large doses of insulin. The above facts would suggest that the sugar stored in the body as glycogen is converted into this peculiar form. Can this be the "Zwischen-kohlenhydrate" which Laquer suggests is formed as an essential step in carbohydrate metabolism?

The Value of the Planck Constant h.

IN NATURE for March 3, p. 287, I directed attention to the desirability of obtaining new data on the value of e/m, from deflexion experiments or from the Zeeman effect.

Dr. Harold D. Babcock, of the Mt. Wilson Observatory, has just finished a series of measurements on the value of e/m, from the Zeeman effect, and obtains as the weighted mean of 49 separate determinations, a value of $1{\cdot}761 \times 10^7$, as compared with my recomputed value of $1{\cdot}758 + 0{\cdot}009$ from spectroscopic data. A thorough study of possible errors leads Dr. Babcock to the conclusion that the error in the above value can scarcely exceed $\pm 0{\cdot}002$. On this basis Dr. Babcock's new value of e/m is the most accurate now known.

Particular interest attaches to the value of the Planck constant h, using this new value of e/m. Of the seven methods listed by the author in his determination of the most probable value of h (*Phys. Rev.*, 14, 361, 1919), the only method involving the value of e/m is that from Bohr's theory of the Rydberg constant N_∞. Using for the sake of technical accuracy the value of $N_\infty (= 109{,}737)$ and the assumed value of $e/m = 1{\cdot}761 \pm 0{\cdot}002$, we obtain $h = 6{\cdot}556 \pm 0{\cdot}011$ instead of $6{\cdot}542 \pm 0{\cdot}011$, using $1{\cdot}773 \pm 0{\cdot}002$ for the value of e/m. This latter value of e/m and its error were obtained from the results given in Kaye and Laby's Tables. It is now evident that the close agreement in the mean value of e/m, from Zeeman effect and from deflexion experiments, given in those tables, is merely an accident, and that the author's previous assumption of error in e/m was unjustifiably small.

The new value of h is not only in very close agreement with my previous most probable value (6·5543), but coincides exactly with Duane's latest value, from the continuous X-ray spectrum. Using these two new values of h (methods 3 and 4 of the article cited), we obtain as a corrected most probable value $h = 6{\cdot}557 \times 10^{-27}$ erg. sec. I believe that the error in this quantity can be scarcely more than a few units in the last place, unless Millikan's value of e is unexpectedly in error.

RAYMOND T. BIRGE.
University of California,
May 18.

A Method of Broadcasting Pictures.

I HAD occasion to suggest to the British Broadcasting Co. a few weeks ago that an attempt should be made to "broadcast" a picture, and proposed a simple method of doing so. The company thereupon invited me to try the experiment on Empire Day (May 24). A photograph of H.M. King George V. was chosen as a suitable subject, and it was broadcast at 5.45 P.M. in 20 minutes, and instructions were given for reproducing the picture, either in typescript or in graduated dots on squared paper.

Most of the pictures show an unmistakable likeness. The best versions were sent in by Gladys Haylock, Queen's Park, London, and Reginald Matthews, King's Lynn. The former, who is 11 years old, states that the reproduction was made in three-quarters of an hour. The B.B.C. has decided, as a reward, to broadcast the portraits of these children in turn.

The method is, briefly, the following: The picture is divided into a number of small squares, and the average brightness of each square is indicated by one of six letters. The estimation is made by any photometric method, but a little practice soon teaches one to estimate it by mere inspection. The six letters are chosen so that the spaces taken up by them in typewriting have different average shadings forming a scale of darkness which corresponds to the average shading of the squares represented by the letters. Another consideration in this choice is the ease of telephonic transmission. The letters X, I, J, G, M differ sufficiently in pronunciation to be unmistakable, and the last four have increasing darknesses when typed; X represents a note of exclamation. The lightest space is indicated by a full stop, dictated as "stop." A blank is indicated by the vowel sound O.

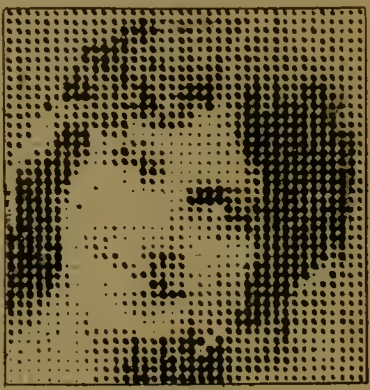

FIG. 1.

Fig. 1 shows a picture consisting of 1520 dots. It is a reproduction of a half-tone picture only 8 mm. wide which I "coded" with the aid of a special microscope kindly lent to me by Prof. R. R. Gates. The number of dots used is somewhat large.

For the Empire Day experiment it was necessary to have a smaller number of dots, so as not to exhaust the patience of the recipients. The result of limiting a picture to 600 dots is seen in Fig. 2.

Each line contains 20 dots. The letters representing these are dictated in fives, thus:

(1) . . . . g j j j j j g . . . .
(2) . . . . g m g j x g j j g g . . .

and so on.

The quickest method of reproduction is to use a special typewriter having six letter keys, each connected with a lever printing a dot of the corresponding size. A simple photographic method with two discontinuous movements might also be used, in which case we might obtain a negative for subsequent multiplication.

Coloured reproductions have also been suggested, but no doubt the chief advantage of the method will be found in its extreme simplicity.

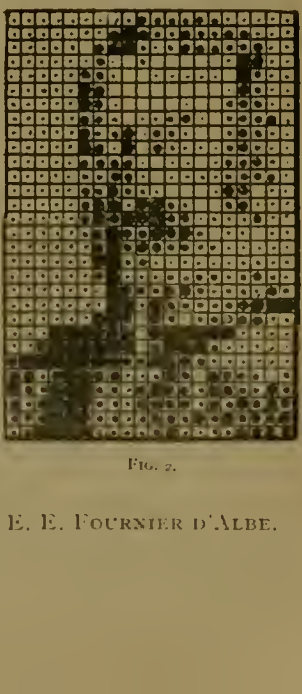

FIG. 2.

E. E. FOURNIER D'ALBE.
21 Gower Street, W.C.

Hay Fever.

HAY fever is a catarrhal affection mainly of the upper respiratory passages, which occurs only in certain individuals and is due to the poisonous action of the pollen of certain plants which they have inhaled. Our knowledge of the disease may be divided into three periods, viz. clinical, experimental, and therapeutic. The clinical period was inaugurated by John Bostock, the physiologist, in 1819. He gave an admirable account of the symptoms as they occurred in himself every summer over a period of thirty-eight years. Other accounts, complete and incomplete, gradually accumulated, and these were analysed with great discrimination and acumen by Phoebus of Giessen, who published his work "Der typische Früh-sommer-Katarrh" in 1862. Nothing has been added to the pure clinical history of the disease since this time. The second period is typified by the masterly scientific research of Dr. Charles H. Blackley, of Manchester, who was also a sufferer from the disease. In his work "Experimental Researches on the Causes and Nature of Catarrhus aetivus," 1873, he established, by ingenious methods, the fact that hay fever is caused by the inhalation of pollen. To this period belong also the works of W. P. Dunbar, of Hamburg. He also was a hay-fever sufferer. Going beyond Blackley, he proved that it is only the protein of the pollen that is the toxic agent. The third period, in which fall attempts to prevent or cure the disease by specific means, is associated particularly with the names of Noon and Freeman in England and Dunbar in Germany.

It was in 1819 that the disease was made known by Bostock, who described the symptoms from which he suffered every June and July almost all his life. These symptoms were, a sensation of heat in the eyes with itching and smarting. After about a week, violent sneezing occurred, with a feeling of tightness in the chest, difficulty of breathing, languor, and loss of appetite. Towards the end of July, all this discomfort spontaneously disappeared. It is remarkable that medical history contains only one or two trivial and doubtful references to such a condition before the appearance of Bostock's paper in 1819. In 1828 he made a second communication and included statements of twenty-eight cases like his own. All developed the disease at the same time of the year—the summer, and nothing special could be ascertained as to its cause from the age, sex, constitution, or mode of life of the sufferers, who were mostly males.

In this second paper Bostock referred, however, to the idea, apparently prevalent even at that time, that the morbid state was engendered by effluvia from new-mown hay, but he was not of this opinion from observations on himself, both at Ramsgate, where there was no hay, and at Kew, where there was much. He considered that the main factors which led to an outbreak were dazzling sunlight and excessive summer heat. Even in 1828, however, MacCulloch refers to the "term hay-fever lately become fashionable"; and William Gordon, writing in 1829 on the "nature, cause, and treatment of hay asthma," said that there could be no doubt that it was due to the aroma emitted from the flowers of grass, particularly from those of *Anthoxanthum odoratum* or sweet-scented vernal grass. He based this view on the grounds that (1) the plant is one of the most strong scented of the grasses; (2) because as soon as it begins to flower, and *not until then*, the asthma begins; (3) because as the flowers arrive at perfection the disease increases; and lastly, because after the flowers have died away previous sufferers can pass through the most luxurious meadows with impunity.

After the accounts of Bostock and Gordon, cases began to be published, and all the authors were of opinion that the disease occurred in certain persons who were presumed to have a predisposition to it, and it was early recognised, especially by Elliotson (1833), that inheritance plays a part in the idiosyncrasy, a belief that all later observation has confirmed. Of 59 histories analysed by Phoebus, 23 occurred alone in their respective families, whereas 36 were associated with one or more other families. The whole of the latter occurred in 13 families, being distributed as follows: in 8 families 2 affected (brothers and (or) sisters); in 5 cases father and child. In 2 families 3 members were affected; in 1 family 4 members, and 2 families 5 members. In one of the latter, a man, his daughter, and three sons suffered, while a fourth son was made asthmatic by the smell of guinea-pigs. The disease was known to be commonest among the better classes, and many of those who have written on the subject were themselves attacked. Among these may be mentioned Bostock, Blackley, Gream, Kirkman, Fleury, Helmholtz (the physicist), Dunbar (the bacteriologist), and Verworn (the physiologist). Among 150 cases collected by Phoebus 100 were male and 50 female.

Although it was early suggested that the origin of the symptoms was referable to vernal grass in flower, there were authors whose experience did not permit of such an exact diagnosis. Some thought that grasses were all equally detrimental, others that only aromatic grasses were the agents, and particularly *Anthoxanthum odoratum*. Others again blamed rye-grass, hay as such, roses, trees in bloom, dust, sunlight, heat, and even bacteria. The last was the view of Helmholtz. Even where grasses were incriminated it was believed that the actual cause was some aromatic effluvium wafted from the plant. Some believed that the chief agent was coumarin. Kirkman (1852) seems to have been the first who tested upon himself the effect of pollen. At Christmas he noticed in his hot-house a single plant of *Anthoxanthum odoratum* in blossom and laden with pollen. He plucked it, rubbed the pollen with his hand and sniffed it up. Almost immediately sneezing and all the symptoms of an attack of hay fever followed.

It was, however, Charles Blackley who, in a series of experiments well conceived and admirably carried out over a long series of years, definitely established the pollen etiology of the disease. Having obtained negative results with benzoic acid, coumarin, odoriferous substances, ozone, dust, light, and heat, he applied himself to the subject of pollen, not of grasses only but from plants belonging to no less than thirty-five other natural orders. The experiments were made at all times of the year, the pollen being applied to himself or other patients by way of the nostrils, tongue or conjunctiva, or by inhalation or actual inoculation in the skin—the most approved modern method of diagnosis. Pollen from a number of grasses produced typical hay fever. Blackley particularly blamed the pollen of italian rye-grass (*Lolium italicum*), meadow fox-tail grass (*Alopecurus pratensis*), rye (*Secale cereale*), wheat (Triticum), oats (*Avena sativa*), and the common hazel-nut (*Corylus avellana*). He also studied the size and shape of different pollen grains, and concluded that the disturbance in predisposed persons was due partly to the mechanical and partly to the physiological action. In experiments on himself, dazzling light and heat were ineffective.

To study the distribution of pollen in the atmosphere Blackley then undertook a long series of experiments with ingenious apparatus which he devised, and he traced by microscopic methods of enumeration the pollen grains in the air in a variety of weather conditions. From May to the end of July he traced from day to day the pollen incidence in the air, and showed how it was subject to great fluctuations depending on temperature and moisture. About 95 per cent. of the pollen found was identified as belonging to the Graminaceae. In dwelling-rooms little or no pollen was found. By means of moistened glass slips attached to the tails of kites flown as high as 1500 feet, Blackley made numerous observations both on the sea-shore and inland, and demonstrated the remarkable fact that in the upper strata of the air there was nineteen times as much pollen as was found near the surface of the earth, and he showed how pollen can be carried to great distances by wind currents in the upper reaches of the air.

Blackley was so far ahead of his time, that despite the excellence of his work the causation of hay fever was still regarded as a *terra incognita*. A common idea prevailed that it was a nervous disease in certain persons with a labile or hysterical nervous organisation. The reinvestigation, on the scientific lines laid down by Blackley, led, in the hands of Dunbar (1903), to a complete confirmation of his results; but Dunbar went further by proving that the deleterious agent in pollen is only its protein. Collecting pollen in large quantities, he showed that extracts are highly toxic in hay-fever subjects.

One of Dunbar's collaborators—Liefmann (1904)—found that, at the time of the worst hay-fever attacks in the centre of the city of Hamburg, no less than 250 grass pollen grains settled in 24 hours on a surface measuring 1 square centimetre (*i.e.* about 2,500,000 per square metre). Year by year it was noted that on the first appearance of pollen in the air patients began to suffer from hay fever. In the beginning of June grass pollen is in excess of all others, and from the third week of July begins to disappear. Kammann estimated that 40 per cent. of the pollen mass was protein, and a solution of a strength of 1 : 30,000—1 : 1,000,000 dropped into the eye could determine an immediate attack of hay fever. Dunbar tested the activity of a large number of pollens other than those from grasses, but mostly with negative results. Besides the pollens of grasses and sedges the following pollens were, however, found to be active: honeysuckle (*Lonicera caprifolium*), lily of the valley (*Convallaria majalis*), Solomon's seal (*Polygonatum multiflorum*), evening primrose (*Œnothera biennis*), rape (*Brassica napus*), spinach (*Spinacea oleracea*), as well as a number of Compositæ and privet (*Ligustrum vulgare*). These experiments were all made in Europe. In the United States of America there is a common form of "hay fever" caused not by grass pollen but by pollen of golden rod (Solidago), and particularly ragweed (*Ambrosia elatior*). From its occurrence in September this variety is widely known as "autumnal" or "fall" fever. According to the records of the American Hay Fever Prevention Association, something like 1 per cent. of the whole population (about 1,000,000 cases) are liable to June or autumn fever.

Hay-fever research is being very actively carried out in the States, and already a very large number of pollens are known to be toxic. Several general principles are emerging from this work; for example, the negligible importance of insect-borne pollens as contrasted with the importance of those that are air-borne, and the great variations which occur from the diversity of the local flora. Important hay-fever and botanical surveys are now being compiled from many of the American States. The diagnosis of the capacity of pollen to produce hay fever is made by cutaneous inoculation, by a scratch on the forearm, of a dilution of the pollen protein, which may be extracted in several different ways. A wheal, 5 or more mm. in diameter, surrounded by a red halo and appearing within half an hour, is regarded as a positive reaction.

It is now known that far more plants can produce hay fever than was formerly supposed. Indeed the term "hay fever" is quite inappropriate. "Toxic pollen idiopathy" has been suggested in its place. Later studies have also directed attention to what are called "group reactions." Thus patients with June fever react to grass pollens, while those with autumnal fever react mainly to the pollen of compositæ, such as golden rod, golden glow, sunflower, and ragweed. The group reaction indicates that the pollens of allied families of plants have a common protein chemical constitution. Although many different pollens can produce symptoms, it does not follow that all such pollens are of practical importance in the disease. The principle that only anemophilous pollen is the natural toxic agent is very important, and thus the entomophilous pollens of golden rod, golden glow, sunflower, and daisy, although they can produce hay fever, do not do so in practice except in unusual circumstances. That such circumstances do occasionally operate is made clear by the recent researches of Pott at Bloemfontein. In this city he has clearly shown that a severe form of pollinosis occurs from October to January, and it is caused by the pollen of the pepper tree (*Schinus molle*). Normally this pollen is sticky and is insect-borne, but in the hot, dry weather prevailing in Bloemfontein it becomes dried and is dispersed by wind. In fact, it was the principal and occasionally almost the sole pollen deposited on glass plates exposed to the air, and it was also demonstrated in the nasal mucous secretions of susceptible subjects. Of great importance also is the determination of the actual dates of flowering of hay-fever plants in each particular district. More than 200 plants are known to be capable of setting up symptoms of "hay fever."

With regard to the nature of the predisposition which renders certain persons susceptible to pollen, nothing is known with certainty. It has been suggested that the affected persons may possess a specific proteolytic ferment which, acting on pollen protein, liberates a poison which is the active agent. The predisposition has been regarded as allied to anaphylaxis—the state of hyper sensitivity, which can be induced especially in guinea-pigs by a sub-lethal dose of a protein of some kind.

Hay-fever predisposition, however, differs fundamentally from true anaphylaxis. The anaphylactic state can be transmitted passively to a normal animal by means of the serum of an animal rendered actively anaphylactic. This is not so with hay fever. Dunbar injected the blood serum of hay-fever persons into guinea-pigs, and twenty-four hours later injected the animals intravenously with rye-pollen protein. No positive results were obtained. Further, normal persons never develop hay fever after the subcutaneous injection of pollen protein. Dunbar injected a normal person with quantities of pollen protein far in excess of what he could have received normally, but this individual was able to take long walks through meadows in full flower, with impunity. A normal person has not the capacity of reacting to pollen protein, nor can he be made to develop this power experimentally. It may be said, therefore, that whatever is the nature of pollen idiosyncrasy, it is not to be ranged alongside the true anaphylactic state. It is allied to those idiosyncrasies which occur in certain persons who develop asthma or catarrhal symptoms from exposure to the secretions or excretions of horses, dogs, cats, goats, rabbits, guinea-pigs, or to such substances as silk, or food-stuffs like white of egg, or certain drugs.

From the great mass of persons who have the pollen idiosyncrasy, and the "annual torment," as Blackley called it, which they undergo, it is not surprising that many different treatments have been recommended. If the hay-fever patient could keep away from pollen, naturally he would not suffer from the disease. Thousands of persons find relief annually at the seaside or on islands or barren districts. The German Hay Fever Association used to recommend Heligoland. In the United States, Fire Island on the Atlantic side of Long Island has long enjoyed a reputation as a suitable refuge for hay-fever sufferers. Blackley in England spoke highly of Lundy Island and some of the islands in the Hebrides. For the great majority of patients such luxuries are manifestly impossible.

From the vast number of methods of treatment praised at one time or another, only two are worthy of consideration. Dunbar recommended the serum called Pollantin, prepared by inoculating horses with repeated doses of pollen protein. This is used either in the liquid or dry state for local application to the nose before the onset of symptoms. The main objection to this treatment, which may be most successful in certain cases, is the temporary character of the relief afforded. The other method, erroneously called desensitisation, is the active immunisation of the patient himself by pollen protein introduced by Noon and Freeman. For its success accurate diagnosis of the specific pollen idiosyncrasy is necessary in the first place, the production of strong protein solutions in the second place, and pre-seasonal inoculation in the third place. As the immunity is not durable the treatment must be annual. By this method Freeman (1914) recorded 30 per cent. of complete successes and no improvement in 11 per cent. Between 1916 and 1920 Cooke and Vander Veer injected 1774 patients with complete success in 25 per cent. and no success in 10 per cent. The recent results of Bernton (1923) are of the same order. It is probable that the state of insusceptibility lasts only for a few weeks, when the patient again manifests his idiosyncrasy unaltered.

W. B.

The Tercentenary of Blaise Pascal.

By Prof. H. Wildon Carr.

No one can read the story of Pascal's life without amazement at the greatness of his genius and sadness at the mode in which it found expression. To Voltaire in the eighteenth century he is a "fou sublime, né un siècle trop tôt." To Chateaubriand in the early nineteenth century he is "cet effrayant génie, qui, à cet âge où les autres hommes commencent à peine de naître, ayant achevé de parcourir le cercle des sciences humaines, s'aperçut de leur néant et tourna ses pensées vers la religion." He lived at the beginning of the brilliant leadership of France in the intellectual development of Europe. In his short life he did notable work in mathematics and physics, and above all (to continue the quotation from Chateaubriand), "toujours infirme et souffrant, fixa la langue que parlèrent Bossuet et Racine, donna le modèle de la plus parfaite plaisanterie, comme du raisonnement le plus fort."

To appreciate the greatness of Pascal and to discern the leading motive in his wonderful activity, it is necessary to enter sympathetically into the spirit of the age in which he lived, and particularly to understand the nature of the religious influence which peculiarly affected him from infancy to maturity.

The outward circumstances of his life may be recorded quite briefly. He was born at Clermont in the Auvergne on June 19, 1623. His father, Étienne Pascal, was King's Councillor and Magistrate, president of the *Cour des Aides*. Blaise had two sisters, Gilberte, three years older, and Jacqueline, two years younger than himself. Their mother died when Blaise was three years old. In 1631 the father retired and settled with his family in Paris for the sake of their education. In 1638 he had managed unfortunately to incur the displeasure of Cardinal Richelieu, and, having good reason to fear a *lettre de cachet*, had to go into hiding. He returned home, however, risking arrest, when he heard that his dearly loved daughter Jacqueline was suffering from small-pox, and he remained constantly with her until her recovery. The following year there was brought about a reconciliation with the Cardinal, and shortly after he received the appointment "Intendant pour les tailles de la généralité" at Rouen, to which city the family then went to live. In 1648 the

"Intendants" were suppressed by Mazarin, and the Pascals returned to Paris. The following year they went back to their native Clermont, where Gilberte, who had married her cousin, Florin Périer, was already settled. In 1651 the father died. Blaise, devoted to his sister Jacqueline, had hoped that after the father's death she would continue to make her home with him, but she had already formed her resolution to enter the religious life, and would not be dissuaded from taking immediately the austere vow at the convent of Port Royal.

The four following years are described by Blaise as his "mondaine" period. He sought distraction in travel and society, but in 1655, after a mental crisis which is described as his second conversion, he decided to retire and devote himself entirely to religion. From 1658 till his death in 1662, although not bedridden or incapacitated from attending to his ordinary wants, he was so weak and in such continual pain that he could do no consecutive work. Jacqueline died in 1661. Blaise in his last illness was nursed by Gilberte. He died in her house. When the end was approaching the doctors attending him were assuring him that there was no danger, and refused to call in the priest. Pascal was in anguish lest he should die without the sacrament, but Gilberte acted on her own initiative just in time. She lived to be sixty-seven, and had five children. She wrote the life of her brother, and also a life of her sister Jacqueline.

Blaise Pascal was educated by his father, and had no other tutor. He never entered the university. All his acquaintance with the intellectual movements of his age, with its science, its philosophy, its religion, was derived directly from his father and conversation with his father's friends. On the other hand, at his father's house he met the most distinguished mathematicians and theologians of the time. Étienne Pascal did not merely supervise his son's education; he undertook it alone and unaided in order to follow out a predetermined method, which reminds us, alike in its conception and in its consequences, of the analogous case of the father of John Stuart Mill. One part of the scheme was to concentrate the boy's mind during his earliest years on perfecting his knowledge of his own language. His lessons were limited to the grammar and syntax of his native French, and the teaching even of Latin was deferred until this was acquired, in the expectation that the new task would then be comparatively easy. The other part of the scheme was to defer mathematics, indeed to forbid the study of it, until the acquirement of languages was perfect. The reason of this is curious. The father was not only himself learned in the mathematical sciences, but also had given his daughter Gilberte thorough instruction in them, yet he feared for his son that they would prove of such absorbing interest that he would be distracted from the study of languages. When the lad was twelve, however, the father discovered that he had acquired, apparently surreptitiously, an acquaintance with geometry which amounted to precocity. He was found one day demonstrating for himself with *barres et ronds* the thirty-second proposition of Euclid's first book. We are told that after this he was allowed to read Euclid, but only in his recreation hours.

Not less powerful than the parental influence was that of his sisters. For their education also the father had original ideas. He did not himself undertake it, but they were educated by a man as men. Their tutor was a Monsieur de Mondory, in favour with the Cardinal and the Court. Jacqueline was an extraordinarily precocious child. She was a very pretty girl before the small-pox destroyed her beauty. She wrote verses from the time of her early childhood, and when fourteen composed a comedy in five acts. She was deeply religious. One of her poems is a hymn of gratitude to God for her recovery, and she describes the scars left by the disease as the impressions of God's seal. She no doubt regarded this illness as a sign of her call to the religious life. Soon after her entry to Port Royal she was appointed sub-prioress, and she consulted her superior as to whether she should cultivate her talent for poetry. The reply of Mère Agnes, Arnauld's sister, is pathetic. "C'est un talent dont Dieu ne vous demandera point compte: il faut l'ensevelir." She signed the formulary imposed on Port Royal condemning the Jansenist doctrine under extreme pressure, though she struggled against it and wished to resist. "Je sais bien," she wrote to Dr. Arnauld, "que ce n'est pas à des filles à défendre la vérité, quoique l'on peut dire par une triste rencontre, que, puisque les évêques ont des courages de filles, les filles doivent avoir des courages d'évêques." Arnauld insisted, however, and the grief hastened her death.

To understand the religious fervour of the Pascal family we must also enter sympathetically into the spirit of the age. The seventeenth century shows in all its philosophy, and even we may say in its science, the influence of a deep personal interest in the problem of the relation of the individual mind to God. The reforming zeal of the sixteenth century had spent its force and been succeeded by the universal conviction of the reflecting believer that Christianity is much more than an institution based upon a verifiable historical revelation, that it is, in fact, a revelation in the philosophical meaning, an interpretation of human and divine nature. We only understand Pascal when we see that his religion is not ordinary piety or superstition, but profound philosophy.

Let us now look at the man himself. He is a younger contemporary of Galileo and Descartes. He survived both, but died before Malebranche or Spinoza had begun to write. This is peculiarly significant in appreciating his attitude towards the Cartesian philosophy, for Malebranche developed that doctrine along Augustinian lines, which may have been actually suggested by Pascal's writings. The illustration of *le ciron* to explain the relativity of magnitudes, expounded by Malebranche in the "Recherche de la Vérité," seems taken directly from a well-known passage in Pascal's "Pensées."

Pascal agreed with Descartes in his doctrine of the soul, or thinking substance, with its corollary that the animals are automata, but he was revolted by the "Principia" and its claim to be able to explain the world by "figure and movement." "Quand cela serait vrai," he says, "nous n'estimons pas que toute la philosophie vaille une heure de peine." Notwithstanding his keen enjoyment of mathematical problems and his intense interest in physical experiments, the whole value of philosophy for him lay in the light it shed on moral problems, and on the power it gave man to interpret the Christian revelation. His point of view, while it accepts the principles of Descartes's philosophy, applies them in a way which makes his doctrine its very antithesis.

Descartes was shown the Treatise on Conic Sections which Pascal composed when sixteen, and refused to believe in its originality. He thought it the work of Desargues, from whom indeed Pascal had learnt much, but Desargues himself acknowledged the originality of Pascal's treatise in its essential points. In 1647 Descartes paid two visits to Pascal, who had come to Paris with his sister Jacqueline for medical advice. Jacqueline has given an account of their meeting in a letter to her sister Gilberte Périer. They discussed the question of the void. Torricelli, the pupil of Galileo, had demonstrated the phenomenon of atmospheric pressure by the famous invention of the barometer, inverting a column of mercury in a glass tube closed at one end, with the other end immersed in an open mercury bath, and then measuring the height of the column.

This was of course the crucial experiment, but there still remained considerable doubt as to its interpretation. To many, including Torricelli himself, it was merely a case in point of the old principle that nature abhors a vacuum. Descartes had rejected this principle on *a priori* grounds. Pascal explained to Descartes his theory of an ocean of air, at the bottom of which we were situated, and assumed that like all fluids it would maintain an equilibrium, and reasoned that above every point of the earth's surface was a column pressing down on us, the weight of which would vary with the altitude. He had already made experiments to prove this on a tower in Rouen, and he now proposed to carry out an experiment on a large scale on the Puy de Dôme in Auvergne. Descartes discussed it with great interest and confidently foretold its success. The experiment was carried out by the aid of Pascal's brother-in-law, M. Périer, with the result that the time-honoured, firmly established principle of the abhorrence of a vacuum passed into limbo.

Pascal's life divides naturally into three periods. To the first belong the mathematical works and the physical experiments, to the second the literary achievement of the "Lettres Provinciales," and to the third the philosophical and mystical "Pensées." In all of them his great genius is manifest, and he might easily have been one of those master minds which determine the direction of human thought. In science and philosophy he showed an intellectual power and incentive which places him on a level with Descartes and Galileo, yet he stands alone, grand but solitary, in the great intellectual movement of humanity. It was more than a religious act, it was typical of his whole intellectual position, when he joined the solitaires of Port Royal. We may count his unworldliness as loss or as gain, but he sacrificed for it alike scientific and philosophic leadership. The tragedy is that the Christian Church did not value what he gave to her when he renounced the world.

The works by which Pascal has immortalised himself are "Les Lettres Provinciales" and "Les Pensées." His mathematical works, like his arithmetical machine which took three years to perfect and is preserved at the Conservatoire des Arts et Métiers in Paris, are valuable for the evidence they afford of the nature of his genius rather than for their originality of discovery, but the two great literary works have been read in innumerable successive editions. Yet strangely enough both are valued and cherished for what to Pascal himself was purely adventitious and no part of the original design. The "Provinciales" are classical on account of their attack on the Jesuits and for the exposure of Jesuit casuistry. The world has little interest to-day in the Jansenist doctrine, which it was the main purpose of the letters to expound and to defend. Were it not for Pascal, the very names of Jansenius and Molina would scarcely be known outside narrow theological circles. The doctrine of sufficient grace has little more than antiquarian interest for students, but for Pascal it was the rationalising of Christian doctrine, the philosophy of a religion of redemption as distinct from the institution of sacraments and formularies founded on it.

The "Lettres Provinciales" had an immediate success, but it is unlikely that they would have accomplished their design, or have afforded even a temporary cessation of the Jesuit hostility against the theologians of Port Royal, but for an event of an altogether different nature, and one which had a powerful influence on Pascal himself. This is what is known as the miracle of the sacred thorn. Pascal's niece, Marguérite Périer, was a pensionnaire at Port Royal, and the little girl suffered from an abscess of the lachrymal gland, which discharged into the eye and into the nose, causing her inconvenience and suffering. Medical treatment had proved wholly ineffective, but after having touched the spot one day with the relic of the sacred thorn, exposed for adoration on the altar, she was completely cured. The doctors certified that "la guérison surpassait les forces ordinaires de la nature," and the miracle was solemnly attested by the vicars-general of the Archbishopric of Paris.

"Les Pensées" was not designed by Pascal for publication in any form whatever. When he died a disordered mass of papers containing his written notes was found. They were unconnected, casual, jottings on odd bits of paper, many being incompleted sentences. It was known that Pascal had had in mind to write an "Apology" of Christianity, a defence against atheistical arguments. The editors took this as the clue to the arrangement of the fragments, and Arnauld, Nicole, and other leaders of Port Royal, after the "peace of the church," which restored them to their monastery in 1669, published the first edition of the "Pensées." Few books have had such a success. Edition has followed edition through the succeeding centuries. The original fragmentary notes still exist, and scholars may now study them in the "Reproduction en phototypie du manuscrit des Pensées de Blaise Pascal," published by Monsieur Léon Brunschvicg.

Such was the marvellous genius, the tercentenary of whose birth is being celebrated this year in his native city, Clermont, and at the scene of his activities, Port Royal des Champs, near Paris.

Obituary.

Prof. John Cox.

The death of Prof. John Cox at Hayes Court, Hayes, on May 13, removes an interesting personality from our midst. Prof. Cox devoted an active life to the cause of education and had a varied educational career, holding, at different times, the post of University extension lecturer, headship of a Cambridge college, and a professorship in physics in a Canadian University.

Born in 1851, Cox was a brilliant scholar of the City of London School under Dr. Abbott, where he was a contemporary and competitor for scholastic honours with his friend H. H. Asquith. He went as a scholar to Trinity College, Cambridge, and studied mathematics, being eighth wrangler in 1874. Equally versed in classics, he took a good place in the Classical Tripos of the same year. He gained a fellowship at Trinity College on a dissertation in which he applied Hamilton's methods to some problems in geometrical optics. He was for ten years warden of Cavendish College, Cambridge—a new College offering residential facilities to a younger class of undergraduates at a reduced cost. Ultimately the College was closed down, though some years after Cox had severed his connexion with it.

In 1890 Cox was appointed professor of physics in McGill University, Montreal. Previous to that time the physics had been taught with small facilities by Dr. Johnson, professor of mathematics. This appointment gave Cox a great opportunity, for it was at the time that McGill University was rapidly growing, through the munificent gifts of the late Sir William Macdonald. Ample funds were offered to build a new physics laboratory, and, before making plans, Cox was sent on a mission to study the physical laboratories in Europe and the United States. He threw himself with great energy into the new project, and the result was a well-designed laboratory which at the time of its opening was one of the finest and best equipped in the world. Under the impetus given by the appointment of Callendar and afterwards of Rutherford, the laboratory became a centre of research in physical science, and Cox followed with pride and enthusiasm the pioneer researches of Rutherford and Soddy on radioactivity.

While keenly interested in all developments of physics, Cox had not the practical training requisite for research in experimental physics, but devoted himself to the teaching and administrative side. A fluent and polished speaker, he was an admirable lecturer, and as a speaker for popular audiences on scientific and general topics he had few superiors. It was characteristic of his temperament that he was somewhat dilatory in ordinary business matters and often required the spur of necessity to deal with correspondence. A man of wide interests and wide social sympathies he exercised a strong influence for good both in Montreal and the University. In 1909 he retired from McGill with a Carnegie pension to live in England, and was awarded the honorary degree of LL.D. by McGill University. He immediately took up the work of lecturing for the Oxford Extension Delegacy and particularly for the Gilchrist Trust. This was a type of work which he thoroughly enjoyed and carried out with great enthusiasm and success. During the War, he offered his services to the Ministry of Munitions and assisted in the work of the munition tribunals.

After the death of his wife, Cox lived at Hayes Court with a daughter. He retained his enthusiasm for science to the end and, before his illness became acute, followed with keen interest the work of Einstein and Bohr. Of his publications, the best known is his book on mechanics published by the Cambridge University Press. This useful work was written on novel lines, being largely influenced by the writings of Marx, of whom he was an admirer. Another small book, "Beyond the Atom," gives a vivid account of the bearing of the earlier radioactive researches, with which he had come in contact in Montreal, on the structure of matter. A man of fine character, of attractive personality and varied gifts, his unexpected end will be mourned by a wide circle of friends. He leaves two daughters and a son, who is a mining engineer in Canada.

Mr. R. W. Hooley.

Mr. Reginald William Hooley, whose death on May 5 at the age of fifty-seven we regret to record, devoted many years to the study of the geology of the Isle of Wight, and to the systematic exploration of the Wealden rocks of the south coast. He made an important collection of the remains of reptiles and fishes from the cliffs between Brook and Atherfield, and established a small museum at his residence at Winchester. He also acquired an excellent knowledge of the Wealden reptiles, which he extricated from the hard rock with great skill, and he wrote several important papers on his specimens. He described new Chelonia in the *Geological Magazine* in 1897 and 1900.

In 1904 Mr. Hooley was elected a fellow of the Geological Society, and he contributed papers on unique specimens of the crocodile Goniopholis and the pterodactyl Ornithodesmus to the Society's Quarterly Journal in 1907 and 1913. During recent years he discovered and prepared a skeleton of Iguanodon, in some respects finer than the well-known specimens at Brussels and showing parts of the skin. Of this remarkable fossil he wrote an exhaustive memoir, illustrated by his own drawings, which he had intended to read to the Geological Society at a recent meeting.

Mr. Hooley was an indefatigable worker, with only scanty leisure to devote to science, and his premature death is regretted by the large circle of geologists and palæontologists who enjoyed his friendship and co-operation. His specimens of Goniopholis and Ornithodesmus are already in the Geological Department of the British Museum (Natural History), and the rest of his collection is destined to be added to them.

A. S. W.

We regret that the date of the death of Mr. F. W. Harmer was given incorrectly in Nature of June 9 as April 24: it should have been April 11.

Current Topics and Events.

Some time ago Dr. George Sarton, of the Carnegie Institution, Washington, and editor of *Isis*, directed the attention of scientific men to the enormous amount of ignorance and superstition which still surrounds them (*Isis*, vol. iii. pp. 449-50). This mental condition is not confined to the poor and uneducated, but is to be found among many people who have had the advantage of a collegiate education. Yet how common is that ignorance has recently been shown by the attacks made in the United States upon the Darwinian theory by Mr. W. J. Bryan, a campaign which has found an echo in Great Britain. On May 25 the writer of a letter headed "War on Darwinism" in the *Daily Mail* gravely assured us that *the origin of man has not been discovered by science*, and that the author of the "Origin of Species" was wrong because "Ruskin laughed the thing to scorn in 'The Eagle's Nest,'" and "Disraeli did likewise in 'Tancred.'" That remarkable epistle emanated from a certain "Modern High School, Lee, London." *Damnant quod non intelligunt!* The logic equals the knowledge: Darwin *wrong* because Froude (a manufacturer of English history), Ruskin (a word-painter), and Disraeli (an imaginative writer) laughed and did other things! One would have thought that the days when Darwinism was "reviled by bigots and ridiculed by all the world" were for ever past, were we not forcibly reminded to the contrary by such fanatical attacks from time to time. However man's origin may have been brought about, no trained mind questions the fact of that origin, which is no mere phantasm but rests upon irrefragable evidence. Whether it would be a good thing to teach the doctrines of evolution in our "modern high schools" may be a questionable matter; but it would indeed be a good thing if teachers in "modern high schools" were to teach their pupils to emulate the noble example set them by such scientific men as Charles Darwin and Thomas Henry Huxley, who devoted their lives to the search for scientific truth.

On June 6, at the Langham Hotel, the Anglo-Batavian Society entertained Prof. H. A. Lorentz at a banquet which was attended by a number of British men of science. The Anglo-Batavian Society was formed a few years ago in order to promote good-fellowship between the English and Dutch races, on a similar basis to that of the Pilgrims' Club, which seeks to promote good-fellowship between Great Britain and the United States. A couple of years ago the Society was instrumental in establishing an interchange of University lecturers between Holland and England. At first this was limited to the medical faculty, but last year it was decided to extend the lectures to other faculties, and to include physicists and others. In that way Profs. J. F. Thorpe, Brereton Baker, and Sir Humphry Rolleston visited Holland in the months of February, April, and May last, while Prof. W. de Sitter, of Leyden (astronomy), H. R. Kruyt, of Utrecht (chemistry), E. D. Wiersma, of Groningen (medicine), and Prof. H. A. Lorentz, of Leyden (astronomy and physics), visited Great Britain. During the months of May and June Prof. Lorentz visited consecutively the Universities of London, Manchester, Edinburgh, Leeds, and Liverpool, where he lectured on the rotation of the earth and its influence on optical phenomena and the theory of the Zeeman effect. In addition to these lectures, Prof. Lorentz addressed the Royal Institution on June 1 on the subject of radiation of light, and gave by invitation a series of three lectures at University College, London, on June 4, 5, and 7, on relativity. The last three lectures formed a connected course, the aim being to present in a simple form the fundamental principles and some of the applications of the theory of relativity. The other lectures were mainly devoted to questions belonging to the quantum theory and to a discussion of the relation between it and former views. In his discourse at the Royal Institution Prof. Lorentz showed how the ideas of the corpuscular and the undulatory theory of light were closely interwoven in Newton's mind and may be interwoven once more in the physics of the future. The banquet given to him by the Anglo-Batavian Society was presided over by Sir Walter Townley, chairman of the council of the Society. In replying to the toast of his health Prof. Lorentz expressed his great appreciation of the welcome which he had received everywhere in England.

A representative and well-attended meeting was held on Friday, June 1, at the Royal Society of Medicine, at which it was decided to establish a memorial to the late Prof. A. D. Waller and Mrs. Waller. In view of their lifelong devotion to, and enthusiasm for, scientific investigation, it was felt that the most fitting memorial would be the formation of a fund to be used for the promotion of scientific research. Further, in recognition of their close association with the London (Royal Free Hospital) School of Medicine for Women, where Prof. Waller succeeded Sir Edward Sharpey Schafer as lecturer in physiology, a post which he held from May 1883 to November 1886, and Mrs. Waller was first a student and afterwards a member of council, a position which she held to the last year of her life, it was decided that the research fund should be entrusted to, and administered by, the council of that School. A committee was formed to carry out this scheme, and the following, among others, have consented to serve: Sir E. Sharpey Schafer (chairman), the Maharaj of Jhalawar, Sir Charles Sherrington, Sir Humphry Rolleston, Sir Sydney Russell-Wells, Sir Walter Fletcher, Sir David Ferrier, Sir David Prain, Sir Frederick Mott, Sir Leonard Rogers, Miss Aldrich-Blake, Mrs. Scharlieb, Miss Tuke, Mr. Bousfield, Prof. Adam, Prof. Halliburton, Prof. Gowland Hopkins, Prof. Starling, and Mr. Alfred Palmer. Already 1100*l.* has been promised, and further subscriptions may be sent to the honorary secretaries, Prof. Winifred Cullis and Prof. J. S. Macdonald, or to the hon. treasurer, Prof. J. Mellanby, St. Thomas's Hospital Medical School, London, S.E.1.

A STATEMENT as to the position of the Scientific Expeditionary Research Association was made at a luncheon at the Trocadero Restaurant on June 7. The objects of this Association were referred to in an article published in NATURE of January 13, 1923. It has now been arranged that the first expedition shall start in September next, the three-masted schooner *St. George*, of approximately 1000 tons register, having been secured for the purpose. The ship, which is designed on the lines of a yacht, is fitted with auxiliary steam-power, and will be under the command of Commander D. Blair. It is intended that seven or eight fully qualified men of science, representing biology in its different branches, ethnology, oceanography, and geology, shall accompany the expedition, and that full opportunities shall be given them for serious scientific work. The expedition will last for about ten months, and the route followed will be Panama, Galapagos, Easter Island, Pitcairn, Gambier Islands, Rapa, Australs, Cook Islands, Tahiti, Rangiroa, Marquesas, Cocos, Panama, Azores. There will be accommodation for not more than thirty paying guests, and the cruise should offer a unique opportunity for any one with scientific interests to visit the Pacific Islands under favourable conditions for research work, which would supplement the organised research of the expedition. The arrangements for the latter are being made by a committee of scientific men who are specialists in the different subjects which will be investigated. The offices of the Association are at 50 Pall Mall, London, S.W.1.

JUNE opened this year with very unfavourable weather conditions. May was dull and cold generally, but statistics of past years show worse weather in May than that experienced this year. The unfavourable atmospheric conditions in May occasioned a drift of cold air over the British Isles from the Arctic regions. A change, however, has occurred since the commencement of June, and the drift of air is chiefly from the Atlantic, with more normal conditions, although the days are mostly decidedly cool. Greenwich records afford a ready comparison with the past for a period of at least 80 years. June 1-6 this year was continuously cold, the day temperatures being below 60°, with the exception of June 3, when a break of warmer weather was experienced over the south-west and south of England, and at Greenwich the maximum in the shade registered 71°, while the sun was shining for 8·4 hours. The lowest mean maximum temperature in June recorded at Greenwich since 1841 is 62·4° in 1909, which is 7·6° below the normal, there being only 3 days during this month with the temperature 70° or above; 1860 and 1916 are the only other years with so small a number of warm days in June. In 1909 the first half of the month was generally cold. In 1903 June was also cold, and the two weeks from June 7-20 were probably colder than any other similar period in June on record; the maximum or day temperature on June 10 was 48·5°, which is the lowest day temperature in June during the last 80 years, and 5° below the coldest day in the early part of June this year.

THE annual conversazione of the Institution of Civil Engineers will be held on Thursday, July 12, at 8 P.M.

SINCE 1917 the Royal Society's Gold Medals have been struck in brass, although the recipients have been informed that in due course the brass copies will be replaced by gold. The receipt of an invitation from a prominent firm of jewellers to view the King's Gold Vase and the Gold Cup made for the Ascot meeting, 1923, gives reason for the hope that at no distant date the Mint may find itself in a position to release the small quantity of gold required to strike these medals in their proper medium.

THE tercentenary of the Oxford University Botanic Garden will be celebrated on Saturday, June 23, in the Garden at 3.30-5.50 P.M. The speakers will include the chancellor of the University, Sir David Prain, the president of Magdalen College, and Sir F. W. Keeble, Sherardian professor of botany in the University.

IT is announced in *Science* that Dr. George K. Burgess has been appointed director of the Bureau of Standards in succession to Dr. S. W. Stratton, who resigned to become president of the Massachusetts Institute of Technology. Dr. Burgess has been connected with the Bureau of Standards for twenty years, becoming chief of the division of metallurgy in 1913.

IN another part of this issue we print an article on the life and work of Blaise Pascal by Prof. H. Wildon Carr. Celebrations commemorating the tercentenary of Pascal's birth are to be held in France on July 8-9. The principal meeting will be in Paris, where the French President will be present at a gathering to be addressed by the Minister for Public Instruction and members of the French Academy. A meeting will also be held at the summit of the Puy de Dôme, the site of Pascal's classical experiment showing the fall of the barometer with increasing height above sea-level.

THE trustees of the British Museum have accepted a portrait of Alfred Russel Wallace, which is being presented to them by a memorial committee of which Sir James Marchant is secretary. The artist is Mr. J. W. Beaufort. The painting will be unveiled in the Central Hall of the Natural History Museum, South Kensington, at 12 noon on Saturday, June 23. Places will be reserved as far as possible for those specially interested in Wallace's work, on the receipt of applications addressed to the Director.

THE arrangements for the International Air Congress, which is to be held in the rooms of the Institution of Civil Engineers, on June 25-30, are now nearly complete. A large number of papers has been received; these have been arranged in four groups, or sections, and the discussions on the four will go on simultaneously. The Congress, of which H.R.H. the Duke of York is president, will be opened at 10 A.M. on June 25 by H.R.H. the Prince of Wales. An inaugural address will be given by the Duke of Atholl, Under Secretary of State for Air; while at the final meeting the closing address will be delivered by the Secretary of State for Air, Sir Samuel Hoare. Among the important papers of general interest may be mentioned those on air mails by General Williamson, on the development of commercial aviation by Mr. Handley Page, on aviation insurance by Mr. Sturge, and on various airship questions by Major Scott and Ing. Nobili. Problems in navigation and in the medical aspects of aviation are not neglected, while the standardisation and the scientific aspects of aviation are represented by papers by Sir Richard T. Glazebrook, Mr. Le Maistre, Wing-Commander Hynes, Dr. Stanton, Mr. Southwell, Mr. McKinnon Wood, and other members of the staff of the Royal Aircraft Establishment.

THE eleventh International Physiological Congress, which will be held at Edinburgh on July 23-27, under the presidency of Sir Edward Sharpey Schafer, is apparently the first scientific meeting of its kind in Scotland, and promises to be very successful. Already more than 250 physiologists from various parts of the world have signified their intention of attending the meeting, and a large number of countries will be represented. The largest contingent from abroad is coming from the United States and Canada, and will number about forty. A second notice has just been circulated, from which we see that, on presentation of an official voucher, return tickets to Edinburgh will be issued at a single fare and a third by any railway booking office in Britain. The provisional programme of the Congress includes a reception by the Lord Provost of Edinburgh and an address by Prof. J. J. R. Macleod, of Toronto, on insulin. Those who intend to take part in the Congress should, unless they have already done so, communicate without delay with one of the secretaries, Prof. G. Barger or Prof. J. C. Meakins, University of Edinburgh.

THE seventh International Congress of Psychology will be held at Oxford on July 26–August 2, and will differ from preceding congresses in that it will be restricted to 200 members, membership being confined to trained psychologists, and a few others approved by the committee. It is hoped to provide international symposia on subjects of present interest, the contributions being circulated in advance, and each day will be devoted to a different aspect of psychology (general, educational, industrial, medical, social, etc.). The mornings will be occupied in the discussion of more general problems (such as the perception of time, the perception of form, the nature of general ability, the concepts of mental and nervous energy, the principles of vocational testing, the psychological value of certain psychoanalytic views), and the afternoons in the presentation of a limited number of papers offered by individual members. Exhibits of apparatus and less technical lectures will be also arranged. The recognised languages of the Congress will be English, French, German, and Italian. Further particulars can be obtained from the assistant secretary, Mr. W. J. H. Sprott, Clare College, Cambridge.

THE ninety-first annual meeting of the British Medical Association is to be held at Portsmouth on July 24-27, and the president-elect, Mr. C. P. Childe, senior surgeon of the Royal Portsmouth Hospital, will deliver his address on the first day of the meeting. The following presidents of sections have been elected :—Medicine : Sir Thomas Horder ; Surgery : Sir Henry Gray ; Obstetrics and Gynæcology : Dr. V. Bonney ; Pathology and Bacteriology : Dr. H. Maclean ; Neurology and Psychological Medicine : Dr. Henry Devine ; Ophthalmology : Sir John Parsons ; Public Health : Dr. A. Mearns Fraser ; Diseases of Children : Dr. E. Cautley ; Laryngology and Otology : Mr. E. B. Waggett ; Radiology and Electrology : Mr. S. Gilbert Scott ; Naval and Military Hygiene : Surgeon Rear-Admiral Sir Percy Bassett-Smith ; Tuberculosis : Sir Henry Gauvain ; Medical Sociology : Mr. H. B. Brackenbury ; Orthopædics : Mr. T. H. Openshaw ; Venereal Diseases : Sir Archdall Reid ; Anæsthetics : Mr. W. J. Essery. A provisional programme has been issued which includes provision for discussions on diabetes (Section of Medicine), in which Dr. F. G. Banting, of the University of Toronto, will take part, on the part played by fungi in disease (Section of Pathology and Bacteriology), to be opened by Dr. A. Castellani, of the London School of Tropical Medicine, and the artificial light treatment of lupus and other forms of tuberculosis (Section of Tuberculosis), to be opened by Dr. Reyn, of the Finsen Light Institute at Copenhagen. The annual exhibition of surgical appliances, foods, drugs, and books will be opened on July 24 and remain open until July 27. The honorary local general secretaries for the meeting are :—Mr. C. A. Scott Ridout, St. Elmo, Clarendon Road, Southsea, and Mr. E. J. Davis Taylor, 20 Clarence Parade, Southsea.

AFTER several unsuccessful attempts under the Russian regime, an institute of geodesy was eventually founded in Finland in 1918. The first report, which has now been published, covers the work accomplished until the end of 1919. The need for accurate triangulation in Finland is great. The existing maps leave much room for improvement. Two chains of triangulation cross the country, one from north to south, surveyed about 1840 in the measurement of an arc of meridian, and the other along the Gulf of Finland from the isthmus of Carelia to the Åland Islands. The latter is very defective and the first is of little use as the triangulation stations were seldom marked on the ground. The first eighteen months of the institute's existence were spent largely in organisation. No funds being available for a new building, a house in Helsingfors was adapted for the purpose. Dr. I. Bonsdorff was appointed director and given a staff of five or six assistants. A small supply of instruments and a library of about 1000 volumes were acquired. It was decided to begin work on a line of primary triangulation from the isthmus of Carelia to the Åland Islands joining to the triangulations of Sweden, Esthonia, and Central Europe. A preliminary reconnaissance for this triangulation was undertaken.

Under the title *Open Air* the proprietors of *Country Life* have commenced the issue of a new monthly magazine for lovers of Nature and outdoor life. All kinds of outdoor activities are to be catered for, and in the first number there appear articles on walking and motoring, camping and yachting, fishing, tennis, birds and flowers, photography and weather forecasting, and the charming scenery of the British countryside. The policy of the magazine is to put within the reach of every one some knowledge of Nature, to increase interest and participation in all outdoor life and pastimes, and to point the way of obtaining the most lasting and satisfying pleasures from the beauties and wonders of Nature. The first number makes a successful attempt to attain this ideal. The articles are simply and attractively written and the illustrations are numerous, charming in effect, and well reproduced. Special mention should be made of the article on Thomas Hardy's county; of the account of the kingfisher at home, by Miss E. L. Turner, illustrated by her own inimitable photographs; and of the description of some of the wild flowers of the countryside by Mr. Bedford. If the standard of the first number is maintained the magazine should appeal to a wide circle of readers.

We have received a copy of the fourth annual report of the Governors of the Imperial Mineral Resources Bureau dealing with the year ended December 31, 1922. The Bureau maintains an intelligence service in matters relating to the mining and metallurgical industries, partly by correspondence with representatives in different parts of the British Empire and by co-operation with various government departments, and partly by a system of indexing published information bearing on mineral resources in all parts of the world. The information thus accumulated is of much value in answering inquiries and compiling reports on mineral resources. This work of answering inquiries and putting producers and consumers in touch with one another is of growing importance in connexion with the Bureau's work. Since the publication of the last report, the compilation of the "Mineral Conspectus of the British Empire and Foreign Countries" for the period 1913–1919 has been almost completed. Special attention is directed to the eight volumes on iron ore dealing with the present and prospective iron-ore supplies of the world, prepared by the request and with the assistance of the National Federation of Iron and Steel Manufacturers. Two legal publications were issued during the year, dealing with Transvaal and British Columbia. A statistical series for the period 1919–1921 is in the press, and the parts dealing with the more important minerals and metals are being published in advance. A review of the mineral industry of the Empire during 1922 is promised at an early date. During the year under review the Bureau continued its efforts towards the unification of mineral statistics, an enterprise in which it is much to be hoped that success will attained.

Part i. vol. 18 of the Journal of the Royal Horticultural Society, dated January 1923, contains much interesting material for students of horticulture. The Rev. A. T. Boscawen has a note upon New Zealand trees and shrubs grown successfully in Cornish gardens; it is illustrated by seven excellently reproduced photographs. Mr. F. C. Stern has an interesting note upon cultivation in a garden made in an old chalk-pit; while few plants succeed in pure chalk rubble, there is a very long list of plants successfully grown in a mixture of chalk and soil. Mr. J. Coutts has a paper upon the cultivation of lilies. As a contribution from the Wisley Laboratory, appears a twenty-page report by Mr. W. J. Dowson upon the wilt disease of Michaelmas daisies; as the result of inoculation experiments the disease is traced to *Cephalosporium Asteris* Dow., provisionally determined as a new species though ultimately culture of the fungus may necessitate its redetermination as a micro-conidial stage of a Fusarium. An important practical conclusion in this paper is the practicability of raising healthy plants by vegetative propagation from diseased stocks, by striking cuttings from the tips of the rooted suckers. Mr. A. H. Hoare briefly describes the Rhododendron bug, *Stephanitis* (*Leptobrysa*) *rhododendri* Horvath, now scheduled under the Sale of Diseased Plants Order of 1922 and the cause of severe damage to rhododendrons in many districts. From the annual report of the council, the Royal Horticultural Society would appear to be in a very prosperous and flourishing condition, the membership of the Society having increased by 1214 during the year 1921.

A note in Nature of May 19, p. 681, referred to the habit of a sparrow in persistently tapping a window pane. Sir David Wilson-Barker writes to say that a chaffinch for about two months last year did almost the same thing, with this difference, that it never settled on the window ledge. Sir David suggests that the bird was playing with its own reflection.

Dr. T. H. C. Stevenson will read a paper on "The Social Distribution of Causes of Death in England and Wales," at a meeting of the Society of Biometricians and Mathematical Statisticians on June 25, at 8 p.m., in the theatre of the Galton Laboratory, University College, London. Visitors will be welcomed.

We have received a copy of No. 142 of the Circular of the Bureau of Standards, entitled "Tables of Thermodynamic Properties of Ammonia." The pamphlet contains some valuable tables, together with an excellent Mollier chart of the properties of ammonia, and should be very useful to those interested in refrigeration.

Messrs. G. Bell and Sons, Ltd., announce the early publication of "The Structure of the Atom," by Prof. E. N. da C. Andrade, and a revised and enlarged edition of "X-rays and Crystal Structure," by Sir William Bragg and Prof. W. L. Bragg, in which the original intention of the authors has been maintained, namely, to describe sufficiently the elements of the physics, the crystallography, the chemistry, and the mathematics required for the understanding of the subject.

THE volume of the *Bulletin International* of the Academy of Sciences of Prague for 1917 appeared in 1919 under new auspices, but with the handsome style and typographic excellence of former issues unimpaired. The Academy continues to publish, in French or German, much geological, anatomical, and physiological work, which will no doubt be recorded in the various *Zentralblätter*; but it is a pleasure to consult these papers in their original form, and to find that their production has so admirably survived the test of political distractions.

THE series of lectures recently given at University College, London, by Sir John Russell and members of the staff of the Rothamsted Experimental Station are to be published by Messrs. Longmans and Co., in the "Rothamsted Monographs of Agricultural Science," under the title of "The Micro-organic Population of the Soil." Another book to be issued by the same publishers is "Lead: Its occurrence in Nature, the modes of its extraction, its properties and uses, with some accounts of its principal compounds," by Dr. J. A. Smythe, in "Monographs on Industrial Chemistry."

THE Geologische Vereinigung continues the issue of its valuable journal, the *Geologische Rundschau*, under the care of Profs. Steinmann, Wilckens, and Cloos, and the subscription price (10 gold marks for foreigners) compares favourably with that of most of our own scientific periodicals. Volume 13, beginning in May 1922, contains original articles, such as that by Steinmann on the uprising of the Andes, as well as the usual critical summaries that embody much independent opinion on the part of their authors. Scientific libraries will do well, by placing the *Rundschau* on their shelves, to keep in touch with a wide range of progressive work, promulgated by progressive thinkers.

PRELIMINARY arrangements for the regular publication of the *Journal of Scientific Instruments* have now been made by the Institute of Physics in co-operation with the National Physical Laboratory. The special attention of those workers who have new designs for instruments is invited to the fact that the *Journal* is to serve as a medium of publication of detailed descriptions and critical surveys of the behaviour of such instruments. Original papers or laboratory and workshop notes dealing with the practical or theoretical aspects of scientific instruments should be sent to the Editor, Dr. John S. Anderson, The National Physical Laboratory, Teddington, Middlesex.

Our Astronomical Column.

PROJECTION OF ALDEBARAN ON THE MOON.—The present series of occultations of Aldebaran has once more directed attention to its apparent projection on the moon's disc when it disappears at the bright limb. The subject is discussed by Mr. R. L. Waterfield in the British Astronomical Association's Journal for March. He describes some interesting experiments that he made, using a card with a minute pinhole and a lamp behind it as an artificial star. It was found that the brighter the illumination of the artificial moon that was made to cover this star, the further was the latter projected on the disc before disappearance.

Since diffraction makes every bright point appear as a disc in the telescope, this will of itself extend the bright limb of the moon beyond its true position, and also extend the disc of Aldebaran inwards; a considerable fraction, but not the whole, of the observed projection is shown to be thus explained. The width of the diffraction ring that can actually be seen depends on the brightness of the object. Thus faint stars do not show the projection.

To explain the full amount of projection observed, it was found necessary to invoke irradiation, which is probably physiological and differs for different observers; this is quite in accord with experience in the case of Aldebaran.

FAMILIES OF ASTEROIDS.—Mr. K. Hirayama's researches on the connexion between the orbits of many of the asteroids have already been mentioned in this column. He returns to the subject in the *Japanese Journal of Astronomy and Geophysics*, vol. i. No. 3. He studies the secular perturbations by Jupiter and the other planets, and finds quantities which he terms "invariable elements," which are a sort of mean of the actual varying elements. The important elements are mean inclination and mean eccentricity. He makes diagrams in which these quantities are taken as ordinate and abscissa, the third important element, the mean motion, being indicated by varying the colour of the dot. He thus finds several families of planets that show such close agreement in these three points that he has no doubt that they had a common origin; he indicates 5 families, each being called after the earliest discovered member of it; the names are Themis, Eos, Coronis, Maria, and Flora, and the numbers of asteroids belonging to them are 25, 23, 15, 13, and 57.

There seems to be little doubt that Mr. Hirayama has hit on a remarkable relation between the orbits of many asteroids, and that there are strong reasons for postulating a common origin for each family. We thus revert in a sense to the old notion of an exploded planet, but a series of disruptions now appears more probable than a single one.

STONYHURST COLLEGE OBSERVATORY, REPORT FOR 1922.—Sunspots are regularly drawn and measured at the College Observatory on every fine day. The spot activity showed a decided decline in 1922, there being 93 days when the sun was seen to be spotless, as against 29 in 1921. On the other hand, the mean daily magnetic range, both in declination and horizontal force, showed a slight increase. Spectroscopic work was also done, both on the sun and on stars, a special study being made of γ Cassiopeiæ. Papers have been contributed to the *Observatory*, to Monthly Notices of the R.A.S. and elsewhere, on the connexion of magnetic disturbances with sunspots, on the prominences, and on the proper motions of stars in the Perseus clusters. Seismological records were also kept. The disturbance in the Chilian earthquake of November 11, 1922, was so great that the boom adhered to the stop, causing a loss of part of the record. The report also contains full details of the meteorological observations. Father Cortie notes that it is intended to utilise the large stock of stellar spectra at the Observatory for the deduction of spectroscopic parallaxes.

Research Items.

MONOLITHS OF THE NAGA TRIBE OF ASSAM.—In the Journal of the Royal Anthropological Institute (vol. lii., 1922) Mr. J. H. Hutton discusses the monoliths erected by the Naga tribes of Assam. He assumes that the monolith erected when the founder gains the highest social rank is the translation into stone of the original phallic posts, which seem to be connected with the monolithic remains at Dinapur. Many Angamis erect a pair instead of a single stone, of which the erect stone represents the male and the prostrate stone the female—the object being a magical means of procuring fertility for the members of the tribe, their cattle, and crops. On the other hand, these monoliths are memorials of the dead. Of two possible explanations, the more likely one is assumed to be that the monolith is merely a translation into stone of the wooden statue erected in honour of the dead by villagers who do not erect memorial stones. The alternative is that the erect stones originally commemorated a feast, and thus became the memorial of the giver. It has always been a problem how monoliths, like those of Stonehenge, were erected. Mr. Hutton was present at the erection of one of these stones, dragged by human labour, and his careful description of the methods employed throws much light on the general question of monolith erection.

THE ROOTING OF CUTTINGS.—Prof. J. Small has a note in the *Gardeners' Chronicle* for May 5 upon his experiments at Belfast, in collaboration with Miss M. J. Lynn, upon the effect of watering with dilute acetic acid upon root production by cut shoots. The experiments appear to be preliminary in nature, and no data are supplied as to the actual hydrion concentration around the base of the cutting, but the results reported certainly seem to show greater root production after treatment with very dilute vinegar. In experiments with cuttings of *Aucuba Japonica* evidence was obtained indicating that carbon dioxide might have a stimulating effect upon root production. These results may prove of great practical importance if confirmed upon further trial, but so far the experiments with species, difficult to strike in ordinary practice, are not sufficiently advanced to justify the drawing of conclusions.

SLEEP MOVEMENTS AND VEGETATIVE REPRODUCTION IN PLANTS.—The *Journal of Indian Botany*, vol. iii., No. 5, contains a paper by W. T. Saxton upon "Nyctinasty," in which it is suggested that instead of the plants adopting a special "sleep" position at night, the leaves then actually resume a normal position, relaxing from a position of "physiological strain" which has been assumed under the influence of daylight. R. H. Dastur has a note upon vegetative reproduction by root runners, in which it is assumed that the current teaching is that buds are only formed upon roots when the plants are old or when the original stems are removed or cut down. The writer is evidently unaware of Beijerinck's classical paper of 1887, in which the natural production of buds on the roots of healthy plants was fully described and the literature of the subject, extensive even at that date, very fully cited.

CHEMISTRY OF SOME JAPANESE PLANT PRODUCTS.—In *Acta Phytochimica*, vol. 1, No. 2, Yasuhiko Asahina gives a résumé of his researches, previously published in Japanese, upon the active principles in the dried fruit of *Evodia rutæcarpa*, which in recent times has been almost exclusively used as tincture in Japan instead of tincture of iodine. In addition to evodin, previously isolated by Keimatsu, Asahina recognises two alkaloids, evodiamin and rutæcarpin, giving different colour reactions with cold concentrated sulphuric acid, and a terpene that is possibly ocimen. Yuji Shibata and Kenshô Kimutsuki make the important suggestion, backed by considerable experimental evidence, that the spectrograph provides a valuable means of identifying and distinguishing the various flavones rapidly and surely, while Keita Shibata, Shôjiro Iwata, and Makoto Nakamura describe baicalin, a compound of a new flavone with glucuronic acid obtained from the roots of *Scutellaria baicalensis*.

INVESTIGATIONS UPON FRUIT TREES.—The *Journal of Pomology and Horticultural Science*, vol. 3, No. 2, April 1923, contains a preliminary report by L. N. Staniland upon the results to date of his quest for apple stocks resistant or immune to woolly aphis. The paper, although preliminary, describes a large number of experiments and observations upon artificial inoculations, from which it appears that the Northern Spy stock is immune under English conditions. As it is not a stock suitable for all purposes in this country, research is now extended to its seedlings, which are also to be tested for immunity. Some of the Paradise stocks at East Malling are very much more resistant than others, while two "Wilding Crabs" have been found which appear to be immune. The search for immune individual stocks is being continued with the view of breeding work in which immunity may be combined with other desirable characteristics. There is also a valuable report by M. B. Crane upon the "Self Sterility and Cross Incompatibility" of cherries, apples, and plums, which describes the continuation of the work upon this problem previously reported upon by I. Sutton in the *Journal of Genetics*, vol. vii. (reprinted in the *Journal of Pomology*, vol. 1). The paper provides an enormous mass of valuable data, supplemented by some striking photographs, of the results of various crosses, and of self-pollination experiments. The results seem to place beyond doubt the fact that many varieties of fruit trees are completely self-sterile, while in the sweet cherry and the plum, cross incompatibility occurs, *i.e.* some varieties crossed with pollen of certain other varieties wholly fail to form fruit. The importance of these conclusions, supported with full data as to varieties and their behaviour, to the grower stocking an orchard, scarcely needs comment. Points of great scientific interest continually arise in the course of such long-continued and carefully controlled experiments; for example, the observation now reported that apple varieties originally quite self-sterile have indubitably become slightly self-fertile with advancing age.

NEW ISOPOD FROM CENTRAL AUSTRALIA.—Prof. C. Chilton describes (Trans. R. Soc. S. Australia, xlvi., 1922) a new species of Phreatoicus, a fresh-water crustacean, which occurred in thousands in the hot water near an artesian bore at Hergott, a little south of Lake Eyre. The specimens had well-developed eyes and were of a dark-slaty colour; hence they evidently had not come up the bore from underground waters. Specimens were later found in various springs and natural waters over an area of about thirty miles, so that the species is widely distributed. Although the species is placed for the present in the genus Phreatoicus, it differs from the other members of the genus in the greater expansion of the basal joints of the last three pairs of peræopods and in the apparent absence of the coxal joints of all the peræopods. The first species of Phreatoicus was described in 1883 from the underground waters of the Canterbury Plains, New Zealand, and other species of the genus and of allied genera were subsequently described from the surface and underground waters of Australia. In 1914, Barnard recorded a species of Phreatoicus from the mountain streams of Cape Colony. The characters and distribution show that the family is an ancient one, and this was proved also by the discovery of a fossil species, from the Triassic beds of New South Wales, not very different from some of the existing species.

NEW SQUALODONTS FROM THE MIOCENE OF MARYLAND.—R. Kellogg describes and figures the remains of two Squalodonts recently discovered in the Calvert Cliffs (Miocene), Maryland (Proc. U.S. Nat. Mus., vol. lxii., Art. 16). Of the two, one is definitely referred to a new species, *Squalodon calvertensis*, the other is at present indeterminate. The introduction to the paper gives a good summary of the history of the Squalodonts generally, and is followed, under the misleading and erroneous title of "Nomenclature," by a descriptive list of the various species and a "key."

THE CONSTITUTION OF CLAYS.—In Bulletin 708 of the U.S. Geological Survey (1922), H. Ries and other authors describe "The High-grade Clays of the Eastern United States." Of all rocks, clays probably offer the greatest difficulties to petrographers. W. Maynard Hutchings (*Geol. Mag.*, 1890, p. 266) prepared thin films from clays for microscopic examination, retaining the particles in their relative positions. Except where lamination has to be studied, no great advantage arises from this method, and H. C. Sorby (Quart. Journ. Geol. Soc., Proc., 1880) did good work on separated grains, which could be pressed down or rolled over under the cover-glass. Allan B. Dick's "smudge" method ("Kaolin, China-clay, etc.," Mus. of Pract. Geology, p. 261, 1914) keeps the constituents matted together for comparison of their optical characters, and something similar seems to be effected by the squeezing-out process adopted in the American researches (Bull. 708, p. 293) by R. C. Somers. His photographs give the impression of coherent sections; but probably only a massing of the mineral particles can be inferred. Chlorite is omitted from the list of minerals observed, and Hutchings failed to recognise it even where altered biotite formed an important constituent of his clays. He found it, however, abundantly in slates derived from the decay of basic igneous rocks, such as his "ash-slates," and H. B. Milner, in his recently published "Introduction to Sedimentary Petrography," regards its appearance in loose sediments as due to the breaking down of slates and schists. It would seem that the green hydrated products from ferromagnesian silicates, wisely called by various authors "chloritic matter," should find a considerable place as constituents of many clays and sandstones, though probably in a highly comminuted form. R. F. Somers recognises halloysite and diaspore in the American clays, in addition to the prevalent flakes of kaolin. The white material known as "indianite" from south-central Indiana is discussed by W. N. Logan (Bull. 708, p. 147), who finds it to consist mainly of the hydrous aluminium silicates, halloysite, and allophane. In the field it is associated and interlocked with a sandstone of Pennsylvanian age, blocks of which graduate into the clay, and H. Ries (p. 161) comes to the very interesting conclusion that the indianite has arisen from replacement of quartz pebbles, through the action of aluminium sulphate spreading from the underlying pyritous shales.

STOKES'S LAW OF FALL OF A SPHERE.—In the issue of the Proceedings of the United States Academy of Sciences for March 15 Prof. Millikan, now of the California Institute of Technology, gives a summary of a theoretical and experimental investigation of the law of fall of a sphere in a viscous fluid which will be published later in full in the *Physical Review*. On theoretical grounds he shows that the viscous resistance to the motion of a sphere of radius a with velocity v in a fluid of viscosity n and mean free path l must be $6\pi anv/(1+A'l/a)$ where A' is a constant which must decrease as the density of the fluid decreases. In order to express this decrease he writes $A'=A+Be^{-ca/l}$ where c is a constant. He finds that his experiments with drops of different materials falling in gases of various constitutions and densities are all reproduced by the complete formula with values of $A+B$ which differ by not more than 3 per cent. from each other.

CURVE FITTING.—In many physical problems, experimental data give the numerical values of a function at regular or irregular intervals of a variable on which the function depends. Often it happens that these experimental values indicate that the function starts at zero, rises to a maximum and then falls again to zero. Frequency distributions, river gauge readings, and certain physical and biological data define functions of this type. In such cases it is often necessary to obtain a theoretical function which gives a reasonable fit to the data and can at the same time be integrated. The constants occurring in the theoretical equation should also be capable of calculation without such laborious computation as to make the work impracticable. In a pamphlet, "A Method of Curve Fitting," issued by the Physical Department of the Egyptian Ministry of Public Works (Cairo, Government Publications Office, 1922, P.T. 5), Mr. S. Krichewsky explains an equation which has been found to include a wide range of observations, including frequency distributions. The equation is

$$z=f(x)=dy/dx=ky^m(a-y)^n,$$

wherein $f(l_1)=f(l_2)=0$, $a=\int_{l_1}^{l_2}f(x)dx$, $y=\int_{l_1}^{x}f(x)dx$, so that z is the ordinate at x, and y the area from l_1 to x. Mr. Krichewsky's method certainly possesses limitations due to the small number of free constants contained in his equation. Much of the pamphlet is concerned with the calculation of the constants to fit the equation to sets of observed data.

HARDENING STAINLESS STEEL.—Messrs. Automatic and Electric Furnaces, Ltd., of Farringdon Road, London, manufacture a special electric furnace for hardening "stainless" cutlery. The demand for stainless cutlery has been affected adversely by the fact that in many cases a permanent edge cannot be obtained by its use. To get over this difficulty the steel is treated as follows: it is first heated in the furnace to a temperature of 970° C. (as shown by the pyrometer) and then cooled in air. It is next reheated to the same temperature and quenched in water. Finally, it is tempered to 220° C. in an electrically heated muffle. A very fine microstructure is thus obtained. Besides its rust-resisting qualities, stainless steel has a thermal conducting coefficient less than one-third that of pure iron. It is an excellent material for making permanent magnets for use in positions where freedom from corrosion is an advantage, as when quenched at 970° C. it has a large coercive force and great remanence. It is also useful for making mirrors of all kinds.

The Liverpool Meeting of the British Association.

THE preliminary programme and invitation circular for the meeting of the British Association to be held at Liverpool on September 12-19, under the presidency of Sir Ernest Rutherford, have just been issued. The Association has met at Liverpool on four previous occasions, the years and the presidents being 1837, Earl of Burlington, afterwards Duke of Devonshire; 1854, Earl of Harrowby; 1870, Prof. Huxley; 1896, Lord Lister. The meeting in 1896 was the fourth largest in the history of the Association, the attendance being 3181, and it is hoped that this number will be exceeded at the forthcoming meeting. Arrangements have been made with the Railway Companies in Great Britain under which members attending the meeting may obtain return tickets to Liverpool on payment of single fare and a third.

The provisional programme of addresses, discussions, etc., is given below, the sections being as follows:—A, Mathematics and Physics; B, Chemistry; C, Geology; D, Zoology; E, Geography; F, Economic Science and Statistics; G, Engineering; H, Anthropology; I, Physiology; J, Psychology; K, Botany; L, Educational Science; M, Agriculture.

Wednesday, September 12, 8.30 P.M.—Inaugural general meeting: presidential address by Sir Ernest Rutherford, on the electrical structure of matter.

Thursday, September 13.—Addresses by presidents of sections:—D, Prof. J. H. Ashworth, on modern zoology, its boundaries and some of its bearings on human welfare. E, Dr. Vaughan Cornish, on the position and opportunity of the British Empire. K, Mr. A. G. Tansley, on the present position of botany. I, Prof. G. H. F. Nuttall, on symbiosis in animals and plants. M, Dr. C. Crowther, on science and the agricultural crisis. Discussions (Sections A, B, G) on cohesion and molecular forces; (Sections F, J) on psychological assumptions underlying economic theory; and (Sections G, J) on vocational tests for engineering trades.

Friday, September 14.—Addresses by presidents of sections: C, Dr. Gertrude Elles, dealing with some aspects of evolutional palæontology. G, Sir H. Fowler, on transport and its indebtedness to science. L, Prof. T. P. Nunn, on the education of Demos. B, Prof. F. G. Donnan, on the physical chemistry of interfaces. J, Dr. C. Burt, on the mental differences between individuals (with special reference to individual psychology in education and industry). Discussions (Sections E, H) on the methods of anthropology in relation to the social sciences; (Sections F, M) on the outlook for British agriculture; and (Sections B, I) on the physical chemistry of membranes in relation to physiological science. Lecture (Section D) by Mr. Julian S. Huxley on the physiology of development in the frog; and by Prof. G. Elliot Smith on the study of man.

Monday, September 17.—Addresses by presidents of sections:—A, Prof. J. C. McLennan, on the origin of spectra; H, Prof. P. E. Newberry, on Egypt as a field for anthropological research; F, Sir W. H. Beveridge, on unemployment and population. Discussions (Sections J, L) on the delinquent child; (Sections E, L) on geography as a basis for a general science course. Lecture (Section K) by Dr. W. L. Balls, on cotton.

Tuesday, September 18.—Discussions (Sections G, L) on the teaching of dynamics; (Sections K, M) on virus diseases of plants; and (Sections E, H) on the origin of domestic animals.

Delegates of the Corresponding Societies will meet on Thursday, September 13, and on Tuesday, September 18, to discuss matters of common interest to the Societies and the Association. The officers of the Conference of the Corresponding Societies are:—*President*: Prof. H. H. Turner. *Vice-President*: Prof. P. G. H. Boswell. *Local Secretary*: Miss E. Warhurst.

An exhibition of scientific apparatus is being organised and will be held in the Central Technical School. Leading scientific instrument and scientific apparatus makers will be represented, and it is believed that this will be the most complete exhibition of its kind that has ever been held. It will include the latest inventions in instruments and apparatus, as well as charts and diagrams, and, in order to make it thoroughly representative, every section has been asked to submit ideas and suggestions.

International Union for Pure and Applied Chemistry.

CONFERENCE AT CAMBRIDGE, JUNE 17-20.

THE International Union for Pure and Applied Chemistry will meet in Cambridge, at the invitation of the Vice-Chancellor of the University, on June 17–June 20, when about 150 delegates, representing more than thirty different countries, will be present.

The majority of the delegates are expected to arrive on Saturday, June 16. On Sunday, June 17, there will be visits to colleges and other places of interest in the afternoon. In the evening there will be a reception of the delegates by Sir William Pope, president of the Union, and the British Federal Council, in the Arts School.

On Monday, June 18, in addition to the meetings of committees, a report by Prof. J. W. McBain, on "The Nature of Soap Solutions," will be presented and discussed. Two receptions will be held on this day, one by the master of Gonville and Caius College and Mrs. Anderson, and the other by the master of Sidney Sussex College and Mrs. Weekes.

On Tuesday, June 19, there will be the usual committee meetings, and in addition two reports will be presented and discussed. The first will be by Dr. E. K. Rideal on "Recent Developments in Contact Catalysis," and the second by Prof. J. F. Thorpe on "New Aspects of Tautomerism." During the afternoon there will be a garden party in the gardens of Sidney Sussex College, and in the evening the annual banquet of the Union will be held in the Hall of Trinity College.

On Wednesday, June 20, after the committee meetings, Prof. F. Gowland Hopkins will present his report on "Chemical Mechanisms involved in the Oxidations which occur in Living Tissues."

At 4 P.M. the degree of Doctor of Science, *honoris causa*, will be conferred on the following delegates: Prof. W. D. Bancroft, Cornell University; Prof. E. J. Cohen, University of Utrecht; M. A. Haller, president of the Paris Academy of Sciences; Prof. C. Moureu, Collège de France; Prof. R. Nasini, University of Pisa; Prof. Amé Pictet, University of Geneva; and Prof. F. Swarts University of Ghent. The ceremony at the Senate House will be followed by a reception by the Vice-Chancellor and Mrs. Pearce in the Fitzwilliam Museum.

Technical Chemistry at the University of Edinburgh.

THE experience gained by Sir James Walker in the manufacture of high explosives during the War strengthened his convictions as to the vital need for strong schools of chemistry in British universities, and led to the view that it might be possible to cater rather more directly for chemistry students aiming distinctly for industrial careers than was possible in Edinburgh at that time. As a result the University instituted a department in technical chemistry to meet the needs of those students who desire definitely to prepare for the practice of chemistry in industry, and now proposes, under a recently instituted ordinance, to grant degrees of B.Sc. in technical chemistry leading to the Ph.D. and D.Sc. degrees.

In order to accommodate its ever-expanding scientific departments, the University recently acquired a site of 115 acres of agricultural land at Liberton, on the southern outskirts of the city. The chemistry department was the first to be given accommodation on the new site, and in 1919 work was begun on a new chemistry building, the first of the King's Buildings of the University, which is now nearing completion. In 1921 a portion of this new chemistry building was set aside for the technical chemistry department, and laboratories were designed to meet its special needs.

To get a clear idea of the technical chemistry department it is advisable briefly to survey the general building of which it forms a part. The chemistry building consists of a two-storey frontage looking towards the city, backed by ranges of single-storey rooms with some cellar accommodation. The two-storey portion contains physical chemistry laboratories, staff rooms, library, and administrative offices. Situated centrally behind this portion is a series of laboratories, having the factory shed type of saw-tooth roof with north window lights, stores, and a number of lecture rooms with necessary service and museum rooms. The lecture rooms are lighted by lanterns supported centrally over the ceilings, and an interesting and convenient feature of this lighting system is the provision of movable ceilings to the lanterns so that by the touch of a button at the lecture bench the ceiling can be lowered to cut off all light from the room for lantern projection purposes. Ventilation is effected by the passage of a gentle current of warmed fresh air across the rooms from front to back. The laboratories are very brightly lighted from above and there is no trouble anywhere with dark corners. Even in winter there is little demand for artificial light during the normal working day. A ventilating fan in one wall of each laboratory near the roof is designed to keep the atmosphere fresh, though the provision of an open fume duct at each student's working place and at each evaporating and drying outfit ensures a reasonably clean atmosphere under heavy working conditions.

Flanking the centrally situated laboratories and lecture rooms are corridors running the whole length of the building and giving access to series of smaller rooms, which run along the east and west fronts of the building. These rooms are research laboratories, balance rooms, etc.

The technical chemistry department is situated at the south-east corner of the building, and apart from its laboratories has the advantages of lecture room, dark room, stores, balance room, etc., accommodation provided in the general scheme. There are three larger and two smaller laboratories, with an adjoining workshop. The larger rooms have north roof lights, and normal ventilation is secured by having some of the windows capable of being opened. Additional ventilation is available when necessary in a uralite fume duct, provided with openings closed by sliding doors, running along the back wall of the laboratories, and discharging to the atmosphere through a large-capacity Keith fan. A bye-pass connexion in the fan house enables this fume duct to be put in connexion with a Campbell fume ejector when required.

The floors are of concrete, and slope to centrally situated grid-covered drains. Further drainage accommodation is provided at intervals round the walls of the rooms.

A system of pipes traverses the walls of the laboratories at a mean height of 4 ft. 6 in., and tap and plug connexions are provided at frequent intervals so that each potential working space has at hand the following services—electric power and light, cold and hot water, steam, gas, compressed air, and vacuum.

Apart from cupboard and shelving accommodation provided as wall fixtures, there is no fixed furniture, but movable tables of various heights are available for use as occasions require.

Plant power units will be driven by their own motors in order to retain maximum flexibility, both as regards equipment and its grouping.

One laboratory is provided with a chimney into which are collected four sheet-iron dampered draught pipes serving as furnace flues. Another room has a range of three superimposed platforms for use where a succession of reactions may require gravity feeds.

Of the smaller rooms one is fitted up on the lines of the larger ones, while the other is designed more as an orthodox chemical research room. Here, however, instead of providing fixed bench accommodation, light movable tables are supplied so that they may be arranged to suit the work in hand.

The technical chemistry courses aim at providing:—

1. A sound instruction in the principles of chemistry.
2. A study of the methods of translating chemical processes from the laboratory to the works, with special attention to the combustion of fuels.
3. Practice in such analyses as those of water, oils, and fuels.
4. Laboratory practice in fundamental operations such as filtration, evaporation, crystallisation, drying, electrolysis, furnace work, nitration, sulphonation, fusion, distillation, etc., with small-scale works plant.
5. A sufficient acquaintance with the elements of engineering practice for the following purposes:
    (*a*) To enable men to co-operate intelligently and satisfactorily with an engineering staff concerned with the provision and working of large-scale plant.
    (*b*) To make men more competent in handling large-scale operations, the success of which is largely dependent on the best use of mechanical and electrical appliances.
    (*c*) To give facility in the interpretation of plans and drawings and sufficient skill in drawing to be able to make working drawings of simple plant parts and structures.
6. An insight into the methods of factory organisation.
7. An acquaintance with methods of factory accounting with the view of a proper understanding of costing processes.
8. When desired—and by special arrangement—detailed study of a particular chemical industry or group of industries.

The Electric Charge of Colloids.[1]

By Prof. H. R. Kruyt, University of Utrecht.

SINCE Hardy's publication in 1900, the electric charge of the particles has been the central problem of colloid chemistry. I propose to develop this point of view for both suspensoids and emulsoids, and indeed in the same manner for both types.

In 1907, Freundlich propounded his theory, according to which the origin of the electric double layer was to be sought in a preferential adsorption of one of the ions of the liquid. This theory was applicable to colloid particles with regard to the external phase, and to capillary electric phenomena with regard to the moving liquid. It gave a satisfactory explanation of many facts concerning the coagulation of suspensoids and of the investigations of Perrin and Elissafoff on electro-omosis, of Kruyt on streaming potentials, and of Powis on cataphoresis. Several problems of colloid chemistry could be elucidated by these investigations, *e.g.* the irregular series of flocculation, peptisation, etc. Nevertheless this theory, according to which the double layer is built up only by ions coming from the external liquid, so that the material of the solid wall does not take any part in the process, could not explain all the facts. Especially the investigations on the alkaline sol of SnO_2, carried out by pupils of Zsigmondy, make it obvious that in this case the inner side of the double layer is built up by stannate and not by hydroxyl ions.

The special conditions of the atoms at the periphery of a crystalline particle can account for the formation of a double layer, as Fajans has pointed out. For example, when a negative sol of AgBr is made from solutions of $AgNO_3$ and KBr, with a slight excess of the latter, the Ag-atoms in the crystal lattice are each surrounded by six Br-atoms, whereas an Ag-atom at the crystal boundary is connected to five only; thus it will attract a Br-ion from the surrounding liquid towards the vacant place. This ion, however, is accompanied by a K-ion, which will place itself near the attracted Br-ion. Thus the double layer is formed by the special selective attraction of the solid phase. This train of thought, when slightly modified, holds too for a disperse amorphous phase. According to Langmuir and Harkins, the molecules at a phase interface are oriented with their electrically polar parts towards the water; therefore the conditions are similar to those at the surface of a crystal lattice.

Has the electric charge in the case of lyophilic colloids, like the proteins, the same capillary electric character as in that of the suspensoids? If not (and most physiologists consider it so), colloid chemistry is on the wrong track. The behaviour of proteins is often explained as if they gave real solutions, electrolytically dissociated as amphoteric electrolytes, following Ostwald's law of dilution. Kruyt and De Jong have made investigations on the sol of agar, the behaviour of which cannot possibly be interpreted in that way, the agar being a carbohydrate though giving a typical lyophilic colloid. They pointed out that there is a considerable decrease of viscosity when small amounts of electrolytes are added, the effect being a function only of the valency of the cation, just as is the case with suspensoids and capillary electric phenomena. This effect is the electro-viscous effect, already predicted years ago by Hardy, and thoroughly discussed in the late von Smoluchowski's last paper.

As the electric charge of the agar particles has, without any doubt, just the same character as that of, say, a gold sol, why should a gelatine sol have a charge of quite another origin? Investigations in collaboration with different pupils (unpublished until now for the most part) have convinced me that with gelatin, glycogen, casein, starch, gum arabic, and even with rubber in benzene, the capillary electric phenomena play the principal rôle and can account for the behaviour, which is often interpreted as if we were not dealing with colloids, but with electrolytes in real solution. The influence, especially, of neutral salts can now be understood much better.

The only difference between suspensoids and emulsoids lies in the fact that the latter are hydrated to a large extent, viscosity showing this fact clearly. Water bound by hydration acts as a stabilising factor, just as the electric charge does. The latter can be removed by electrolytes, as mentioned before, and the hydration by adding alcohol or acetone. When hydration only is removed, there remains a suspensoid with all the typical properties of such. Salting out a protein is a combination of the removal of charge (according to the valency) and of hydration (according to the lyotropic strength). Special experiments with agar have made this obvious.

Dr. Bungenberg de Jong has pointed out that the action of tanning agents, like tannin, is a mere dehydration, causing just the same effects as alcohol, though by a very different mechanism.

As a general conclusion, I wish to emphasise the view that the electric charge of all colloids has the same origin, namely, a capillary electric one. The electric charge of suspensoids is their only stabilising factor, the emulsoids having a second in their hydration. With both, the way in which the double layer is built up is not always independent of the material from which the particle is made: with a gold sol, as well as with an agar sol, the double layer behaves in perfect accord with the adsorption theory of Freundlich. With the sol of stannic oxide, as well as with a protein sol, the ions of the molecules situated in the periphery of the particles play an important rôle in the constitution of the double layer.

The advantage of the train of thought developed here lies in the principle of unity according to which colloid-chemistry can be treated.

[1] Synopsis of a lecture delivered at the Universities of London, Edinburgh, and Aberdeen in May 1923.

Plant Ecology.

IN "Die Vegetationsverhältnisse der Grimselgegend im Gebiet der zukunftigen Stauseen" (Bern, Wyss Erben, fr. 8), Dr. Eduard Frey records the character of the vegetation of an area which will soon be submerged in connexion with a water-power scheme in the upper Aare. The area is of special interest in affording a unique opportunity for studying the colonisation of naked siliceous rock and broken soil exposed by the prolonged retreat of the glaciers. Dr. Frey describes in detail the physical characters of the district and the statics of the different plant associations, and also traces the succession of plant life from the original colonisation of unoccupied rock and debris by lichens and mosses to the ultimate condition in which vascular plants are mainly concerned. He remarks on the crowding in a very narrow space at the edge of the glacier of different plants and plant societies. Compared with the Bernina, the flora of the Grimsel is poor in number of species, a fact due primarily to the uniform character of the mineral which forms the basis of the soil. The general features of the district and its vegetation are illustrated by nine very good photographic plates.

Dr. Mario Jäggli's study of the vegetation of the Maggia delta (" Il delta della Maggia e la sua vegetazione," Rascher, Zürich, fr. 7) on Lake Maggiore, between Locarno and Ascona, deals with a fluctuating low-lying area, just above water-level, or periodically or permanently submerged. The writer describes the general character of the delta and its recent transformations, as well as the climatic conditions in relation to the vegetation. He gives an account of the plant associations at the different levels and also a complete systematic list of the species and their distribution in the area. The work is illustrated by a coloured phyto-geographical map and a section in profile.

A widely differing area forms the subject of a communication by Rolf Nordhagen (" Vegetationsstudien auf der Insel Utsire im westlichen Norwegen " ; Bergens Museums Aarbok, 1920–21, Hefte 1), who gives an account of the vegetation, with the constituent plant-associations and a list of the species, of a small isolated island, about 614 square kilometres in area, off the west coast of Norway. The flora of the island bears a strong resemblance to that of the Faroe Islands, though, unlike the Faroes, it has no high lands, the highest point being only 80 metres above sea-level. The value of the work is enhanced by a large number of photographically produced text-blocks.

University and Educational Intelligence.

CAMBRIDGE.—Mr. H. M. Fox, Gonville and Caius College, has been appointed demonstrator of comparative anatomy. The following members of the staff of the Solar Physics Observatory have been reappointed for five years : Messrs. C. T. R. Wilson, Sidney Sussex College, F. E. Baxandall, C. P. Butler, and W. Moss.

The Committee for Geodesy and Geodynamics reports that funds have now been secured for the erection of a small building for practical work near the Observatory. It is expected to be ready early in July. A grant of 200*l*. has been made by the Royal Society from the Caird Fund towards the purchase of pendulum apparatus for research purposes. A pair of transit instruments, an astronomical clock, and a twelve-inch theodolite have been presented to the School of Geodesy by the Surveyor General of the Trigonometrical Survey of India, with the approval of the Government of India ; and other valuable loans and presents have been received.

Prof. Nils Bohr has been proposed as an honorary member of the Cambridge Philosophical Society on the occasion of his receiving an honorary degree from the University.

LONDON.—The following doctorates have been awarded :—*Ph.D. in Science* : Mr. L. G. F. Dolley (University College) for a thesis entitled " The Compressibilities of Binary Gas Mixtures " ; and Vidya Sagar Puri (King's College) for a thesis entitled " Studies in Alternating Current Electrolysis."

The chairman (the Rt. Hon. the Viscount Chelmsford) and members of University College committee, the Provost and members of the academic staff, will hold a reception at the College on Saturday, July 7. The new anatomy building and the extensions of the physiology and engineering departments will be open to inspection.

MANCHESTER.—The award of the degree of D.Sc. has been recommended to Mr. J. C. Duff for a thesis on " Complex Metallic Ammines," and to Mr. W. F. Rawlinson for papers dealing with X-ray spectra and with the properties of supersonic waves in water.

Mr. W. H. Dearden has been elected Hadfield research scholar in metallography. This is the first award of the scholarship, which was instituted last year by Sir Robert Hadfield on the occasion of the inauguration of the Metallographic Institute at Stockholm. The scholarship is tenable at the Institute, and the scholar works under the direction of Prof. Benedicks. Mr. Dearden was a student of the Department of Metallurgy, 1919–22, and being head of his year in the Final Examination was awarded a graduate scholarship. During the past session he has carried out research on the causes of the failure of manganese bronze as a result of the attack of solders.

OXFORD.—The annual report of the Savilian professor of astronomy, Prof. H. H. Turner, was presented to Convocation on June 5. Reference is made in the report to the seismological work done at the observatory, especially on the determination of the depth at which earthquakes take place, and on the various periodicities which have been found in the recurrence of earthquakes, notably one of about four years which seems to be connected with a change in the earth's interior. In this department Prof. Turner has received much assistance from Mr. J. S. Hughes, of New College, whose services have been made possible by the financial help of Dr. J. E. Crombie, of Aberdeen. Voluntary work on the Vatican Zones of the Astrographic Catalogue has been given by Messrs. F. Sargent, A. Burnet, and C. Martin. Dr. Fotheringham has lectured on ancient chronology, and has published papers on the ' Visibility of the lunar crescent " and on a correction of the secular acceleration of the moon's mean motion as determined from occultations and conjunctions in the Almagest. Mr. F. A. Bellamy has continued his general supervision of the observatory as first assistant, and has published a paper on faint stars with large proper motions on plates of the Oxford Astrographic Catalogue. Miss E. F. Bellamy has continued her revision of the Vatican Zones of the Catalogue.

At the ensuing Encænia it will be proposed to confer the degree of D.Sc. on Sir Ernest Rutherford and on Prof. Louis Lapicque, professor of physiology in the University of Paris.

THE University of Geneva has conferred the degree of doctor *honoris causa* on Prof. A. C. Seward, professor of botany in the University of Cambridge, and on Mr. Douglas W. Freshfield.

APPLICATIONS are invited by the Imperial College of Science and Technology for the Henry George Plimmer fellowship in pathology. Candidates must be qualified to undertake research in morbid anatomy, histological anatomy, chemical pathology, protozoology, bacteriology, and allied subjects in either zoology or medicine or botany. Further particulars can be obtained from the Rector of the College, South Kensington, S.W.7. The latest date for the receipt of applications is June 25.

THE Imperial Education Conference, which will open on June 25 at the Board of Education and remain in session until July 6, is the second conference of its kind, the first having been held in 1911. The Chief of the Imperial General Staff convened an Imperial education conference in 1919, but this was limited to the discussion of problems which had presented themselves to the Imperial Education Committee, War Office, as a result of the experience gained in the working of the educational schemes within the British Army and the Forces of the Dominions. Most of the discussions at the coming conference will take place in private, but there will be public (evening) sessions on June 26, June 27, and July 3 devoted to infant education, the boy-scout and girl-guide movements, and "The Island and the Empire" (paper by Sir Charles Lucas) respectively. Educational films will be exhibited at the Central Hall, Westminster, on July 5, and an exhibition of the work of elementary schools and training colleges in England will be opened by the president of the Board of Education on June 25. No public official announcement has been made by the Board of the subjects to be dealt with in the course of the private discussions.

THE International Federation of University Women sends us a pamphlet (Occasional Paper, No. 2) containing, *inter alia*, an article by Prof. Kristine Bonnevie, of the University of Christiania, on the work of the League of Nations Committee on Intellectual Co-operation, of which she is a member. Prof. Bonnevie is of opinion that the most fruitful field for intellectual co-operation will be found in bibliography, and she notes that a special committee is investigating systems of cataloguing and other questions with the view of facilitating co-operation between libraries of different countries. Another special committee is studying exchanges of professors and students, equivalence of studies, degrees, and diplomas, and the establishment of international scholarship funds and international holiday courses. Information is also being collected about the condition of intellectual life and the conditions of life for intellectual workers (typically university professors and artists) in various countries. Particulars are given of the Federation's campaign for raising funds for the acquisition of Crosby Hall as part of an international university women's residential club-house.

THE April number of "The University Bulletin" issued by the Association of University Teachers contains some interesting statistics of salaries of teachers in the English provincial universities, 15 of the London colleges, the Welsh colleges, and 4 other university colleges. From these statistics the following mean salaries of full-time teachers have been calculated: of 478 professors, 933*l.*; 970 assistant professors, readers, and lecturers, 450*l.*; 548 assistant lecturers and demonstrators, 299*l.* Another table, designed to indicate the extent of the hardship suffered by university teachers who have spent some years in school teaching through those years not counting towards pension, brings out the fact that in 12 universities and university colleges 175 teachers have had 1446 years of school service, while in some as many as one-third of the teachers have taught in schools. Steps are being taken to cultivate relations with teachers in universities in the Dominions Overseas and in the United States. It is stated that university teachers' associations already exist for South Africa, Australia, Melbourne, Queensland, West Australia, and Tasmania, and that others are projected for Manitoba, Saskatchewan, Adelaide, Sydney, and Hong-Kong. The American Association, formed in 1915, embraces 180 institutions in the United States and Canada.

Societies and Academies.

LONDON.

Royal Society, June 7.—Sir Charles **Sherrington** and E. G. T. **Liddell**: Stimulus rhythm in reflex tetanic contraction.—K. N. **Moss**: Some effects of high air temperatures and muscular exertion upon colliers. The mean daily energy value of the food consumed by the colliers investigated was 4712 calories. Men working in hot mines consume more food, and a larger proportion of salted food, than men in cool mines; oxygen consumption per minute in various kinds of work at the face by an efficient collier varies from about 1300 c.c. to 2000 c.c. In persons not acclimatised to heat, the maximum amount of sweat lost per hour is about 1·4 lbs., whereas in a collier accustomed to work in a hot place the maximum loss was 5½ lbs. The sweat contains about 0·2 per cent. of chloride, and the loss of chloride during a shift is very considerable. A group of symptoms known to the men as miners' cramp, or stokers' cramp, is referred to water-poisoning brought about by the combination of great loss of chloride by sweating, excessive drinking of water, and temporary paralysis of renal excretion.—F. A. E. **Crew**: The significance of an anchondroplasia-like condition met with in cattle. Dexter cattle are remarkable for their bodily conformation. They produce four classes of calves in such proportions as to suggest that the Dexter itself is a di-hybrid in respect of its characters—coat colour and bodily conformation. A proportion of these calves are still-born and characteristically deformed, presenting certain constant features simulating closely those which constitute the condition of anchondroplasia in the human. The proportions in which these monstrous calves occur suggest that the "bull-dog" calf results from the action of complementary lethal factors which are amplifying factors producing an exaggerated form of the Dexter characterisation. The pituitary, thyroid, and adrenals are abnormal. The lethal factor in this case is probably such as affects the functioning of the pituitary. It may be possible to eradicate the "bull-dog" calf by breeding methods.

Physical Society, May 25.—Dr. Alexander Russell in the chair.—C. H. **Lees** and J. E. **Calthrop**: The effect of torsion on the thermal and electrical conductivities of metals. A method is described of measuring the effect of twisting on the thermal conductivity of a wire. In each of the steel, aluminium, copper, and lead wires tested the twist decreases the conductivity along the wire by a small amount which is approximately proportional to the square of the twist per unit length. The change of electrical conductivity is in general less than the change of thermal conductivity, but is also approximately proportional to the square of the twist per unit length. A. **Rosen**: The use of the Wien bridge for the measurement of the losses in dielectrics at high voltages, with special reference to electric cables. One difficulty in the application of large potential differences to a bridge is the effect on the arm which has to withstand the high voltage. In the arrangements due to Monasch and Schering, this arm is the known condenser; in the bridge used by the author the voltage is applied to the ratio coils. The errors introduced by earth impedance are eliminated by using the Wagner auxiliary bridge. Measurements can be made on cables, and the use of the double bridge in determining the "wire-to-wire" and "wire-to-sheath" losses in a multi-core cable is described. Corrections due to imperfections of the bridge arms and a simple quantitative theory of the double bridge are given.—C. R. **Darling**: An experiment on the production of an intermittent pressure by boiling water. If a glass tube, open at both ends, and of about 5 mm. bore, be stood in a beaker of boiling water, steam bubbles form at the point of contact, causing the water to rise in the tube. The column of water sinks after a time, and then rises again, the rising and falling occurring at irregular intervals. If, however, the tube be narrowed to about 1 mm. near the top of the water, and widened out considerably just above the water surface, the action becomes regular. The water is apparently superheated at the points of contact of the tube and beaker, so that the steam produced can sustain a higher pressure of water. When the water reaches the widened part it is cooled and increases in density until the extra steam pressure at the bottom of the tube is overcome, when it discharges completely. The capillary bore slows down the rate of flow in both directions. A separating funnel with open tap and short stem is well suited to the experiment. The arrangement constitutes a simple heat engine, with source and sink, automatically passing through a regular cycle of operations.—N. W. **McLachlan**: A novel instrument for recording wireless signals. The device consists essentially of a drum of Swedish iron with an annular recess in which are situated coils of fine wire, the ends of the coils being connected to corresponding slip rings. The periphery of the drum is faced with cast-iron rings. A small steel shoe rides on the rings, and side play is prevented by a brass guide-piece with a projection which fits into the annular recess. At each end of the guide-piece a hook is formed, and one of the hooks is connected by a light rod to a duralumin lever pivoted to turn in a horizontal plane. A silver syphon passes through the lever and rests lightly on a moving paper tape. The drum is revolved by a small electric motor, and when a current flows in one of the coils the shoe is attracted to the drum and a large pull is required to prevent relative motion of the two. This pull actuates the syphon-lever mechanism, which can be used to show the dots and dashes of the Morse code. The instrument is extremely sensitive, and will work at a speed of 150 words a minute with a current of 25 micro-amperes.

EDINBURGH.

Royal Society of Edinburgh, May 21.—Prof. F. O. Bower, president, in the chair.—A. P. **Laurie**: An interesting property of the water molecule. On a modification of Langmuir's theory of chemical combination, namely, that the two nearest magnetons of two approaching atoms, forming the Langmuir pair, move outwards laterally in opposite directions, thus binding the two atoms together as one common molecule, a water molecule has four external magnetons, in addition to the four which are attaching the two hydrogen nuclei. This molecule can, therefore, form groups combining one with another to give hollow shells or rings which have the property, peculiar to water alone, of having no external magnetons. In the same way, the hydrates formed by combining water with a molecule or ion have no external magnetons, the result being the formation in solution of molecular groups, which may be regarded as chemically neutral to each other. They can account for the properties of water solutions of salts, resulting in their obeying the gas laws in dilute solutions, and also for the part played by water as the only possible medium for organic life.—H. Stanley **Allen**: A static model of the hydrogen molecule. A theory of the constitution of molecules is developed on the basis of the "quantum force" introduced by Langmuir with the view of securing a static model of the hydrogen atom. It is here assumed that the "quantum force," which, like the repulsive force employed by Sir J. J. Thomson in the same problem, varies inversely as the cube of the distance, is a repulsion or an attraction according to the sign of the electrical charges between which the force acts. On this assumption a hydrogen molecule is possible, having many of the properties of the molecule imagined by Bohr but with the electrons at rest relatively to the hydrogen nuclei. Various configurations of equilibrium are theoretically possible, but not all of these are stable. The calculated ionisation potentials are in moderately good agreement with the experimental results. Though the numerical values may need modification, it is now possible to postulate a hydrogen molecule in which the electrons are at rest instead of in orbital motion. The principles may be applied to more complex atomic and molecular systems.—Henry **Briggs** and John **Mallinson**: Further tests upon metal Dewar flasks intended to hold liquid air. The pressure in the vacuous envelope was obtained by direct measurement, and a series of results are given for British- and German-made flasks of different kinds. Radiation is by far the chief source of heat transfer in a flask holding liquid air, and further improvement is to be sought only by better attention to the polished surfaces. Losses by conduction down the neck and (unless the vacuum has much deteriorated) by conduction across the vacuous space are generally relatively small in amount. The charcoal used makes it unnecessary to evacuate by pumping to a pressure of less than 0·1 or 0·2 mm. of mercury.

SHEFFIELD.

Society of Glass Technology (at University College, London), May 16.—Prof. W. E. S. Turner, president, in the chair.—F. **Twyman** and F. **Simeon**: On the refractive index changes in optical glass occasioned by chilling and tempering. Chilling dense barium crown and borosilicate crown glasses may lower the refractive index by as much as 0·004 and 0·0013 respectively. This lowering of refractive index can be removed by heating to a temperature and for a length of time which have been ascertained in certain cases. A want of homogeneity can be produced by moulding, owing to surface chilling, which requires for its removal a longer maintenance at the high temperature than would suffice to remove elastic stress from a homogeneous sample.—V. **Stott**: Notes on burettes. Accurate readings can be obtained much more quickly by using a long emptying time and a short drainage than by using a short emptying time and a correspondingly longer drainage time. The errors occurring through using a burette calibrated for a certain delivery time, with a jet which gave a different delivery time are, in some cases, too large to be negligible.—A. **Ferguson**: A new method of glass-melting. The process consists of employing a cone or column of whirling gases at 1800° C., into the vortex of which batch ground to a 60-mesh standard is dribbled at the rate of two pounds per second; the carbon dioxide of the limespar and soda ash is first driven off in a preheater, so that the work of the furnace is only to raise the temperature from 850° C. to 1350° C. instead of from 20° C. All reactions necessary to form glass molecules take place in a gas at least two million times less viscous than tank metal.—S. **English**: Natural sillimanite as a glass refractory. This material possesses properties of considerable value to glass-makers. Test pieces were made up by mixing 100 parts of sieved sillimanite with 10 parts of finely ground ball clay; such a mixture can be made into slabs and pressed into crucibles, if care is taken in working it.

DUBLIN.

Royal Irish Academy, May 28.—Prof. Sydney Young, president, in the chair.—J. J. **Drumm**: The constitution of catechin, Part I. Benzopyranol salts are prepared from catechin of a type closely allied to the anthocyanidins. Von Kostanecki's coumarane formula for catechin is no longer tenable; A. G. Perkin's chromane formula with slight modifications is again put forward.

Royal Dublin Society, May 29.—Prof. J. A. Scott in the chair.—Rev. H. C. **Browne**: A simple from of photographic depth chart. The chart consists of four concurrent lines, and may conveniently be drawn on squared paper. A straight edge laid anywhere across these lines intersects them in points which give respectively the stop diameter, the nearest distance in focus, the distance to be sharply focussed on, and the furthest distance in focus. The readings are all direct, reciprocals being avoided. Three sample charts were described, one suited for general work, a second especially adapted for the photography of small objects at short distances and on an enlarged scale up to 12 or more diameters, and a third intended for carrying in a photographic note-book, which, though only $3\frac{1}{2}$ in. × $2\frac{1}{2}$ in. in size, gives clear readings for distances up to 60 feet, and stop diameters up to 1·5 inches.—T. G. **Mason**: Ligneous zonation and die-back in the lime (*Citrus medica*, var. *acida*) in the West Indies. Tangential bands of parenchyma are distributed in the wood in both normal lime tree and in specimens affected with "die-back"; they originate during periods of relatively great aridity. The wood from trees affected with die-back exhibits considerable irregularity in the distribution of the parenchyma bands, and the sections suggest that the cambium had been exposed to sudden checks in its activity. Rapid and repeated desiccation of the meristems may be an important factor in causing die-back of the lime.—L. B. **Smyth**: On a problematic structure in the Oldhamia Rocks of Bray Head. These rocks consist of scattered tabular bodies 0·3 mm. in thickness, with rectilinear outlines and of variable size (average, 1-3 mm. diameter) and shape, lying on a bedding plane of chlorite-sericite shale. Their composition differs from that of the shale only by the greater proportion of chlorite. A considerable number of the bodies are lozenge-shaped. They may be crushed pseudomorphs of crystals.

PARIS.

Academy of Sciences, May 22.—M. Albin Haller in the chair. The president announced the death of M. de Freycinet, Free Academician.—A. **Vayssière**: The characters suitable for classifying the gasteropods of the family of the Cypræideæ. These have hitherto been mainly classified according to the character of the shell and this is shown to be insufficient.—M. **Pélissier**: An account of the formation of a new volcanic island south of Poulo-Cécir de Mer. Plans of the island and crater, together with a chart showing soundings round the new island are given.—Paul **Lévy**: A functional operation generalising the derivation of non-integral order.—P. **Zervos**: Some transformations of partial differential equations.—A. **Guillet**: The rapid and precise measurement of the frequency of rotation of the shaft of a motor by the stroboscopic method. A description of the construction and use of an improved form of stretched wire stroboscope.—M. **Dumanois**: The utilisation (in a motor) of a mixture of lamp oil and alcohol containing a high percentage of the latter. A mixture of alcohol (70 per cent.) and kerosene (30 per cent.) was successfully used to replace petrol in a motor car: the car was run on this mixture (after suitably modifying the carburettor) from Paris to Toulouse, 450 miles, without trouble.—Jean **Durand**: Contribution to the study of methods of testing foundry iron.—Albert **Bazin**: The hovering flight of birds: flights without motor in undulating winds.—M. **Auric**: Demonstration of Stefan's law.—A. **Leduc**: The loop of J. Thomson and the new equation of state of gases.—E. **Brylinski**: The propagation of maintained electromagnetic waves along an iron wire. Remarks on a recent communication of M. G. Laville on the same subject.—J. **Rossignol**: Researches on the cathode phosphorescence of the ruby. An examination of the influence of the velocity of the stimulating cathodic electrons on the law of decrease of phosphorescence of the ruby with time. Synthetic rubies were employed, with percentages of chromic oxide varying between 0·1 per cent. and 10 per cent. Curves for one ruby are given, showing the relation between the intensity of phosphoresence, voltage of the poles of the cathode tube, and fall of intensity with the time.—Mlle. Irène **Curie**: An arrangement for measuring strong ionisations due to the α-rays. The principle of the method consists in utilising for the ionisation current only a fraction of the α-rays. This portion is allowed to escape through sectors in a brass cover and the ratio of reduction, which can be varied, may be as high as $\frac{1}{1500}$.—M. **Volmar**: The action of light on the tartar emetics. Tartrates of the type $CO_2H . CH(OH) . CHO(RO) . CO_2K$, in which R may be antimony, arsenic or bismuth, are decomposed by ultra violet light, gas being evolved (carbon dioxide, carbon monoxide and hydrogen and hydrocarbons in the case of antimony), and metal deposited. Double tartrates of copper and of iron are also changed by exposure to light of short wave length.—Albert **Noyes**, jun.: The photochemical decomposition of solid bodies.—A. **Bigot**: Kaolins, clays, etc. Colloidal plasticity. Experiments on baking clay briquettes prepared in different ways, compression of dry powder, compression of slightly moistened powder, reduction to plastic state with water. The colloids play an important part in the results of firing ceramic materials.—F. **Zambonini**: Thorium molybdate, $Th(Mo O_4)_2$. An account of the mode of preparation, crystal form and molecular volume of thorium molybdate.—Pierre **Jolibois** and Pierre **Lefebvre**: Baking of plaster of Paris and its preservation in moist air. Plaster of Paris which has been dehydrated at temperatures between 150° and 300° C. rapidly absorbs water vapour from saturated air: if the dehydration temperature has been above 400° C. the rate of absorption of water vapour is very slow.—F. **Diénert** and F. **Wandenbulcke**: The estimation of silica in water. The method suggested is based on the colour developed by the addition of ammonium molybdate and dilute sulphuric acid, utilising a standard solution of picric acid as a colour standard.—Max and Michel **Polonovski**: Ethescrolene.—Ch. **Mauguin**: The arrangement of the atoms in crystals of cinnabar. The results of an X-ray study of cinnabar crystals.—Mlle. Gertrude **Weber**: The limit between the Danian and the Maestrichtian in the Crimea.—L. **Vegard**: The constitution of the upper layers of the atmosphere. In a previous communication on the spectrum of the aurora borealis it has been shown that nitrogen is the dominating element at the upper limit of the atmosphere. It is probable that the nitrogen is solidified in the form of small crystals, and that this nitrogen dust is charged electrically by the photoelectric effect of the solar radiation.—Henri **Coupin**: Remarks on the locomotion of the Oscillatoria.—H. **Colin** and H. **Belval**: The supposed reserve dextrins of Monocotyledons. A revision of the work of Leclerc du Sablon (1898–1899). The bulb of *Hyacinthus orientalis* contains no dextrin: the reserve carbohydrates consist of starch and a soluble levulosan only.—R. de **Litardière**: Remarks on the fixation of Merkel's liquid and on certain so-called nuclear structures provoked by fixing reagents with osmic acid base. An adverse criticism of the results of Overton on the somatic kinesis in *Podophyllum peltatum*, with special reference to the action of various fixing fluids.—Raphael **Dubois**: The toxicity of copper with respect to moulds. Remarking on a recent communication by M. and Mme. Villedieu on the non-toxic action of copper on moulds, the author directs attention to the fact that he arrived at a similar conclusion in 1890. An explanation of the undoubted beneficial effects of copper suspensions in fighting mould in the vine and other plants has still to be found, and it is suggested that since it has been shown that salts of copper may act both as oxydase and peroxydase, this may be the cause of the observed beneficial action.—Jivoin **Georgévitch**: New researches on the Goloubatz fly. From the heads of this fly a poisonous substance can be extracted by either water, alcohol, chloroform, or ether, and injections of this material proved rapidly fatal to guinea-pigs, rabbits, and white mice. Losses of cattle through the ravages of this fly have been unusually heavy this year in Serbia, Roumania, and Bulgaria.—Alfred **Maubert**, Léon **Jaloustre**, and Pierre **Lemay**: The influence of thorium-X on the catalase of the liver. Thorium-X acts on catalase from the liver, stimulating in small doses and paralysing in large doses. The action is due to the α-radiation.—René **Jeannel**: The origin of the entomological fauna of the Carpathians and of the Bihor mountains.—Pierre **Lesne**: A new appearance of *Leucotermes lucifugus*. A Strelitzia in the hot-house of the Natural History Museum at Paris has been found to have been seriously attacked by this ant.—Alphonse **Labbé**: The genesis of the nemato cysts of the nudibranchs.

Calcutta.

Asiatic Society of Bengal, May 2.—B. **Prashad**: Observations on the luminosity of some animals in the Gangetic Delta. Notes on the various methods of the production of light by different animals are given.—N. **Annandale**: Plant and animal designs in the mural decorations of an Uriya village. The designs discussed are painted on the walls of houses on an island in the Chilka Lake. They are mostly of a very simple nature, consisting of outlines in white chalk on a red background. The plants or parts of plants most commonly represented are the maize, the cocoanut, the sola plant, and the kadumba flower; the animals—ducks, peacocks, and fish. The last are always represented in pairs, forming a well-known Indian symbol. Other symbols such as the footprints of Krishna are combined with the plant designs.—Johan van **Manen**: on the 44th verse of the Dhammapada. Comparison of the Pali, Prakrit, Chinese, and Tibetan versions, with conclusions concerning "metaphysical punning" as an essential element of some of the earliest Buddhist utterances, ascribed to the Buddha himself.

University and Secondary Education.

AT the break of gauge between school and university some confusion and loss of time must be expected in a country where both systems are not subject to the control of a state department, and will be excessive unless the responsible authorities on both sides are in general accord as to aims and principles. In England the Board of Education has, during the past twenty years, worked steadily for such an accord and has provided machinery, such as the Secondary School Examinations Council, for making it effective. The report of the Committee on Natural Science in Education helped to focus attention on the subject.

This Committee held that it is desirable on educational and other grounds that boys who intend to pass on to a university should, as a rule, remain at school up to the age of 18 ; that a general course, which should include science work planned as a self-contained course of physics and chemistry with some study of plant and animal life, should be completed normally about the age of 16, when the First School Examination should be taken. This should be followed by two years of advanced work at school during which those specialising in science should continue some literary study and those specialising in literary study should give some time to science work. Then the universities should adopt such an examination as the First School Examination as the normal test for entrance, with such limitations or amplifications as they may find necessary, *e.g.* "credit" in a certain number of subjects or some measure of success in the Second Examination. It was also considered most important that university degree courses in pure science should be so arranged that students who come well prepared from secondary schools should not be put back to do elementary work.

The dovetailing (without wasteful overlapping) of two years of specialised study in the secondary school with the first year of university work presents certain difficulties. Endeavouring to guard against the mishandling of these difficulties, the Committee points out that it is undesirable that work of pupils between 16 and 18 should be disturbed by having to prepare for an examination (for example, the University Intermediate) not primarily designed to meet school needs ; candidates in a Second School Examination who do satisfactory work in any of the subjects required for the Intermediate should, therefore, be exempted from further examination in these subjects. This warning is emphasised in Sir Frederic Kenyon's report of conferences on secondary and university education between the Council for Humanistic Studies and the Conjoint Board of Scientific Societies. The following resolution was passed by the conference :-

"A clear distinction *in kind* between the first-year studies of a university in any faculty and the upper-form studies of a school is a fundamental principle of education. A school year should, therefore, in no case be reckoned as the equivalent of a university year, and the practice of allowing pupils to present themselves for a university examination, beyond the matriculation, before or upon entrance to a university is to be deprecated as confusing the educational functions of school and university and leading to an inappropriate type of teaching at both."

In the best secondary schools the science work is really on as high a plane in every respect as that done in the first year at some of the universities, and the staffs are just as well qualified. Pupils from such schools should be able to obtain exemption from the whole of the Intermediate examination: in other cases partial exemption is valuable as minimising the university student's pre-occupation with the business of preparing for examination. But the introduction of advanced courses in secondary schools ought not to be allowed to obscure the principle that work in those schools should be based on the mastery of fundamentals.

As to the results of neglecting this principle, a useful lesson may be learnt from the recent history of education in the United States, as interpreted by the president of the Carnegie Foundation for the Advancement of Teaching in his report for 1921–22. This indicates such confusion of aims and principles and, in consequence, waste, that by correlation and simplification of curricula the normal aggregate duration of studies in the elementary and secondary schools and the college of liberal arts could be reduced with great advantage to all concerned from 16 years to 12.

The typical American secondary school, known as the high school, was formerly called the "People's College," and gave an intellectual training quite comparable with that provided in the authentic college, which was itself little more than a secondary school. The courses were on parallel lines and were such as were deemed suitable respectively for pupils destined for trade and industrial occupations and for those who would enter the learned professions. From being parallel the high school by degrees became anterior to the college course. Hypnotised on one hand by the social prestige of the college for which it came to serve as a vestibule, and driven, on the other, to cater for the needs of pupils who ought to have been in trade schools, the high school became involved in an attempt to teach something of everything from typewriting to psychology. Meanwhile the colleges, although assuming some of the functions of the university, continued to give during the first two years of the college course what was really secondary education. Surveying the situation with special reference to the rate of increase, lately accelerated in the cost of education, the report deplores the results of the so-called enrichment of the secondary school curriculum:

"The high school of to-day has been transformed from a distinctively intellectual agency into one that offers instruction concerning every field of human knowledge, and assumes to provide training for every vocation and profession. . . . In the process the notions of sincerity and thoroughness in education have been displaced. . . . The striking characteristic of our schools under the process of enrichment of the curriculum is superficiality. . . . The total result is to present education and to present technical training as ends to be gained by superficial means. It would be difficult to find a graduate of our undergraduate colleges who knows his native language, who has read the books, or who has done the thinking, of the youth of eighteen who graduates from a German gymnasium, from a French Lycée, or from an English Public School like Eton or Harrow. . . . He knows almost nothing of intellectual discipline, and is neither able nor in the mood to bend himself heartily and effectively to a sharp intellectual task."

It is interesting to compare with this the notes written eighteen years ago by Mr. A. C. Benson, after twenty years' experience of teaching at Eton, on the system then prevalent in English secondary schools and colleges:

"We send out so many boys not only without intellectual life, but not even capable of humble usefulness . . . they have not had time to read any English to speak of . . . I would raise the standards of simple education, and force boys to show that they are working honestly . . . a few subjects thoroughly taught are infinitely better than a large number of subjects flabbily taught. . . . It is difficult to imagine a condition of greater vacuity than that in which a man leaves the university after taking a pass degree. . . . The education is of a contemptible, smattering kind; it is really no education at all. It gives no grip, or vigour or stimulus."

Since then this critic's conception of the principles and aims of secondary education have been widely adopted, and it is owing to the consequent improvement of British secondary school teaching that it can so well bear comparison with the American system, which seems to be now afflicted with some of the former vices of the British. But it would be a mistake to assume that these vices have been eradicated completely and for ever from the British system. They have their roots in human nature, and we must be on the alert to detect their revival. It is certain that attempts to give effect to the recent recommendation of the Consultative Committee of the Board of Education that a more prominent place in the ordinary curriculum should be assigned to æsthetic subjects will entail conditions favourable to precisely that illusive "enrichment" of the curriculum which has had such unfortunate results in America. The recommendation itself is well founded and, given teachers capable of an adequate conception of the meaning of art, whose æsthetic faculties have been adequately cultivated, nothing but good can result from its adoption, but circumspection is needed; art, like religion, is caught rather than learned.

In the February number of the United States publication *School Life* appears a somewhat detailed description of a type of school organisation adopted by certain "progressive" city school boards, notably in Detroit, Pittsburgh, and Akron, with the object of providing the varied curriculum and instruction by specialist teachers now generally demanded, while keeping expenses within reasonable bounds. The pupils spend half of each day in ordinary class-rooms or "home-rooms," where they are taught formal subjects—reading, writing, arithmetic, formal language, hygiene, and history—and the other half in special rooms or laboratories where they are taught by specialist teachers of science, art, music, literature, manual training or shop work, domestic science, etc. One of these rooms called the auditorium is devoted to co-ordinating all other work by dramatisations and other modes of expression, vocational guidance, and various devices for preparing pupils "for more complete living and the self-control and self-direction needed therefor." These "platoon" or "work-study-play" schools use all their rooms all the time, each of the teachers in the "home-rooms" having the care of two groups of pupils, one in each half of the day. Equipment is minimised and the cost of supplies lessened. Supervision is easier because fewer teachers are responsible for results in any one subject. "Properly directed, the platoon school epitomises socialised education."

Technology of Fuels.

American Fuels. By Dr. Raymond Foss Bacon and William Allen Hamor. (Mellon Institute Technochemical Series.) In 2 vols. Vol. 1. Pp. ix+628. Vol. 2. Pp. vi + 629-1257. (New York and London: McGraw-Hill Book Co., Inc., 1922.) 60*s.*

In the preface of this work the authors or editors, one of whom is a consulting chemical engineer of New York and formerly a director of the Mellon Institute, and the other the assistant director of that Institute, state that "they have attempted to condense into a series of specially prepared chapters the fruits of the experience of specialists, thereby placing in the hands of manufacturers, engineers, and chemists a composite book representing authoritative accounts of the fuels now regarded as technically important in the United States."

The immediate responsibility of the two authors is therefore limited, since other names are attached to most of the twenty-six chapters into which the work is divided. Most of these names guarantee a first-hand knowledge of the subject treated, and the editors "hope that the treatise will be found to give informative summaries of sound practice and the practical details which are generally not to be found in the literature." This method of treatment has both advantages and disadvantages. The book abounds with detailed information on all sorts of subjects connected with the treatment of fuel, and of apparatus designed for its utilisation, information of a quantity and quality which it would have been exceedingly difficult, if not impossible, for any one or two authors to provide. At the same time the number of subjects and appliances treated is so great, and their detailed consideration covers so much ground, that it has been impossible for the editors to maintain any attitude of appraisement or to reconcile what may be regarded as conflicting claims. To have done so would have been a very awkward task and would have lengthened the book unduly, although it must be remembered that, in consulting it for the purpose of making a selection of a process or apparatus, the reader will be called upon to do this for himself.

The editors say "some of the chapters have been written from the viewpoint of men who are enthusiastic advocates of the particular fuels treated," and reading the book will undoubtedly lead a discriminating reader to the same conclusion. The treatment awarded to some of the processes and appliances is such as one would expect to find in the correspondence of a well-informed agent, or in an intelligently prepared catalogue, and its appearance in a book of this kind is unusual. This is not said in a spirit of condemnation, but is intended to convey a warning, which may be necessary, to a reader who consults it in any expectation of finding the judicial statements on processes and plant to which we have become accustomed in the best of our technical literature.

Approached in the proper spirit, the book is undoubtedly one which can be made of very great service to everybody concerned with its subject-matter. There is, however, an aspect of this work to which some exception may be taken by those who look for well-balanced international treatment in scientific and technological writing. To some extent criticism from this point of view is disarmed by the title, but although fuels may be American, the technology of fuel is international and the scientific basis of that technology even more so. The authors cannot, however, be said to be very deeply imbued with this principle. The reader will reap some advantage from the process of selection which has taken place, inasmuch as this work will present to his notice much more fully the contributions to the science and practice of fuel technology which have been made by America than would have been possible in anything like the same compass if corresponding notice had been taken of contributions to the subject from other than American sources. Partly perhaps on this account, the scientific treatment of fundamentals is somewhat sketchy and inadequate. Here, again, if the book is approached with the full knowledge that it is primarily concerned with the setting out of American contributions to fuel technology and the treatment of American fuels (the latter according to title), little harm is done, and the many excellences of the book can be utilised to the full.

Reviewing the work more systematically, after a first chapter on "The Coals of the United States" (which includes a six-page table of analyses of representative coals), and a second on "The Principles of Combustion," we find a full and informing chapter on "The Technology of Coke," by F. W. Sperr, the chief chemist of the Koppers Company, Pittsburgh. This occupies 160 pages, and is well done, although it is charitable to suppose that the work of Sir George Beilby and others on the structure of coke during the last two years must have been published a little too late to allow of its consideration. A useful inclusion here is a summary on methods of sampling and testing. Briquetted or compressed fuels are treated next, and various processes are described, but when the author says that "there are no unsolved fundamental problems in briquetting practically any kind of material, especially in the field of fuel," and that "there is nothing that stands in the way of the design and construction of a briquetting plant to briquet any kind of coal," he will find many to question his judgment.

An excellent economic review of coal preparation raises a number of interesting questions, and in discussing power-generation and the possibilities of the turbine we are told that "higher efficiencies may be more readily obtained by using two vapors in series, such as mercury and steam. Mercury vapor has a much greater density than steam and a lower heat of vaporisation; hence the spouting velocity is low and it may be used in a high-temperature turbine of very simple design. A mercury turbine and boiler are being developed by the General Electric Co."

"The Gasification of Fuels," including that of low-grade fuels, is broadly treated by Mr. Coffin of the General Electric Co., and conveys a detailed description of a horizontal rotary gas producer made by the General Reduction Gas and By-Products Co., for which quite high thermal efficiencies are claimed, and the capacity to deal with most unpromising materials, such as anthracite slush containing 20 per cent. moisture and 25 per cent. ash, a mixture of coke breeze and slush containing 45 per cent. of ash, and sawdust. The statement is made that it has been found possible to make methane from blue gas synthetically in the presence of a nickel catalyser, but an expansion of the term "possible" would have been useful in this connexion.

In the chapter on the "Distillation of Coal at Low Temperatures" the excellent and comprehensive review of the history, theory, and practice of the low-temperature carbonisation of coal, which was submitted to the Society of Chemical Industry by Mr. Edgar C. Evans, has been printed in condensed form, and a number of processes are described in some detail. One of the most interesting chapters is on the use of finely divided fuel, the technique of this subject having been much more highly developed in America than in Great Britain. A chapter on "Fuel Oil and its Utilisation" is followed by one on "Colloidal Fuel," for which that well-known authority on the subject—Mr. Lindon W. Bates—has made himself responsible. Natural gas and producer gas technology are treated in turn, and we are informed that "lack of proper operating organisation has been the cause of many failures," and that "another cause is the over-enthusiastic salesman. Most producer projects look good on paper." There is a section on freak producers, and a summary which includes such prohibitions as "Do not employ an engineer who has never made a mistake on producer gas work," and "Do not lose your nerve after the first six months of operation."

Water-gas does not receive anything like so much attention as might have been expected in an American work of to-day, and although some costs are given there is no satisfactory thermal or chemical analysis of the process.

The chapter on "Blast Furnace Gas" is short, but useful. It is followed by one on the Dayton process, little known in Great Britain, which is essentially an air-oil-gas process in which partial combustion of the oil with air takes place within the retort, thus supplying internally the heat necessary for the thermal decomposition of the hydrocarbons. The need for external heating is thereby minimised. The nitrogen of the air used is, of course, present in the gas made, which may be of various grades. It is stated that approximately 4 gallons of fuel or gas oil is required for the production of 1000 cu. ft. of 450 B.Th.U. gas. A statement which would require very serious examination before acceptance is that "theoretically it has been found, and under practical conditions of industrial operation it has been proved, that Dayton gas of 450 B.Th.U. per cu. ft. is required in no greater *volume* than illuminating gas of 630 B.Th.U. per cu. ft. for the same work." The metal retorts used seem to undergo rather drastic treatment, and it would be interesting to know their length of life.

The chapter on "Surface Combustion," by Mr. A. E. Blake, reports mainly progress obtained with the impact type of burner, and is followed by one on the "Future of the Artificial Gas Industry," and by others of a general character, such as "Fuel Conservation," and "Some Problems in the Utilisation of Fuel," both these making interesting reading. An appendix deals with methods for the analysis of coal and fuel oils.

The book is well printed and generously illustrated throughout. It is certain to be very useful, not only in America but also in other countries, particularly if read with the discrimination suggested above.

John W. Cobb.

The Teaching of the Calculus.

Common Sense of the Calculus. By G. W. Brewster. Pp. 62. (Oxford: Clarendon Press; London: Oxford University Press, 1923.) 2*s.* net.

From time to time in recent years, small books have appeared which would be more or less correctly describable under the title "How Not to Teach the Calculus." We are sorry to find the present volume to be no exception to this rule, at least in its methods of treatment of infinitesimals.

Its main peculiarity is the way "quantities of the second order" crop up continually, and the way in which readers are led to believe that it does not matter much whether these are put in or left out. The main advantage of this kind of treatment is that students who have neglected their class-work and absorbed such a book for their examination are easily detected by their examiner, as they are certain to do something against which they were warned in class.

If we take $y=x^2$ and define δy as the difference between x^2 and $(x+\delta x)^2$ we undoubtedly get

$$\delta y = 2x\delta x + \delta x^2.$$

But surely it would be more in accordance with most people's ideas of common sense if instead of bringing in the notion of "second order quantities" the author had pointed out that this δy represents the change taking place in the value of the square in an interval which *begins* with the value of x and continues for a distance δx *beyond* that value. It would also surely be easier for a student to see that the *greater* the interval δx the more does this variation fail to give a correct idea of the manner in which the function was varying round about the instant that it passed the value x. Also, as the term δx^2 *increases* in relative importance when δx is made *larger*, it would not be difficult for a reader to infer that this squared difference represents the *error* introduced by measuring the change in a *finite* interval situated all on *one side of* the value x.

In fact, instead of being small quantities which may be included or omitted in this way, these "second order quantities" are really rather of the nature of *errors* which *must* be taken off if we wish to study a continuous process closely at every instant. For example, they represent the correction that would have to be applied to obtain the velocity of a train *at* any instant from the average velocity in an interval of one, two, or more seconds *after* that instant.

Now, it is customary among mathematicians to use δx to denote a finite variation in which second-order quantities may be involved, and dx to denote the limiting form. But Mr. Brewster in his preface says, "The difference between any two values of x is an easy idea to grasp, and the use of δx or dx (it does not matter much which) emphasises the fundamental meaning of a differential." . . . "My advice would be to regard dx and δx as the same thing provided δx is taken very small, and to be satisfied with a common-sense explanation of the omission of terms of the second order." And on p. 23, speaking of dy/dx and $\delta y/\delta x$, he says, "You can get on quite well without bothering to distinguish between the two."

Again, surely it would be more in accordance with common sense if some account were also taken of what happens to a function *before* the variable reaches the given value x, and if this were done with the function x^2 we should get a second value of the variation, say

$$\delta^1 y = 2x\delta x - \delta x^2.$$

The differential equation $dy=2xdx$ has now a precise meaning, as it describes a variation which always lies intermediate between the first and second estimates, however small the interval δx. As a matter of fact, fluctuations in statistics, such as increases of population, rise or fall of stock exchange quotations, *are* always and *must* always be estimated by comparing the value on any day or year with a *previous* value.

The same mistake is made in dealing with integration as applied, for example, to areas. Mr. Brewster's figures replace the actual area of a curve by a series of rectangles the *left-hand* sides of which are ordinates of the curve. Why does he not try taking the right-hand sides as well? If he would only shove his rectangles one space to the left, taking off the first and adding one at the end, he would have spared all his arguments by showing that the true area lies between two limits the difference of which can be made as small as we like by making the slices thin enough.

There is undoubtedly a great demand for a book that will introduce the notions of a differential coefficient and an integral and illustrate them with applications not involving any other functions than series of positive integral powers. So far as relates to selection of subject matter in the form of examples and applications, "Common Sense of the Calculus" exactly meets the case. We should be glad if Mr. Brewster would republish this collection based on a different method of dealing with infinitesimals. He would probably find that instead of making his book larger it would be possible even to make it *smaller*. The "terms of second order" which give so much trouble in this treatment can be got rid of completely by adopting the definition of "limiting equality" mentioned in a letter to NATURE of February 10, as the interpretation of such formulæ as $dy=f^1(x)dx$. "Zero" is a dangerous quantity to put in the hands of a beginner, and so are quantities which "may be neglected," and it was only a year ago that we had a student trying to take mathematical honours who said that two quantities da and db were "of the same order, therefore they are equal"! On the other hand, we have found it possible to condense into five or six pages of stencilled notes all the information required to explain differentiation and integration and to introduce such differentials as dx, dy, ds, dr, $rd\theta$, $\frac{1}{2}r^2d\theta$, and even $dx\,dy$ and $dx\,dy\,dz$ in a form in which finite quotients and sums of products can be built up in perfect safety, second-order quantities being tabooed, but $ds^2=dx^2+dy^2=dr^2+(rd\theta)^2$ being legitimate. A recent paper by Prof. Alfred Lodge in the *Mathematical Gazette* evidently is based on the same principle.

G. H. B.

Christopher Wren and the Tom Tower.

"*Tom Tower,*" *Christ Church, Oxford. Some Letters of Sr Christopher Wren to John Fell, Bishop of Oxford.* Hitherto Unpublished. Now set forth and Annotated by W. Douglas Caröe; with a chapter by Prof. H. H. Turner, and another by Arthur Cochrane. Pp. xii + 127 + 28 plates. (Oxford: Clarendon Press; London: Oxford University Press, 1923.) 25*s*. net.

THIS book was published in honour of the bicentenary of Wren's death on February 25. The author had been called upon to direct some necessary repairs to the buildings of Christ Church College, particularly to the "Tom Tower," when his attention was directed to some unpublished letters and documents dealing with the original design and building of the tower, and these have now been published in the present volume. In addition to a contemporary copy of the contract between the College treasurer and the contractor for the building of the tower, there are seven autograph letters written by Wren to John Fell, Bishop of Oxford, the first dated May 26, 1681, and the last September 9, 1682, when the work was nearing completion. The last letter is reproduced in facsimile, showing Wren's firm and very distinct handwriting.

An analysis of each letter follows, and Prof. H. H. Turner has supplied a commentary to the sixth and most interesting one. This letter (dated from Whitehall, December 3, 1681) is a reply to a proposal on the part of the bishop, that the tower should be converted into an observatory. Wren is too polite to reject the proposal altogether, but gives good reasons why it should not be hastily adopted. It would involve a change in the whole design; the bell would have to be lowered so as to heighten the loft, and it might then not be well heard. The Gothic roof, agreeing with the rest of the College buildings, would have to be abandoned, and a flat roof with a horizontal balustrade substituted, while instead of windows there would have to be wooden shutters without mullions or bars. In addition to these objections from the point of view of an architect, Wren next produces others from the point of view of an astronomer, and here also he could speak with authority, having held the office of Savilian professor of astronomy for twelve years (1661–73) until pressure of other work obliged him to relinquish it.

"Give me leave to add that such a room as this will be when built, is no way necessary for observations, as now they are managed. Were I to set up the Trade again I was once well acquainted with, and I think the world doth or may justly own some improvements of it to me, I should require nothing else but these things. First a large mural quadrant fixt to a wall truly built in the meridian, and this is best in an open court or garden, 2dly a pole to raise large telescopes and manage them, and the like place is properest for this also. 3dly a quadrant to take distances fixt to a foot so as it may turn to all sort of planes . . . must be housed for its better preservation, but the best house will be a little house of boards and no other roof but what may be taken quite off when the instrument is used. . . . We built indeed an Observatory at Greenwich not unlike what your tower will prove, it was for the Observators habitation and a little for pomp; it is the instruments in the court after the manner I have described which are used, the room keeps the clocks and the instruments that are laid by."

This statement as to what an observatory ought to be like is very interesting, as showing that Wren thoroughly agreed with Flamsteed about the requirements of practical astronomy. Therefore Oxford did not get an observatory on this occasion (there were only two University Observatories in existence at that time, at Copenhagen and at Leyden), and nearly a hundred years had to pass, before the Radcliffe Observatory was built, including a very big tower!

Mr. Caröe devotes a chapter to "Wren and Greenwich Observatory," but the contents are nearly all taken from Baily's book on Flamsteed. That Wren designed the Octagon room seems certain, but he had nothing else to do with the building or the equipment of the Observatory. This chapter is illustrated by two plates giving most interesting views of the buildings and of the interior of the Octagon room, copied from some old engravings given by Baily to the Royal Observatory. It seems, however, very doubtful whether the telescope for observing sun-spots by projection and the large quadrant (Plate XXI.) can have been at Greenwich in Wren's time; at least it is not likely that the quadrant is the 10-foot quadrant made by Hooke and declared by Flamsteed to be useless. But if Wren had been able to devote some of his time to astronomy, he would doubtless have made his mark in that science. It should not be forgotten (we have not found it mentioned in the book under review) that Wren (as well as Hooke and Halley) had realised independently of Newton, that attraction if it existed must be according to the law of the inverse square of the distance, and this was expressly acknowledged by Newton (Princ. lib. I. Prop. IV. Scholium). The silly and slanderous accusation of plagiarism made by Hearne the antiquary against Newton, in favour of Hooke and Wren, should not have been quoted by the author (p. 11) without comment.

The book is beautifully and most profusely illustrated and will appeal to many different classes of readers.

J. L. E. D.

The Future of Arctic Lands.

The Northward Course of Empire. By Vilhjalmar Stefansson. Pp. xx + 274 + 8 plates. (London and Sydney: G. G. Harrap and Co. Ltd., 1922.) 7*s.* 6*d.* net.

MR. STEFANSSON shows, with characteristic force of expression and wealth of example, that every effort to colonise the frontiers of the familiar world has been retarded by fear bred of ignorance. He regards the popular repute of the Arctic regions as a survival of the ancient shrinking of the Mediterranean peoples from cold and darkness, intensified by tales of the sufferings of explorers, which he holds to have been partly unnecessary and partly exaggerated. On the other hand, he shows that throughout the whole history of civilisation the centres of political power of the most advanced races have undergone a steady displacement northward from the neighbourhood of the tropic. He holds that this migration of the dominant races is accompanied by an increase in physical and mental vigour, and he would perhaps be inclined to agree with Richard Chenevix's bold generalisation of ninety years ago, that character is expressible as a mathematical function of latitude.

Mr. Stefansson indicates that the natural northward course of civilisation is now being held up by a superstitious tradition maintained by faulty educational works based on misleading narratives of polar travel. He insists on the fact that Montana, Dakota, and Manitoba are far colder in winter than the low-lying coasts and islands of the Arctic Sea or the North Pole itself. Yet in these far severer climates children go to school daily in temperatures that a polar explorer is very rarely called upon to encounter, so that cold need not deter a sturdy people from moving north.

The main object of the book is to combat this specific ignorance of polar conditions, and Mr. Stefansson enters on the struggle with Berserk gusto. He firmly believes that, even after the mineral resources of Arctic lands—*e.g.* the gold, coal, copper, iron, and oil of Alaska and Northern Canada—have been exhausted or have at least lost their sensational attractive power, there remains a vaster and more permanent source of wealth for the outer world to draw upon in the incredible richness of millions of square miles of Arctic meadows. These are grazed over by herds of reindeer and ovibos, capable of forming the basis of the largest meat and wool production the world has ever seen. In fact, the author goes so far as to hold that Arctic meat alone can furnish a safeguard against famine on an unheard-of scale when the population of the world has doubled itself a century hence.

The facts cited as to the growth of reindeer herds in Alaska, and the popularity of reindeer flesh in large cities, are most impressive, and the prospects of the Hudson Bay Company's experiment in rearing the ovibos (its old name of musk ox is banned) in Baffin Land appear to be extremely favourable. Mr. Stefansson points out that the failure of farmers in northern lands has almost always been due to their attempts to introduce plants and animals natural to southern localities, whereas success as surely attends their efforts when they devote their attention to those native to the climate.

An interesting chapter is devoted to the prospects of Polar travel by aircraft and submarines, and it would almost appear that the adventures of Capt. Nemo under the ice in Jules Verne's old story were coming true. Mr. Stefansson is usually careful to base his calculations and projects on established facts and the opinion of experts; but we fear that in one point he has failed to do so, and we cannot accept his prediction on p. 186, that "ordinary tramp steamers" can ever navigate the ice-encumbered Arctic waters. Mr. Stefansson wants to provoke controversy and inquiry with regard to the grounds of his faith in the future of the North, and the vigour, resourcefulness, and good humour of his propaganda should make even his critics his friends, for every one likes a strong man in pursuit of a great idea. HUGH ROBERT MILL.

Our Bookshelf.

Occultism and Modern Science. By Prof. T. Konstantin Oesterreich. Translated from the second German edition. Pp. vii + 181. (London: Methuen and Co., Ltd., 1923.) 6*s*. net.

PROF. OESTERREICH's book is intended to be a popular presentation to the German public of the evidences of "occult" phenomena, which are fairly well known to English-speaking people. He points out that this field of knowledge has been little cultivated in Germany, and, with great impartiality, places such facts as have been observed before his readers. He examines the cases of Helene Smith, Mrs. Piper, Palladino, and Eva C. in detail, and arranges his phenomena under the heads of states of impersonation, psychometry, cross-correspondence, telekinesis, and materialisation. His conclusions are adverse to spiritism; but, on the evidence, he seems to have no doubt of the occurrence of the phenomena in question, though there is no indication in the book of any first-hand acquaintance with the subject. Indeed, there is a lack of judicial balance in the admission of the evidence. Crawford—though the facts were clearly not known to Oesterreich when this work was written—is cited as an authority for telekinesis and materialisation. The introduction is remarkably good, as is the general plea for scientific examination without prejudice of the facts; but the chapter on theosophy has little connexion with the rest of the book, and rather marrs it by the personal note with regard to Rudolf Steiner which it introduces.

Department of Scientific and Industrial Research: Food Investigation Board. Special Report No. 15 *by the Engineering Committee of the Board. Insulated and Refrigerator Barges for the Carriage of Perishable Foods.* Pp. iii + 21. (London: H.M. Stationery Office, 1923.) 1*s*. net.

WHILE in normal circumstances the barges thermally insulated with four inches of cork at present used in Great Britain for the conveyance of perishable food such as frozen meat from the importing ship to the quay or cold store are found to be adequate, conditions arise in practice under which they fail. This report will serve as a valuable guide to those who wish to provide something better. It is shown that the ordinary insulated barge is only satisfactory for 48 hours if the frozen cargo is well packed, so that its rise of temperature owing to its having to cool the barge may be as small as possible, and if the temperature of air and water do not exceed 50° F. If the barge can be pre-cooled to 20° F. it is adequate under the same temperature conditions for 96 hours. If the temperature of air and sea water rises above 70° F., the barge, even when pre-cooled to 20° F., will only prove effective for about 40 hours, and if it is to carry its cargo longer it must be provided with refrigerating machinery. In one experiment with a barge so equipped a cargo of frozen meat was carried for seven days without its temperature rising more than 3° F.

Electric Transients. By Prof. C. E. Magnusson, A. Kalin, and J. R. Tolmie. Pp. viii + 193. (New York and London: McGraw-Hill Book Co. Inc., 1922.) 12*s*. 6*d*.

THIS book was primarily written for the electrical engineering students of the University of Washington. It discusses in detail many of the transient phenomena which ensue whenever any of the electric "constants" of a circuit suddenly alters in value. Excellent oscillograms are given, the study of some of which will be of value to advanced students. As a rule, the transient quiver induced in the current wave by a sudden disturbance of the circuit dies away rapidly. In some cases, however, it attains excessive values and does damage. In a few cases it is continually in evidence, as, for example, when an electric arc forms part of the circuit. The question of "transients" therefore needs to be studied carefully by electrical engineers. The introduction is rather too condensed. For example, we are told that the Ohm's law of the dielectric circuit is that the dielectric flux equals the voltage divided by the elastance of the circuit. The elastance is the reciprocal of the condensance. The former is measured in "darafs" and the latter in farads. It is not easy to picture what the authors mean, as apparently the cross-section of the dielectric circuit is constant.

Surface Tension and Surface Energy and their Influence on Chemical Phenomena. By Dr. R. S. Willows and E. Hatschek. (Text-books of Chemical Research and Engineering.) Third edition. Pp. viii + 136. (London: J. and A. Churchill, 1923.) 6*s*. 6*d*. net.

THE study of "Surface Tension" has been modified profoundly by the conception of oriented molecules which was introduced by Langmuir in 1917, and has since been developed on a rigid quantitative basis by the researches of N. K. Adam. These new developments are described and discussed in the new edition of this work. The fact that the subject is treated from the physical rather than the chemical point of view increases the value of the book as a contribution to physical chemistry, since it leads to the introduction of information which is not usually available in books written by chemists.

Intelligence Tests and School Reorganization. By Lewis M. Terman and others. Prepared as a Subcommittee Report to the Commission on Revision of Elementary Education, National Education Association. Pp. viii + 111. (London, Calcutta, and Sydney: G. G. Harrap and Co., Ltd., n.d.) 4*s*. 6*d*. net.

A USEFUL little set of monographs on the use of intelligence tests. Chapter 3—"Methods of Individual Instruction in the Adjustment Rooms of Los Angeles"—by A. H. Sutherland, is perhaps the most valuable, as indicating a means of securing the incentive of personal interest in acquiring information in the case of backward children.

Letters to the Editor.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, nor to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

Dr. Kammerer's Experiments.

As I had the privilege of entertaining Dr. Kammerer in my house when he was passing through London, and of discussing his experiments with him, and as I acted as his interpreter when he replied to his critics at the meeting of the Linnean Society, space may be permitted me in which to reply to the criticisms of Mr. Cunningham which appeared in NATURE of May 26, and to those of Dr. Bateson in the issue of June 2.

I will deal with Dr. Bateson's remarks first. From his speech at the Linnean Society I gathered that Dr. Bateson completely withdrew his charges of bad faith on the part of Dr. Kammerer, and accepted his published results as genuine, claiming, however—as he had the full right to do—to differ from the deductions which Dr. Kammerer drew from them. But Dr. Bateson's letter reads like a prolonged imputation of fraud to Kammerer; he refers to Dr. Kammerer's illustrations as like "spirit photographs," and demands further evidence before he will base any conclusions on Dr. Kammerer's work. Now, Dr. Kammerer explained at the meeting that the specimens shown by him constituted the salvage of the utter wreck of the experimental laboratories at Vienna owing to the War. His work has been going on since 1900—the year in which, unless I am mistaken, Dr. Bateson began his Mendelian work—and, in my opinion, the work has yielded results which are of as much importance in the study of heredity, from the evolutionary point of view, as all the Mendelian experiments together.

The main point in Dr. Bateson's letter is, however, that the specimen of Alytes shown by Dr. Kammerer to the Linnean Society did not show a typical "nuptial pad" (*Brunstschwiele*), and that the alleged pad was in the wrong place, because it was only the back of the hand which came in contact with the body of the female, so that the rugosities should be there and not on the palm; further, that a typical nuptial pad showed papillæ, and that he could not see them in the specimen. In proof of his assertion that the normal contact between male and female takes place with the dorsal surface of the male hand, Dr. Bateson publishes a print from a photograph of a pair of *Rana agilis* killed in the nuptial embrace. I ought to add that he was kind enough to send me privately a positive of this photograph, which shows his point more clearly than the print in NATURE.

Let us deal first with the structure of the horny patch. Dr. Bateson omits to say that at the meeting a section through one of these patches was shown under the microscope, and that, when the point of structure was raised in the discussion, Dr. Kammerer thought it too frivolous to reply to; he merely referred to the section which he had exhibited as answer. Dr. Kammerer, who has cut sections of the nuptial pads of all our common Anura, and can detect the species by the appearances shown by the microscopic preparation, assumed a similar knowledge on the part of his audience—but, to judge from Dr. Bateson's letter, he was rash in doing so. I have, however, taken the trouble to refer to Lataste's original figures of the callosities ("Mémoire sur les brosses copulatrices des batrachiens anoures," *Annales des Sciences naturelles*, 6me series, vol. 3, 1876), and I have no hesitation in saying that the section shown in the Linnean Society displays almost exactly the same appearances as those figured by Lataste in the figure of a section through the nuptial pad of the closely allied genus Pelodytes. Further, I have had sections through the nuptial pad of *Rana temporaria* prepared in my laboratory, and I can see in them the same structures as were shown in Dr. Kammerer's slide; of course, in Rana, as Lataste's figures show, the papillæ are very strongly developed—much more so than in Pelodytes or Alytes—but the essential structure is the same. The pad in Rana, to the naked eye, looks like a simple patch of pigment, and passing my finger over it I could not detect the papillæ by feeling.

As to the position of the pad, Dr. Bateson seems to think that he has settled this question *for all Anura* by his photograph. Now Alytes belongs to the small family of the Discoglossidæ, probably the most primitive family of the Anura. This family includes, besides Alytes, the genera Discoglossus, Bombinator, Pelodytes, and Pelobates. Boulenger, in his monograph, "The Tail-less Batrachians of Europe" (Ray Society, 1897), gives details of the position of the pads:

(1) Pelodytes, on the *inner side* of the two inner fingers—the antibrachium, the brachium.

(2) Discoglossus, on the *inner* and upper side of the three inner fingers.

(3) Bombinator, on the *inner* side of the three inner fingers and the antibrachium.

(4) Pelobates, copulatory excrescences absent.

The fact is that the primary contact between male and female takes place neither with the dorsal nor the ventral surface of the hand, but with the *radial edge*, and this is in accordance with Dr. Kammerer's experience; for in Alytes the pad first appears here, as shown in Dr. Kammerer's figures[1] (those criticised by Dr. Bateson in NATURE of July 3, 1919), and only later extends to the other fingers. In tight embrace, as indeed Dr. Bateson's photograph shows, the hand of the male becomes embedded in a fold of the female's body, and it is then a question of the direction in which pressure is exerted whether the additional callosities will appear on the inner or on the upper sides of the fingers. Perhaps I may add that the specimen shown in the Linnean Society had been previously exhibited at Cambridge, where it was inspected by Dr. Gadow, probably the best herpetologist at present living in Britain.

Dr. Gadow raised none of Dr. Bateson's objections, but he added the extremely interesting information that in the Portuguese species, *Alytes cisternasii*, old males occasionally develop callosities on the tips of the two inner fingers.

Dr. Bateson refers to Dr. Kammerer's reply "as disquieting to his disciples," since Dr. Kammerer stated that he did not regard the nuptial pad as an adaptation. I fear that my translation of the reply must have been singularly defective if Dr. Bateson drew any such conclusion. Dr. Kammerer's reply was that while, of course, the pad in Alytes was the revival of an ancestral nuptial pad, he had not made up his mind with certainty as to the *stimulus* which had revived it (*i.e* whether it was pairing in water or the contact with the female). He did not allude to the stimulus in his lecture, and only with caution and reserve in his paper. The tight embrace necessary to hold a slippery partner seems to me,

[1] After consulting with Dr. Kammerer, it is obvious to me that Dr. Bateson mistook a patch of dirt adhering to the fourth finger of the specimen shown in these figures for the pad.

however, as it does to Dr. Kammerer, the most likely explanation; and as the male is frequently smaller than the female, this may lead to a deeper embedding of his hand in her flank and a larger area of contact, and thus to an extension of the callosities.

Since the pad only appears on males in the third generation after they have begun to pair in water, and then in the same place as it appears in Pelodytes and Bombinator, to suggest that it is not a functional adaptation but a chance mutation throws a singular light on what I may term the constitution of the Mendelian mind.

Turning now to Mr. Cunningham's letter in NATURE of May 26, I find that he criticises Dr. Kammerer's experiments on Salamander and Ciona. Taking his remarks on Salamander first, he has misunderstood Dr. Kammerer's reference to the ovary of the Salamander as being enclosed in a membrane, while that of the bird is not. It really does not assist in the controversy for Mr. Cunningham to accuse Dr. Kammerer of childish mistakes which would disgrace a first-year student in biology. Translating Dr. Kammerer's statement into modern technical language, it reads thus: "The ovary of the Salamander is completely invested by peritoneum and suspended to the back by a mesentery" (a fact which I have verified), "whereas the ovary of a bird is covered only on its ventral surface by peritoneum and is largely retroperitoneal, and therefore more difficult to remove in its entirety."

Next, Mr. Cunningham refers to Dr. Kammerer's Mendelian experiments with naturally and artificially striped Salamanders and the "forma typica." It is indeed disquieting to find so sound a Lamarckian as Mr. Cunningham so much under the influence of what I may term Mendelian dogmatism as to suggest that because the artificially-striped Salamander does not "Mendelise" when crossed with "typica," therefore the character is not gametic or hereditary! Truly a vicious circle of thought: the test as to whether a character is hereditary or not is surely whether or not it can be transmitted to the offspring.

I agree with Mr. Cunningham that Dr. Kammerer's results in Mendelising and in ovarian transplantation are extremely unexpected, and I may add that Dr. Kammerer himself did not expect them, and frankly admits that he has been unable to frame an explanation for them which is satisfactory to himself. I will not waste space by attempting to suggest an explanation, but I will refer Mr. Cunningham to Dr. Kammerer's long paper, where full details are given. I think he will find that the results are such that it would be difficult for mistakes to be made, and therefore, unless Dr. Kammerer is to be charged with deliberate bad faith, they must be accepted.

Dr. Kammerer regarded his experiments on Ciona as affording the clearest proofs of the inheritance of acquired characters. He showed photographs of his results. Mr. Cunningham objects that no photographs of the controls, *i.e.* of ordinary adult specimens of Ciona, were shown, in spite of the fact that Dr. Kammerer stated at the meeting that the experiment had been conducted on 100 specimens, and that, of course, controls had been made—that, indeed, the establishment of controls was the A B C of experimental science. I think that Mr. Cunningham, on reflection, will see that by this attitude he is joining the ranks of those who seek to escape from the inevitable deductions to be drawn from Dr. Kammerer's results by accusing him of deception, and this is an attitude with which none of us who had the pleasure of meeting Dr. Kammerer and seeing his specimens and discussing matters with him would have any sympathy.

E. W. MACBRIDE.

Law governing the Connexion between the Number of Particles and their Diameters in grinding Crushed Sand.

THE discovery of a simple law relating to continuity of particle size in fine grinding (or the breaking up larger into smaller particles) has long been a matter of scientific and technical importance. By means of experiments extending over some years, the British Portland Cement Research Association has definitely ascertained that, so far as a crystalline substance such as "standard sand" is concerned, a definite law does undoubtedly exist, which may be defined mathematically as follows:

In a given weight of W of finely crushed sand, if N be the number of particles of diameter x and if N and x be considered as variables, then in every case so far tested

$$N = ae^{-bx}, \qquad (1)$$

where a and b are two constants characteristic of the particular sample tested.

Differentiating (1) we obtain:

$$\frac{dN}{dx} = -b \,.\, ae^{-bx} = -b \,.\, N. \qquad (2)$$

In other words, *the rate of increase with decrease of diameter, of the number of particles present of any given size is proportional to the number of particles of that size.*

It is therefore possible to calculate the number of particles of any given diameter without going through the laborious process of sieving.

Another result of this law is that it now becomes possible to calculate exactly the theoretical amount of work required to produce powders of different degrees of fineness, and in that way do for the art of grinding what has long since been done for steam and electricity, namely, reduce grinding to an exact mechanical science. In other words, just as the engineer knows the amount of electrical energy or steam necessary to perform a given amount of work under definite conditions, so also he will in future be able to estimate the amount of work required to reduce a given material to a given degree of fineness under given conditions. It will thus be possible to deduce the efficiency of any grinding machine. These and other matters will be gone into in a paper now in preparation, in which the experimental details will be fully described.

The physical significance of this law is simple.

Consider a set of sand particles A (Fig. 1). By *grinding*, *each* of the particles A gives rise to the same number k (in our illustration $k = 2$) of smaller particles B, each of which in its turn gives rise to the same number k of still smaller particles C, and so on *all down the scale so far as we can pursue the matter by means of the microscope, with the ultimate production of colloidal particles.*

The law is probably the expression of the fact that crystals have a definite and fixed structure, and consequently break up when subjected to percussion or pressure in a regular and definite manner, which follows a definite mathematical law when the number of particles considered are sufficiently numerous to allow of the application of the law of probability.

The subject is of great scientific interest. For example, there is an obvious thermodynamical connexion between the work done in grinding (*i.e.* producing small particles from large ones) and the amount of heat required theoretically to *gasify* the material. For—considering the simplest possible case—in gasifying a homogeneous solid material (without passing through the intermediate liquid state) we are merely reducing the material to particles of molecular dimensions and separated by distances beyond each other's sphere of molecular attraction. Whereas in ordinary grinding the same action is performed but the particles remain of considerable size. It follows from this that a homogeneous crystalline substance such as the diamond—which requires a large amount of heat and a high temperature to gasify—would be expected to require the expenditure of more work in reducing it to a certain fine state of division than a substance like ice (supposed kept at a temperature below freezing-point of water), which can be comparatively easily gasified.

This aspect obviously opens out a large field of research until now quite untouched; for example,

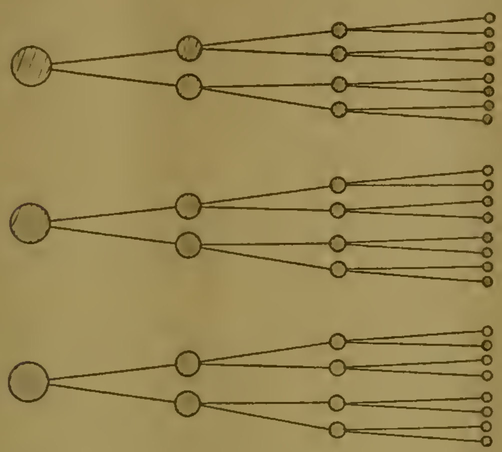

FIG. 1.

there exists a large number of organic crystalline compounds of which the heats of volatilisation are known, and the action of which under percussion or pressure could be investigated from this point of view.

The research work carried out has already proceeded sufficiently far to allow one to hope that in the near future the art of "grinding" will be transferred from its present chaotic state of empiricism into that of an exact science. The importance of this development in the gold-mining, pigment, and other industries—which depend so largely upon the production of materials in a state of fine division—will be apparent when we reflect on the great advances which occurred in the electrical and steam engineering sciences when the underlying laws were worked out.

Adsorption and Hæmoglobin.

ONE fundamental difficulty in the hypothesis that oxygen and carbon monoxide are "adsorbed" by hæmoglobin lies in the highly specific nature of the absorption spectrum of the compounds so formed. The change in colour of reduced blood, or of a dilute solution of reduced hæmoglobin, when shaken with air or oxygen, is very obvious to the naked eye, as also is the change when the oxygen is replaced by carbon monoxide. These colour changes can be used, either as in Haldane's method with direct vision, or as in Hartridge's by the spectroscope, for the exact quantitative measurement of the amount of gas taken up. Such remarkable, definite, and highly specific changes in the absorption spectra have no parallel, so far as I am aware, in any well-authenticated case of adsorption (unless the phenomena of electrolytic dissociation be classed as such), and must be explained by any theory, as of course they are by that of a specific chemical change in the nature of hæmoglobin by its combination with gas.

Sir William Bayliss, in his letter to NATURE of May 19, p. 666, and elsewhere, argues that the "widely divergent results obtained by different investigators of the heat of combination between oxygen and hæmoglobin" have not been adequately explained. The explanation really is simple, experimental error. If the solutions, or the blood, be reasonably aseptic, if due attention be paid to the carbon dioxide driven off when oxygen passes in, and if the observations be made with sufficient care and criticism, divergent results are *not* obtained. Any theory can be confused by imperfect experiments.

Again, Sir William Bayliss states that "in connexion with the relations between hæmoglobin and carbon dioxide, no proof has yet been given that the union is of a different nature from that with oxygen." Several such proofs exist: (*a*) it can be shown that nearly all, if not all, of the CO_2 taken up by blood at small CO_2 pressures (*i.e.* within the "physiological" range) exists there as actual bicarbonate (HCO'_3) ions; no other reasonable explanation is possible of the manner in which the hydrogen ion concentration of blood varies with CO_2 pressure; (*b*) the reaction of blood with CO_2, over the same range of CO_2 pressures, produces no change whatever in its absorption spectrum; (*c*) as the CO_2 pressure is increased the amount of CO_2 taken up does not approach a maximum in the same definite manner as does the amount of oxygen when the pressure of the latter is increased; neither is there any such precise relation between the Fe and the CO_2 as between the Fe and the O_2 or CO; (*d*) the effect of CO_2 on the hæmoglobin-CO reaction is precisely equal to that of a change of hydrogen ion concentration, exactly equal to that produced by the CO_2 but set up by another acid, such as HCl; in other words, the total effect of CO_2 on the hæmoglobin-CO reaction is exactly equal to that due to its acid character, which leaves no margin at all for any specific effect of CO_2 in turning out CO; in contrast to this, the considerable effect of oxygen on the same reaction is certainly not due to any change of hydrogen ion concentration produced by the oxygen, for (provided the hæmoglobin be kept saturated with CO and O_2) this change is *nil*; (*e*) the effects (i.) of oxygen and (ii.) of CO_2 on the combination of hæmoglobin with carbon monoxide are quantitatively quite different; (*f*) the effects of carbon monoxide on the reactions of hæmoglobin (i.) with oxygen and (ii.) with CO_2 are also different.

Sir William Bayliss affirms that "sometimes . . . workers are so convinced that the mass action view is all that is necessary, that they are not interested in testing the truth of the assumption." I can assure him that at least ten active workers of my personal acquaintance are "sometimes" very much interested, and indeed have recently applied the most stringent and searching tests to the view that the combinations of hæmoglobin with oxygen and carbon monoxide are in the ordinary sense of the word, chemical, and obey the usual laws of chemistry. The accepted manner of "testing the truth of an assumption" is to make theoretical (and preferably quantitative) deductions from it, and then to see if, and how far, these deductions are verified experimentally. This is being done repeatedly with the chemical theory of the dynamics and statics of the hæmoglobin reactions. If only those who believe in the adsorption theory would make some precise deductions from their theory, it would be easy to test that also. At present it evades any quantitative trial.

Attempts have been made to apply the Phase Rule, and to attribute the properties of large-scale matter to the single ultimate unit of hæmoglobin as it exists in solution. Presumably this ultimate unit has a diameter about 10 times that of the oxygen molecule; it is presumably in violent, oscillatory (thermal) movement; there is no good evidence that it has ever been observed with the ultramicroscope. To regard it therefore as a separate phase is to disregard the statistical basis of the Second Law from which the Phase Rule is deduced. *If* the hæmoglobin unit be indeed a separate phase, then admittedly the known number of degrees of freedom of the hæmoglobin-oxygen system prohibits the possibility of regarding oxy- and reduced hæmoglobin as separate chemical compounds. No evidence, however, can be given for the existence of hæmoglobin, in solution in water, as a phase separate from the water, except that it can be precipitated by various violent means—which surely is not evidence; the separate phase is a pure hypothesis and must be judged by its fruits, which at present are difficult to discern.

Sir William Bayliss's attitude of continual and friendly scepticism, on this particular subject, has had one important and valuable effect, the effect which he set out to achieve, which, however, his modesty prevents him acknowledging, or possibly even from appreciating. It has urged a number of workers to produce, what was badly needed, a body of sound quantitative experimental evidence on one of the most fascinating problems in the borderland between biology and chemistry. The evidence is not complete and we cannot convince him yet; but if he will only maintain his scepticism, in an equally friendly way, for a few years more, he will really force us to produce all the testimony which he requires. A. V. HILL.

The University, Manchester,
May 31.

IN the recent correspondence touching the nature of the combination of hæmoglobin with oxygen, references have been made to Wo. Ostwald's adsorption theory. It may clarify the issue if I remind readers of NATURE what that theory was. Wo. Ostwald argued that the equilibrium between oxygen and hæmoglobin could be expressed by a curve based on the following equation, $X = KC^m$, where X is the amount of oxygen combined with the hæmoglobin, C the concentration of oxygen in solution, K a quantity proportional to the total mass of hæmoglobin present, and m a constant. The graphic expression of this equation must necessarily be a simple curve which is at all points concave to the abscissa. No published curve representing the equilibrium between hæmoglobin and oxygen, which has been determined experimentally, is of this character, all being more or less S-shaped, though in some cases the convex inflection is very slight.

It may seem strange that a theory should have been put forward which is at variance with the facts in so fundamental a respect. In justice to Wo. Ostwald it must be pointed out that he wrote before the experimental technique now in use had been elaborated. The most recent curves at his disposal were those of Bohr, Hasselbalch, and Krogh (for the oxygen hæmoglobin equilibrium at various CO_2 pressures). These are S-shaped in character, but at the time commanded less confidence than they deserved; I think because they were determined not as individual curves but as a surface in three dimensions, the published curves being contours. All modern work has confirmed the essential character of the curves of Bohr, Hasselbalch, and Krogh.

Finally, may I pay a tribute to the helpful nature of Sir William Bayliss's criticism (NATURE, May 19, p. 666), and suggest an extension of that help in the direction of his modifying Ostwald's theory, expanding it into an equation which would fit the facts sufficiently exactly to stimulate further research on the subject. J. BARCROFT.

Physiological Laboratory, Cambridge,
June 6.

IN his letter published in NATURE of May 19, Sir William Bayliss suggests that two cases of adsorption do not come within the definition of adsorption to which I directed attention in NATURE of April 14. These are the cases when two or more substances are adsorbed upon a surface, and when a substance is adsorbed to a thickness of several molecules. Both these cases were intended by me to be included, and I think reasonably so, with the definition that it is a case of adsorption, if the substance is taken up uniformly over the whole surface; uniformly, that is, when the scale of measurement is large compared with individual molecules. This sense of uniformity is well understood in the theory of gases, where a mixture of gases or a single gas may be said to fill space uniformly, with equal correctness. I had no intention of limiting the definition to layers only one molecule thick; indeed perhaps I may be permitted, as it is suggested that I accept Langmuir's views, to point out that the theory employed by Langmuir does not seem to me necessarily to postulate that adsorbed layers are always one molecule thick. Such a proposition could only be established by estimating the amount adsorbed on unit area and calculating the thickness of the layer in terms of known data as to the size of the molecules in every case of adsorption; it does seem to be established by the beautiful experimental work of Langmuir in many cases, but is not, I think, claimed by him to be an invariable law governing adsorption.

Sir William Bayliss says in his first paragraph that no serious attempt has been made to consider surface phenomena in the combination of oxygen and hæmoglobin, since Wo. Ostwald showed that the data of the taking up of oxygen by hæmoglobin could be expressed by the adsorption formula; but he seems to have overlooked that the *sole* argument put forward in my letter of April 14, to prove that the attraction of hæmoglobin for oxygen is a highly localised property of the hæmoglobin particle, was that the hæmoglobin is so much larger than the oxygen with which it combines that the oxygen must be attached to only a very small portion of the surface. If there were general attraction of the surface of the hæmoglobin particle for oxygen, then combination would not stop when only a small fraction was covered, but hæmoglobin would take up much more oxygen than it actually does. Surely this is a very definite attempt to consider the surfaces of the particles. It is a mistake to confuse the argument used in my letter with those based on the well-known mass-action formulæ of Barcroft and Hill; it is entirely independent of them, and essentially treats the hæmoglobin in solution as a heterogeneous system, possessing an interface; it shows that this interface is, in fact, very much too large to be satisfied by the amount of oxygen which is actually taken up at saturation, and that therefore the oxygen *must* be held by some other means than adsorption.

Relation between Hæmoglobin-Content and Surface of Red Blood-Cells.

BÜRKER (*Archiv für die gesammte Physiologie*, cxcv., 1922, p. 516) has demonstrated that the relation between the hæmoglobin-content and the surface of a single red blood-cell is constant, whatever may be the divergencies in size and hæmoglobin-content of the blood-cells of different animals.

Taking as examples the rabbit, the chromocytes of which are of medium size, and the goat, which has very small red blood-cells, he gives the following numbers:

	Hæmoglobin-content per 100 c.c. Blood in Grams.	Number of Red Blood-cells per mm. in Millions.	Average of a Single Cell.	Surface of one Blood-cell in μ^2.[1]	Average Hæmoglobin-content per μ^2 Surface in 10^{-14} gm.
Rabbit .	11·9	5·86	20×10^{-12} gm.	68·4	27
Goat . .	10·9	13·94	$8 \cdot 10^{-12}$ gm.	25·1	29

[1] These numbers are to be multiplied by 1·09; *vide* NATURE, January 6, 1923.

Now, as is already evident from the numbers given by Abderhalden ("Lehrbuch der physiologischen Chemie"), the relation between the hæmoglobin-content of a blood-cell and its volume is also constant. In the following experiment the volume of the red blood-cells was determined by centrifugation of blood after addition of a trace of sodium fluorate.

	Hæmoglobin-content per 100 c.c. Blood in Grams.	Number of Red Blood-cells per mm. in Millions.	Average of a Single Cell.	Volume of all the Blood-cells from 5 c.c. Blood.	Hence Volume of one Blood cell in μ^3.	Relation.
Rabbit .	10·6	5·7	19×10^{-12} gm.	1·7 c.c.	60	32
Goat . .	9·6	16·3	6×10^{-12} gm.	1·5 c.c.	18·4	31

The constant is the same in both cases. How are these two results to be reconciled?

One hypothesis is that the chromocytes of the goat have not the same shape as those of the rabbit. This hypothesis, however, does not seem to be satisfactory, because microscopic examination of the red blood-cells from the rabbit and the goat does not show an important difference in form.

A second hypothesis is that the method of determining the volume of the red blood-cells by centrifugation of the blood is not trustworthy.

The difficulty may be solved if, for example, the larger cells lost more water by the centrifugal force than the smaller ones; but this does not seem very probable either.

I am specially interested in the solution of this problem, because I am studying the question as to whether the hæmoglobin is distributed about the surface of the red blood-cell in such a way that all the iron is in the position that enables it to act as a catalyser. If we calculate how much iron can be placed at the surface of one human red blood-cell, it appears that this iron can form exactly one monomolecular layer, provided that one atom of iron occupies a surface of 8×10^{-16} cm^2. If, however, all the hæmoglobin should be placed at the surface in one monomolecular layer, this surface would have to be a hundred times greater. It seems probable that the surface that governs the law of Bürker must be the surface of all the "micelles" of the hæmoglobin-solution.

First of all, however, it ought to be definitely settled whether Bürker is right, when speaking of a "Hämoglobinverteilungsgesetz."

E. GORTER.

Leyden, May 7.

A Lost Collection of Indian Sketches.

IN the *Geographical Journal* for March 1922, it is stated (p. 219) that the Indian sketches made by me could not be found. As these are numerous, quite 160, made between 1852 and 1858, some details regarding them, their value as sketches, where and how they were made, may be of interest, and may possibly assist the authorities at Scotland Yard to trace them; even the discovery of one sketch might do so. It will also show fellows of the Royal Geographical Society and others why I have so persistently directed attention to the loss.

The sketches are not a traveller's collection of the ordinary kind; they were made to illustrate the country I was in, and the work on which I was employed. I cannot take a better example than the very first, made after landing in Burma. It was a water-colour sketch of the Lake at Rangoon, from the stockade which then surrounded the Pagoda hill, in its pristine state, now known as the Royal Lakes in Dalhousie Park, its artificial state. This sketch also showed the Rangoon River and hill on which stands the Syriam Pagoda, and how greatly the delta of the Irravady differs from that of the Ganges.

The first sketches go back to 1852, the year I obtained my commission and sailed for India, round the Cape, in a small troopship of 590 tons. Landing at Calcutta after a five months' voyage, and finally going on to Burma, where I passed my nineteenth birthday, all my spare time in that country was given up to making a geological map. Burma was then practically unknown, and on being appointed A.D.C. to General T. Godwin, on tours of inspection I saw much of the country.

This work compared well with the Geological map of Pegu as surveyed some years after by Messrs. W. Theobald, W. T. Blanford, and Feddon, only they were able to put an age to the formations seen; beyond knowing that the limestone of Akouk-thoung was very much the oldest, I could not. It was good practice, and many years after when I was surveying Manipur the knowledge gained was of immense value.

I must explain why when so young an officer I was able to do this. From an early age I had had most unusual opportunities to learn: my father was a geologist, always at work, always collecting, geological friends such as Edward Forbes always in the house. After learning surveying at Sandhurst I was able to help him to make plans near home to illustrate a paper he was writing—"On the Gravel Beds of the Valley of the Wey," Q.J. Geolog. Soc., vol. vii., 1857.

I helped to make the plan "On the Valley of the English Channel" (Q.J. Geolog. Soc., February 1850, vol. vi.), and learnt a great deal from seeing so much of the plans which finally illustrated the paper

"On the possible Extension of the Coal-measures beneath the South-Eastern part of England (Q.J. Geolog. Soc., February 1856). Among the geologists I met at home were Dr. Falconer and Thomas Oldham; they were the first friends to meet again in Calcutta in September 1852. I had read the work of the first with Lt. Cautley, R.E., and knew something of the Sivalik Formation when I crossed it at Kasauli in 1853. The 160 drawings cover a very large extent of country, which I roughly spread over thus:

1. Burma	29
2. Calcutta to Simla, via the Ganges Valley and on to Sealkote	26
3. Peshawar to Kashmir, through Hazara .	73
4. On appointment to the Trigonometrical Survey of India and joining Capt. Montgomerie .	10
5. When at Sealkote with 24th Regt. of Foot. In Sivaliks near Jammu . . .	10
6. Various at Cape of Good Hope. Historical of the time	20
Total . .	168

Science and Economics.

THE function of NATURE is not to expound economics or finance, but when a famous man of science uses its widely-read pages to challenge the fundamentals of the almost ubiquitous system under which humanity lives—or perishes, the humble individual who has undertaken to defend the philosophy of the system must be pardoned if a little extra space is required to try to elucidate an aspect of the subject overlooked both by would-be reformers and unreflecting conservatives.

(1) Prof. Soddy tells us now quite plainly (NATURE, May 19, p. 660) that economics should be classified as natural physical phenomena, and, in effect, that all would be well with humanity were we to reorganise our economic system according to the laws formulated by men of science from their investigations in inorganic chemistry and physics. This is, if I may say so, a purely theoretical conception that is not substantiated by experiment or experience. Prof. Soddy lays stress on the physical aspect of phenomena. I had thought that scientific investigators had ceased to view any natural phenomenon as purely physical. However, that is perhaps only a matter of definition; but granting his terminology, I cannot agree that it is, or ever could be, possible to apply the laws of physical nature to the activities of mankind. Inorganic nature appears to be a finished product, since the laws of its atomic systems are unalterable by human means. Humanity, on the other hand, is obviously "in the making," and the doctrines and social systems adopted in different periods are temporary expedients that assist its evolution and correspond to the stage reached at any given time. As an Eastern proverb says, "The gods of one age become the devils of a succeeding age." Now, this makes life interesting and gives us all something to do. If mankind were to be reconstituted as is inorganic nature, instead of being organised as it is, those of us who now form theories and opinions and exercise our minds would be without occupation, if we had not shaken the dust of this dull world from our arrogant heads and departed to conquer other worlds.

Seriously, "economics" describes a human method; it is not a natural science and, hence, cannot be exact. There is an element in man not governed by the laws of physical nature, and this principle seeks to govern and direct them. This may imply "distorting physical nature to suit human nature," but the father of experimental science started it on the way by commanding us to "torture Nature," and thoroughly well have we obeyed him! The object of science is surely to understand Nature in order to use it for human ends. Prof. Soddy would reverse this, and advocates modelling our economic system on the laws of physical nature, a proposal tantamount to an attempt to baulk human evolution and to impose on man the rules of an inferior order of existence. Theoretically it would be easy to formulate a *fool*-proof economic system according to the laws of an atomic system; practically, any such system could not be *genius*-proof, and, certainly, if we value the evidence of history, we should be most unscientific to discount the geniuses who, ever so often, appear and alter existing conditions and methods. The "Robots" of the drama could never become a permanent feature of the human world.

(2) With regard to the age of our present system, it is necessary to make clear the essential difference between *the financial system* and *economic methods*. The principles of the former accord with fundamental characteristics of the human race; the methods of the latter are adjusted to changing environmental conditions and advancing knowledge of the resources of our planet. The essence of the financial system is, and always has been, *credit*, without which no civilisation would ever have been initiated by the trusted geniuses and leaders of the mass of mankind. I fear there is confusion in the minds of economists, both orthodox and heterodox, as to the origin and basis of credit as distinct from money and currency. Economics is a study of methods and theories. When orthodox, its laws are deduced from observations of a system at work *which it did not originate*; when heterodox, it consists of speculations, most of which are useless anachronisms, as their formulæ, like those of Karl Marx, do not take account of the fact that science is transmuting the economic basis of man's existence, which depends less and less on human physical "work," more and more on the application, direct and indirect, of "mental energy."

The financial system, on the other hand, is a principle in actual operation, and at present its methods are simply a modification of a tradition of credit-control handed down through many civilisations. Rome, Egypt, Babylon, India, China, etc., had their financiers who controlled credit according to the accepted code of laws. Archæological investigations, for example, have produced huge vaults of Babylonian cylinders containing the records of the accounts of banking concerns, their debts and credits. It would be naïve to imagine that the personal and commercial intercourse between the peoples of earlier civilised nations, such as Greece and Rome, was conducted on a cash basis without the assistance of credit. When a boy could be sent from Greece to school in Rome with a note to his father's banker in that city to pay his school expenses it is apparent that the credit-system was in operation. The kind of currency is quite subsidiary to the principle of credit—for if the Emperor of Rome had had bone or other discs of different sizes etched with the Royal insignia and issued in amount to meet the exchange needs of his Empire, the Greek boy would have got on as well with these as with the silver, gold and copper coins he used while in the Imperial city. His father, a merchant, had a credit account in Rome, for use as and when required.

The fact that many of us are only just realising the erroneous theories the economists had formulated and taught about the intrinsic value of gold as the basis of currency, is no proof that the initiators of the financial system, whoever they may have been, laboured under the same absurd delusion. The reasons why a particular kind of currency came into use are fairly obvious to any one who has thought about it in relation to different stages of civilisation and human development. The problem of counterfeit money has also to be considered in this connexion. Our present system is an evolution of the Italian banking system bequeathed to that nation from a former civilisation. Since the founding of the Bank of England in 1694, industry and the financial system have expanded together on the basis of personal integrity and national credit. The fundamental principle of the system has never changed as far back as we can trace it into the remote past. It is founded on the permanent principle in human nature described as *a sense of responsibility* (individuality) and *a desire for action* (progress and evolution), and it is this which has guided the granting of credit and the use of a nation's currency. Individuals who obtain the use of the community's credit at any time are those who are able to produce what mankind desires, or is taught to desire, whether goods, ideas or adventures. It is a fact that gold alone did not finance the first factories erected and operated mechanically in this country, and credit has been issued ever since in increasing amounts on the basis of the ability of industrial concerns to produce what men desire to consume.

(3) Prof. Soddy says of the financial system that "Such a system as the present has never even been attempted before." This is not correct, as I have tried to indicate briefly above. He says, further, that "It is an absolute innovation." An *absolute* innovation is impossible under the laws of evolution and is not known in all the annals of human history, with the single exception of revolution, which is always followed by a restoration of tradition in a modified form. But the innovation here referred to is evidently the alteration in the class of persons to whom credit was granted after the introduction of mechanical power. It appears to have been a fundamental innovation because mankind then entered upon a new stage of evolution under new economic methods and new incentives and desires; and, therefore, the ostensible basis of credit was gradually transferred from land to the more productive industrial plant. The use of mechanical energy made it possible to satisfy growing desires, and the financial adaptation took place naturally as an "inflation" of currency necessary for the distribution of the increased products. This was not a fundamental change in the financial system as such; it was a change in economic methods: a new form or symbol of credit came into use.

The century or more since then has afforded ample time for the evolutionary process to complete the cycle of existence of this form so that the signs of age are apparent, as I suggested in a previous communication. The reasons are obviously that—

1. Machines are becoming more and more perfect and human labour less and less necessary for the production of the means of existence.
2. Most countries, even into the East, are becoming industrialised and their products cannot be marketed abroad as readily as in the nineteenth century.
3. Credit facilities have become too concentrated in the extension of industrial production, and the desires of those devoted to learning and the fine arts have been comparatively neglected under a democratic regime.

The results of 1 and 2 will gradually operate to inaugurate a new modification in the use of credit, because a wider base, another symbol or form of credit, must be found by which the means of human evolution and of existence under new conditions can be more adequately distributed. As machines now perform so much of the world's work, an extensive "unearned" distribution of currency would be possible and would benefit the skilled staffs of industries because of the increased expenditure of the people. The "out-of-work" allowance, however, is admitted to be an undesirable method, as the recognition of the mere "right to live" is not sufficient for those who realise the responsibilities of human government. The ethical effects cannot be disregarded, and the problem in this age of transition is to find suitable occupations for certain types. The latent powers in human beings are developed by individual effort, and it is evident that the financial system and social laws were originally formed with the view of inspiring and rewarding such effort. It is in this respect that our present methods require modification, and doubtless many new, and extensions of old, occupations would suggest themselves were the standards of character and attainment different. The scholarship method of encouraging self-development and distributing currency could be extended in other directions and to other occupations, and incentives devised for human endeavour toward worthier ends than now attract the majority. But it would be unsafe to attempt a change on a wide scale until the principles which should guide the innovation are clearer.

(4) Finally, Prof. Soddy describes the present system as "counterfeit." I presume (under correction) that he has in mind the "interest" on credit-loans. The philosophy of "usury" is very interesting, as it involves the polar principle which science has demonstrated, and also the principle of growth or development which evolution implies. Interest is roughly the measure of the increased productive capacity from year to year, and this increase is returned immediately to industry as new "loans" and distributed as currency in wages, salaries and dividends, according to the ability of industry to absorb and use it. Interest or "usury" acts as an automatic regulator and indicator; it shows where the energy and desires of man are expended. It also acts as a check and restraining influence on impetuous individuals, although to economists who may not realise the polar principle of "debt" and "credit" it is rather of the nature of the red flag.

Greed and selfishness (concomitants of the evolutionary process) would be even more in evidence were human beings not automatically controlled and regulated by the laws of its own credit system, which at the same time fulfils the human function of providing for changing conditions, growing desires and the development of individuality—otherwise we might, indeed, perish. Even as things are, honest intention to meet "promises to pay" and ability to perform what this industrial age and its ideals demand (Mr. Lane Fox Pitt's "practical instruction," May 19, p. 670) underlie our credit system, and any one who has the "credulity" to evade these conditions comes sooner or later to the end of his rope and his character.

In conclusion, my object is elucidation and is not to prove any person wrong, least of all Prof. Soddy, whose courageous tilting at economic conditions has stimulated thought and will help to hasten a most urgent readjustment of methods and conditions which, in my opinion, can be brought about only by a change of ideals. Separation of Isotopic Ions.

IN the issue of NATURE for June 2, p. 763, there is a reference to a paper by Kendall and Crittenden (Washington: National Academy of Sciences, vol. 9, No. 3) which describes a method for separating isotopic ions. This method was first described by Prof. F. A. Lindemann at the Royal Society conference on isotopes (March 1921). A considerable number of experiments on this subject have been carried out here during the past year, but it seemed desirable to postpone publication until a definite result had been achieved.

Haze on Derby Day—June 6.

THERE was a dense haze overlying Southern England on June 6, becoming worse towards evening and greatly interfering with visibility. It was very marked in Surrey in the neighbourhood of Epsom, where the race-goers found it difficult to see clearly. Records of this haze taken with my dust-counter at Cheam, between 7 and 7.30 P.M., gave a greyish deposit of dust particles upon the cover-glass. These particles varied in diameter from 1½ microns down to ultra-microscopic size; the average diameter was about ½ micron. Most of them were irregular in shape and insoluble in water, but scattered among the irregular dust particles were a number of small spheres. The proportion of these spheres present was about 3 per cent. of the total number of dust particles. They were transparent and usually colourless, but some were distinctly brown or reddish. The maximum diameter of the spheres found was 1½ microns, but most of them were less than this. They were insoluble in water. The haze was unusually dense for a country district, and the number of dust particles per cubic centimetre was between 9000 and 10,000.

It will be remembered that on Derby Day there was very little wind, but what there was was from the north. It is difficult to avoid the conclusion that a large proportion of this dust travelled south from the manufacturing districts of the Midlands. The presence of coloured and colourless transparent spheres points towards ash particles ejected from chimneys, while the grey colour is not what one would expect if domestic smoke were the origin. The records obtained during London fogs are black, and a dense fog gives 40,000 to 50,000 particles per cubic centimetre.

For comparison with June 6, a dust record taken at 7 P.M. on the evening of June 10 at Cheam gave less than 100 dust particles per c.c. The wind was strong and blowing from the west, and visibility very good.

J. S. OWENS.

Perseid Meteors in July 1592.

WITH reference to Dr. Fotheringham's interesting comments in NATURE, June 9, p. 774, on the probable shower of Perseids in 1592, I thought it best to accept the date kindly sent to me by Mr. Beveridge, as it fell near the time when a shower might be expected to occur. However, the shower of 1592 appears to have been 19 days earlier than the correct time, and this (with another reason stated later) at once throws doubts on the identity of the display with the true Perseids.

The near correspondence in epoch may still, however, occasion some suspicion that the Perseid shower formed the incident recorded in history, though the exact date and direction of the meteor flights are incorrectly given. This idea is encouraged by the fact that in two other cases (A.D. 784 and 865) the shower dates differed 10 days from the normal.

It is perhaps important to remark in this connexion that several rich showers of non-Perseids have been frequently observed in modern times which do not differ materially from the date of the Perseids. Three of these may be mentioned as possibly the same as the ancient showers recorded which failed to conform with the exact Perseid dates.

(1) There is a strong shower at $303° - 9°$ near α Capricorni on July 25-August 6.

(2) A rich display from $339° - 11°$ in Aquarius on July 26-August 2.

(3) A fine shower seen in 1879 from Draco $291° + 60°$ on August 21-25.

If the meteors of 1592, to which Mr. Beveridge has directed attention, "traversed the heavens from west to east," as stated in the ancient chronicle, they could scarcely have been Perseids, for the latter are moving nearly from east to west, and this seems an important detail.

The direction of the meteors of 1592 from west to east means that their apparent motions must have been slow and that they were overtaking the earth in its orbit. The Perseids belong to another class; they are swift objects meeting the earth at a velocity of 38 miles per second. I was not aware until I saw Dr. Fotheringham's letter that the direction of the meteors had been described as from west to east.

I adopted a period of 11·75 years (*Observatory*, May 1923) as agreeing with a large number of abundant returns of the Perseids and as it seemed the best to be derived. I directed attention to it in the hope that future observers would bear it in mind and test it in the light of additional observations.

Tactile Vision of Insects and Arachnida.

WITH regard to Father O'Hea's letter in NATURE of May 26, p. 705, I wish to point out—

(1) That I originally questioned the statement that the house-fly and certain spiders avoided the approach of one's hand by detecting "convection currents."

(2) That experiments in this direction can only be made with *totally blind* insects.

(3) That I have not stated that vision is universal or even general among insects and arachnida possessed of eyes, and I offer no explanation (at present) of the use or purpose of "sightless eyes." Neither can I enter a discussion on "vision and light-sensitiveness."

I do maintain, however, that many species form comparatively clear images and can judge distances. The fact that a male Attid (and some Lycosids) will perform for the benefit of a female in an adjacent glass tube is at present only explicable on the assumption of vision. Father O'Hea has not, he says, worked on this point, and I persist in offering it as a preliminary objection to his hypothesis. This discussion cannot, however, proceed to any satisfactory conclusion until we have his further evidence for a large number of species; and until this is forthcoming I should suggest that a generalisation on the question of vision among arthropods cannot be made.

The Eötvös Torsion Balance and its Use in the Field.

By Capt. H. Shaw and E. Lancaster Jones.

The problem of locating from the surface mineral deposits in the interior of the earth presents numerous difficulties, and has been considered by many investigators who have employed methods based on the physical properties of these bodies, utilising electrical, magnetic, seismic, and density effects. Speaking generally the useful minerals are of either very high or very low density, so that a method dependent upon the difference in density between the mineral and its surroundings would appear to be suitable for the location of such deposits, especially as these effects are noticeable at a considerable distance.

The attraction due to a heavy body is superimposed upon the normal force of gravity at any point in its vicinity, and it is by observations on this local field by means of a torsion balance that the disturbing mass may be located most readily.

The torsion balance of Michell and Cavendish was redesigned and employed for this purpose in 1888 by Baron Roland von Eötvös, professor of physics at Budapest, who gave to the balance a new construction which is retained essentially in the modern instrument, although numerous improvements have since been introduced.

The essential features of the balance can be seen on reference to Fig. 1. A light aluminium beam loaded with platinum weights is suspended by a fine platinum iridium torsion wire. One of the weights is attached directly to one end of the beam, but at the other end the weight is suspended about 60 cm. below the beam by means of a fine wire.

The forces of gravity acting on the two masses are not wholly vertical, but have small horizontal components which give rise to a minute horizontal torque tending to rotate the balance arm. The displacement of the beam relative to its case is observed by means of a telescope and scale fixed to the case, with the aid of a mirror carried by the beam.

When the position of equilibrium of the system has been read, the entire beam and case are rotated through 72° and the observation repeated. Five observations are thus obtained in one revolution of the balance, and the readings in these positions are sufficient to furnish the information required for the station at which the balance is situated.

The modern type of balance consists of two similar beam systems placed side by side, with the suspended weights at opposite ends, and as with this type only three observations at angles of 120° are required for a complete determination, a considerable saving of time results. These improved instruments are in some cases fitted with photographic recording arrangements, the balance case being rotated automatically into its new azimuth after the beam has come to rest and the exposure made.

The suspended system requires most careful protection against convection currents and other disturbing influences, and consequently is enclosed in a double or treble-walled brass case of uniform thickness. Temperature and radiation effects are thus reduced considerably, while the additional precaution is taken of working at night, thereby eliminating solar radiation effects and securing a greater constancy of temperature. Under these conditions the instrument is found to give uniform and satisfactory results in the field when protected only by a tent.

In order to secure the necessary degree of sensitivity it is essential that the period of oscillation should be large, and Eötvös has succeeded in obtaining a period of swing of 1500 to 1800 seconds by employing weights of 30 grams and a beam of 40 cm. length, the lower

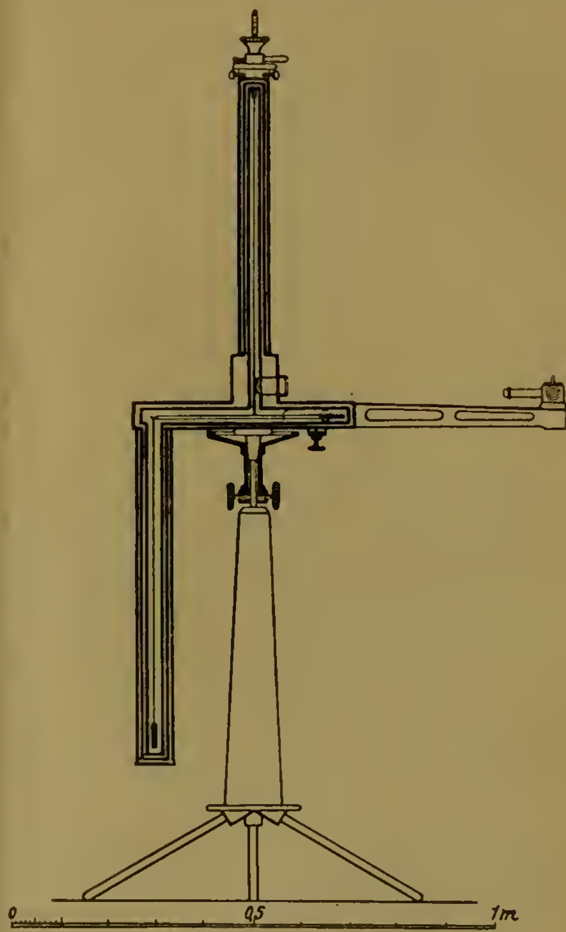

Fig. 1.—Section of balance.

weight being suspended at a depth of about 60 cm. below the beam. The sensitivity of the instrument is partly controlled by the coefficient of torsion of the suspension wire, and by using a platinum wire 0·04 mm. in diameter, alloyed with 20 per cent. iridium, it is possible to measure variations of gravity to within one 10^{-9} C.G.S. unit per centimetre. These wires, which have hitherto proved the most suitable for the purpose, are previously subjected to a special "baking" treatment with the view of eliminating remanent torsion. Similar instruments of smaller dimensions have been constructed and tried by Eötvös, but were subsequently abandoned as being unsatisfactory. Quartz fibres have also been employed in place of the torsion wire, but it was found by Eötvös that a quartz fibre which is sufficiently strong to carry the loaded beam is more rigid than the platinum iridium wire and in consequence a smaller deflexion of the beam results. It was partly owing to this fact and partly owing to the exceptional fragility of the quartz fibre that it was not adopted by Eötvös in his field instrument.

The action of the balance and the nature of the quantities measured may be appreciated from the following consideration. Let a system of rectangular co-ordinates Ox, Oy, Oz, Fig. 2, have its origin O at

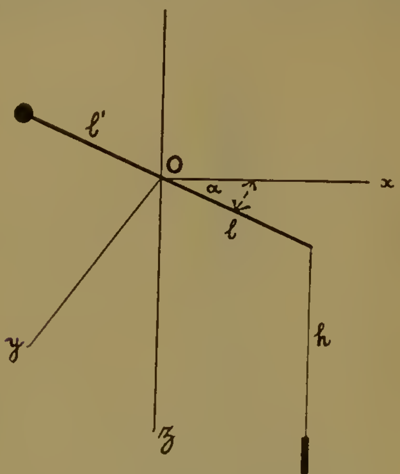

FIG. 2.—Diagram of beam system.

the centre of gravity of the balance beam, the axis Oz directed downwards in the line of resultant gravity at O, and the axes Ox, Oy towards the geographical north and east respectively. It is assumed that a potential function U exists for the gravitational field about O and that, for points not outside the range of swing of the balance beam, we can put

$$U = U_0 + g_0 z + \tfrac{1}{2}U_{11}x^2 + \tfrac{1}{2}U_{22}y^2 + \tfrac{1}{2}U_{33}z^2$$
$$+ U_{12}xy + U_{13}xz + U_{23}yz,$$

where U_0 is the value of U at O,
,, g_0 ,, ,, ,, the resultant force at O,

and U_{11}, U_{12}, etc. depend only on O, not on x, y, and z. Such an assumption is justified whenever gravity is normal, or even if there are irregularities in the field, provided the disturbing masses are fairly distant from the balance.

If the balance beam lies in any position in the plane Oxy, making an angle α with the axis Ox, its main mass is concentrated at two points of which the co-ordinates are $(l' \cos(\alpha+\pi), l' \sin(\alpha+\pi), 0)$ for the upper weight and $(l \cos\alpha, l \sin\alpha, h)$ for the lower. The potential of the whole system will therefore depend on α, and will only be a minimum or maximum for a limited number of values of α. For all other azimuths the beam will tend to rotate so as to set itself in a position of minimum potential, and will actually rotate until this tendency is balanced by the torsion of the suspension wire. The latter, measured by means of the telescope and scale, affords a means of determining the twisting moment due to the gravitational field at any value α, and thus enables us to evaluate the quantities which specify the field and the torque due to it. It is shown in the mathematical theory that these quantities are none other than the magnitudes

$$(U_{22} - U_{11}),\ U_{12},\ U_{13},\ \text{and}\ U_{23},$$

which are thus determined for every station O.

APPLICATION OF THE BALANCE.

The magnitudes $(U_{22} - U_{11})$, U_{12}, U_{23}, U_{13} determined by the balance are not sufficient to enable us to reproduce the complete gravitational field about O—in other words, to describe its equipotential surfaces—since we require to know both U_{11} and U_{22} separately, and also U_{33} and g_0. Eötvös, however, has shown that, by means of the four magnitudes determined by his balance, and one or two pendulum measurements, the magnitude of g, the force of gravity, can be determined throughout a region where the earth's surface deviates only slightly from the equipotential surface through the base point. The balance is thus of great service to geodesy.

In recent years, however, the balance has been extensively employed for work having a wider appeal than the problems of geodesy. By its capacity to explore the regions below the earth's surface, not by penetrating it but by remaining always on the surface, it has proved itself a valuable ally to the geologist, and its use is superseding much of the costly boring and drilling hitherto necessary in locating mineral deposits. Wherever such deposits differ sufficiently in density from their surroundings, and are sufficiently extensive to cause appreciable irregularities in the gravitational field at the surface above them, the balance not only registers their existence, but also helps to determine their density, shape, extent, and depth below the surface, so that, in favourable circumstances, a single boring may suffice to settle any remaining doubts regarding the nature and size of the deposit. In this work of exploring subterranean disturbing masses, the same four quantities $(U_{22}—U_{11})$, U_{12}, U_{23}, and U_{13} are employed, but the influence of all known disturbing masses, and the normal field due to the size and shape of the earth, must be calculated and eliminated before accurate conclusions regarding the unknown masses can be drawn. This may be a very laborious and complicated process, and may even be impossible in unfavourable regions, *e.g.*, where there are mountain ranges of an irregular character in the vicinity.

In such regions, however, the variations of strata as regards character and shape are frequently sufficiently apparent from surface indications to render the use of the instrument unnecessary, so that the balance is of most use where it is most accurate, namely, in regions presenting a regular and comparatively unbroken surface, but having important irregularities below the surface.

In this work, certain simple combinations of $(U_{22} - U_{11})$, U_{12}, U_{23}, U_{13}, are more useful than the magnitudes themselves. Those mainly used are S, R, λ, μ, where

$$S = \sqrt{U_{13}^2 + U_{23}^2}, \qquad R = -\frac{1}{g}(U_{22} - U_{11}) \sec 2\lambda,$$

$$\tan\mu = \frac{U_{23}}{U_{13}}, \qquad \tan 2\lambda = -\frac{2U_{12}}{U_{22} - U_{11}}.$$

The magnitude S represents the "maximum gradient of gravity in the horizontal surface," *i.e.*, the maximum amount by which the vertical force of gravity is increased as we proceed from the origin through unit distance in any direction in the horizontal surface, and is obviously the resultant of U_{13} and U_{23}, the gradients in the direction Ox, Oy respectively. Also the direction of this maximum gradient is given by μ, the angle which it makes with Ox.

The magnitude R is equal to the difference between the reciprocals of the principal radii of curvature of the level surface at O, and is always positive. Thus, if ρ_1 is the least radius of curvature at O, and ρ_2 the greatest,

$$R = \frac{1}{\rho_1} - \frac{1}{\rho_2},$$

while λ is the angle which the plane of greatest radius of curvature, or least curvature, makes with the plane Oxz.

The work of survey consists in finding these values S, R, λ, μ at as many stations as possible, correcting them for normal gravity effects and known irregularities, and plotting the final values, representing the maximum gradient S by an arrow drawn through the station in the direction μ, and proportional in length to the magnitude of S, and indicating R by another arrow in the direction λ. The positions, directions, and lengths of these arrows are then compared with the corresponding arrows given by certain simple mass distributions of which the effects can be calculated, and the probable distribution corresponding to the observed results is deduced.

To illustrate the gravitational effect of a subterranean mass and the variation of the magnitudes measured by the balance from point to point on the earth's surface above such a deposit, we may consider the simple case represented in Fig. 3. Here a horizontal layer of matter, having a density greater by unity than its surroundings, is bounded on the top and bottom by horizontal surfaces at depths 200 and 300 metres below the earth's surface. The layer extends to infinity in the north, east, and west directions, but terminates at the south end in a vertical plane through the east-west line. Let O be a point on the earth's surface on the line where this vertical boundary meets the latter, x'Ox the meridian through O, and Oz the downwards vertical meeting the faces of the deposit in A and B. Consider the force of gravity due to the deposit alone—which is thus to be regarded as having a density unity—at any point X on x'Ox. The force at X will be wholly in the plane xOz, and the corresponding potential surface through X will be a cylinder having its axis perpendicular to this plane. In these circumstances the magnitudes U_{11}, U_{12}, etc., specifying

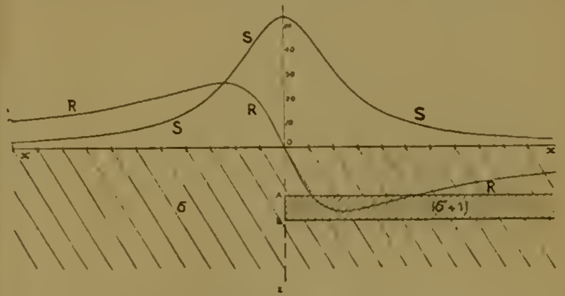

FIG. 3.—Results for a simple case.

the disturbing field due to the deposit, can easily be calculated. Moreover we have

$$U_{12} = U_{22} = U_{23} = 0,$$

and therefore

$$\lambda = \mu = 0 \text{ or } \pi,$$
$$R = U_{11},$$
$$S = U_{13}.$$

In Fig. 3 the values of U_{11} are plotted as ordinates corresponding to the abscissæ OX in the curve RRR, and the values of U_{13} in the curve SSS. It will be noticed that the point O, vertically above the edge of the deposit, is strongly marked in each curve by a maximum on one and a zero value on the other. The maximum value of S has a magnitude 53×10^{-9} C.G.S. units, and the maximum of R is 26×10^{-9} units. Since values of R and S as low as 1×10^{-9} unit affect the balance, it is apparent that the instrument would readily show the effects due to such a subterranean deposit, and indicate its extremity.

Science and Industry in Sweden.

THE exhibition recently opened at Gothenburg to celebrate the tercentenary of the founding of that city by Gustavus Adolphus, with its display of Swedish manufactures, is an eloquent reminder of the part taken by Sweden in the development of certain industries and also of the debt of the world to Swedish men of science. Though she cannot lay claim to mathematicians of the rank of Leibnitz, Newton, or Euler, or to astronomers equal to Galileo or Herschel, in chemistry and mineralogy Sweden has often led the way, and few countries can boast of names more widely known than those of Bergmann, Scheele, Gadolin, Berzelius, Nilson, Cleve, and Arrhenius.

The rise of science in Sweden is generally traced to Linnæus, but it really had its foundation in the middle of the seventeenth century. Like all the western nations Sweden felt the influence of the discoveries of Copernicus, Kepler, and Galileo, and one of the objects the young and eccentric Queen Christina had in view when she invited Descartes to her capital, was to place him at the head of the academy she proposed to establish. The plans of Christina, however, came to nothing, for Descartes died in 1650 and four years later she herself abdicated.

Sweden has a comparatively large territory but a very limited population. Until recent times there were but two seats of learning, Uppsala and Lund. Both are still small cities, the former having about 20,000 inhabitants, the latter some 4000 less. Uppsala is about 40 miles north of Stockholm, while Lund is not far from Malmö in the extreme south. Lund University was founded in 1666, Uppsala in 1476. It was in Uppsala that Swedish science had its birth, and there it has found its principal home. Johann Gestrin and Magnus Celsius (1621–1679) were among the mathematicians of Uppsala during the seventeenth century, the former being the author of a commentary on Euclid and works on astronomy and mechanics. The grandson of the latter, Magnus Celsius, was Anders Celsius (1701–1744) who accompanied Clairaut and Maupertuis on their degree-measuring expedition to Lapland. To him we are indebted for the Centigrade thermometer. For some years he was professor of astronomy at Uppsala.

The great Swedenborg (1688–1772), the learned Klingenstierna (1698–1785), Martin Stroemer (1707–1770), Peter Elvius (1710–1749), and Peter Wargentin (1717–1783) were all either students or professors at Uppsala, as was Melanderhjelm (1726–1810), whom Brougham met when he attended a meeting of the Royal Academy of Sciences at Stockholm in 1799. Klingenstierna was the discoverer of the fact that refraction of light could be produced without colour; Stroemer made the first Swedish translation of Euclid, while Wargentin devoted much of his life to a study of Jupiter's satellites and was associated with Lacaille in his work on the parallax of the moon. He was also the first director of the observatory at Stockholm founded in 1759 largely through the instrumentality of the capable and public-spirited administrator, Claude Grill (1704–1767).

Of all the men of science connected with Uppsala the place of honour must be given to Linnæus, whose tomb is in the Cathedral there. Whether we think of him as a boy watching the bees and flowers in his father's beautiful garden at Rashult, as the budding botanist at the school at Wexio, or as the struggling student first at Lund and then at Uppsala, or again as the intrepid explorer in the wilds of Lapland, we are impressed with his untiring energy and his singleness of purpose. Born in 1707, at the age of twenty-three Linnæus became an assistant professor at Uppsala, but the years 1735 to 1738 he spent in travel. In Holland he became the friend of Boerhaave and worked in the garden of the wealthy Clifford, near Haarlem. He also visited England, France, and Germany, and it was during this time he brought out the first edition of his "Systema Natura." Returning to Sweden he was made the president of the newly founded Academy of Sciences at Stockholm, and in 1741 became professor of anatomy at Uppsala, where he died on January 10, 1778. With his never-ceasing industry he combined a passionate love of order, and it has been said that thus "he was able to serve his own generation with great effect, to methodise the labour of naturalists, to devise useful expedients for lightening their toil, and to apply scientific knowledge to the practical purposes of life."

Contemporary with Linnæus, but occupied with a different branch of science, was Johann Wallerius (1709–1785), the writer of many scientific books and for a long time professor of chemistry, metallurgy, and pharmacy. It was to his chair that Bergmann succeeded in 1767. A native of West Gothland, where he was born in 1735, Bergmann as a student came under the influence of Linnæus and passed nearly the whole of his life at Uppsala. He was one of the earliest chemists to deal with chemical problems in a strictly scientific manner, and he was the pioneer of systematic chemical analysis. Holding his chair until his death in 1784, he counted among his pupils Johann Gahn (1745–1818), who added manganese to the list of elements and instructed Berzelius in the use of the blowpipe, and Johann Gadolin (1760–1852). Gadolin became a professor at the university of Abo, then belonging to Sweden, and to him Finland was indebted for the introduction of a knowledge of the discoveries of Lavoisier and the other French chemists. The town and university of Abo were destroyed by fire in 1827, but when visited by Bishop Heber, the writer of the hymn "From Greenland's icy mountains," in 1805, he described it as "a place possessing an archbishop, fifteen professors, three hundred students, a ruined castle, a whitewashed cathedral, and certainly the most northerly university in Europe."

Gadolin had been a candidate for the chair left vacant by the death of Bergmann, but this was given to Afzelius (1755–1837). Bergmann's greatest contemporary was undoubtedly Scheele. Seven years younger than Bergmann, Scheele began life as an apprentice in Gothenburg. From Gothenburg he removed to Malmö, then to Stockholm and to Uppsala, and finally settled at Koping where he purchased a business. It was here he made his great discovery of oxygen. Endowed with a genius for resolving the most obscure chemical reactions, Scheele stands almost unrivalled for the number and value of his discoveries. He died two years after Bergmann, and his statue now adorns the Swedish capital.

Though, with the death of Bergmann and of Scheele, the progress of chemical discovery slackened somewhat, the greatest of Swedish chemists had yet to appear. Berzelius, who stands beside Linnæus in the roll of Swedish science, was born in 1779, a year after Davy. In 1798—the year Davy went as assistant to Beddoes at Clifton—Berzelius became an assistant to the medical superintendent at Medvi. While Davy was establishing his reputation at the Royal Institution, Berzelius as a professor of medicine was gaining the admiration of Stockholm, and on Davy's death in 1829 he was recognised as the leading chemist in the world. Sir William Ramsay once remarked that he believed that since the time of Boyle none had done more for the advancement of chemistry than had Berzelius. His kitchen laboratory at Stockholm was as famous as that of Lord Kelvin in the cellar beneath the old College of Glasgow. Dulong, Mitscherlich, Gmelin, Gustav and Heinrich Rose were all taught there by the great master, and Wöhler has fortunately left a description of it. "The laboratory," he said, "consisted of two ordinary rooms furnished in the simplest possible manner; there were no furnaces or draught places, neither gas nor water supply. In one of these rooms were two common deal tables; at one of these Berzelius worked, the other was intended for me. On the walls were a few cupboards for reagents; in the middle was a mercury trough, while the glass blower's lamp stood on the hearth. In addition was a sink, where the despotic Anna, the cook, had daily to clean the apparatus." When in 1833 Berzelius married, the King of Sweden wrote of him, "Sweden and the whole world were debtors to the man whose entire life had been devoted to pursuits as useful to all as they were glorious to his native country."

Berzelius died in 1848, and the torch of chemistry has been handed on by worthy successors such as Lars Fredrik Nilson (1840–1899) and Per Theodor Cleve (1840–1905), while to-day science in Sweden has no more illustrious name than that of Svante Arrhenius, the originater of the theory of electrolytic dissociation and the director of the Nobel Institute of Physics, who began his career in the old university where Bergmann had taught.

While chemistry in particular has flourished in Sweden, other sciences have by no means been neglected. In all that appertains to the sea and fisheries, to agriculture and forestry, and to exploration, much valuable work has been done. One of the meetings to be held at Gothenburg this summer is the Congress of Scandinavian Naturalists. In astronomy, in physics, and in geology, Sweden has also played her part. Uppsala has possessed an observatory since about 1730, and during the nineteenth century this was directed by Gustav Svanberg (1801–1882), Herman Schultz (1823–1890), known for his micrometrical measurements of nebulæ, and by Nils Christophr Duner (1839–1914), who devoted himself to a study of stellar spectra and in 1892 received the Rumford Medal of the Royal Society. Another well-known astronomer was Hugo Gylden (1841–1896), for more than twenty years head of the Stockholm observatory, where Backlund was his pupil. Anders Jonas Ångström (1814–1874) began his career in the Swedish observatories, but his great work on the solar spectrum was done while he held the chair of physics at Uppsala to which he was appointed after the death of Adolph Svanberg (1806–1857). Ångström's successors, Tobias Thalen (1827–1905) and Knut Johan Ångström (1857–1910), were also distinguished workers in spectroscopy, while it was said that Thalen's magnetometer was in use in every iron mine of importance in Sweden.

Geological studies in Sweden may be said to have been begun with the writings of Urban Hiarne (1641–1724), physician to the king, who in 1694 published his views on the history of the earth. Some of the earliest geological maps of Sweden were prepared by Gustav Hermelin (1744–1820) a student of Uppsala and an officer in the Swedish mining service. Geological surveys of Norway and Sweden were inaugurated in 1858. Among the directors have been Otto Torell (1828–1900) and Alfred Törnebohm (1838–1911). In a country possessing rich mineral deposits, the work of these geologists has been of the greatest value.

Apart from agriculture, which still employs about half the population of 6,000,000, the main industries of Sweden depend on the iron mines, the magnificent forests, and the ample water power. The manufacture of wood pulp and the timber trade have grown enormously. At one time Sweden was the principal iron-producing country in the world. Though to-day her position in this respect is much more modest, the quality of her iron is still unrivalled. The steam engine was introduced into Sweden by the Swedish man of letters, Abraham Edelcrantz (1754–1821), while the first marine engine was made by Samuel Owen, whose bust has been placed in the Gothenburg Exhibition together with a model of the engine he built. In the field of shipbuilding Sweden has done much pioneering work, and at one time no writings on naval architecture were more highly esteemed in England than those of Chapman (1721–1808), who was a native of Gothenburg. The famous engineer and naval architect, John Ericsson, was a Swede, and began work on the Göta Canal, which had been first surveyed by Swedenborg, but was built to the plans of the British engineer Telford. Ericsson was in England from 1826 to 1839; he then emigrated to the United States and it was there that he produced the *Monitor* which during the civil war saved the North. After his death in 1889, Ericsson's body was sent to Sweden in an American warship, and it now lies at Filipstad in the beautiful Wermland district.

Many Swedish civil and mechanical engineers have gained a world wide-reputation. Nordenfelt, who died in 1920, was one of the pioneers of the submarine, Goransson, who died in 1900, assisted in perfecting Bessemer's great invention, while Fredrik Kjellin (1872–1910) was a pioneer of the electric steel industry. Of the three brothers Nobel, it was Alfred Bernhard Nobel (1833–1896) who first produced dynamite and afterwards left more than a million sterling to found the Nobel prizes. The list could be lengthened considerably, but few names have stood higher than that of Gustav de Laval (1845–1913), whose cream separators are to be found in use all over the world; he is also widely known as the inventor of the de Laval steam turbine, the first patent for which was taken out in 1884, the same year that the Parsons turbine was patented. De Laval, it may be added, was a student and graduate of Uppsala University, and was thus one of the makers of modern Sweden who laid the foundation of their knowledge in the ancient university where Swedish science had its birth.

Current Topics and Events.

An important paper by Prof. Georges Dreyer, of Oxford, in the last number of the *British Journal of Experimental Pathology* has been the subject of widespread comment, as, apparently, it is likely to inaugurate a new era in the specific treatment of infective disease, and particularly of tuberculosis. It is a matter of common knowledge that the "tuberculins" hitherto employed have not been completely successful against the highly resistant bacillus of tuberculosis. Dreyer's main thesis—and it is supported by a mass of accurate experimental evidence—is that the relative failure of certain vaccine preparations is due to the presence in some bacteria of various lipoidal substances which, covering or incorporated with the protoplasm of the microbe, offer a considerable protection to the latter, so that it is able to escape the destructive bactericidal and other antibodies which are evoked by the host in response to the infection. By a process consisting essentially of the extraction of the lipoids, the "defatted" bacteria have been found not only to preserve their antigenic properties, but also the latter are actually enhanced when compared side by side with antigens which still preserve their lipoids. The bulk of Dreyer's work refers to tubercle bacillus, and there can be no doubt that, so far as this microbe is concerned, he has proved his point experimentally. From his protocols he appears to have done what has not been done before, namely, the arrest, clinical and histological, of tubercle in guinea-pigs. It has always been felt that any method which could bring this about offered great hopes in the treatment of tuberculosis. It is necessary, however, at this stage to adopt an attitude of caution as regards the treatment of human pulmonary tuberculosis, for it will be a long time, probably years, before the full value of the method can be assessed.

In the issue of *Science* for May 18 prominence is given to a communication entitled "Problems in the Field of Animal Nutrition," issued by the sub-committee on Animal Nutrition of the United States National Research Council. The paper is an endeavour to indicate problems and fields of research worthy of study in relation to animal nutrition. It is noteworthy that under this heading are included such diverse subjects as human dietetics, animal and forage husbandry, judging and food requirements of farm animals, and diet in relation to reproduction. There are undoubtedly great advantages in describing and defining the objects of scientific research, but it is, perhaps, permissible to stress the fact that, in the last resort, the organisation of research depends upon the supply, and, what in this connexion may be termed, the "nutrition," of qualified scientific workers! So far as Great Britain is concerned, it would appear that the majority of the problems indicated (with the exception, perhaps, of the scientific judging of farm animals) are the subject of study in one quarter or another. For example, at Cambridge great additions to the knowledge of nutrition continue to be made at the School of Bio-chemistry under Prof. Gowland Hopkins, and at the School of Agriculture, under Prof. T. B. Wood, workers on nutritional calorimetry and the physiology of reproduction continue to make progress. The most prominent consideration, however, before workers on the scientific aspects of nutrition in Great Britain is the need for the careful study of what may be termed the balance of essential food substances, as distinct from the absolute amounts of each of such, and it would appear that a great deal has still to be learned as to the interplay in nutrition between the relative quantity of proteins, carbohydrates, minerals, and even vitamins, which may be contained in diets, both in health and disease. On the applied side of the subject, the ultimate (and most difficult) problem is, undoubtedly, how effectively to introduce science into a subject so much at the mercy of fashion and prejudice as the feeding of animals.

A paper by G. McCready Price on "The Fossils as Age-markers in Geology" (*Princeton Theological Review*, vol. 20, p. 585, 1922) affords interesting evidence, even in its place of origin, of the campaign that is being carried on in the United States against the recognition of organic evolution. The author states that he is a geologist, who has convinced himself that no true sequence of faunas is traceable in the rocks, and that zoological provinces may have existed in which trilobites, nummulites, and ammonites lived simultaneously in various portions of the globe. The apparent absence of eroded surfaces between stratified series that are judged, by their fossil contents, to differ widely in their age is regarded as a proof that no gap in the sequence has occurred. On this matter the author should study L. F. Noble's paper on the succession in the Grand Cañon of Arizona, which was recently noticed in Nature (April 7, p. 480). It is alleged that thrust-planes and reversals by folding have been called in as explanations by those who still cling to the views put forward by William Smith. It may be noted that the pioneers in the establishment of faunal sequences had no concern with doctrines of evolution; but Mr. Price states that those geologists who are "acquainted with scientific methods" have recently changed their views and accept a "new geology." When we find that the new geology accounts for an imaginary mingling of strata by the occurrence of a universal deluge, we realise that its scientific outlook is not younger than that of the Chaldees.

The Albert Medal of the Royal Society of Arts, which was instituted in 1862 as a memorial of the Prince Consort, and is given annually for "distinguished merit in promoting Arts, Manufactures, or Commerce," has been awarded this year in duplicate by the council, with the approval of the president, H.R.H. the Duke of Connaught, to Sir David Bruce and Sir Ronald Ross, in recognition of the eminent services they have rendered to the economic development of the world by their achievements in biological research and the study of tropical diseases.

At a meeting held recently at the Mansion House, a committee was formed with the object of providing a national memorial to the late Sir Ernest Shackleton. The aim is to establish some suitable memorial of a permanent nature, but the first object of the committee will be to provide for the education of Sir E. Shackleton's children and to take his place in supporting his mother. The balance that remains, after meeting these two obligations, will be devoted to the encouragement of exploration. The hon. treasurer of the memorial fund is Mr. Howard Button, 61/62 Lincoln's Inn Fields, London, W.C.2. Subscriptions may be sent to him or to any branch of the National Provincial and Union Bank of England.

In order to commemorate the late Dr. W. S. Bruce, the polar explorer, a Bruce Memorial prize has been founded by subscription among his friends and admirers. The prize, which will take the form of a bronze medal and money award, is to be given from time to time for notable contributions to natural science in the nature of new knowledge resulting from personal visits to polar regions. The prize will be open to workers of all nationalities, with a preference for young men at the outset of their careers as investigators. Arrangements are being made to leave the selection of the recipients of the prize to a representative committee in Edinburgh. Further subscriptions will still be welcomed by the hon. treasurer, Mr. A. N. G. Aitken, 37 Queen Street, Edinburgh.

THE resignation is announced of Sir George Beilby after nearly seven years' voluntary service as director of fuel research and chairman of the Fuel Research Board under the Department of Scientific and Industrial Research, which was established in 1917 to investigate the nature, preparation, and utilisation of fuel of all kinds. Dr. C. H. Lander has been appointed director of fuel research, and Sir Richard Threlfall, a present member of the Board, to be chairman. The Hon. Sir Charles Parsons will continue as a member of the Board for a further period. Sir George Beilby retains his membership of the Advisory Council of the Department, and has consented to act as honorary adviser to the Board. The following have been appointed additional members of the Board: Mr. R. A. Burrows, Sir John Cadman, Dr. Charles Carpenter, Mr. Samuel Tagg, Sir James Walker, and Prof. R. V. Wheeler.

IN his recent presidential address to the Institute of Physics, Sir J. J. Thomson gave some account of the work he saw during his recent visit to America in the research departments of some of the great manufacturing firms. These laboratories were established in the face of considerable opposition, but now the unanimous opinion appears to be that the research department is one of the most profitable in manufacturing concerns, and, however great the necessity for economy, its cost would be the last to be reduced. The scale of the laboratories is far greater than anything in Great Britain, and much of the work carried out is not merely what may be called development work, but is fundamental scientific work, worthy of a university laboratory. On the other hand, the American universities do not seem designed to produce a large number of men qualified to take up advanced research work. For example, few of the science students have the necessary equipment in mathematics, and the stern training which a good honours man in a great English university has to go through appears to be unknown. The system is doubtless good for the average man, but a successful research institute requires something more than the average man: it needs men with high scientific knowledge. In this regard, Great Britain has a distinct advantage which is sorely needed if it is to hold its own in competition.

THE annual conversazione of the Institution of Electrical Engineers will be held at the Natural History Museum, Cromwell Road, S.W., on Thursday, June 28, at 8.30 P.M.

IT is announced in the *Times* that Sir E. Wallis Budge, keeper of Egyptian and Assyrian antiquities at the British Museum, has been elected a foreign correspondent associate of the Lisbon Academy of Sciences.

A REPLICA of the portrait of Benjamin Harrison, painted a short time before his death by Mr. Cyril Chitty of Ightham, has been purchased by private subscription and presented to the Maidstone Museum. It has been placed in the room in which selected examples of Mr. Harrison's flint implements are exhibited.

THE annual general meeting of the Institution of Gas Engineers is to be held on June 26-28 in the City Hall, Belfast. At the first session of the meeting the Birmingham medal will be presented to Mr. W. Doig Gibb, and Mr. J. D. Smith, engineer and manager of the Corporation Gas Works, Belfast, will deliver his presidential address. A number of reports and papers will be presented to the meeting and discussed.

"NATIONAL Baby Week" will be observed on July 1-7, and we have received from the National Baby Week Council (117 Piccadilly, W.1) pamphlets explaining the object of baby week and how to organise a baby week celebration, and dealing with the activities of the Council. The Council desires to promote in the widest sense the safeguarding of infant life.

IT is stated in the *British Medical Journal* that Dr. Kleiweg de Zwaar, of Amsterdam, has instituted a triennial prize of the value of 2500 francs, which will be awarded for the first time in 1924 for the best work in physical or prehistoric anthropology during the preceding three years. Candidates should apply before November 1 to the Secretary, École d'Anthropologie, 15 rue de l'École de Médecine, Paris.

THE Society of Glass Technology has issued a provisional programme for its visit to France on June 30-July 6. The details of the meeting are being arranged by M. Delloye, of the Glaceries de St. Gobain, Chauny, and Cirey, and visits to a number of glass factories in and near Paris are promised. On July 2 there will be a joint meeting for the presentation and discussion of papers with the French Society of Civil Engineers, and it is hoped that Prof. H. le Chatelier will address the meeting.

THE centenary of the death of the famous horologist, Abraham Louis Bréguet, will be celebrated in Paris on October 22-27, by an exhibition of his works at the Musée Galliera, a special meeting at the Sorbonne, and a reception at the Hôtel de Ville. The Congrès National de Chronométrie will also meet in Paris in October, under the honorary presidency of M. Baillaud, director of the Paris Observatory, and of General Sebert. Besides discussing general questions relating to chronometry, the congress will aim at the formation of a Chronometric Union under the direction of the International Research Council.

THROUGH the great generosity of Mr. Charles Heape, of Rochdale, the Manchester Museum will shortly come into possession of a fine collection of native implements, ornaments, and weapons, which will add greatly to the value of the ethnological collection that it already possesses. The bulk of the specimens are drawn from the Pacific, but the collection also contains some objects from the Eskimo and from Egypt. The collection has been catalogued by Messrs. Heape and Edge-Partington, and the catalogue was printed some time ago, and issued privately. It would be of great advantage to ethnology if, some day, this invaluable source of information should be reissued, if necessary by subscription. The collection contains a representative set of Polynesian weapons. There are also many examples of shell-work, especially of mother-of-pearl, which should be of great interest, and much that will be of considerable use to the student of ornament. When the exhibits are classified and exhibited they will form an excellent foundation for the study of the material culture of Occania.

AT a recent meeting of the council of the Royal Agricultural Society, some account was given of the work in hand by the Society's Research Committee. Experiments are in progress in Leicestershire to test the value of basic slags and other fertilisers as measured by the increase in weight of cattle and sheep. Silage is to be made in clamps or pits at Cambridge and tower ensilage in East Suffolk, and the products are to be used next winter as feed for dairy cows; the effects of the silage on the yield and quality of the milk will be watched. Pig-feeding is also being investigated at Cambridge, where experiments will be made on the effects of grinding, soaking, and cooking on the nutritive value of maize, and on feeding with barley and potatoes, while similar trials will be made at the Harper-Adams Agricultural College on the value of home-grown products; in each case, the weight of flesh produced as well as its quality, will be investigated. The Research Committee of the Royal Agricultural Society is doing valuable work in thus supplementing the investigations carried out at research institutes and aiding in bridging the gap between the research worker and the practical farmer.

THE Société Française de Physique celebrates this year the fiftieth anniversary of its foundation, and to mark the event the Société is organising a National Physical and Wireless Exhibition which will be held in the Grand Palais, Paris, on November 30–December 17, concurrently with the Aeronautical Exhibition. The list of patrons, headed by the president of the Republic and the chiefs of the various ministries, includes leading personalities of the French scientific and industrial world. A guarantee fund of one million francs has been subscribed by eighty-two firms and individuals. The exhibition, which will embrace the principal scientific and industrial applications of physics, is to be divided into the following sections: Experimental physics; retrospective display of physical apparatus; radio-telegraphy and telephony; vacuum, X-ray and thermionic tubes; biological physics, physiology; telegraphy, telephony, signalling; various industrial and domestic applications of electricity; electro-chemistry; electric cables; glass, porcelain and other insulating materials; optics; photography, cinematography; illumination; rarefied and compressed gases; heating; metallurgy; acoustics; measuring and control apparatus; and instruction, books, reviews.

THE forthcoming meeting in London of the International Association of Navigation Congresses is an event of outstanding importance in shipping and port circles. The Congress will be held on July 2–July 6, and will be attended by numerous and influential delegates from all over the world, many of whom are contributing reports on matters of which they have expert knowledge. It is the thirteenth meeting of the Association; normally a congress is held every third year, but the regular sequence was broken by the War. The last meeting was at Philadelphia in 1912; consequently much interest and importance attaches to the revival of the gatherings after a lapse of more than ten years. The King has graciously accepted the position of patron; Lord Desborough is president, and there is a strong and influential British organisation committee. The subjects to be discussed include the following: (*a*) Inland navigation: the utilisation of waterways for the production of power and its consequences and applications; the influence of surface waters and subterranean sheets of water on the flow of rivers; and estimation of the water consumed for navigation and irrigation purposes, and the portion returned to the subterranean sheet of water. (*b*) Ocean navigation: the accommodation to be provided for ships in order to satisfy the future dimensions of vessels; mechanical equipment of ports; concrete and reinforced concrete: their applications to hydraulic works; means to assure their preservation and their water-tightness; the use of liquid fuel for navigation and its consequences; the utilisation of tides for the production of power for the working and lighting of ports; and the principal advances made recently in lighting, beaconing, and signalling of coasts, and standardisation (unification) of the languages of maritime signals.

THE Museums Association will meet at the Guildhall, Hull, on July 9-13. On Tuesday morning, July 10, there will be an official welcome by the Lord Mayor, and the president, Mr. T. Sheppard, will give an address on "The Place of the Small Museum." Later, at the Hull Luncheon Club, the delegates will be entertained, and the president will give an address on "The Evolution of a Yorkshireman." A number of papers will be read upon various aspects of museum work, and there will be numerous social functions and visits to places of interest. On Friday morning, July 13, there will be an address on "American Museums" by a delegate from the American Museum of Natural History, New York, and also cinematograph exhibitions. In the afternoon one section will visit York and will be entertained by the Yorkshire Philosophical Society in the grounds there; another party will sail for Copenhagen on the s.s. *Spero*, and from a preliminary programme received from Dr. C. M. C. Mackeprang, of the National Museum at Copenhagen, it appears that the members will be received on Monday morning, July 16, at the National Museum and inspect the National Collections; they will be then entertained to lunch in the Museum. In the afternoon they will visit Rosenborg Castle and later will attend a reception at the Town Hall. On

Tuesday, visits will be paid to Thorvaldsen's Museum and the Museum of Applied Art. In the afternoon the National Art Gallery and the Zoological Museum will be visited, and later there will be a trip in the Danish Expeditionary ship *Dana*, which is under the charge of Dr. Petersen. On Wednesday, July 18, there will be a visit to the Open-Air Museum at Lyngby, a visit to the Natural History Museum in Frederiksborg Castle, where the members will be entertained to lunch, and later a visit to the famous castle at Elsinore. On the following day the members will visit the Glyptotheke, returning to Hull by the s.s. *Spero* on the same evening.

Mr. I. H. N. Evans, of the Federated Malay States Museums, Taiping, has written, for appearance with the Cambridge University Press, "Studies in Religion, Folk-lore, and Custom in British North Borneo and the Malay Peninsula," giving the results of research carried out in the years 1910–21. The same house will publish in the summer "The Banyankole," by the Rev. J. Roscoe. It will form the second part of the report of the Mackie Ethnological Expedition to Central Africa.

In the chairman's report of the National Illumination Committee for 1922, now issued in pamphlet form, it is stated that the provisional definitions of photometric terms and units have now been adopted, and form the basis of a series to be issued shortly by the British Engineering Standards Association. The latter body has been invited to form a sectional committee on illumination. Reference is also made to the committee which is investigating the subject of motor-headlights, and, as a preliminary to suggestions, is considering the recommendations already made in other countries. The pamphlet contains an official translation of the French text of the photometric definitions.

Our Astronomical Column.

Announcement of a New Comet.—Mr W. N. Abbot, the British schoolboy in Athens who recently announced the brightening of Beta Ceti, now reports the discovery of a comet on June 12. The Right Ascension is given as $15^h\ 13^m\ 4^s$, and the Declination 53° 26′ N., in the constellation Draco. As the telegram is not quite in the regular form, there is some doubt whether the Declination may not be the complement of the above, that is, 36° 34′. No further information is at present to hand.

Proposed Solar Observatory in Australia.—This observatory has now been planned for several years; a message, dated April 17, from Melbourne to the *Times* indicates that the arrangements are making considerable progress. The site has been chosen at Mount Stromlo, near Canberra, the federal capital.

Prof. Duffield, of University College, Reading, was then in Australia and was being consulted, together with the Astronomer Royal and Prof. Turner, on the question of the selection of a director. It was proposed that the new director, when selected, should be given an opportunity of visiting, among other observatories, the solar observatory on Mount Wilson. As that observatory takes the leading place in researches on solar physics, it is obvious that the director of the new observatory should be intimately acquainted with its methods, and should arrange a programme of work that would supplement the results obtained there. As the two observatories are some 90° apart in longitude, the Australian station could continue the record of interesting outbursts after sunset in California.

Photometric Observations of the Planet Mercury.—It is of considerable importance to measure the brightness of this elusive little planet, since the result has a considerable bearing on the estimate we form of the condition of its surface. The conditions for doing so are much easier in the tropics, owing to the shorter twilight, the prevalence of clearer skies, and the greater altitude of the planet. Mr. J. Hopmann, who visited Christmas Island for the recent eclipse, utilised the occasion to compare Mercury with neighbouring stars (Arcturus, Spica, Procyon, Regulus, Deneb, Denebola, etc.) and the planets Saturn and Jupiter. On September 5 it was brighter than Saturn by a whole magnitude, on November 5 even brighter than Jupiter, which was, however, lower down. It was seen at Malta on November 15 when only 12° from the sun.

Mr. Hopmann has reduced his observations to distance of Mercury from the sun 0·3871, from the earth 1·0, and obtains the formula $-0{\cdot}711$ mag. $+0{\cdot}03582$ mag. $(\alpha - 50°)$, α being the phase angle sun-Mercury-earth. The first term was given as $-0{\cdot}998$ mag. by Müller and Jost, their second term being practically the same as his. In other words, he makes the planet a quarter of a magnitude fainter, thus indicating a still lower albedo, and a condition of surface probably approximating to that of the moon (*Astr. Nachr.* 5220).

Photographic Studies of Nebulæ.—Mr. J. C. Duncan contributes his third paper on the studies of the form and structure of nebulæ from photographs made with the 100-inch and 60-inch reflectors and the 10-inch Cooke refractor in the years 1920 to 1922 to the *Astrophysical Journal* (vol. 57, No. 3). The previous papers appeared in volumes 51, p. 4, and 53, p. 392, of the same journal. The present communication is accompanied by eleven excellently reproduced plates. Evidence of the existence of dark nebulosity is found in N.G.C. 1977, M 78, the Trifid nebula, the dark objects Barnard 72, 92, 93, and 133, and the American nebula. Of great interest is N.G.C. 4038-4039, a bright spiral of unique form with faint extensions of extraordinary appearance. In a field the size of the full moon in Coma Berenices, the 100-inch telescope photographs no less than 319 small nebulæ. The object N.G.C. 6822 is found to be a mixture of stars and small nebulæ resembling the magellanic clouds.

In examining these reproductions taken with the great 100-inch mirror, one cannot but recall and admire the fine photographs which Dr. Isaac Roberts took with his small mirror of only 20-inches aperture. To take a case in point, it is interesting to compare the reproduction of the nebula N.G.C. 1977 in Orion taken with the 100-inch mirror with Roberts's reproduction in plate 17 in his volume of "Photographs of stars, star-clusters and nebulæ," taken in 1889 and published in 1893. The exposure for Roberts's photograph was 3 hours 25 minutes, while that with the 100-inch was 5 hours 40 minutes. There is very little difference between these photographs except the sharpness of the details and the greater contrast in light and shade, which in the 100-inch reproduction has been secured purposely by repeated copying.

Research Items.

Ethnology of Malta and Gozo.—In the Journal of the Royal Anthropological Institute (vol. lii., 1922) Mr. L. H. Dudley Buxton publishes an exhaustive essay on the ethnology of Malta and Gozo. The skulls discovered in the course of excavation and examination of the existing population lead to some interesting conclusions. The First Race, the Megalith builders, are certainly akin to the early and present inhabitants of North Africa, Sicily, Corsica, Sardinia, and Spain, all belonging to the Mediterranean races. Their successors, the Second Race, exhibit Armenoid characteristics, and were probably immigrants from the eastern Mediterranean. Their arrival probably occurred towards the end of the Bronze or in the Early Iron Age. Armenoids with an admixture of Mediterranean blood, they probably came to Malta from Carthage. They may have destroyed the previous inhabitants, or they may have pursued methods of peaceful penetration. At any rate, they established themselves firmly in Malta, and all later introduction of foreign blood has failed to raise the variation. In later times there have been local variations, but the differences between Malta and Gozo are not greater than the differences between the general population of Malta and at least one, and possibly more, of the more isolated villages.

Treatment of Leprosy.—In a recent lecture delivered to the Royal Society of Arts and published in the Journal of the Society for May 18, p. 452, Sir Leonard Rogers dealt with the problem of leprosy. He estimates that at least three million lepers exist. The disease is communicable, though its infectivity is very slight, and isolation of the infective cases is the only practical preventive measure. Hitherto no effective treatment has been known; but during the last few years, and largely through the researches of Sir Leonard Rogers, certain derivatives of chaulmoogra oil, an old Indian remedy for tuberculosis and leprosy, have been found to exert a beneficial action, and many of the treated cases have lost all signs of the disease and appear to be cured.

Giardias living in Man and other Animals.—*Giardia Lamblia* is a well-known protozoan parasite of the human intestine, and other similar parasites are met with in the intestinal tract of the rabbit, dog, and tadpole. It has been supposed, therefore, that man may become infected from these lower animals. In order to throw some light on this question, the various species have been critically examined by R. W. Hegner (*American Journ. of Hygiene*, vol. ii., No. 4, pp. 435 and 442). *G. duodenalis* from the rabbit and *G. canis* from the dog are considered to exhibit such differences in size, form, and structural details as to constitute species distinct from each other and from *G. Lamblia*. *G. agilis* from the tadpole is more like *G. Lamblia* than the two others, but is sufficiently different to constitute a distinct species. *G. alata*, another giardia from the tadpole described by Kunstler and Gineste, is considered to be identical with *G. agilis*.

Cancer in Plants.—The exhaustive researches of Erwin F. Smith, of Washington, in the pathology of crown gall in plants have led him repeatedly to emphasise the resemblances between the abnormal growths which may be produced in plants by the experimental inoculation of *Bacterium tumefaciens* and malignant tumours in animals. According to his view, which is shared by Jensen, the bacteria provide the stimulus at the beginning of the disease, which is then continued by the stimulated but uninfected cells behaving as parasitic cells similar to cancer cells. A careful re-investigation of the facts by W. Robinson and H. Walkden in Manchester (*Annals of Botany*, vol. cxlvi., 1923, p. 299) does not, however, bear out this interpretation. They find that the careful examination of serial sections usually reveals the relatively close proximity of the causal bacteria to the proliferating tissues, and that there is no evidence that the cells continue to grow in an abnormal way when they are removed from the immediate influence of the bacterium. The analogy with animal cancer, in their view, wholly breaks down.

Fruit-growing in North Carolina.—Supplement No. 19 to the U.S. *Monthly Weather Review* contains a discussion by Mr. Henry J. Cox, meteorologist, on "Thermal Belts and Fruit-growing in North Carolina," and an Appendix by Mr. W. N. Hutt, former State Horticulturist, on "Thermal Belts from the Horticultural View-point." The whole subject is treated with minute detail, specially screened temperature observations having been taken at several fruit orchards and at different positions on the slopes of the same orchard. The subject is well illustrated by plates and diagrams, and the results obtained are scientifically manipulated. Minimum temperature and its duration are the chief factors involved in the growing of fruit. Valley floors must in nearly all cases be avoided unless means are available for orchard heating, since on critical nights of temperature inversion the thermometer at the bottom of valleys often falls 15° or 20° F., and sometimes even 25° or 30° F., lower than higher up on the slope. Dense vegetation is responsible for great loss of heat through radiation, and a cultivated orchard is therefore warmer than one planted in grass. The topography of a region is paramount. The Appendix shows the differences of temperature at 16 stations, and a summary of the horticultural data, such as first bloom, full bloom, and bloom all shed, of apples and peaches, with the cause and date of injury where experienced, and the yield. Much of the damage sustained is due to cold-air traps or frost pockets. In some years a heavy yield of grapes is secured, while apples are a failure, this being due to the later blooming period of grapes. The apple tree is normally an alternate bearer, and the heavy drain on the energies of the trees one year is usually followed by a weaker bud development and lighter crop the following season.

Miocene Cichlid Fish from Haiti.—Prof. T. D. A. Cockerell describes and figures under the name of *Cichlasoma woodringi*, n. sp., an interesting fossil fish from the Miocene of Haiti (Proc. U.S. Nat. Mus., vol. lxiii. art. 7). Cichlid fish abound in South and Central America and in tropical Africa, while fossil representatives have been found in Algeria (Palæochromis) and in the Eocene of Wyoming (Priscacara). Six species or races of Cichlasoma are living to-day in Cuba, and the question arises whether these last are an invasion from the south or the remains of a once widely distributed Antillean fauna. Prof. Cockerell is inclined to hold the latter view.

The Formation of Vitamin-A.—It has been known for some time that the only source of vitamin-A is the plant, and that the green parts are richer in it than the colourless parts are. Dr. Katharine H. Coward has carried the investigation further, and her results are given in two papers in the *Biochemical*

Journal (vol. 17, No. 1, 1923). She shows, first, that light is necessary for the formation of vitamin-A, although neither chlorophyll, carbon dioxide nor oxygen need be present. It can also be formed in the almost complete absence of calcium. A further clue was given by the apparent close association of the lipochrome pigments (carotene, etc.) with vitamin-A in various articles of diet. It had indeed been suggested that the two substances might be identical. But this was disproved by Drummond. The orange-yellow pigment, carotene, is well known as giving the colour to carrots. Dr. Coward found, however, that flowers, or parts of flowers, exposed to light, if they contained carotene, also contained vitamin-A, and that absence of the pigment meant absence of the vitamin. But both may be present in tissues not exposed to light, as in the root of the carrot. Evidence is given that the vitamin has been transported to the root from the leaves. Although the investigator ventures no hypothesis on the matter, it seems highly probable, from the necessity of both light and carotene for the production of vitamin-A, that the pigment acts as an optical sensitiser, similar to chlorophyll for the formation of formaldehyde. It would be of interest to know whether the rays absorbed by carotene are the most effective.

STRUCTURE OF CARBON MONOXIDE AND NITROGEN.—In an interesting paper in the Proceedings of the Physico-Mathematical Society of Japan for April, H. Nagaoka discusses the band spectra of nitrogen and carbon monoxide. He starts with the assumption put forward by Langmuir, that the external electron configurations of the two gases are very similar. The band spectra, which are presumably due to the external electrons of the molecule, should therefore be in close agreement. This is shown to be the case, with small differences indicating slight peculiarities of structure. The author then remarks that the ratio of the specific heats of the two gases cannot be accounted for on the assumption of Langmuir that the two nuclei are in the same cube (a difficulty pointed out by Partington in 1921), and he therefore proposes another model for the gases, in which two cubes are joined at an edge. This would give the correct value of 1·40. The two connecting electrons in the edge are pulled together by the nuclei, so that the resulting external electronic arrangement is that of two tapering six-faced figures connected by a narrow neck. The author points out that the values of the ratio of the specific heats can serve as a useful criterion in differentiating between possible and impossible electron configurations.

PHOTO-ELECTRIC CONDUCTIVITY OF CRYSTALS.—A number of contributions to our knowledge of this subject have been made during the past three years by Drs. B. Gudden and B. Pohl, of the University of Göttingen, in communications to the *Zeitschrift für Physik* and the *Physikalische Zeitschrift*, and a short summary of these is given in the issue of *Die Naturwissenschaften* for May 11. They find that all crystals with high refractive indices possess this conductivity, and that if, when withdrawn from the influence of light, they are insulators, when exposed to it they show an initial conductivity which is relatively large and proportional to the energy of the incident light. When the wave-length of the light is altered, the quotient of the quantity of electricity transmitted divided by the energy of the light incident shows the usual maximum at the wave-length of greatest absorption, but when it is calculated for the energy of the light absorbed, it continues to increase towards the longer waves and eventually becomes a linear function of the wave-length. Over this region the authors consider that the observations justify the conclusion that one quantum of light energy absorbed gives rise to one electron in the crystal.

AMMONIUM SULPHIDES.—Although a solution of ammonium sulphide has been in use in the laboratory for many years, the anhydrous substances are not well known. The solid compounds NH_4HS and $(NH_4)_2S$ were said to have been obtained by Bineau in 1838-39 by the interaction of gaseous ammonia and hydrogen sulphide in the required proportions by volume, but doubt was thrown on the formation of the second compound by experiments of Bloxam in 1895. The matter has been reinvestigated by Thomas and Riding, whose experiments are described in the May issue of the Journal of the Chemical Society. Anhydrous NH_4HS is best prepared by alternately passing ammonia and hydrogen sulphide into dry ether. Attempts to prepare $(NH_4)_2S$ were not very successful. The prolonged action of ammonia on the hydrosulphide in ether produced no sulphide, but on the addition of alcohol a yellow oil separated, which on standing gave some transparent cubic crystals, believed to be $(NH_4)_2S$. The research throws very little light on the formation of the latter substance, but the method of preparation of NH_4HS is a convenient one.

ABSORPTION SPECTRA AND ATOMIC STRUCTURE.—In the *Comptes rendus* of the Paris Academy of Sciences for April 23, M. Victor Henri derives from the study of the absorption spectra of a large number of substances, both in solution and in the state of vapour, some important conclusions bearing on Bohr's theory of atomic structure. He shows that the absorption spectrum of a solution may be either one composed of narrow bands (10-30 Å) disposed in regular series, or one of broad bands (200-500 Å); in a few cases both types of bands are present, but the narrow ones then occur only in the less refrangible regions. When the vapour of the substance is examined, the narrow bands of the solution are replaced by fine lines, while the broad bands of the solution appear also in the vapour as unresolved bands. He explains the narrow bands by the theory of quanta, the molecule being supposed to possess a series of stationary states, of which the energy is determined by the movements of the electrons, atoms, and the molecule. He distinguishes four cases. When the molecule contains only a single double bond, such as C=C, C=O, C=N, N=O, the other atomic groups in the molecule being all saturated, only broad bands are afforded either by the solution or the vapour. When the molecule is as simple as possible, but contains two or more groups with double bonds, narrow bands are given by the solution and fine lines by the vapour, distributed in series conformably to the theory of quanta. When the two double bonds are removed by the introduction of CH_2, the narrow bands run together and form wide bands both in the solution and the vapour. When the molecule is rendered more complex by the substitution of more and more complicated groups of atoms, the narrow bands of the solution enlarge and the fine lines of the vapour fuse together, so that eventually a complicated molecule shows only broad continuous bands. He therefore finally concludes that for molecules containing only one double bond, the first postulate of Bohr is inapplicable, only the second postulate being valid; whereas for molecules with two adjacent double bonds both postulates apply, the first being determined by the existence of an electric polarity in the molecule.

South-Eastern Union of Scientific Societies.

THE twenty-eighth annual congress of the South-Eastern Union of Scientific Societies was held at Maidstone on May 30-June 2 inclusive. Dr. Alex Hill occupied the presidential chair, in succession to Sir Charles F. Close. The headquarters of the Congress were at the Museum, where members were given every convenience by the curator, Mr. J. H. Allchin, and the assistant curator, Mr. H. J. Elgar.

The Mayor opened the meetings by welcoming members and delegates at the Town Hall, where the ancient maces and charters were exhibited and described by Mr. W. H. Day, one of the secretaries, and Mr. W. Dale. Visits followed to various ancient buildings in the town, of which the town possesses a large number. All Saints' Church was visited by more than a hundred members, and was described by Mr. Dale. The church was built in 1395 by Archbishop Courtenay and, although renovated in the last century, remains in practically its original condition, showing in its fine, delicate and lofty columns and its windows the best of the perpendicular characteristics. A very fine set of the original oaken sedilia, with elaborately carved canopies, were seen, and about a score of ancient miserere seats in the choir, which when tipped up have a small seat beneath, giving a sort of rest for tired singers and others. Hard by is the Archbishop's Palace, a stately Elizabethan building, now used as a welfare centre, with wainscoted rooms and old carving. The interesting building known as the tithe barn, with external stone staircase, was also seen. Near at hand and completing the group of ecclesiastical buildings is the massive gateway to the old monks' college, while all were close to the slope leading down to the Medway, much used in early days for travel and transit. The refectory of the Guild of Corpus Christi, in Earl Street, dating from the fourteenth century, was next visited. As a fine piece of mediæval architecture, it deserves a better fate than to be used by a brewery for the making of barrels. It is in dilapidated condition, but the fine roof and the beautiful windows give an idea of its former magnificence. It has a dole window. For nearly three centuries it was occupied by the Grammar School until 1871. Another party of members visited at the same time the bacteriological and chemical laboratories of the Kent County Council, under the guidance of Dr. C. Ponder and Mr. F. W. F. Arnaud.

Dr. Alex Hill's presidential address was on "Antipodean Flora," and in this he gave some interesting facts of the mimicry practised by certain plants observed by him during his journey round the world. Reference was made to the possibility of the isolation of the Australian flora having been accomplished by the dividing-up and the shifting of the land-masses of the Indo-Australian continent in accordance with what has come to be known as Wegener's theory. The means by which eucalyptus and other trees adapt themselves to a rainfall of 8 or 9 inches were described. Exploring the caves at Yallingup, the root of a jarrah tree was met with which had gone down 120 feet in search of water.

The morning session of the second day of the meeting was devoted to botanical papers, and Sir David Prain spoke on "The Story of some Common Garden Plants," the potato, the artichoke, and others being dealt with. A paper by Mr. Robert Paulson on the "Fungus Root" followed. In the afternoon three excursions were arranged. Geologists went to the Aylesford gravel pits and to a Kentish Rag quarry. Botanists followed Dr. A. B. Rendle on an enjoyable ramble, while a large party visited Allington Castle, by permission of Sir Martin Conway. A castle is thought to have occupied the site in Saxon times, and to have been demolished by the Danes prior to their traditional defeat at Aylesford. Owned by Harold Godwin's brother, Ulnoth, it passed into Norman hands and was rebuilt. As it appears to-day, it is for the most part the work of Sir Stephen de Pencester, who fortified it in the reign of Edward I., in about 1281. Tudor additions were made. The famous Sir Thomas Wyatt was once the owner, and as leader of the rebellion to oppose the Spanish marriage of Queen Mary, he suffered the usual fate on its failure. Tennyson lays the first scene of the second act of "Queen Mary" in the court of Allington Castle. In the evening the Mayor and Mayoress (Councillor and Miss Wallis) received the Union in the Museum.

The third day was devoted to papers in connexion with the Regional Survey Section. Mr. Victor F. Branford gave an address on "The Natural and the Social Sciences," a paper which will later be printed in full. A lecture by Mr. F. W. F. Arnaud on "Vitamins" reviewed the history of the discovery of these elusive bodies and showed the present position of our knowledge of the subject. Botanical and archæological excursions followed. The famous Coldrum burial-place was visited, and a description given by Mr. W. H. Cook. Halling burial-place followed, where the site was shown from which the only Aurignacian skeleton found in this country was exhumed, and where true implements of that culture were found. In the evening a lecture by Mr. Reginald A. Smith, of the British Museum, was delivered on "Prehistoric Man in Kent." The most ancient remains, those found by Benjamin Harrison, of Ightham, are well represented in the Maidstone Museum.

On the morning of the last day of the meeting, a masterly address was given by Prof. E. B. Poulton on "Recent Advances and Discoveries in the Study of Entomology." The afternoon was devoted to visiting various megalithic remains in the district. The "Countless" Stones proved of great interest. They consist of about twenty large and small stones, and appear to be the thrown-down remains of more than one dolmen, or, as was suggested, of a double row of standing stones. Some of them are sarsens, but the majority are apparently Greensand or Wealden sandstones. An old record was found, showing that they were thrown down by a farmer by the aid of gunpowder towards the end of the eighteenth century. Kits Coty House was next seen, and a description given by Mr. W. Dale. The "house" is fenced round and is now safely looked after by the Office of Works. The stones are probably sarsens and have been shaped to the necessary requirements of the builders. Discussion ensued as to the origin of the name the dolmen bears. The guide-book derivation from Catigern was not thought quite satisfactory. It is said that a shepherd named Kit made it his dwelling, and it may once have been Kit's Cottage. The so-called White Horse Stone was then visited, another sarsen about which some fantastic romance has been weaved. A noticeable point about these megaliths is that they bear many cup-shaped hollows, but geologists agree that these may be due entirely to weathering. *Helix lapicida* was found on the White Horse Stone.

The Congress was very successfully carried through, and the local secretaries, Messrs. W. H. Day and J. W. Bridge, were congratulated upon the arrangements they had made.

The Constitution of the Alloys of Iron and Nickel.

THE joint paper by Dr. Hanson, of the National Physical Laboratory, and Mr. J. R. Freeman, jun., of the United States Bureau of Standards, on the above subject, presented at the May meeting of the Iron and Steel Institute, is one of great value. Of the elements used for alloying with iron for scientific and industrial purposes, none is more important than nickel. Moreover, the fact that it is an invariable constituent of meteoric iron, which may be regarded as a natural nickel-iron alloy, has invested the question of the equilibrium of these two elements with a high degree of interest. Its determination, however, has presented serious problems, due, on one hand, to the high melting ranges of the alloys and consequent pyrometric difficulties, and, on the other hand, to the difficulty of preparing the alloys free from carbon. Three years ago Dr. and Mrs. Hanson carried out a revision of the constitution of these alloys at temperatures below 900° C. The present publication completes this work right up to the liquidus of the system.

The alloys were prepared by melting the purest materials available in a "carbon ring" furnace; 50-gram melts were made in crucibles of fused alumina enclosed in a refractory muffle made of a mixture of China clay with 10 per cent. of alumina. Purified nitrogen was passed into the muffle to prevent oxidation of the melt. In taking cooling curves the melts were inoculated by means of a sawdust of iron or nickel for the pure metals or a mixture of the two for the alloys, which prevented supercooling. Platinum rhodium thermo-couples suitably protected were used for determining the temperatures, but they rapidly deteriorated with use, and in the case of the alloys rich in iron, possessing the highest melting points of the series, it was necessary to discard from one to two inches of the wire at the bulb end after each determination and remake the junction. The authors succeeded in keeping errors in temperature measurement, due to couple contamination, within 2°.

The results are shown in diagrammatic form in Fig. 1. It will be seen that, starting from pure iron, the liquidus curve drops from 1530° to 1502° at a concentration of about 5·8 per cent. of nickel. Over this range δ iron separates. The solidus is the line AEB. Within this triangle liquid and crystals co-exist. The area AEG represents the limits of existence of δ iron. Below G δ iron inverts to γ. It is somewhat remarkable that this transformation is rapidly raised by the addition of nickel, as shown by the line GE, and 3 per cent. of this element is sufficient to raise the transformation point by 100°. The line EFB represents the equilibrium between δ iron, γ iron and liquid, and its meaning may be expressed in the following way:—Solid E (δ iron) + liquid (B) react to form solid F (γ iron). The exact position of the point F has not yet been determined. The experiments thus indicate that the maximum solubility of nickel in δ iron is 3 per cent, and that this occurs at a temperature of about 1500°.

To the right of B there is an entirely different state of affairs. The liquidus curve drops continuously and much more slowly than hitherto from B to a minimum at C (1436° C.), the trough being very shallow, and then rises continuously to D, the melting point of pure nickel (1452° C.). Over the whole of this range there is complete miscibility between the metals in the solid state. Nickel, therefore, is much more soluble in γ than in δ iron, and the alloys consist when just solid of a continuous series of solid solutions. The solidus between B and D has, however, not been determined by experiments and is shown dotted. The authors state, however, that it is very close to the liquidus line, and throughout the range from B to D, all the alloys have very sharp freezing points similar to those of pure substances. Clearly, therefore, the temperature range between the liquidus and solidus is very small.

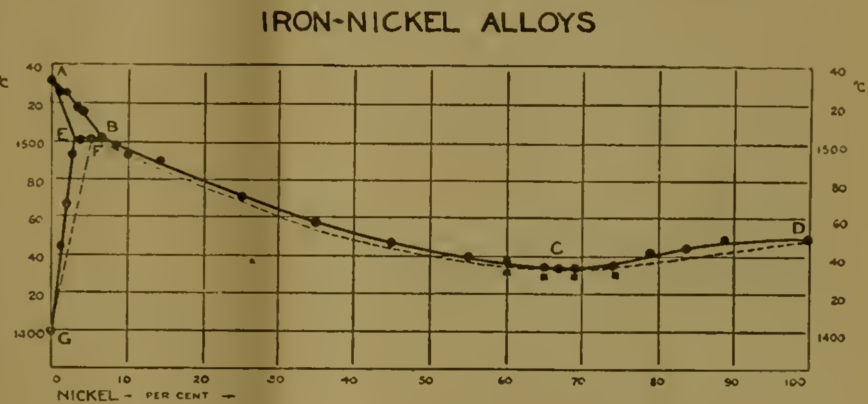

FIG. 1.

It is always difficult to determine the exact position of the minimum point of two curves of shallow inclination, and between 65 and 70 per cent the freezing point curve was found to be approximately constant, so that the exact location of C cannot be stated nearer than between these limits. Within the same range a second and smaller arrest point was observed between 2° and 5° below the liquidus. These are shown in the diagram. The authors have carefully tested whether these indicate the existence of a eutectic, but with negative results, and their conclusion is that C is the composition corresponding to a minimum in the freezing point of a continuous series of solid solutions.

In the latter half of the paper an account is given of attempts made to differentiate by means of the microscope between δ and γ iron, and to establish the fact that the change from one to the other is accompanied by a recrystallisation of the material. Transformations in iron and iron-nickel alloys take place so rapidly on cooling, that it is impossible to preserve by quenching the δ and γ modifications. Accordingly attempts were made to stereotype the structures existing at high temperatures by a vacuum etching of polished surfaces previously prepared. No clear indications, however, were obtained, and the surface markings on the specimens after this treatment were very complex. Experiments were carried out on polished specimens placed in narrow silica tubes filled with nitrogen at 20 mm. pressure, which were inserted in a furnace at 1300° C. Two tubes were used. After two hours at the above temperature, one of them was removed and cooled quickly, the other was raised rapidly to 1450° C. (within the δ range) and similarly cooled. On examination, a striking difference in structure between the two was found, constituting evidence that there is a distinct change in crystal structure at the δ to γ transformation. This may be regarded as a confirmation of Westgren's conclusion,[1] based on X-ray analysis, that δ and γ iron are constitutionally different. He found that the former has a body-centred and the latter a face-centred cubic lattice. H. C. H. C.

The Indian Eclipse Expedition, 1922.[1]

THE story of an expedition to observe the total eclipse of the sun, seen under the most perfect atmospheric conditions, but which failed to achieve any results, is described by Mr. Evershed in the report before us. Mr. Evershed's programme was of a high-class order, and those who know him and his great ingenuity in the construction and manipulation of astronomical apparatus will share his regret at his extreme misfortune on this occasion.

Originally Mr. Evershed proposed to occupy the Maldive Islands as his observing station, but, owing to difficulties of transportation, he and his party went to Wallal, near Broome, situated on the north-west coast of Australia, and joined Dr. Campbell's expedition. For the Einstein effect he took out with him a 12-inch photo-visual lens particularly well adapted for this problem, giving, as he states, "a large field of good definition and a larger scale than the lenses used previously, or that would be likely to be used by other expeditions." It was worked in conjunction with a 16-inch cœlostat, and it was the erratic behaviour of this instrument that spoilt the results. In spite of constructing a new tangent screw and refiguring the teeth of the driving sector to secure better driving qualities, the fifteen seconds exposure plates showed movement of the star images and poor definition of the corona due to the bad driving of the cœlostat. Two short exposure plates were badly fogged "in some unexplained way" over two-thirds of the surface, but otherwise the remaining portion showed the ends of the coronal streamers beautifully defined.

The second main effort of the expedition was to photograph with large dispersion the spectrum of the corona on the east and west limbs simultaneously, in order to determine the displacement of the green corona line due to the solar rotation, and to secure a more accurate wave-length of this line. Here again disappointment was experienced, for the corona line did not appear at all on any of the plates owing, probably, to the unusual faintness of this radiation at this eclipse. Perhaps Mr. Evershed rather courted disaster on this occasion, as it is generally conceded that during the time at and near a minimum of solar activity this radiation is also near a minimum of brightness.

It will be remembered that the Greenwich expedition to Christmas Island purposely eliminated the use of a cœlostat in its work by taking out a complete equatorial photographic telescope. This was done because experience at the eclipse of May 29, 1919, seemed to suggest that the definition of the star images on the astrographic plates was poor, owing probably to the distortion of the cœlostat mirror by the heat of the sun. Mr. Evershed's view regarding the employment of a cœlostat is that it is "good for the Einstein effect.' For only with a cœlostat is it practically possible to get an adequate scale." That he is emphatic on the point is shown by his statement that "the question of the cœlostat mirror introducing complications is, I think, a bogy. Plane mirrors can now be constructed of large size and perfect figure, and experience with mirrors, good and bad, has shown that little is to be feared from distortion of the surface when the silvering is fresh and good, and simple precautions are taken."

In the opinion of the present writer, the great drawback to the use of a mirror during eclipses, whether mounted as a cœlostat or siderostat, is due to the change of figure of the plane surface of the mirror, which causes an alteration in the position of the focus of the object glass. On many occasions during eclipse expeditions, although extreme care had been taken to secure a "perfect" focus on star spectra at night (the mirror then being comparatively cool), the focus was quite different for the solar spectrum during the daytime. Thus during eclipse work it was always found most necessary to watch very carefully the disappearing crescent of the sun on the ground glass almost right up to the time of totality, and if necessary alter the position of focus accordingly.[2]

It is satisfactory to note that Mr. Evershed did not return to India with an empty bag. During a short stay at Broome on the return journey he set up the 16-inch siderostat and 12-inch lens and succeeded in obtaining a good high dispersion spectrum of Canopus and Achernar to use in connexion with his work on the spectrum of Sirius.

During this expedition Mr. Evershed was ably assisted by Mrs. Evershed and by Mr. Everson of the physics department of the University of Western Australia. WILLIAM J. S. LOCKYER.

Liberal Education in Secondary Schools.

ON Saturday, June 9, a conference of educationists in Yorkshire was held in the University of Leeds under the presidency of the vice-chancellor, Sir Michael Sadler, in response to a widespread desire to discuss certain questions affecting the supply of full-time education for boys and girls beyond the age of eleven years, and the choice of subjects in the School Examinations. In order to make the conference widely representative of educational opinion in Yorkshire, invitations were issued to the local education authorities, the universities, the training colleges, secondary schools, associations of secondary and elementary teachers, and other persons of educational experience. Upwards of 270 representatives attended the conference and were welcomed by the pro-chancellor, Mr. E. G. Arnold.

In an introductory speech, the chairman referred to the growing desire for wider opportunities of a liberal education in various parts of the world. This desire cannot be wholly explained as due to self-regarding motives. Ambition for advancement is no doubt a strong motive, but is not in itself blameworthy, especially when cherished by parents for their children. Sir Michael Sadler believes the movement has its counterpart in the movement towards greater freedom in self-government, and its deepest sources lie in a desire for liberty and the more generous development of human personality. Enlightenment and self-discipline are the two inseparable sides of a true liberal education. The force behind the desire for such an education is so powerful that it is the part of wisdom not to disregard it. He thinks that a liberal education begins away back in elementary education and extends beyond the limits of university education; that some of its indispensable factors cannot be tested by examination; and that it may be secured through diverse curricula, provided that in every curriculum a humanising spirit prevails.

Certain resolutions were thereafter submitted to the conference. After a lengthy and interesting discussion, in which a large number of delegates took part, the following motion was adopted: "That representations be made to the Board of Education urging the pressing need of further provision (by legislative change, if necessary) for the full-time education of boys and girls up to the age of sixteen, to include instruction of varying types." To this was added an addendum in favour of the pressing need of joint action between elementary and secondary branches of the Board of Education with the view of such provision and the closer combination of elementary and higher education. It is perfectly evident that there exists a large body of opinion in Yorkshire strongly in favour of greater facilities for education beyond the age of eleven and up to the age of sixteen. It is not so clear that opinion has definitely crystallised out as to the form this education should take. County Alderman Jackson, chairman of the West Riding Education Committee, expressed the opinion that the atmosphere of the mine and factory is not suitable for children between fourteen and sixteen; at that age they should be in cultured surroundings, and without doubt he expressed the views of an overwhelming majority of those present.

On the question of greater variety in curricula a discussion arose as to the desirability or otherwise of creating a new type of school in which instruction might be given of a kind different from that now normally offered in the secondary school. It was argued with some cogency that such a school might come to be looked upon as a school inferior in grade, providing an education of an inferior type, notwithstanding the suitability of the courses of instruction provided by it for the particular purpose. There is the danger, too, of segregating one class of children. Undoubtedly the great bulk of the pupils who would attend such schools would be drawn from the elementary schools. It is quite evident that many members of the conference would view with disfavour any further differentiation of schools while accepting the principle of greater differentiation of curricula. Obviously to them the logical position is to demand a common name for all full-time education, whatever its type, between the ages of eleven and sixteen.

Sir Henry Hadow, vice-chancellor of the University of Sheffield, in an interesting speech introduced a motion which, while welcoming the greater freedom in the choice of subjects for the First School Examinations now allowed by the Joint Matriculation Board of the Northern Universities, expressed the opinion that there should be greater freedom in regard to the groupings of courses for the Higher Certificate. The motion was agreed to unanimously.

Rothamsted Experimental Station.

Annual Visitation.

At the invitation of Lord Bledisloe, chairman of the Lawes Agricultural Trust Committee, a number of guests representing various agricultural interests visited the Rothamsted Experimental Station on Wednesday, June 13, for the annual inspection of the fields and laboratories.

The morning was occupied in a tour of some of the experimental plots, including two of the classical fields—Broadbalk, on which wheat is grown continuously, and Hoos, where barley is similarly grown. These have been for many years of the utmost value and interest to agriculturists in general, and the opportunity was taken to show the visitors some of the other plots laid down to test points that had, directly and indirectly, arisen from the results of these classical experiments. Among these may be mentioned the top-dressing series, designed to ascertain how the yield of the crop is influenced by spring dressings of artificial fertilisers applied in varying amounts and at various times; the malting barley series, in which the relation between malting value and manurial treatment is being examined; and the residual value of different manures on the succeeding crops. On this latter field the crop this year is clover, and the beneficial effect of previous organic manures, in particular cake-fed dung, is most striking.

After luncheon Lord Bledisloe briefly reviewed the purpose and recent progress of the Station. He laid stress on the care that is taken to avoid the erection of water-tight partitions between the scientific worker and the practical farmer, without in any way limiting the work of fundamental investigation, on which the application of science to agriculture is of necessity founded. Lord Bledisloe also referred to a number of the external activities of the Station, as indicative of the efforts made to keep in touch with the whole life of the countryside.

Sir E. J. Russell, director of the Station, then gave his statement on the work of the Station during the past year. The reorganisation of the laboratories has been completed, and the experimental work on the farm will shortly follow suit. Very considerable progress has been made in extending the outside centres: the experimental fields on the Woburn Farm are now in charge of Rothamsted, and Dr. Voelcker, who for many years has been in charge at Woburn, has consented to continue the work. Through the generosity of Mr. E. D. Simon, the use of an extensive farm—Leadon Court, Herefordshire—has been given to the Station, and under the management of Mr. J. C. Brown an extensive trial of the soiling system is being carried out. In addition, the Station has many centres on farms throughout the country, at each of which a repetition of a carefully designed experimental programme is being carried out. By this means it is possible in a comparatively short time to obtain trustworthy information on the degree to which the results of field trials at Rothamsted are modified at centres possessing different soil and climatic conditions. The work is being carried out at present on malting barley and potatoes with especial reference to the action of artificial fertilisers, and wherever possible the aid and support of the industrial organisations concerned have been enlisted.

Passing on to the work in progress in the laboratories, Sir John discussed it under its three main headings,—the cultivation of the soil, the feeding of the crops, and the maintenance of healthy conditions of plant work. In connexion with the work on soil cultivation and the physical properties of the soil, he stated that the Empire Cotton-growing Corporation has given a substantial sum for the development of this work, as it is convinced that questions of soil physics are of great importance in those parts of the Empire where cotton is grown. Among other recent developments are apicultural investigations and work on the control of insect pests by means of parasites. The New Zealand Government has been supplied with parasites of certain pests,—the earwig, pear slug larvæ, and pear leaf midge,—which cause extensive damage in that country.

Sir Matthew Wallace also spoke of the value of the work at Rothamsted to the practical farmer. He compared the present wave of agricultural depression with that of 1880 when he started farming, and said that the comparison made him optimistic for the future. The close relations that must exist between research centres and agricultural colleges if both are to keep ahead of the times were alluded to by Principal M. J. R. Dunstan, of the Royal Agricultural College, Cirencester. Mr. George Dallas, of the Workers' Union, said he was very greatly encouraged by the attention now being devoted by the Ministry of Agriculture and Stations like Rothamsted to the improvement of the lot of the farm labourer. He expressed the opinion that the recent increase of educational facilities will be of great benefit to the whole industry, and further it will help to prevent the departure of the best and keenest men from the land.

In the afternoon the visitors made a brief inspection of the work in progress in the laboratories.

New Principle of Therapeutic Inoculation.

In collaboration with L. Colebrook and E. J. Storer, Sir Almroth Wright published in the *Lancet* (February 24, March 3 and 10) an elaborate communication which is an expansion of a special lecture delivered before the Royal Society of Medicine in November 30, 1922. It is entitled "New Principles of Therapeutic Inoculation."

The new principles may be best understood by a brief reference to the older principles which they are intended to augment or replace. In the therapeutic inoculation for infective disease, it has hitherto been the custom, following Sir Almroth Wright's earlier work, to inoculate the infected individual with a vaccine prepared with the virus with which the individual is infected. While the results in chronic infections have been on the whole excellent, there has been disappointment in the cases in which a heavy infection of a septicæmic type occurred. This was due to a certain extent to the fact that the elaboration of specific protective substances was a matter of time, and the state of the individual might be such that he was incapable of elaborating protective substances at all.

For a long time, however, it was known that non-specific bacteria, or indeed substances not bacterial in origin at all, might be employed to augment quickly the patient's resistance by a process, it was thought, of leucocytosis and phagocytosis. While not agreeing with this suggested action, Sir Almroth Wright, by many new and ingenious technical methods, shows that what he calls an "epiphylactic" response may be evoked by bacteria which are not identical with those with which the patient is infected. This epiphylactic response occurs when inoculation is made into the blood *in vivo* or even *in vitro*, and takes place immediately by an extrusion of opsonic and bactericidal elements from the leucocytes—an ectocytic rather than a phagocytic process. These ectocytic substances are polytropic in character, *i.e.* they act not only on the homologous but also on heterologous bacteria.

There is, in fact, a non-specific immunity, and it is this which Wright and his collaborators aim at producing to tide the patient over the critical days of his severe infection. The process adopted is named "immuno-transfusion," and consists of the incorporation of healthy human blood which *in vivo* or *in vitro* has been made, by inoculation, to develop an adequate epiphylactic response and is laden with protective substances. In this process it is clearly pointed out that quantitative determinations are of the utmost importance, as a dose of antigen optimal for one patient may be highly detrimental for another. The methods recommended are complicated, and treatment of severe cases of generalised sepsis, if it is to be successful, must lie in the hands of highly trained serologists.

University and Educational Intelligence.

Aberdeen.—The Blackwell prize for 1923 has been awarded to Mr. F. C. Diack, the subject of the essay being "The Sculptured and Inscribed Stones of the North-east and North of Scotland."

The University Court has appointed the following lecturers to the newly instituted grade of reader in their respective subjects: Geography, Mr. J. M'Farlane; bacteriology, Dr. J. Cruickshank; public health, Dr. J. P. Kinloch; embryology, Dr. A. Low.

Prof. C. R. Marshall has been appointed John Farquhar Thomson lecturer on "The Human Body" for the year 1923–4.

Cambridge.—Mr. J. Barcroft, King's College, Dr. Adrian, Trinity College, and Dr. Hartridge, King's College, have been reappointed reader in physiology, University lecturer in physiology, and University lecturer in the physiology of the senses respectively; Mr. A. H. Peake, St. John's College, and Mr. T. Peel, Magdalene College, have been reappointed as demonstrators of mechanism and applied mechanics. Senior studentships have been awarded by the Royal Commissioners for the Exhibition of 1851 to D. Stockdale, King's College, and J. H. Quastel, Trinity College.

Sheffield.—An anonymous gift of 20,000*l.* has been accepted by the University for the purpose of founding an undergraduate scholarship and a number of post-graduate scholarships. The undergraduate scholarship is to be in the faculty of pure science, and is restricted to boys from King Edward VII. School, Sheffield. The post-graduate scholarships are to enable graduates to pursue research in ferrous or non-ferrous metallurgy.

At a meeting of the trustees of the Albert Kahn Travelling Fellowships Foundation on June 14, Mr. W. Randerson was elected to the fellowship for 1923. Mr. Randerson was educated at the Imperial College of Science, South Kensington, and during this year has been a research fellow of the Salters' Institute of Industrial Chemistry; recently he obtained the degree of M.Sc. (London) for a thesis on the chemistry of the soil solution. The value of the award, which is to enable a student of proved intellectual attainment to enjoy a year's travel for research, is again to be 1000*l*.

THE British Research Association for the Woollen and Worsted Industries is to award shortly a number of research fellowships and advanced scholarships. The fellowships, which are tenable in the first place for one year, are of the annual value of 200*l*. The advanced scholarships, also of one year's tenure, carry a maintenance grant, and are designed to afford opportunity for specialisation. They are tenable either in Great Britain or abroad. Applications for fellowships must reach the secretary of the Association at Torridon, Headingley, Leeds, before July 21, and should contain particulars of the candidate's training and experience.

AN article by Mr. H. A. L. Fisher in the *Empire Review* for June surveys the progress of education in the Empire since 1911, the date of the last Imperial Educational Conference. It has been marked in the Dominions by a development of university and college influence even more remarkable than the similar development in Great Britain, and by a quite noticeable family resemblance between the expedients adopted in the various parts of the Empire for dealing with school and college problems. As examples of this resemblance he cites the Ontario Continuation Schools enactment modelled on the British Act of 1918, the raising of the school age in Alberta to 15, Tasmania's new separate infant department, and Queensland's extended scheme of medical inspection. There has been likewise a very general augmentation of teachers' salaries, but this has failed conspicuously to meet the needs of the situation in sparsely populated tracts of country. The Director of Education in Manitoba writes of inexperienced girls placed in charge of district schools because capable men willing to accept such posts can no longer be found. Australia organises either correspondence classes or itinerant teaching. New Zealand employs group supervising teachers. In Canada, as in the United States, there has been an important movement in the direction of concentrating children of rural areas in central schools. Mr. Fisher concludes his article with a prophecy that during the next decade the four most important tasks will be the development of adolescent education in Great Britain, the strengthening of the Arts Faculties in Canadian universities in such a way as to save these institutions from degenerating into mere groups of professional schools with predominantly materialistic motives, the raising of the matriculation age in India, and "such reforms (including in the first place the geographical concentration of the higher teaching in the Arts and in Pure Science) as may enable London University to take its rightful place as one of the great High Schools of the Empire."

IN a paper on methods of college teaching read to the Association of Land Grant Colleges of America, an interesting sketch was given by Dr. W. W. Charters of experiments carried out by him as professor of education in the Carnegie Institute of Technology. When he joined the Institute some three years ago he found that while many of the experienced teachers in the four divisions—Engineering, Industries, Fine Arts, and Women's College — had worked out excellent methods of teaching by themselves, many of the younger members of the staff, who had had no specific and formal training in methods, needed guidance which it became his duty to provide. Finding nothing for the purpose in books on teaching methods, the authors of which concern themselves almost exclusively with elementary and secondary education, he organised a weekly seminar and made the instructors who enrolled for it draw up lists of their duties and difficulties. He thus obtained a list of 14 real practical difficulties. He next made a list of 30 of the best teachers in the faculty, and the members of his seminar class were let loose on the chosen 30 to wrest from them the secret of how to handle the 14 difficulties. The professors surrendered at discretion, and the storm troops returned stimulated by the encounters and laden with intellectual spoil, which they proceeded to hammer out into a pamphlet which has been in use ever since. In the following year in the course of a similar campaign, undertaken with the object of elucidating the difficulties of getting students to think, it was found that inductive sciences such as chemistry and physics afforded less opportunity than others for practice in reasoning. This was attributed to the technique of investigation being so refined and the equipment so elaborate that principles have to be for the most part merely verified by students without being re-discovered. In the third year difficulties in shop and laboratory teaching were dealt with. Great stress is laid by Dr. Charters on the value of the weekly seminar for inexperienced teachers, to be followed when practicable by criticism of actual performances.

THE report for 1921–22 of the Commissioner of Education of the United States, who, by the way, is an old Rhodes scholar and graduate of Oxford, shows that if the Federal Government's appropriation for his Bureau—the Education Office of the Department of the Interior—is, as he says, "infinitesimal," it is nevertheless made to go a long way. Education in the States enjoys the ministrations of 48 Boards of Education or their equivalents, each of the sovereign States determining for itself the amount and character of the instruction provided for the children of its citizens: "This is as it should be, for the genius of the American people will probably never accept the idea of a centralized national system of public schools." In the circumstances invaluable service can be rendered by an unbiased, disinterested agency which "makes available to all the States the experiences of the most progressive and the achievements of the most highly endowed." Of the services rendered by the Bureau the conduct of surveys of State school systems and of universities and colleges, whether individually or by groups, is, the Commissioner says, probably the most far-reaching in effect. This work has grown very rapidly during the past two years. Among the developments recorded are: the new radio broadcasting service, which, as a means of reaching the general public, particularly parents and taxpayers, has proved cheaper than printing, reaches its audience quicker, reaches the mass of people who will not read printed articles, is more effective because it establishes more intimate contact, and, above all, educates public opinion *continuously*; promoting co-ordination of schools of commerce with schools of engineering with the view of improving methods of marketing at home and abroad; stimulating special training for foreign service, both Government and commercial; organising home-reading circles on the lines of the National Home Reading Union in Great Britain and associations of parents and teachers. Of interchange of students between countries the Commissioner says, "It is a desirable practice making for permanent peace and international comity, and is encouraged by every progressive nation. There are at least 10,000 foreign students in our institutions of higher learning and probably as many more in secondary schools."

Societies and Academies.

LONDON.

Royal Society, June 14.—C. **Chree**: Magnetic phenomena in the region of the south magnetic pole. Magnetographs were in simultaneous operation from April to October 1912, at the base stations of the British and Australasian Antarctic expeditions on opposite sides of the south magnetic pole. A comparison is made of the regular diurnal inequalities and the amplitudes of the absolute daily ranges of the magnetic elements at the two stations. The data show the remarkable sensitiveness of the regular diurnal variations in high latitudes to the presence of magnetic disturbance. The results are also applied to the question of a suitable criterion for the daily activity of magnetic disturbance.—O. R. **Howell**: The catalytic decomposition of sodium hypochlorite by cobalt peroxide. The rate of decomposition of sodium hypochlorite solution by cobalt peroxide is directly proportional to the amount of peroxide present. It is accelerated by sodium salts and (in the case of sodium chloride) is directly proportional to the square root of the concentration of sodium ions present. The mechanism of the reaction probably consists in the linkage of hypochlorite ions to the positive oxygen, and sodium ions to the negative oxygen of the peroxide, with immediate decomposition of the quadrivalent oxygen compound. With a fixed amount of hypochlorite the rate is then proportional to the degree of adsorption of the sodium ions. The rate is retarded by alkali and the retardation is proportional to the adsorption of hydroxyl ions. The average temperature coefficient of the reaction between 25° and 50° is 2·37 and the Arrhenius activation coefficient E is 16,574. The catalyst is not affected by any of the common catalytic poisons.—N. M. **Hosali**: On seismic waves in a visco-elastic earth. Seismic waves are subject to damping and dispersion dependent on the period. For each type of wave—dilatational, distortional, or surface—there exists a minimum period below which a wave cannot be transmitted, and for any period above the minimum two distinct waves can be propagated, one heavily damped and slow travelling and one lightly damped and quick travelling. Observations indicate that if the material in the outer layers of the earth obey the theory here developed it should have a viscosity of order 10^8 or 10^9 C.G.S. units. This would have no appreciable effect on the velocity of propagation of earthquake waves.—J. W. **Landon** and H. **Quinney**: Experiments with the Hopkinson pressure bar. With a bar of uniform diameter the pressure wave produced by detonation of gun-cotton is considerably distorted as it is propagated, but the rate of distortion decreases as the wave travels along the bar. Pressure falls away rapidly as distance from the axis of the bar increases. To determine the maximum pressure produced in the detonation of gun-cotton the bars were submitted to special heat treatment in the hope that overstrain might be reduced. A substantial improvement was observed except in so far as the life of the bars was increased. The highest maximum pressures recorded were 117 tons per square inch for a 1-ounce gun-cotton primer in contact with the end of the bar, and 82 tons per square inch with the primer $\frac{3}{4}$ inch away from the end. These results were obtained with a short bar of $\frac{3}{4}$-inch diameter. With concrete bars the phenomena exhibited are the same in general as with steel bars, except that the front of the wave appears to be entirely obliterated, and only the part in which pressure is less than the crushing stress of the concrete is propagated along the bar.—S. F. **Grace**: Free motion of a sphere in a rotating liquid at right angles to the axis of rotation. The density of the sphere is equal to that of the liquid, and the motion a small disturbance from one of uniform rotation like a rigid body. The motion of the centre of the sphere is wholly in a plane perpendicular to the axis of rotation, and the disturbed motion of the liquid is symmetrical with respect to this plane. The path of the centre of the sphere is a spiral with a definite pole. The sphere winds round the pole in a direction opposite to that of the rotation of the liquid, the motion being such that the time of a complete turn tends to become constant and equal to one-half the time of a revolution of the undisturbed liquid. At points along the prolongation of the polar axis of the sphere the motion is parallel to the equatorial plane and is a maximum at the sphere. Parts of the solution are not applicable for large values of time.—B. F. J. **Schonland**: The passage of cathode rays through matter. The absorption of cathode rays of velocity 6×10^9-$1{\cdot}2\times10^{10}$ cm./sec. in various metals has been studied with an arrangement designed to eliminate interference from secondary rays and to measure both the fraction of the beam passed through and that actually absorbed in the foil. The latter fraction varies with thickness and velocity in the same manner for all elements; the nature of the variation of the former depends upon the absorbing material. The results are explained by applying the theory of absorption due to Bohr, with which they are in quantitative agreement.

Association of Economic Biologists, April 27.—C. M. **Wenyon**: Recent observations on parasitic Protozoa in animals and plants. Certain parasitic Protozoa, such as the Coccidia, and some Hæmogregarines, which are inhabitants of the intestinal canal or wall of the intestine of vertebrates, and pass from host to host in the encysted form which escapes in the dejecta, have become so modified in the course of evolution, that they are no longer transmitted by means of cysts but are carried by bloodsucking invertebrates. It is probable that the well-known parasites of malaria are modified Coccidia. Intestinal flagellates, such as Trichomonas, which are normally inhabitants of the lumen of the intestine, may occasionally enter the blood stream. Reichenow has shown that in the lizard the entry of the intestinal flagellate Eutrichomastix into the blood may lead to infection of the mites, which again give rise to an intestinal infection of lizards which devour them. Similarly flagellates of insects like the flea or flies which usually live only in the invertebrate, may establish themselves in the intestines of vertebrates which eat them. Thence they may invade the blood of the vertebrate and are undoubtedly ingested by blood-sucking insects. It is possible that the parasite of the disease "Kala azar" of man may be an insect flagellate which enters man by way of the mouth, gains access to his intestine, and thence invades his tissues. Plants may be infected in like manner, for flagellates of the typically insect type have been found in various species of Euphorbia and other plants, and it has been shown by Franca that they are derived from bugs which feed upon the plants. M. S. G. **Breeze**: Some causes of sterility in Solanaceous plants due to Protozoa and Chytridiaceous parasites. The plants investigated were varieties of potato and petunia, and the following points were noted: (1) An Amœba, similar to *Amœba gleba*, attacks potato flowers virulently though without any outward sign. The tissues are hypertrophied and turgid. (2) Chytridiaceous zoospores (probably synchytrian) occur in anthers in half-grown buds of Up-to-Date potatoes damaged by the Amœba; and some of the Amœbæ may migrate to the adjacent ovarian tissue; the zoospores swim to and fro by an anteriorly directed flagellum. Associated with the above is a spore-bearing bacillus with rounded ends, probably a saprophyte. (3) "Bird's eye" bodies in petunia and potato ovaries are regarded as possibly a phase of (2), and therefore synchytrian parasites.

Zoological Society, May 29.—Dr. A. Smith Woodward, vice-president, in the chair.—C. Tate **Regan**: (1) Some deep-sea fishes taken by the *Dana* Expedition, under the leadership of Dr. Johannes Schmidt. The fishes belong to the very rare and little-known genera Gigantena and Stylophorus, which agree in having telescopic eyes placed close together and directed forwards. (2) The skeleton of Lepidosteus, with remarks on the origin and evolution of the lower neopterygian fishes.—C. F. **Sonntag**: The comparative anatomy of the tongues of the mammalia.—IX. Edentata, Demoptera, and Insectivora.—S. **Maulik**: New cryptosome beetles.

Paris.

Academy of Sciences, May 28.—M. Albin Haller in the chair.—Charles **Moureu**, Charles **Dufraisse**, and Ph. **Landrieu**: The principle of a general method for determining the calorific capacity of solids and liquids. Application to the determination of the water equivalent of calorimetric bombs.—P. **Villard**: A hydrate of iodine. Iodine and water, compressed with oxygen or nitrogen to 150 atmospheres, give crystals of a hydrate of iodine. The crystals are crimson-violet, strongly contrasting with the brown colour of the aqueous solution of iodine.—M. **Wallerant**: Extract from a note of M. Astbury. The structure of the crystal of tartaric acid, determined by the X-ray method, is in agreement with the views expressed by Pasteur in 1860.—Charles **Depéret**: The glaciations of the valleys of the French Pyrenees, and their relations with the fluvial terraces. From observations in the Ariège, Garonne, Neste, Aure, Gare de Pau, and Gare d'Ossau, there is complete identity between the Alps and Pyrenees for the number and periods of extension of the quaternary glaciers.—M. Henri Villat was elected a corresponding member for the section of mechanics in the place of the late R. Ariès.—René **Garnier**: Uniform functions of two independent variables defined by the inversion of an algebraic system of total differentials of the fourth order.—N. **Saltykow**: The methods of integration of partial equations.—M. **Angelesco**: Certain biorthogonal polynomials.—H. **Milloux**: Infinite series of functions and meromorphic functions with asymptotic value.—Charles N. **Moore**: The generalised Fourier series of non-integrable functions.—J. **Haag**: The problem of Schwarzschild in the case of a curved universe.—F. **Gossot** and R. **Liouville**: The principles of internal ballistics.—Jean **Chazy**: The secular effects of the theory of relativity in the planetary movements.—J. **Le Roux**: The field of gravitation.—A. **Luthy**: The ultra-violet spectrum of glyoxal. In hexane solution, this substance gives a series of narrow absorption bands in the ultra-violet; no compound of the aliphatic series has hitherto been known to give narrow absorption bands in the ultra-violet.—Guillaume C. **Lardy**: The ultra-violet absorption spectrum of diacetyl. In alcoholic solution previous observations have shown only a band in the violet and another in the middle ultra-violet. In hexane solution the author has found narrow bands. These bands are not so clearly separated as the narrow bands shown by glyoxal in the same region.—F. W. **Klingstedt**: The ultra-violet absorption spectrum of paraquinone. This substance shows in hexane solution fourteen narrow bands in the visible part of the spectrum between the green and the violet. In addition, in the middle ultra-violet there is one large band, and in the extreme ultra-violet ($\lambda = 2410$) there is one very strong band.—Albert **Colson**: Contribution to the laws of solubility.—A. Ch. **Vournazos**: The bismuthamines, a new class of bodies. These substances are obtained by the interaction of bismuth chloride (bromide or iodide) and an ammonia (or amine) salt in an organic solvent. As a typical example, the compound $BiCl_3I(NH_4)$ is obtained by the action of $BiCl_3$ on a cold solution of ammonium iodide in acetic acid. It forms silky transparent needles, decomposed by water.—Alfred **Gillet** and Fernand **Giot**: An application of the antioxygen power of the polyphenols: increase of fastness to light of dyes on the fibre. All the acid azo dyes, both on wool and on cotton, are relatively protected against the action of air under the influence of light by the *o*- or *p*-diphenol function, whether the latter is, or is not, a part of the molecule of the dye. Some eosin dyes behave similarly, but the nitro dyes, triphenylmethane derivatives, and basic colours are not protected.—Paul **Corbin** and Nicolas **Oulianoff**: Certain characters of the Hercynian fold in the Servoz-Les Houches region (Arve valley).—Conrad **Kilian**: The folds of the crystalline schists of Ahaggar; the Saharides.—René **Souèges**: The embryogeny of the Geraniaceæ. Development of the embryo in *Erodium cicutarium*.—G. **Hamel**: The limit of vegetation in the Channel according to the dredgings carried out by the *Pourquoi-Pas?* No algæ were found at depths greater than forty-five metres, and it concluded that at greater depths than this all vegetation, with the exception of diatoms, and plankton, is absent.—Jules **Stoklasa**: The origin of the nitrate deposits of Chili. According to one hypothesis, the nitrate deposits result from the accumulation of excrements and bodies of animals: another view (C. Noellner) is that the nitrates arise from the accumulation of submarine plants, since these plants contain iodine, and iodine is an invariable constituent of "caliche." The author gives reasons for regarding a volcanic origin as more probable than either of the preceding hypotheses.—J. **Lopez-Lomba** and Mme. **Randoin**: The state of scurvy produced by a complete regime in biochemical equilibrium, deprived only of the factor C.—W. **Kopaczewski**: Surface tension, swelling, and narcosis.—R. **Argaud**: The sclerogenic rôle of the giant cells.

Washington.

National Academy of Sciences (Proc. Vol. 9, No. 4, April).—R. L. **Moore**: Concerning the cut-points of continuous curves and of other closed and connected point-sets.—J. **Belling** and A. F. **Blakeslee**: The reduction division in haploid, diploid, triploid, and tetraploid Daturas. During the first division in the pollen-mother-cells of diploid, triploid, and tetraploid Daturas, homologous chromosomes are usually connected by their ends. Non-reduction occurs generally only in haploid plants. The volume of cytoplasm in the pollen-mother-cells is nearly proportional to the number of haploid groups present. T. **Ellinger**: The variation and inheritance of milk characters. The records of a herd of 700 cows at Tranekjaer

Castle, Denmark, which consisted originally of Red Danish dairy cattle and Jersey cattle, are discussed. The yield during the first 10-week period of milking appears to be the most trustworthy measure of a cow's milk-yielding qualities. The records of the cross-bred cattle (F_1) show no indication of any single Mendelian factor in the inheritance of milk characters.—A. R. **Olson** and G. **Glockler** : The critical and dissociation potentials of hydrogen. A heated platinum filament covered with calcium oxide in a vacuum tube containing purified dry hydrogen at 0·1 mm. of mercury pressure was used as the source of electrons. The beam of electrons passed through platinum stops to which varying accelerating and retarding potentials could be given, and fell on an ionisation cylinder connected with a quadrant electrometer. The dissociation potential of hydrogen appears to be 3·16 volts; eight breaks occur in the current-potential curves, five of which correspond with lines of the Lyman series.—G. L. **Clark** and W. **Duane** : (1) The reflection by a crystal of X-rays characteristic of chemical elements in it. Crystals of the compounds KI, KI_3, CsI, CsI_3, and CsIBr have been investigated and X-rays characteristic of iodine, cæsium, and bromine have been identified which obey the regular laws of crystal reflection. The method used is to determine the position of peaks in the ionisation curve by rotating the crystal (corresponding to reflections from the various planes), and, setting the ionisation chamber at one of these peaks, to move the crystal and the ionisation chamber, the latter at twice the rate of the former. A series of peaks are obtained referring to one set of planes alone. For KI, wave-lengths of these correspond with the $K\alpha$ and $K\beta$ wave-lengths of iodine. The distance between the 100 planes is $3{\cdot}53 \times 10^{-8}$ cm. KI_3 is found to be a cube slightly distorted with the edge $4{\cdot}70 \times 10^{-8}$ cm. long. CsI_3 appears to be a rhombic crystal with cæsium atoms at each corner and iodine atoms at the centre and at points equidistant from the centre along the body diagonals. $CsIBr_2$ is also a rhombic crystal. (2) On the abnormal reflection of X-rays by crystals. Reflections of X-rays have been obtained from potassium iodide which are not in accord with the usual laws of crystal-reflection. The peaks caused in the ionisation curve are termed "X-peaks." For small deviations of the X-ray beam, the X-peak is outside that due to the 130 planes; for larger deviations, it is between those due to the 100 and 130 planes. The X-peak does not appear unless the incident beam contains X-rays of shorter wave-length than those in the K-series of iodine.—G. L. **Clark** : The significance of the experimentally determined crystal structures of the alkali polyhalides. It appears from X-ray analysis of the polyhalides KI_3, CsI_3, $CsIBr_2$, $CsICl_2$, that the three halogen atoms lie a diagonal of the crystal lattice, the heaviest in the centre; the metal atoms are at the corners. Other polyhalides are closely related chemically and crystallographically, and probably have similar structures, apparently closely related to the simple halide unit cubes, the halide group replacing a halogen atom. The size of the metal atom determines the dimensions of the unit cell and thus the relative stabilities of the polyhalides of the group.—E. B. **Wilson** : Electric conduction : Hall's theory and Perkins' phenomenon. Perkins has shown that the addition of a negative charge to a conducting strip of graphite decreases the conductivity. This is contrary to what might be expected on a free electron theory of conduction, but can be explained on Hall's theory of conduction by streams of electrons and ions, the latter taking a predominant part.

Official Publications Received.

Diary of Societies.

MONDAY, JUNE 25.

ROYAL SOCIETY OF BIOMETRICIANS AND MATHEMATICAL STATISTICIANS (at University College), at 8.—Dr. T. H. C. Stevenson : The Social Distribution of Causes of Death in England and Wales.

ROYAL SOCIETY OF MEDICINE (Odontology Section), at 8.—L. E. Claremont : Case of Fibro-Cystic Disease of the Lower Jaw.—Dr. A. Hopewell-Smith : Two Odotomes ; Some Observations on the Histology and Pathology of the Dental Pulp.

ROYAL INSTITUTE OF BRITISH ARCHITECTS, at 8.30.—Presentation of the Royal Gold Medal.

TUESDAY, JUNE 26.

IMPERIAL EDUCATION CONFERENCE (at Institution of Mechanical Engineers), at 8.—Miss L. De Lissa : Recent Developments in Infant Education and their Connexion with the Work of the Elementary Schools.

ROYAL ANTHROPOLOGICAL INSTITUTE, at 8.15.—de Barri Crawshay : Exhibit of Eoliths from the South Ash Pit on the Kentish Chalk Plateau, and of Stone Implements from Mesopotamia.—S. Hazzledine Warren : The Palæolithic Succession of Stoke Newington.

SOCIOLOGICAL SOCIETY (at Royal Society), at 8.15.—Dr. E. Jenks : The Function of Law in Society.

WEDNESDAY, JUNE 27.

ROYAL SOCIETY OF ARTS, at 4.—Annual General Meeting.

ROYAL SOCIETY OF MEDICINE (Surgery Section), at 5.30—Dr. W. Mayo, Sir Berkeley Moynihan, J. Sherren, G. Grey Turner, and A. J. Walton : Discussion on the Surgery of the Hepatic and Common Bile Ducts.

IMPERIAL EDUCATION CONFERENCE (at Institution of Mechanical Engineers), at 8.—Lt.-Gen. Sir Robert S. S. Baden-Powell, Bart. : The Boy Scout and Girl Guide Movement.

THURSDAY, JUNE 28.

ROYAL SOCIETY, at 4.30.—Prof. V. H. Blackman, A. T. Legg, and F. G. Gregory : The Effect of a Direct Electric Current of very Low Intensity on the Rate of Growth of the Coleoptile of Barley.—Miss R. M. Tupper-Carey and Prof. J. H. Priestley : The Composition of the Cell Wall at the Apical Meristem of Stem and Root.—L. J. Harris : The Titration of Amino- and Carboxyl-Groups in Amino-Acids, Polypeptides, etc.—Dr. M. S. Pembrey, N. W. MacKeith, W. R. Spurrell, E. C. Warner, and H. J. Westlake : Observations on the Adjustment of the Human Body to Muscular Work.—F. A. E. Crew : Studies in Intersexuality. II. Sex-Reversal in the Fowl.—Prof. W. Finkler : Analytical Studies on the Factors causing the Sexual Display in the Mountain Newt (*Triton alpestres*).—Prof. G. A. Schott : The Scattering of X- and γ-Rays by Rings of Electrons—The Effect of Damping of the Incident Radiation.—Major P. A. MacMahon : A Class of Transcendents of which the Bessel Functions are a Particular Case.—Dr. L. C. Martin : The Photometric Matching Field.—Prof. G. P. Thomson : Test of a Theory of Radiation.—Dr. A. Ll. Hughes and P. Lowe : Intensities in the Helium Spectrum.—A. A. Dee : The Effect of Quenching from above the Carbide Transition Temperature upon the Magnetism of Steel.—T. S. P. Strangeways and H. E. H. Oakley : The Immediate Changes observed in Tissue Cells after Exposure to Soft X-Rays while growing *in vitro*.

INSTITUTION OF ELECTRICAL ENGINEERS (at British Museum (Natural History)), at 8.30.—Annual Conversazione.

ROYAL SOCIETY OF MEDICINE (Urology Section), at 8.30.—Prof. C. G. Cumston : Certain Points in Connexion with Nephritis.

FRIDAY, JUNE 29.

SOCIÉTÉ DES INGÉNIEURS CIVILS DE FRANCE (British Section) (at Institution of Mechanical Engineers), at 8.30.—M. Barrillon : The Port of Rouen and the Lower Seine.

Position and Needs of the Science Museum Collections.

IN an article in another part of this issue an outline is given of the present state of advancement of the Museum building scheme at South Kensington, which was approved in 1912 and started in 1913. The scheme was that which the Departmental Committee on the Science Museum and the Geological Museum proposed in its Report of 1911 and 1912 as to (1) the purposes these museums should serve in the national interests; (2) the nature, arrangement, and development of the collections required for these purposes; and (3) the buildings required on the South Kensington site to house these collections. This was a logical reference, and the report dealt with it faithfully and effectively.

The discussion of the reference inevitably brought the reporting committee face to face with the problem of co-ordinating these two museums with one another and with the Natural History Museum. The committee found that there was in practice little or no overlapping of the fields of the three museums, and in the end it was able to formulate proposals by which the buildings of the three museums would be brought into direct communication. Thus the related parts of the great national collections in the sections of science concerned would be brought into a continuous series.

Under the scheme thus initiated, the individuality of the several museums and their administration under their existing responsible authorities would not be affected in any way; at the same time the group of museums would afford at a single centre, and in intercommunicating buildings, a real national museum representative of science. This feature of the recommendations of the committee was made possible by an arrangement with the Trustees of the British Museum, who were willing that the new Geological Museum building should be placed on a part of the ground allotted to the Natural History Museum, and should be a part, structurally, of the eastern extension of the Natural History Museum building.

The scheme is an admirable one. It provides for the mineral products of the earth complete museum representation as to natural history, geological structure, economic conditions, mining, metallurgy, and all physical and engineering investigations and appliances bearing on these. Further, it suggests lines for obtaining similar advantages in relation to other branches of science as the scheme comes to be applied in later stages.

The first item of the scheme was the erection of the Eastern Block of the new Science Museum, and this has shown so little progress since the War that the councils of a number of leading scientific and technical societies have found it necessary to direct attention to the matter and to ask that the building be expedited. In these times of financial straits it has been a national necessity to go slowly in the matter of new public buildings, and precedence in such work must be most carefully considered. In recent years few things have been so generally and so fully recognised as the magnitude of the contributions which physical and mechanical science have made to the progress of the country in knowledge, in industries, in trade, and in war, and accordingly it might have been assumed that the work on the Science Museum building, interrupted by the War, would have had a place in the first rank of the priority list. Yet here is the Science Museum, which is charged with the duty of affording public illustration and visual exposition of the great current advances in the physical sciences and in the applications of science to industry, practically obstructed in all new work by lack of space. The functions of the museum are so closely related to important national interests that its equipment has become a matter of urgency, and the facts summarised in our article on the subject suffice to show the need for an emphatic appeal that the continuance of the work on its building should have an assured place in the programme of new national buildings.

The building now in progress is the outcome of action taken in pursuance of representations made to the Board of Education in 1909 by a deputation and a memorial from those prominently interested in the advancement of pure and applied science. In presenting the memorial, Sir Henry Roscoe quoted from the 1874 report of the Duke of Devonshire's Commission on Science, strongly recommending the establishment of a museum representative of all branches of physical science, both pure and applied. He and those with him in the deputation then emphasised the necessity for proper housing for such a museum, and the advantages of properly housed collections. They pointed out, too, that without adequate accommodation the Museum could not benefit as it otherwise would by gifts of many objects of interest which have high value for museum collections.

The fact is that, in the matter of buildings, this museum has lagged far behind the museums that represent other branches of knowledge and of culture. One may well ask how this has come about. The answer is largely one of history. The Science Museum is the youngest of our national museums: for although science collections were first prepared for museum exhibition in 1857, it was not until twenty years later that the real possibilities of such collections began to be widely recognised. The earlier collections were formed with the view of following up in particular directions the impulse which the Exhibition of 1851 had given to public interest in science and industry. At that time the larger groups of objects came under the following headings: Foods, animal products of industrial value, building structure and materials, models of machinery and educational apparatus. It was the Fourth Report (1874) of the Royal Commission on Scientific Instruction and the Advancement of Science that directed attention to the wide field of usefulness that was open to well-devised science collections; and it was the demonstration afforded by the great loan collection of scientific apparatus, formed at South Kensington in 1876, that proved the turning-point in the aims of the museum collections. Many of the objects lent for that temporary collection became the property of the nation and formed the nucleus of the collections of to-day. It is right to note here that the advance then made in the museum ideal owed much indeed to the initiative and to the indefatigable labours of the late Sir Norman Lockyer, who was secretary to the Commission.

Almost concurrent with the wider conception of the relation of the Museum to pure science came the recognition of the importance of preserving and exhibiting actual examples of great inventions. The many-sided appeals of such objects had led Mr. Bennet Woodcroft to form a collection that was, and must always be, unique, and the transference of his collection to the Department of Science and Art in 1883 laid the foundation of the fine collection which now illustrates machinery and the history of invention.

Successive committees have reported on various aspects of the uses and needs of the Science Museum. Their reports in 1886, 1889, 1897, 1898, and 1900 form a long chain of scientific and technical opinion. These, however, failed to secure the full measure of official backing and of national support which they well merited. Yet in their estimates of needs they were most modest—perhaps *too* modest. Men of science accustomed to work in laboratories providing only the bare necessaries for their investigations, failed to realise that the great museum-visiting public needs space in which to move about freely, and requires the exhibition of objects rather than a mere opportunity of examining them under difficulties. Be that as it may, in accordance with scientific habit they limited their recommendations, in matter and in measure, to needs which could be proved up to the hilt; but people accustomed to the evaluation of reports in other interests—reports made, it may be, with greater imagination and longer views—had acquired a habit of making a large discount from the claims made in commission reports generally.

Since the new departure in the early 'eighties the Science Collections, alike in pure and in applied science, have had many acquisitions of great and abiding interest, and the methods of displaying these have developed steadily. The aim of the Museum has been to do all that considered preparation of objects and appropriate methods of exhibition can do to enable scientific instruments, machinery, models, etc., to speak for themselves. By exhibited objects, it affords telling illustration and exposition pertaining to the various branches of science within its field and of their applications in the arts and industries. It also preserves appliances which hold honoured places in the progress of science or in the history of invention, and with such exhibits it associates the names of the great men to whom the world owes these successive advances. This human element in the interests which the Science Collections present accounts for no small part of the crowds who visit the galleries at times when any large section of the public is free from work. The exhibited machines, or other inventions which have created or revolutionised industries and have altered conditions of life, arouse in even the most casual of visitors something more than admiration for the genius and skill of the inventor. Such objects as those illustrating early steam-engines, telegraphs and telephones, or the successive stages of the development of ships, never fail to appeal to popular intelligence and imagination. Indeed, many of the treasures of the Science Museum are irreplaceable in respect of value for the intellectual inspiration of the people.

For the use of the Museum by the general public, larger space for exhibition and more ample gangways for the circulation of visitors are the most pressing needs; but a suitable setting for the collections, and a worthy front and entrance to the building, are essential to the recognition of the real value of the Museum as a factor in the intellectual machinery of the nation. Students and investigators who use the Museum need all these; but they need more. The report of Sir Hugh Bell's committee sets out the directions in which material facilities are required for the critical examination of instruments, or for public or private exposition of objects, but until an adequate building is provided for the Museum collections these uses are seriously limited; thus individuals and institutions interested in physical and applied science must wait for some years yet before they can enjoy the wider uses pointed out in the committee's report.

The deputation to the president of the Board of Education in 1909 pointed out that by far the largest part of the Science Collections come as gifts or loans, so that if an adequate and worthy building were provided, it need not be anticipated that the annual subsidy for purchases would be on the high scale required for the other great national museums and galleries. The maintenance vote is also relatively small, and the capital expenditure required for the building is not even now deterrent. It is not too much to expect that in these circumstances the work on the buildings will be pushed forward vigorously and without break.

Meteorological Physics.

The Air and its Ways: the Rede Lecture (1921) in the University of Cambridge, with other Contributions to Meteorology for Schools and Colleges. By Sir Napier Shaw. Pp. xx+237+28 plates. (Cambridge: at the University Press, 1923.) 30*s*. net.

IN this volume Sir Napier Shaw has collected fifteen different lectures and papers upon a variety of different subjects, to a few only of which we can here refer. Throughout the whole book is a number of leading ideas, for which the author has been an indefatigable and mostly also a successful advocate, to the benefit of meteorological science.

The first point which strikes the reader when he opens the book is twenty-four plates representing the normal distribution of the meteorological elements over the globe. Several of these charts are new from the author's hand. By placing these charts at the beginning of the book, and by returning to them incessantly in discussing the special questions in the subsequent papers, the author has succeeded in emphasising strongly his view of "the weather of any locality as part of the weather of the world." Statistics can be made for a single locality. Atmospheric events, on the contrary, can never be understood from local, but only from universal points of view.

To understand the phenomena of the weather means, according to Sir Napier Shaw, "to bring our knowledge of the air into relation with the laws of physics, as established in the laboratory, and therefore particularly with the law of energy." We meet with this view already in the charmingly written first lecture, "Meteorology for Schools and Colleges," and it follows us all through the book to the last lecture on "The Artificial Control of the Weather." An important consequence of this view of meteorology as applied physics forms the subject of the second lecture on "Pressure in Absolute Units."

Among the leading ideas of a more special meteorological nature the author emphasises in the preface three as especially important—those of "balanced forces," of "eviction," and of "resilience." In his discussions of meteorological phenomena these principles recur repeatedly. We meet with an example of the application of the principle of resilience on the first page of the first lecture, when we read this characteristic remark concerning the conditions for the formation of orographic rainfall: "But when you come to think of it, the explanation requires that the air on the windward side has to be made to flow up-hill, and no fluid which technically must be called heavy, as it is affected by gravity, even if it is as light as air, flows up-hill without protest. It prefers to go round, and will exhaust all the possibilities of doing so before submitting to be driven over." This principle of resilience should be remembered not least by mathematicians who will work out the theory of atmospheric movements. In theoretical hydrodynamics we generally assume the equation $s=f(p)$, density as a function of the pressure. This equation leads to that state of "unlimited miscibility" which excludes resilience and would make it possible for the air to flow up-hill without protest. But the true equation $s=f(p, \theta)$ permits the air to take a stable stratification, a permission of which it makes a most extensive use; with the consequence that we have laws of motion very different from those of the idealised fluid, in which $s=f(p)$. I can scarcely be wrong when I say that this equation has for more than a century acted as a barrier which has prevented the representatives of theoretical hydrodynamics from taking up meteorological problems with success.

The principle of "balanced forces" merits great attention, not only in qualitative discussions but also perhaps still more by the attempts to work out mathematical theories of atmospheric motions. The author gives no mathematical formulation of the principle. But if I have understood him rightly, I should call it rather very good advice than a principle. The most obvious way of developing atmospheric movements might seem to be this: first to consider the state of equilibrium, and then to examine the consequences of a disturbance of it, in the case before us of a disturbance of thermal origin. But on account of the rotation of the earth there is a very long and difficult way from the state of equilibrium relative to the earth to the ultimately resulting motion. The primary tendency is the production of a direct flow from the cold to the warm areas. But this tendency is almost completely checked by the effect of the earth's rotation. Instead of the direct flow from cold to warm areas, we get a circulation cyclonic round the warm and anticyclonic round the cold areas. Only a small residual leakage is left, conveying very gradually air from the cold to the warm areas. For this leakage the process of "eviction" plays an important part.

Now Sir Napier Shaw's advice is to shorten this long development, which it is very difficult to give in a satisfactory form, and to start with that state of steady motion relative to the earth which is characterised by the "gradient wind." This gradient wind, by which pressure gradient and deflecting force balance each other, gives immediately the cyclonic circulation round the warm areas and the anticyclonic circulation round the cold. Then, in the second approximation, we have to add to this pure circulation the further disturbances, as those connected with convection and that particular form of convection for which Sir Napier Shaw has introduced the word eviction. No doubt his advice will be followed more and more, both in elementary treatises and especially in mathematical theories, for which this may prove to be the only practicable way.

I cannot finish this notice without mentioning Sir Napier Shaw's brilliant style of writing, the many adequate expressions and striking comparisons by which he succeeds in making the subject clear and ensures that the reader does not forget the main points. He is a master of finding the right words, and is not less a master of illustrating the text by characteristic diagrams. I only regret that he has not found place in the book for that really historical diagram by which he formulated his protest against the old cyclone theory and gave the main structure of the new one, replacing the fine logarithmic spirals running asymptotically to a centre in the old model simply by three sets of straight lines, of which two sets meet each other at right angles. V. BJERKNES.

Philosophy for Men of Science.

Scientific Thought. By Prof. C. D. Broad. (International Library of Psychology, Philosophy, and Scientific Method.) Pp. 555. (London: Kegan Paul and Co., Ltd.; New York: Harcourt, Brace and Co., Inc., 1923.) 16s. net.

As men of science are usually impatient, if not contemptuous, of philosophical discussion, Prof. Broad may be thought rash to address a philosophical work specifically to them, particularly as he is occupied in discussing the notions of space, time, matter, and motion, about which the man in the laboratory considers himself better qualified to speak than the philosopher. The author, however, brings to his task both a knowledge of mathematics and physics and an appreciation of the efforts of philosophers in the "peculiarly obstinate attempt to think clearly," which constitutes their chief task. Moreover, unlike many philosophers and men of science, he expresses himself clearly, so that any one who reads his book will discover at least one philosopher who does not "tell us what every one knows in language that no one can understand."

Part 1 consists of an analysis of the conceptions of space and time in modern physics and leads up to an account of the special and general theories of relativity. This has all been done before, but not quite in the same way. The author starts at the beginning, or what ought to be the beginning of any such discussion, by giving a simple account of Prof. A. N. Whitehead's "Principle of Extensive Abstraction." This principle provides a rational method of passing from the actual facts of sense-experience to the highly sophisticated conceptions, such as points and lines, that are necessary for geometry and mathematical physics, and is indispensable for any proper theory of space and time. Prof. Broad's exposition provides a good introduction to Prof. Whitehead's own decidedly difficult works. In the second chapter on time and change, with Prof. Whitehead's treatment of time as a basis, some valuable and original ideas are developed. This chapter is perhaps the most important in the whole book. The rest of Part 1 follows well-established lines and does not call for special comment, except in so far as it gives a clear account of a difficult subject.

In Part 2 the author takes up his problem from a different point of view, that of the relation of the physical theory of material bodies to the facts of sense-experience. Here Prof. Broad is for the most part breaking new ground, and for that reason alone his argument is rather more difficult to follow. Moreover, he is now dealing with problems which do not appeal greatly to the man of science, who may refuse to recognise them as problems at all. He will probably assent vaguely to the saying of Petronius standing at the head of chapter 7:

> Fallunt nos oculi, vagique sensus
> Oppressa ratione mentiuntur.

The man of science may even confess that the ridiculous theory of pp. 272 and 273 is not an unfair summary of his own and his friends' views as to the nature of physical objects and their sensible appearances, but still he may be inclined to say, "Why make all this fuss about it? I know it is easy for a philosopher, with his puzzles about pennies that are 'really' round, though they 'look' elliptical, and about mirror images, and so on, to pick holes in the ordinary common-sense and scientific notion of material objects, but what does it all come to? The ordinary theory, however silly ultimately, is simple and familiar and works well in practice. The philosophical theories are not simple, there are several different ones, and there is nothing to show that they are better for ordinary purposes."

Prof. Broad has not played his cards very well in order to refute such contentions as this and induce the man of science to read on, for he has kept his best arguments for his last chapter. The argument is, briefly, that the ordinary view only works in practice by leaving out the facts that do not fit in with it. It so happens that these inconvenient facts have not, up to the present time, been important and that the man of science has been well advised to forget them and get on with his work, but this happy state of affairs may not last for ever. The history of the theory of space and time supplies the moral. The traditional theory was simple and easy to understand and worked well; the engineer and the chemist still ask for nothing better. It has only been gradually that the incompatible facts have been forced on people's attention in spite of struggles to ignore them; and some people still ask, "Why all this fuss about the principle of relativity?" The only answer is that clear ideas, if we can get them, are better than muddled ones, however comfortable. What is worth doing for space and time is also worth attempting for sense perception and material objects.

It is impossible in the course of a short notice to make any detailed criticisms of this latter part of the book; suffice to say it is the kind of thing scientific philosophers ought to write and philosophical men of science to read.

The author shows wit and erudition in his chapter headings, though he might have translated King Alfred for us. The index is full and carefully compiled. As the author shows some pedantry in the matter of authors' names and titles, it is not unfair to point out that Galileo is a Christian name, consequently there was no such person as "Galileo, G." A. D. R.

Geology in War.

(1) *The Work of the Royal Engineers in the European War, 1914–19. Work in the Field under the Engineer-in-Chief, B.E.F. Geological Work on the Western Front.* Pp. 71 + 7 plates + 19 figs. (Chatham: W. and J. Mackay and Co., Ltd., 1922.)

(2) *The Work of the Royal Engineers in the European War, 1914–19. Work in the Field in other Theatres of War. Egypt and Palestine—Water Supply.* Pp. vi + 64 + 7 maps + 10 plates. (Chatham: W. and J. Mackay and Co., Ltd., 1921.)

IN 1914 there was no geological organisation in the British Army, though it would appear that the Germans had a definite geological establishment in connexion with each of their Armies. Very early during the War the need of geological advice was felt in connexion with the supply of water to the troops both in the battle zone and on the lines of communication, but it was not until April 1915 that a geologist was appointed, and not until the following June that he joined the staff of the Chief Engineer in France. In 1916 Lieut.-Col. Sir T. W. Edgeworth David joined the staff and eventually became Geological Adviser at G.H.Q. on matters connected with military mining. Now a permanent geological establishment is suggested.

The volume under review gives a concise account of the work carried out by the geological staff on the Western Front and is copiously illustrated by maps, sections, and photographs. The chief method of supply of water was from borings in the Upper Chalk (Senonian), and though in many cases the sites for bores were chosen for military rather than geological considerations, the maps showing the possibilities of obtaining a supply in different parts of the area were invaluable to the Army Water Supply officers. Water was also obtained from the Thanet Sands, and the various kinds of apparatus employed in boring and pumping are described in detail.

An investigation of the water-table in the Chalk was made in connexion with water supply, and the fluctuations of level were studied for the purposes of military mining and the construction of dug-outs. The importance of a thorough knowledge of geological structure in connexion with the construction of military mines is demonstrated, and details are given of several series the success of which depended on such knowledge.

Other military activities requiring the services of the geologist were the winning of road-metal, the provision of sand and aggregate for concrete, and the working of such coal mines as remained in the hands of the Allies.

The plates include a map showing by colour-washes the suitability of the country for dug-outs and others indicating the ancient excavations ("Souterrains"), which were so largely used as cover for troops in Northern France.

The second volume under notice contains an interesting account of the enormous difficulties successfully overcome by the Royal Engineers in the supply of water to the army during its advance across the Desert of Sinai from Egypt into Palestine.

The work included the laying of a pipe-line, by means of which a daily supply of 600,000 gallons of Nile water was carried to the troops in El Arish, and along the lines of communication; the transport of water in railway tanks and on camels; the development of local supplies in Beersheba and Ghaza and in the plains of Palestine, and finally the reorganisation of the water supply of Jerusalem itself.

The Antiquity of Disease.

The Antiquity of Disease. By Prof. Roy L. Moodie. (University of Chicago Science Series.) Pp. xiv + 148. (Chicago: University of Chicago Press; London: Cambridge University Press, 1923.) 1.50 dollars.

Studies in the Palæopathology of Egypt. By Sir Marc Armand Ruffer. Edited by Prof. R. L. Moodie. Pp. xx + 372 + 71 plates. (Chicago: The University of Chicago Press; London: Cambridge University Press, 1921.) 17*s*. net.

AT a time when those concerned with medical education are concentrating their endeavours as never before upon the problems of the causes and prevention of disease, a book that attempts to probe into the distant past and discover the early history of pathological processes is sure of a welcome, even if the subject is described by the wholly unnecessary and ambiguous word "palæopathology." The chief value of Prof. Roy Moodie's fascinating and well-illustrated little book is that it directs attention to the scope and interest of such studies and provides a bibliography extensive enough to start the inquirer on his way to enlightenment. The pathological conditions revealed in fossil vertebrates, and the identification of the destruction wrought in fossil bones by contemporary bacteria and fungi, prepare us to accept the evidence that bodies resembling bacteria and cocci in fossils as old as the Palæozoic are actually fossilised micro-organisms.

The part played by bacteria in remotely ancient times is as yet only a subject for speculation. "The pre-Cambrian bacteria so far known are supposed to have had an activity allied to that described by Drew for *Bacterium calcis* and other marine calcium-precipitating bacteria." "The results of infection by bacteria are not definitely known prior to the Permian. Bacteria and fungi, possibly, however, chiefly those of decay, are widely distributed and well known from the Carboniferous rocks. Here lies a wide field of research, although a difficult one, dealing with the origin of that type of disease which is so troublesome to humanity to-day. It seems probable from present evidences that a wide distribution of the bacterial types of disease and the resulting pathology is a relatively recent phenomenon, with an antiquity of a few million years, which, when compared with the scores of millions, possibly hundreds of millions, of years which animal and plant life have existed, is a very brief time" (pp. 13 and 14).

The earlier part of the book, which deals with these interesting problems of palæontology, is very suggestive and stimulating. The latter part, dealing with early man, makes a more immediate and personal appeal and is distinguished by the same qualities of suggestiveness;

but unfortunately its accuracy cannot be trusted. The author commits many mistakes which are scarcely excusable on the part of the editor of the late Sir Armand Ruffer's works. It is natural that he should feel a deep sense of gratitude to the genial scholar whose writings directed his attention to the study of the effects of disease in ancient man; but the works of Sir Armand Ruffer give no warrant for the many misleading statements in the final chapter of this book. Hence it becomes necessary to warn readers of this chapter not to accept its statements as facts until they have been checked by reference to the standard work on the pathological conditions found in ancient Egyptian bodies, Prof. Wood Jones's statement in the Report for 1907–08 of the Archæological Survey of Nubia. It is particularly necessary to correct Prof. Moodie's misleading references to syphilis (p. 117), smallpox (p. 119), pyorrhœa (p. 126), and Pott's disease, which he says is "so common in Egypt" (p. 133), when I think he was aware of only *one* case (or at most six cases) found among thirty thousand bodies!

I refer to these blots on a very fascinating and stimulating book before such insidious errors get fully launched upon a career of diffusion. In several places in the book Prof. Moodie refers to the history of these modern investigations in the pathology of the ancient Egyptians, and as his account is quite fictitious, perhaps I might explain how they did begin. Two months after my arrival in Egypt in 1900 the late Dr. W. H. R. Rivers, who was working on the problems of colour vision in the natives of Upper Egypt, wrote directing my attention to the natural preservation of the brain in the Pre-dynastic bodies being excavated by Dr. Randall-MacIver at El Amrah. I went to Upper Egypt to study this remarkable phenomenon, and the first ancient Egyptian grave I looked into contained the skeleton of a boy who lived nearly sixty centuries ago and had suffered from stone in the bladder. I sent the specimen to Dr. Shattock at the Royal College of Surgeons, who published a report on it, and for the next seven years I devoted much of my leisure to the collection of pathological specimens from ancient graves until, in 1907, Dr. Wood Jones began his epoch-making work of making the collection now in the Museum of the Royal College of Surgeons, and writing the only trustworthy account of the pathological conditions found in Egypt and Nubia that has yet been published.

The late Sir Armand Ruffer did not begin his work until Prof. Wood Jones and I had completed ours. In 1908, having discovered a hunch-back among the mummies of the priests of Amen from Thebes, I asked the late Profs. Ferguson and Ruffer whether they could detect tubercle bacilli in his psoas abscess. This started Sir Armand on the work. In attempting to put the history of these events into their proper sequence I ought to direct attention to the real achievements of the late Sir Armand Ruffer in this field. These were, first, the perfection of the technique for the histological study of mummies; and, secondly, the discovery of the eggs of the Bilharzia worm in mummies embalmed thirty centuries ago. These results were attained only after long and wearisome experiment carried on with exceptional skill and persistence, and represent a very great achievement.

G. Elliot Smith.

Our Bookshelf.

Factors affecting the Control of the Tea Mosquito Bug (Helopeltis theivora, *Waterh.*). By E. A. Andrews. Pp. iv + 260 + 44 diagrams. (London: Indian Tea Association, 21 Mincing Lane, 1923.) 3*s*. 6*d*.

The work which Mr. E. A. Andrews has carried out in India in connexion with the mosquito bug of tea is described in this book. The limitations in the control of the pest by spraying are discussed, and an inquiry into the question of natural checks has led to the conclusion that the problem could not be solved by such means. The effects of climate and the variety of bush which is cultivated are discussed in some detail.

The action of various manures has been investigated, lime and potash manures having been shown to be of benefit. The relation of cultural operations to the severity of attack is also included. Whereas no relation is evident between the total quantities of potash and phosphoric acid present in the soil and the extent of attack, manuring experiments have yielded interesting and definite results. Immunity would seem to depend on the ratio of the available potash to the available phosphoric acid. Great benefit is derived from an increase in the available potash in the soil, the effect, however, being only transient. Analyses of the leaves show differences corresponding to those deduced from observation of the soils. Immunity has been induced experimentally by the direct introduction of potash to the plant, tea bushes so treated remaining immune for the rest of the season.

The importance of this work from an economic point of view is very great. The future of economic applied entomology lies far more in the detailed study of the relations between the insect, the plant, and the natural conditions influencing both, than in direct control by means of insecticides or entomological methods: such research, however, requires organised team work between the various branches of science. Mr. Andrews's work would be valuable if it emphasised this need alone; but it also embraces sound investigation and a great hope of the discovery of a practical control for the most serious insect pest of the tea crop.

The author is to be congratulated on his results and the patience with which he has collected his numerous data.

H. M. L.

Agriculture in the Tropics: An Elementary Treatise. By Dr. J. C. Willis. (Cambridge Biological Series.) Third edition, revised. Pp. xvi+223+24 plates. (Cambridge: At the University Press, 1922.) 12s. 6d. net.

DR. WILLIS's book was intended, not as a practical guide in field methods for the tropical agriculturist, but to serve mainly as an introduction to the study of the leading economic principles governing the modern practice of agriculture and planting in the tropics. With the remarkable developments taking place in tropical agriculture, such a book will require periodical revision to keep abreast of the times. The second edition was published in 1914, and the call for the present (third) issue has afforded a further opportunity for revision. It is a pity that no preface to the new edition has been printed, and, except for special information supplied by the publishers for the convenience of the reviewer, it would be difficult to trace new matter or corrections.

No important re-arrangement of the book has been adopted. The four parts remain the same and the slight revisions made in them are neither numerous nor very important. There are still opportunities, however, for improvement in the text. In dealing with the West African oil-palm (*Elæis guineensis*) due reference is made to the recent planting of the palm in the East, but the student would gather very little as to the origin of the "pericarp" oil (not mentioned as such) from the account given; while the statement that "of late another oil has been obtained from the seeds of the palm" is a little naïve. Definite reference also should be made to the wide use of coco-nut oil for the manufacture of margarine. Further, as regards gingelly oil, while it may be true that comparatively little of the oil is exported from the countries of production, the statement should be completed by reference to the important export of the seed for oil extraction in Europe.

The book remains, however, an excellent introduction to a subject of great and increasing importance, and should be read by all interested in the practice and administration of tropical agriculture and planting.

Crystallisation of Metals: being a Course of Advanced Lectures in Metallurgy delivered at the Royal School of Mines, Imperial College, under the Auspices of the University of London, in February and March 1922. By Col. N. T. Belaiew. Pp. 143+21 plates. (London: University of London Press, Ltd., n.d.) 7s. 6d. net.

COLONEL BELAIEW has written a book on the "Crystallisation of Metals," which is remarkable in that it deals with the coarse structure rather than the microstructure of metals. It is therefore noteworthy that a great many of his illustrations are natural size, while others are ×2, 5, or 10. Only in rare instances are higher magnifications used, although in certain extreme cases remarkable pictures are given in which the magnification is as high as 4500. At the other extreme, two illustrations are given on a *reduced* scale (×⅓) of Tschernoff's famous crystal, more than fifteen inches in length, which was found in the upper portion of the pipe in the sinking head of an ingot of soft open-hearth steel weighing about 100 tons. The final paragraphs of the book deal with the structure of Damascene steel, and include two beautiful illustrations, of approximately natural size, of Damascene blades, as well as microphotographs with an enlargement of 1000 diameters. The little book forms an admirable supplement to existing treatises on metallography, and reaches a level which entitles it to a place among standard works on this subject.

Visual Illusions: their Causes, Characteristics, and Applications. By M. Luckiesh. Pp. ix+252. (London, Bombay, and Sydney: Constable and Co., Ltd., 1922.) 15s. net.

IN this book Mr. Luckiesh presents one hundred illustrations of familiar and little-known optical illusions, round which the text is written. On account of the great complexity of the subject, the author confines himself to static illusions, and dispenses to a large extent with theory. It is inevitable that there should be some overlapping in any classification of visual illusions, since not seldom more than one factor enters into them; but the arrangement or grouping together in the various chapters which is adopted in the book is a convenient and practical one. After chapters on the eye and vision, geometrical and depth, or distance, illusions are considered in detail. These are followed by illusions due to irradiation, colour, and lighting. A special chapter is added on natural illusions, such as the apparent size of the setting sun as compared with the sun at the zenith, the magnification of objects seen through fog, and mirage. The last four chapters are devoted to applications of the natural principles of visual illusions to practical purposes, in the shape of painting, decoration, architecture, and camouflage. The book is well written and attractively produced, and should be of interest to others as well as to students of psychology.

Geology. By C. I. Gardiner. (Science for All Series.) Pp. x+138. (London: J. Murray, 1923.) 3s. 6d.

IN 1914, Mr. Gardiner produced his "Introduction to Geology" (see NATURE, vol. 94, p. 362), in which he found more scope for originality than is given by this smaller volume. The conception of a work on geology "for all" must vary with the outlook of the author, and Mr. Gardiner has had long experience in the training of beginners in the region where the foundations of stratigraphical geology were laid within the British Isles. We cannot help thinking that "all" would like to hear something of the Laurentian cauldrons in which the oldest strata of Canada were immersed; of the rich fauna of the Olenellus-beds; of the coming of the race of reptiles that was so long to dominate the world; and of the amazing development of mammals, from South Dakota and the Paris Basin to the Trinil river-bank in Java. But Mr. Gardiner knows well that a fossil picked up in a Gloucestershire lane or from a talus in the Isle of Wight may loom more largely than Atlantosaurus or the titanotheres. All reputable English text-books insist upon the Woolhope Limestone and the Thanet Sands. That we cannot escape from them in so small a volume is no sign of Mr. Gardiner's personal limitations. His style is always clear, and throughout he is in touch with recent observations.

Letters to the Editor.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, nor to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Mechanical Equivalent of Heat.

WITH the assistance first of Dr. J. K. Roberts, now of the National Physical Laboratory, and later of Mr. E. O. Hercus, I have been engaged for some years upon a determination of the mechanical equivalent of heat. It is believed that an indication of the lines upon which the experiment is being made may be of use to other workers in this branch of physics.

A number of determinations of what may be called the electrical equivalent of heat have been made, including the very thorough work of Jaeger and Steinwehr at the Reichsanstalt, but since the time of Joule the only direct measurements of the mechanical equivalent of heat are those of Rowland published in 1880 and of Reynolds and Moorby. The work of the former has for long been regarded as of high accuracy. Reynolds and Moorby's result is in terms of the mean calorie, and there is considerable room for doubt as to the value of that calorie in terms of the 15° or the 20° calorie. This doubt arises from the conflicting values found for the specific heat of water from, say, 60° to 100° C. It appeared, then, to be desirable to have a direct determination of the mechanical equivalent of sufficient accuracy as to be available for comparison with the electrical equivalent of heat. Such a comparison may throw light on the absolute values of the electrical units. It must be admitted, however, that to obtain the necessary accuracy in the value of the mechanical equivalent for that purpose will be a problem of some difficulty. But there appears to be no reason, if the same attention is given to the question as has been given to the realisation of the electrical units, why it should not be attained.

In our experiment, work is indirectly converted into heat; the work done and the heat developed are directly measured. The work is found, as in Rowland's experiment, in terms of a couple and a number of revolutions; the heat is measured by a continuous flow calorimeter in terms of a quantity of water and its rise of temperature. A correction is made for the heat lost during an experiment. The relation between these quantities is

$$2\pi nmgd = Jw(t_2 - t_1) + L$$

where J ergs per calorie is the mechanical equivalent of heat. The apparatus is designed so that the heat lost can either be directly determined, or be eliminated by taking the difference between the equations for a heavy and a light run.

The efficiency of an apparatus for finding the electrical or the mechanical equivalent of heat, which may be briefly called a J apparatus, is expressed by two characteristics, namely, (1) the percentage of the heat developed which is lost, and (2) the accuracy with which the lost heat can be determined, or eliminated from the expression for J.

We have gradually developed, after many failures, an apparatus which, measured by this test, is an efficient one. We set out in the following table average figures for the power absorbed, and the percentage of heat lost in experiments by the observers named:

Observer.	Power.	Percentage of Heat lost.
Rowland	0·4 H.P.	3
Callendar and Barnes .	0·03 ,,	2
Reynolds and Moorby .	70 ,,	0·8
Laby and Hercus . .	0·2 ,,	about 0·2

Any apparatus for the direct determination of J is a brake dynamometer. Reynolds and Moorby, for example, used the Froude hydraulic brake, which is the same in principle as the devices used by Joule and by Rowland, but the design is more efficient. We

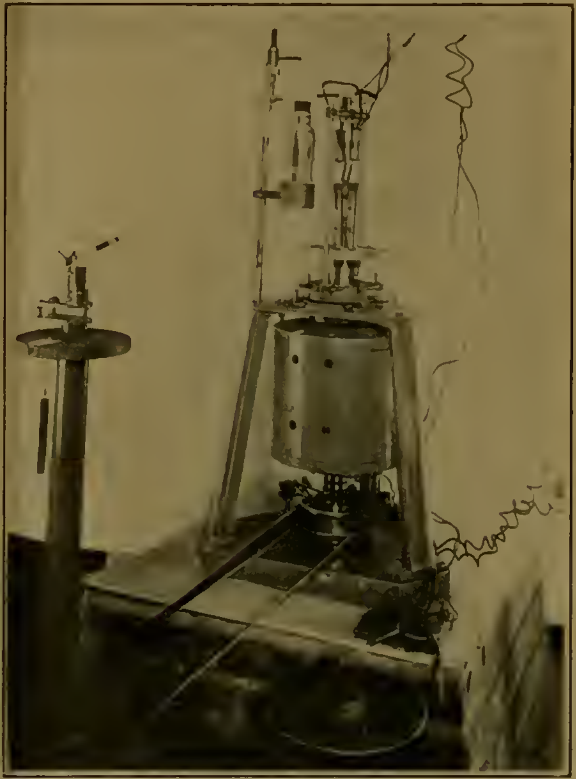

FIG. 1.

decided to enclose the brake in a vacuum flask, in order to obtain high thermal insulation, and to use continuous flow calorimetry. The brake we are using is an electro-magnetic induction brake, which is closely analogous to an induction motor. The construction of the brake is shown in Figs. 1 and 2. An electromagnet (see Fig. 2) rotates about a vertical axis; in the rotating magnetic field so produced a copper cylinder (Fig. 2) and an iron core are placed. The copper and iron cylinders are attached by means of a glass tube to the inner sleeve of a bearing. This part of the apparatus is called the stator. The rotating magnetic field induces eddy currents in the copper cylinder, which is thereby heated, and the reaction between these currents and the rotating field causes a couple to act on the stator.

The couple acting on the stator is balanced by the tensions in two wires attached to the torsion wheel carrying two weights, one of which is shown at the left of Fig. 1. The only details which need be mentioned of this part of the apparatus are the devices used to reduce friction. The bearing (Fig. 2) is a parallel ball-bearing for which the friction is less than 1/10,000 of the couple acting on the stator. To eliminate friction, the wheels over which the above-mentioned wires pass are carried on steel knife-edges resting on hardened steel planes.

For the temperature measurements we use platinum thermometers which are connected differentially to a Wheatstone bridge made to Müller's design. During the course of a year the average variation of the fundamental interval from its mean value has been 1/20,000 for one thermometer and 1/80,000 for the other. This would imply that the thermometry is of satisfactory accuracy.

The evaluation of the heat lost has proved far the most difficult part of the experiment.

In the earlier designs the loss in some experiments

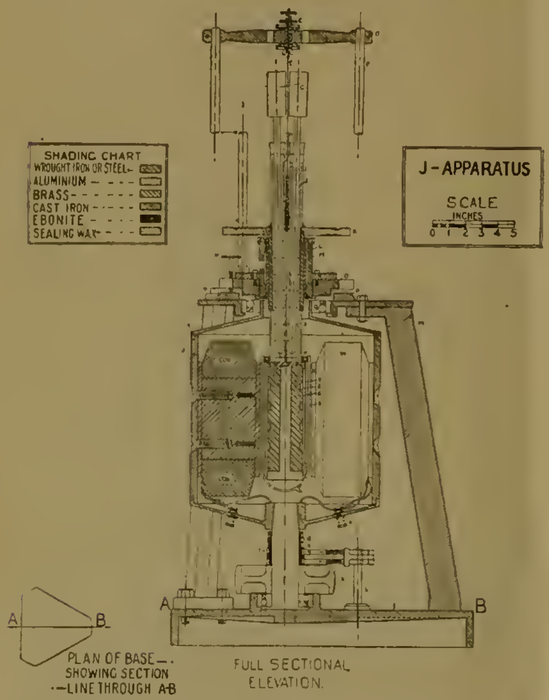

FIG. 2.

was as high as 2 per cent of the heat developed. All attempts to determine it correctly, or to eliminate it by taking the difference between a heavy and a light experiment failed, for reasons which cannot be given here. To overcome this difficulty the calorimeter system was reconstructed, by bringing the thermometers close to the vacuum flask and highly insulating them, as shown in the accompanying figures. This has reduced the heat loss to about 1/10 of its previous value. Means have been provided for determining the loss, and the stator is being modified so that the loss may be eliminated in the usual manner in continuous flow calorimetry by taking the difference between a heavy and a light experiment. It is expected that this alteration will increase the heat developed, and so reduce the percentage of heat lost still further.

The Transformation of Electronic into Electro-Magnetic Energy.

THE fundamental propositions given below, which do not refer to the excitation of characteristic but to that of the ordinary rays which have been called "independent" X-rays, have sufficient experimental evidence supporting them to justify the following statements so that they may serve as guiding principles for further investigations.

1. When a definite number of electrons in motion (cathode or β-particles) of definite velocity traverse very thin layers of different substances, the average fraction of their energy transformed into that of electromagnetic radiation (X- or γ-rays) is, per atom of any one substance, proportional to the square of its atomic number.

2. In these circumstances, for a given layer, the energy so transformed depends only on the mass per unit area of the layer and on the number of cathode or β-particles traversing it, being independent of their velocity.

By a very thin layer is meant one so thin that the ratio of the number of particles emerging from the layer to the number entering it is very nearly equal to unity.

The reason for the above statement is as follows. If cathode or β-particles of definite type and of total energy E traverse a layer of a substance of unit area and mass dm, the energy of the X-rays formed in the layer may be written as $\lambda E.dm$. We call λ the mass transformation coefficient. The atomic transformation coefficient, α say, is then obtained by multiplying λ by A/N, where A is the atomic weight and N is the number of atoms in a gram of hydrogen. I find that α, which gives the average fraction of the energy transformed per atom, varies approximately as the square of the atomic number Z, while λ varies as Z^2/A and both α and λ vary inversely as the energy of a single bombarding particle. Hence the above propositions hold approximately, since the total energy E is proportional to the energy of a single particle and their number n, so that $\lambda E.dm$ varies as $n.dm$.

With respect to the physical processes underlying the excitation of "independent" X-rays, certain considerations incline me to the provisional view that these X-rays are produced by a collision or by close interaction between the cathode or β-particles and the actual nuclei of the atoms rather than with the electrons surrounding them.

McGill University, Montreal,
May 21.

Dr. Kammerer's Alytes.

PROF. MACBRIDE's letter in NATURE of June 23, p. 841, did not at first seem to require any rejoinder. But I find that some botanists, and perhaps others unfamiliar with zoological terms, suppose that the quotations from Boulenger contradict my statement that rugosities are not formed on the palmar surfaces. Boulenger, of course with perfect accuracy, states that rugosities in various genera appear on the *inner* side of the digits (italicised by Prof. MacBride). This is the *radial* side, as emphasised in both our letters, not the palmar surface, which was the part which bore the extraordinary structure visible in Dr. Kammerer's specimen.

W. BATESON.

The Breeding Period of *Echinus miliaris*.

THE breeding period of the sea-urchin, *Echinus miliaris*, is very interesting from many points of view; and especially as this animal readily yields ripe eggs and sperm with which to carry out artificial fertilisation in inland laboratories for the observation of fertilisation, segmentation and gastrulation stages in the living state. The records made at this laboratory down to 1919 showed that *E. miliaris* has been found to breed from about February-March to August. In 1920 I arrived at the conclusion that certain marine animals, such as the oyster, breed continuously so long as the sea-temperature remains above a definite temperature, providing the general biological conditions are otherwise normal. On this view, and if the type of breeding in *E. miliaris* were the same as that of the oyster, the breeding period of this sea-urchin should be found to extend to about November-December, on the average.

In March and April 1920 many successful artificial fertilisations of *E. miliaris* were made, and it may be assumed that similar successful fertilisations could have been obtained onwards to August. After August periodical collections of this urchin were made *from the shore* to test the view mentioned above. On September 14 the proportion of ripe individuals collected was high and six excellent artificial fertilisations made; on October 13 the proportion of ripe individuals collected was smaller, but good fertilisations were still obtained, and on October 29, although the proportion of ripe individuals was now lower, an optimum fertilisation was obtained yielding very fine and healthy plutei on November 1. The observations at Plymouth were interrupted at this time, but on November 3 a high proportion of *E. miliaris* which had been *dredged* from the oyster beds off Whitstable were found to be ripe and yielded healthy larvæ, which lived in some bowls as plutei until at least January 5, 1921. A batch of similar urchins forwarded to Plymouth yielded an excellent fertilisation on November 10,[1] and although no fertilisation was made later, it was observed at various times during the winter that the gonads of Whitstable specimens examined remained full. A sample of urchins examined at Plymouth on January 26, 1921, showed that a small proportion of ripe males with full gonads still occurred but no ripe female was found, and the big variation in size of the gonad observed in the remainder of this sample points to a distinct physiological difference between the Plymouth and Whitstable groups.

It is thus clear that successful artificial fertilisations of *E. miliaris* may be obtained from Plymouth specimens during about the period February-March to November, and that the breeding period in the south of England may be considered to extend over the same range, but it is nevertheless open to doubt whether the capacity to yield a successful fertilisation may be good evidence that a species is breeding.

The fact that breeding individuals may be obtained over such a long period of the year affords good reason to believe that single individuals may spawn several times a year, but there is no evidence that collective spawning occurs in this species at one given phase of the lunar cycle such as Fox found to be the case in the Mediterranean sea-urchin *Diadema setasum* (see NATURE, February 23, 1922). In three collections of *E. miliaris* from Looe Is. near Plymouth, on September 23, October 12, and October 28 respectively, the unripe individuals showed variation in the size of the gonad ranging from about 1/12 to a full gonad. These observations do not, however, rule out the possibility of spawning occurring normally—in those individuals which are ripe—at certain definite phases of the lunar cycle, for example, after any low-water springs; for it has been observed not infrequently that ripe specimens collected at low-water spawn before arriving at the laboratory.

The sex-conditions in the collection of *E. miliaris* mentioned above were examined closely for any appearances indicating sex-change; for a condition of sex-change in sea-urchins may be regarded as a possibility in view of Mortensen's discovery of the common occurrence of protandric hermaphroditism in ophiuroids and of Fox's observation referred to above but not known at that time of the very rapid (monthly) filling and emptying of the gonads in the sea-urchin, Diadema: it is also worthy of note that Gray (Proc. Camb. Phil. Soc., xx. pt. 4, 1921) has described isolated cases of apparent and true hermaphroditism in the sea-urchins Arbacia and Strongylocentrotus. In *Echinus miliaris*, however, no definite hermaphrodites were found, but in several gonads at about the period of change from the spent condition to the rematuring stage, a small quantity of sperm was found together with gonocytes apparently too large for spermatocytes, and gonads were found having a colour generally associated with one sex but with young sex-elements of the other sex. The female gonad in *E. miliaris* varies in colour from white when young to yellow or orange when mature, whereas the male gonad varies from brown to grey. These differences of colour are undoubtedly an outward expression of the differences in metabolism in the sexes leading up to—or consequent upon—the production of mature sex-elements.

A similar sexual colour difference is observable in the gonad of other animals; for example, in *Crepidula fornicata* the gonad in the male stage is brownish red but yellow in the female, while that of the hermaphrodite stage is orange, and it has already been shown (Orton, Proc. Roy. Soc., vol. 81, B, 1909) that in the case of Crepidula the primary sexual characters precede in development and forecast the appearance of the secondary sexual characters. Thus the colour of the gonad in animals is undoubtedly closely connected with deep-seated changes—probably induced by sex-hormones or, as Geoffrey Smith visualised them, sexual formative substances—which are different for the mature male and female condition, and apparently also for a potential condition of sex while sex is yet unrecognisable in the primary sex-elements.

It would, therefore, seem possible that a chemical test might be devised to detect a sex-potentiality in an undifferentiated gonad. Such a test if obtained would be a very valuable help in investigating suspected cases of sex-change, especially in cases where a change-over of sex may occur between successive periods of growth of the gonad as is possible in *Echinus miliaris*, *Mytilus edulis*, and other animals, but more probable in the case of the common limpet, *Patella vulgata*. In this kind of sex-change the residual sex-elements in a gonad would often give a clue to the recent sex-condition, while the chemical test would provide evidence of the forthcoming or potential sex-condition.

The rapid change-over of sex in the oyster is also very strongly suggestive of the existence of a sex-hormone, as the gonad in a female-functioning oyster normally changes over quite suddenly after the extrusion of the ripe ova to the production of male elements only. There is good ground, therefore, for looking for a chemical test for sex-potentiality, especially in invertebrates, and there is no doubt that our knowledge of sex-conditions would increase rapidly after the discovery of such a test.

J. H. ORTON.

Marine Biological Laboratory,
Plymouth, May 24.

[1] This fertilisation and the one at Plymouth on October 29 were made by Mr. A. J. Smith. The larvæ from the Whitstable urchins November 3, and the Plymouth ones October 29, showed a fine apical tuft of cilia, which appears not to have been recorded in *E. miliaris*, although MacBride has described a similar tuft in *E. esculentus*.

An Einstein Paradox.

The letter with the above title in Nature of June 2, p. 742, contained two oversights which I should like to be allowed to correct.

1. In the second part I inadvertently changed the meaning of x'. Overlooking the fact that x' in the first part meant, by implication, the distance of K_1 from L at the time that the light reached him, I used it in the second part as the distance K_1L at the instant the signal was given. I should have employed a different letter, x_1; and then, if required, $x' = c/(c+v)$ of x_1.

2. A term was omitted from the value of x', which should have been $(1+v/c)x - vt$.

R. W. Genese.

The Concilium Bibliographicum.

My attention has been directed to a statement in Nature of April 28, p. 584, made in connexion with the report of a meeting concerning the "Zoological Record." It is stated that "With the exception of the 'Archiv für Naturgeschichte,' which is about nine years behindhand and consequently of very little use, the 'Zoological Record' is at present the only bibliographic guide to zoological literature being published in the whole world."

Permit me to recall that the Concilium Bibliographicum at Zurich, founded in 1895 by Dr. Herbert Haviland Field and approved by the International Zoological Congress, is still continuing his work. After Dr. Field's death in 1921, the Concilium was placed under the auspices of the Swiss Society of Natural Sciences and the United States National Research Council, and has published since that time volumes 30 and 31 of the "Bibliographia Zoologica," containing an international review of zoological papers. Two other volumes (32 and 33) are already in progress of publication.

J. Strohl,
Director of the Concilium Bibliographicum.

49 Hofstrasse, Zurich,
May 15.

[We have also received a letter from Messrs. Louis B. Prout and George Talbot, of the Hill Museum, Witley. They suggest the issue of cards so that "subscribers would have the current literature available say every month, and no one would be obliged to purchase sections which would not be useful to him." They too direct attention to the reorganisation of the Concilium Bibliographicum and strongly urge co-operation with it.

Zoologists will be glad to learn that the Concilium Bibliographicum is still in being. There was some excuse for the incorrect statement to which Dr. Strohl objects, for inquiry at the two chief zoological libraries in London has failed to produce a volume of "Bibliographia Zoologica" later than vol. xxx., which, though it purports to deal with the literature down to the end of 1920, is mainly composed of titles from 1915–1917; it also omits Lepidoptera, Hymenoptera, and Vertebrata. But, even were "Bibliographia Zoologica" more up-to-date, more complete, and more accessible, its plan scarcely enables it to compete with the "Zoological Record" for the support of systematists. In the past the peculiar contribution of the Concilium has been the separate cards, but we have not seen any of these for a long time. We hope their issue has not ceased, for it is along those lines that co-operation seems most promising. If the Concilium could furnish the titles completely and promptly, the Zoological Recorders could work up the analytical index they have been accustomed to provide. We may remind Messrs. Prout and Talbot that the several sections of the "Zoological Record" have been sold separately for the past twenty years.—Ed. Nature.]

Educational Problems of Tropical Agriculture.

It is exceedingly important at the present moment that the attention of men of science should be directed to some of the needs and problems connected with tropical agricultural education. As many readers of Nature are aware, a college of tropical agriculture, the only one of its kind with pretensions to University standing within the Empire, was opened last year in Trinidad, and the ultimate success of this institution, both from the point of view of education and research, will, quite irrespective of financial support, depend upon the institution's outlook and policy and, what is equally important, the degree of acceptance which this receives in Great Britain and America.

In England agricultural colleges have not, from an academic point of view, achieved a very high status; nor have they been free from adverse criticism on the part of practical farmers. The policy of the institutions, therefore, has been somewhat unstable, tending to oscillate between the solar force of the universities and the lunar attraction of the practical farmers. This condition has been produced through misunderstandings on the following points: (*a*) the nature of agriculture; (*b*) the definition of the word "practical"; and (*c*) the difference between education and instruction.

Agriculture is to some extent an art and to some extent a profession, but fundamentally and comprehensively it is a business, or, if another term be preferred, it is biological industry. The trouble has been that most students of agriculture have thought of it as a profession, whereas the practical farmers have regarded it as an art. By definition, both are wrong fundamentally. Unenlightened, the students have tended to specialise in applied natural science (often of questionable quality), while the farmers have been the advocates of concentration on the art ("real practical work"). The misunderstanding as to the word "practical" is, therefore, clear. Neither is practical; for agriculture is fundamentally economics, in which faculty practical work can be purely intellectual, for example, accountancy and statistical inquiry. Misconceptions as to the meaning of practical have been responsible for confusion as to the difference between education and instruction. The word instruction should be relegated with patent rights to the Army, Navy, and Police Force. Except as connoting the routine of one person telling or showing something to another, it means nothing and leads to nothing. Education implies understanding and a training of the faculties including the practical instincts. Instruction alone is useful for those who do not want to be, or are incapable of being, educated; but matriculated students, such as one now finds in agricultural colleges, ought to be anxious for, and capable of, some education.

In the tropics, the so-called agricultural education of the past has been little more than instruction. A youth has been instructed how to read a polariscope or do a Babcock test—and becomes a chemist! Another is taught to bud oranges or run a sugar mill, and becomes a planter. This has suited the tropical temperament and climate, and in most cases, it is to be feared, the average type of mentality. But if tropical agriculture is to advance we must aim at, and insist upon, higher standards. The planter of the future must be taught to think and to understand his economic and biological universe. This is realised at the West Indian Agricultural College, but are we going to live up to it? Will such an outlook receive the support of tropical public opinion on which we are so largely dependent for funds? Is it, for the present, to be expected? It is therefore important that the matter should be appreciated by scientific opinion in this country to which scientific workers in the Crown Colonies look very largely for encouragement and protection.

Reference to research has been purposely avoided in the above observations for the sake of simplicity. But research, the mother of scientific education, has also its disabilities in the tropics. Up till quite recently, the demand, the popular demand, has been for "trouble-curing" rather than research. The present danger, however, is that research work may be interfered with through depriving investigators of their time in order that they may give instruction.

Gravitation and Light-Pressure in Nebulæ.

IN NATURE of June 16 there is a most interesting letter by Dr. Jeans on my suggestion that spiral nebulæ may consist of dust repelled from the stars by light-pressure. My original note must, I fear, have been somewhat misleading to have called forth the particular criticism which Dr. Jeans's letter contains. As was, I think, brought out in the discussion at the Royal Astronomical Society, it was never my intention to suggest that the dust clouds are so thick that there is any appreciable shielding; indeed it is perfectly obvious, as Dr. Jeans points out, that the whole theory would break down unless the particles are assumed to be so far apart that they can be treated individually.

The misunderstanding is due to a somewhat ambiguous sentence at the end of the paper, which I admit is capable of giving quite a wrong impression. I had anticipated that my suggestion would be criticised unless I presented some explanation of the so-called "novæ" in spirals. The suggestion put forward was that they were similar to terrestrial meteoritic showers. In order to show that this was not impossible I put in some very rough quantities, and endeavoured to show that they would not lead to absurd results for the characteristics of the nebula. The density found, based, it may be remarked, upon the time in which the meteoritic stones are supposed to evaporate, leads to a mass over the depth of one light-year of 0·1 grams per square centimetre. I agree, of course, that this cannot be supported by radiation pressure; indeed a remark by me to the same effect may be found in the *Observatory* some years ago. It would have been better had I said that this result was some 10^3 times too high in view of the obvious transparency of parts of the spirals. The great uncertainty of the quantities used, however, emboldened me to say this was of the right order of magnitude; compared with the results derived from other hypotheses to account for the "novæ," which led to results 10^6 times greater, this was perhaps excusable.

Dr. Jeans's criticism, to which I admit my somewhat optimistic sentence laid me open, applies, therefore, to that part of my paper from which this unduly large mass was derived; *i.e.* the hypotheses introduced to account for the "novæ." It is possible that the quantities which I used might be altered plausibly to give a more acceptable value. It is perhaps even more likely that a more satisfactory hypothesis may be evolved to account for the phenomenon. But the main outlines of my suggestion do not seem to be controverted.

F. A. LINDEMANN.

Clarendon Laboratory, Oxford,

The Heape and Grylls Rapid Cinema.

OWING to arrangements deemed necessary at the Soirée of the Royal Society on June 20, I was unfortunately deprived of the opportunity I had hoped there to gain, of making a personal explanation which is important to me and which I beg to be allowed to make in NATURE.

The conception of devising a camera wherewith photographs could be taken at the rate of 5000 a sec. occurred to me in consequence of some chance remarks made to me by an official of one of the great armament-producing companies in this country. The lion's share of credit for the successful completion of the design of the camera, however, is due to my friend Mr. Horace B. Grylls, who became partner with me in this adventure in 1914; while both of us are indebted to my friend Prof. Boys, who, as all who know him will readily believe, gave us with both hands all the help and advice he had to give.

The interest which has lately been aroused by the exhibition of some of the films I took while the machine was still in Messrs. Thos. Cooke and Sons' workshop in York—experimental films and far from perfect, I regret to say—calls for some such statement as I now, with great satisfaction, make here.

Adsorption and Hæmoglobin.

SIR WILLIAM BAYLISS has pointed out, in NATURE for May 19, p. 666, that he is unable to find any account of experiments on the dissociation curve of hæmoglobin at gas pressures considerably greater than that at which the hæmoglobin is presumed to be saturated. He seems to imply that there is no proof that hæmoglobin cannot take up more gas than is required by the theory that a chemical compound is formed, in which one molecule of O_2 or CO corresponds to one atom of iron.

The point is important, not only as evidence on the relative merits of the chemical and adsorption theories, but also because experimental methods of determining the oxygen dissociation curve depend on the assumption that hæmoglobin becomes completely saturated, in contact with air, at the ordinary temperature of the laboratory.

I have tried to test this question by shaking equal samples of the same blood (partly reduced) in the Barcroft differential apparatus, (1) with the bottle filled with air in the ordinary way, and (2) with the bottle filled with a mixture of air and CO, containing rather more than half an atmosphere of CO.

It is known that hæmoglobin takes up CO more than 200 times as readily as oxygen, so the effective gas pressures in the two cases were in the ratio of at least 500 : 1. If the hæmoglobin takes up gas by adsorption, one would expect to find appreciably more CO taken up than oxygen. As a matter of fact, a little more CO was taken up, but only that quantity which is accounted for by the difference of solubility of CO and air in the liquids present (blood and dilute sodium carbonate solution).

There was no evidence that the hæmoglobin itself

2 C 2

took up any more CO than oxygen, in spite of the great difference between the effective concentrations of the two gases.

Sir William Bayliss also asks for experimental tests of the assumption that oxyhæmoglobin is a stronger acid than hæmoglobin itself. The limitations of the hydrogen electrode make the measurement of the hydrogen-ion concentration of hæmoglobin solutions, in the presence of oxygen, a difficult problem. I have been able to show, however, that if gas is boiled off in a vacuum from dialysed hæmoglobin solution, the electrical conductivity of the solution is considerably increased by shaking with oxygen or CO. (Precautions have, of course, been taken to exclude the possibility of the increased conductivity being due to impurities in the gas used.)

While this is naturally not a proof that combination with oxygen increases the acid dissociation constant of hæmoglobin, it is nevertheless the result to be expected if this be the case, and is a fact to be explained by any theory, chemical or physical.

Prof. Hill and I have pointed out that the divergent results of investigators of the heat of combination of oxygen and hæmoglobin may be due partly to bacterial action, and (in experiments on blood) partly to failure to allow for the heat changes involved when oxyhæmoglobin turns out CO_2 from carbonates. By eliminating these sources of error we have been able to get quite consistent results in experiments on defibrinated blood.

Without making any assumptions other than the recognised laws of chemical combination and chemical equilibria, it is possible to explain the behaviour of hæmoglobin by regarding its reactions with CO and oxygen as purely chemical. Sir William Bayliss has said that he doubts whether it is justifiable to apply these laws to a system in which the number of the phases may be uncertain. Surely the best way to decide this is by results, and, judging by results, the chemical theory has amply justified its position as a fruitful working hypothesis.

Can the adsorption theory explain the phenomena so completely, with so few untested assumptions? Since the paper by Wo. Ostwald in 1908, no attempt has been made, so far as I am aware, to put forward a complete theory of the reactions of hæmoglobin as adsorption phenomena. Much experimental work has been done since then, and until such a theory is put forward it is difficult to weigh up satisfactorily the merits of the two views.

At present the adsorption theory is in danger of going by default.

A Puzzle Paper Band.

AN easy solution of the paper-band puzzle described by Prof. C. V. Boys in NATURE of June 9, p. 774, is obtained as follows: Hold the hand with thumb up and palm towards you; place the paper band over the index finger, letting the ends hang down. Observe which way the original four half-twists were applied. Treat the nearest of these to the index finger on the palm side of the hand as if it were that of an ordinary single half-twist band; which complete, by looping up one-half of the band over the finger (the other twists being pushed out of the way into the remaining half). Then apply the surfaces one upon another at the finger; and turn the other half of the band inside out so as to get rid of two of the twists. It will be found to fit exactly upon the first half, as required.

ANNIE D. BETTS.

Hill House, Camberley, Surrey, June 11.

Paradromic Rings.

PROF. C. V. BOYS, in his letter "A Puzzle Paper Band" in NATURE of June 9, p. 774, gives scant credit to the geometers. Forty years ago they described the endless band of paper with a half-turn twist in it, and found that if cut down the middle line it gave a single endless band with four half-twists. But they were so obsessed, he says, with the consequence of cutting down the middle line that they missed the result he now describes. This consists in taking a band with four half-twists and converting it by manipulation into a half-twist band of double thickness.

But the difference between the known result and the proposed novelty seems not more than trivial: for if the medially cut band has its adjacent half-widths simply slid sideways, one over the other, along the entire length of the band, the double-thickness band of half-width is at once produced. Or, reversely, if the pulleys of Prof. Boys are made twice as wide, and the outer band is teased sideways at its entry on to each revolving pulley, the two halves of the band will presently come edge to edge throughout and are then seen to be nothing but the half-twist band medially cut.

As regards this lateral shifting, it is obvious that any endless band, however much twisted and knotted, may, when cut down the middle, be continuously "shuffled," in the way in which a "pack" consisting of only two cards may be shuffled. Each neighbour slides over the other in perpetual oscillatory contact, alternately face to face and edge to edge. Two different superpositions and two different edge-to-edge positions occur alternately and cyclically. In particular, the band with four half-twists may be arranged as a two-ply half-twist not in one way only but in either of two ways. For either of the two different faces of the former may be completely exposed or completely concealed in the latter.

The sheer puzzle of the manipulation Prof. Boys plans to make even harder by varying the sense of the twists, as right-handed or left-handed. I should propose (somewhat on behalf of the geometers) to escape this difficulty by letting the paper discriminate for itself. The instructions would be these. Strip the band along, two-handedly, until the twists are concentrated on a short section. They come to form roughly a circular cylinder, showing two turns of a ribbon screw. Take two adjacent widths, touching helically edge-to-edge at any point, and fold them together as if closing an open book. Then feed the short circuit at the expense of the long loop until they come equal, and fit together by stripping. These operations may quite easily be done blindfold.

Prof. Boys says that the double band shows only two of the half-turns, and that it is amusing to find where the other two have gone. But this is *vieux jeu*: for Tait explained it in his first paper on "Knots" in 1877; and he was only following Listing, who had these things clear in his "Topologie" of 1847. If the paradox is still alive it may be reinforced, for those who do not know that torsion and curvature are convertible; for the double-twist may be hung over one finger as a festoon of three equal loops, with the six pendant planes all (approximately) parallel to the finger, and then not merely half but the whole of the twist appears to have gone.

In a parenthetic confession Prof. Boys admits that he made his discovery while lying awake one night; but this may almost be interpreted as an indirect testimonial to the day labourers.

Chemical Symbols and Formulæ.[1]

By Sir JAMES WALKER, F.R.S.

SYMBOLS are both an aid and an obstacle to thought. Their brevity and simplicity may help us, working according to a fixed system, to perform mental operations which without their aid might be practically impossible. Their generality too may, as in algebra, enable us to solve thousands of problems in one. On the other hand, we sometimes find in science a system of symbols which, at first of great value, may in virtue of its very success so warp our thought or limit our mental outlook as to constitute a real hindrance to scientific progress. There is always the danger, arising from our familiar and constant use of the symbol, either of forgetting what it properly symbolises, or of confusing the symbol with the thing symbolised.

The function of the symbol is a practical one; in Mach's phrase, it is to effect economy of thought, and it is precisely because mankind at large is so economical of thought that the dangers of symbolism originate. The danger, however, must be faced by the student of chemical science, for without symbols systematic advance is impossible: the symbols are based on a theory and permit the representation of that theory in detail.

If we examine the practical requirement of a satisfactory system of symbols, we shall find that the system must be simple in itself and simple to operate. Consider the Roman schoolboy confronted with the problem of multiplying MCMXXIII by CXLIV. The system of notation is not too complicated, but to operate with it is practically impossible. To perform his task he must abandon the symbolism and have recourse to concrete objects—the fingers or an abacus. The Arabic notation, on the other hand, with its consistent valuation by position and the introduction of a symbol for zero, enables us, once we have passed the barriers of the addition and multiplication tables, to perform arithmetical calculations of all kinds with ease and speed. It is simple in itself and simple to operate.

The same requirements are essential to a system of chemical symbols. The first symbols, those for the metals known to the ancients, indicated nothing but their supposed association with the planets and the gods ruling them. Thus the solar disk stood for gold, the lunar crescent for silver, the mirror of Venus for the Cyprian metal copper, and so on. Towards the end of the eighteenth century we see the beginnings of our present system of elementary symbols. Hassenfratz and Adet (1787) used for the non-metals straight and curved lines which could be combined together (much as in phonetic shorthand) to represent the qualitative composition of compounds. The symbol for a metal was a circle, and to distinguish one metal from another the initial of its Latin name was written within the circle—thus (Sb) was the symbol for antimony.

Dalton used for metals and non-metals alike only circular symbols, doubtless to represent spherical atoms, and in his hands the symbols assumed a quantitative significance based upon his atomic theory. For the simple non-metals these symbols were arbitrarily chosen, ○ representing an atom of oxygen, ⊙ an atom of hydrogen, ⦶ an atom of nitrogen, and so on. For the metals he adopted the same device as Hassenfratz and Adet, using, however, the English instead of the Latin names, so that for example (L) represented an atom of lead. Compounds could be represented by the juxtaposition of the elementary symbols, which now gave, not only the qualitative, but also the quantitative composition of the compound. Thus, for Dalton, water was represented by the symbol ○⊙, denoting the combination of 7 parts of oxygen with 1 of hydrogen.

Berzelius (1815) took the final step by using Latin initials for all the elements, dropping the circles which had surrounded them, and employing affixed numerals to indicate the number of times the symbol had to be repeated. It is true that Berzelius spoiled the uniformity of his system by using a special dot symbol for oxygen and writing such formulæ as $\dddot{S}$ for sulphur trioxide. These dotted symbols, however, found little favour except amongst mineralogists, and gradually passed out of use. The disuse of the circles is not without significance—the symbol to Berzelius represented a combining weight rather than a concrete atom, and the dual quantitative use persists in the interpretation of symbols to-day. The symbol C stands for one atom of carbon or "twelve parts by weight" of carbon. So we may say that more than a hundred years ago a system of formulation had been reached which, with minor alterations, is in use at the present time for the representation of elements and the composition of compounds, and is never likely to be superseded. It is uniform, plain, and simple in itself, and simple to use in the equations representing chemical change.

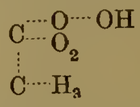
The purely compositional formulæ, however, fall far short of expressing what calls for expression in various classes of chemical compounds: action and structure have to be considered as well as composition. The dualistic formulæ of Berzelius illustrate early attempts in this direction. The formula of sodium sulphate is not written empirically as Na_2SO_4, but dualistically as Na_2O,SO_3. This formula indicates *inter alia* that the sodium and the sulphur belong to two essentially different parts of the compound. The modern electrochemical dualism writes Na'_2SO_4'', again indicating the same division of a positive from a negative portion. In organic chemistry the representation of structure by means of formulæ achieved success by the clear recognition of valency—in particular, the quadrivalence of the carbon atom. At this point of development the notion of the atom as structural unit becomes indispensable.

The valency of an element on its experimental side is in essence a numerical conception. We divide a weight by a weight, namely, the atomic weight by the equivalent weight, and obtain in consequence a mere number. When we pass from element to atom, however, the conception undergoes a transformation, and receives a concrete meaning. The valency of an atom may be interpreted as its capacity for combining with other atoms, again a numerical conception, but one

[1] Presidential address delivered at the annual general meeting of the Chemical Society on March 22.

leading directly to a symbolism and indirectly to a mechanical interpretation. Each atom is conceived as having a definite number of places for the attachment of other atoms, and as the number is in each case small we can conveniently represent it in a graphic symbol.

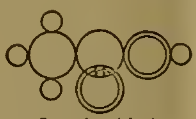
It is not without interest to look back to the origin of graphic or constitutional formulæ and see the beginnings of our conventional system. Couper and Kekulé, the originators of the idea, suggested systems widely differing from each other. Couper (1858) symbolised acetic acid as follows,



in appearance a near approach to present-day usage if we allow for the fact that he assumes O=8 and C=12. The manner of linking of various atoms is indicated, but their valency is not clearly symbolised. Kekulé's graphic formula (1859) for the same substance is shown below.

Acetic Acid.

(Kekulé.)

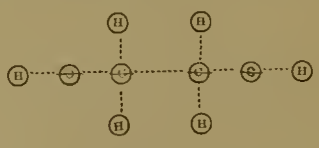


(Loschmidt.)

The valency is satisfactorily represented, but the linkage of the atoms is confused. Only atoms touching in a vertical line are supposed to be directly linked. The system is cumbrous, and Kekulé himself used it but sparingly. For branched chains it becomes impracticable.

Loschmidt (1861) devised a clear logical system which, although he formulated by its means hundreds of compounds, some of a very complex nature, found no favour amongst chemists. His symbol for acetic acid is given in the figure. Here linkage and valency are adequately represented, but the atomic symbols are arbitrary, and the system, like Kekulé's, is cumbrous to use.

Simultaneously with Loschmidt, Crum Brown (1861), although he was unaware of Couper's work, used a symbolism resembling his, and practically identical with that in current use. He writes glycol as follows:



Here valency and linkage are clear, and the atomic symbols are no longer arbitrary. Wurtz in 1864 gave the following formula (I.) for the same substance:

(I.) 
 (II.)

 (III.)

The line of development of modern graphic formulæ, then, is through Couper, Crum Brown, and Wurtz, and not through Kekulé or Loschmidt. The reason for the preference shown by chemists is that the symbolism adopted is more obvious, simpler to use, simpler to reproduce, and easily adaptable to all organic compounds.

There is a dual character in our graphic formulæ which it is important that we should realise. Let us begin with the graphic symbols of the elements, thus:

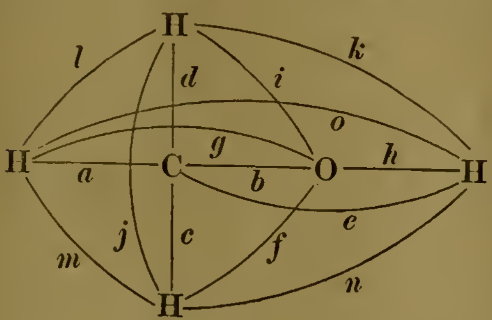
H–, –O–, –C–, where each short line represents a unit of valency. To the graphic symbols of molecules is but a step; the atoms are represented as united together, the valencies indicating the manner of attachment (II.). The directness or indirectness of union of the atoms is here given; no hydrogen atom is in this formula directly attached to another; they are only indirectly united through carbon or oxygen. For brevity, we join up the lines representing the valencies of the various atoms and obtain the customary formula (III.). A great change in significance has, however, at this stage taken place: the valencies have become "bonds"—the idea of force has entered. What that force is remains indeterminate; it is merely something binding atoms together, and the interpretation of the symbols is not quantitative in this respect. The "bonds" do not represent equal forces; it is patent that the bond between hydrogen and carbon in the formula for methyl alcohol represents a different force from that between hydrogen and oxygen. The current symbolism may then be interpreted in two senses; the lines joining the atomic symbols may be taken to represent on one hand merely the union of the atoms to the symbols of which they are attached, or they may represent forces existing between these atoms. Confusion of these two senses sometimes leads to erroneous reasoning.

This dual character of graphic formulæ is noticeable from their earliest employment, and I need make no apology in illustrating it from the work of Crum Brown, whose recent death deprived our Society of its senior past-president. In the formula for glycol quoted above he states (1861) that the dotted lines therein employed represent polar forces. In 1864 he represents ethane thus (IV.),

(IV.) 
 (V.)

each valence being written independently. He says: "I may here shortly explain the graphic notation which I employ to express constitutional formulæ. . . . An atom is represented by its usual symbol surrounded by a circle with as many lines proceeding from it as the atom contains equivalents. . . . When equivalents mutually saturate one another the two lines representing the equivalents are made continuations of one another." Here he has discarded the idea of polar force in his original formulation in favour of the simpler conception of number of equivalents. In 1866 he writes continuous lines between the symbols, and in 1868 puts the matter thus: "The structural formula of formic acid [V] indicates first, that the four carbon equivalents form one atom, the four oxygen equivalents two atoms, and the two hydrogen equivalents two atoms; secondly, that these equivalents are united in pairs, thus—*co, co, co, ch, ho*; but it does not in any way indicate (and we do not know) what is the *potential* of each of these pairs—that is, how much energy would be required to separate the equivalents from each other. We know that this potential depends upon the structure, and we can to a certain extent trace the nature of this dependence, but as yet we cannot express the potential numerically, and till we can do that we do not fully know the constitution."

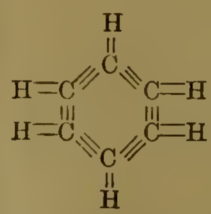
On one hand, then, our "bonds" stand for mere units of valency; on the other, they are an imperfect representation of forces. Were the representation of forces more complete, methyl alcohol would appear somewhat as shown in the figure below, the small letters representing numerical values. Even this formula, however, only gives the magnitude and not the real direction of the forces, and is besides static, not kinetic. We naturally shrink from complexity such as this: imagine the formula of sucrose on a similar basis. We must content ourselves with something simpler, and

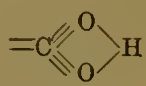


Methyl Alcohol.

yet the simple valency formula has for long been felt to be inadequate. Apart from the idea of definitely directed valencies which leads to stereochemical formulæ, the idea of representing partial valencies has been constantly in the foreground. We cannot properly split valencies in the old sense, but we can subdivide forces *ad libitum*. If the subdivision is carried too far, however, the formulæ may approach in complexity formulæ with quantitatively measured forces, such as that indicated in the figure.

What the chemist requires in his system of formulation is something, not which he can *measure*, but which he can *count*—counters, in short. Such numerical counters he possesses in valencies, in co-ordination numbers. He may be forced to consider the adoption of counters of different kinds, for the purpose of representing essentially different distributions of force; but these counters, if they are to be of general practical value, must neither be too numerous nor of too great variety. Partial valencies, augmented valencies, diminished valencies, virtual valencies, represented by lines of various sorts, thick, thin, curved, dotted, etc., all tend to complicate formulæ, which lose in obviousness what they gain in definition. The humiliating fact must be admitted that the average man does not succeed in counting quickly and accurately by inspection any larger number of "bonds" than he has fingers on one hand, unless they are appropriately grouped—witness the wrong valencies found, not merely in examination scripts, but even on the printed page. We ought, then, to set strict limits to the splitting of "bonds" and the issue of fractional valency counters. Fortunately, the physicist has provided us with a new counter, the electron, which has the great merit of being a physical reality, and, moreover, of being an undecomposable magnitude, so that there is no temptation and no possibility of dividing it further. This counter enables us practically to halve ordinary valencies, and so offers many advantages. In the original form given by J. J. Thomson, lines in the formulæ are made to represent tubes of force passing from an electron of one atom to the positive core of another, and since in electrically neutral atoms, for each tube of force which passes out of an atom a return tube must come in, directly or indirectly, one valency line on the old scheme is represented by two tubes of force on the new. The new formulation enables us to write, for example, symmetrical formulæ for benzene and for the carboxyl group, if we so desire, thus:





Or, again, we may represent the valency electrons directly in our formulæ, each atom being equipped with its doublet, sextet, or octet. Such formulæ, or modifications of them, are coming extensively into use when multiple bonds are in question, and there is no doubt that with the electron or electronic tube of force as counter we obtain a more adaptable and more flexible formulation of organic compounds than that afforded by the older valency formulæ, although only with some sacrifice of their simple character.

It will be gathered from what I have said that my plea is for the utmost obviousness of our symbols and formulæ. Their content and connotation may be as rich as we please; the symbols themselves should be of elementary simplicity. But, it may be asked, why should we seek to limit the investigator striving for chemical self-expression to four whole valencies for carbon if he wants a dozen partial valencies to facilitate his own thought or to convey his exact meaning? And why should he hesitate to adorn his formulæ with arrows or positive and negative signs of polarity if he feels the necessity? The answer to such questions must be of a practical nature. The investigator for his own use may employ a symbolism as elaborate and as complex as he chooses, but if he wishes to secure the understanding and sympathy of others he must curb any spirit of exuberance. A system of chemical formulation to have general currency must not be too elaborate. Otherwise, although it effects economy of thought to the expert who devises it, it may demand such a mental strain of the general chemical reader as to defeat a main purpose for which it was planned, namely, the communication of knowledge. I would quote, both with regard to chemical symbolism and to chemical nomenclature, the words used by a character of Henry James concerning literature, "The observer is nothing without his categories, his types and varieties. . . . That's for his own convenience; he has privately a terminology to meet it. . . . But from the moment it's for the convenience of others, the signs have to be grosser, the shades begin to go. . . . Literature, you see, is for the convenience of others. It requires the most abject concessions." Scientific literature is, above all, for the enlightenment and convenience of others, and scientific specialists must be prepared to make concessions to their weaker or less expert brethren. But whether the symbols we use are simple or complicated, we should always be clear as to their true significance, and be on our guard against their distracting our thoughts from the realities which they partly reveal and partly obscure.

Recent Contributions to Aviation Problems.

By Prof. G. H. Bryan, F.R.S.

The attempts which have hitherto been made to explain the continuous sustentation of tropical and other birds without the performance of muscular work have left many doubtful points requiring to be cleared up. Observers have frequently sought to attribute the phenomena to something acting in violation of the principles of elementary mechanics, and have succeeded in establishing this peculiarity, not perhaps in the way that they intended, but by the chaotic way in which such terms as force, momentum, weight, energy, lift, pull, drag, and gravity are confused by them, and occur indiscriminately mixed up in their writings. In a paper on "Meteorology and the Non-Flapping Flight of Tropical Birds," published in the Proceedings of the Cambridge Philosophical Society, xxi. 4, Dr. Gilbert T. Walker has now sought to bring sound scientific principles to bear on the numerous observations in India published by Dr. Hankin. From observations of the temperature of the air at Agra at different altitudes and hours of the day, Dr. Walker finds conditions of instability leading to the formation of strong ascending air-currents, and observations in Egypt and various parts of India indicate conditions of "bumpiness" in the atmosphere caused by ascending currents, covering the periods employed by birds for "soaring."

Dr. Walker finds that the angle of gliding of the most efficient recent aeroplanes is sufficiently low to satisfy the conditions necessary for continuous sustentation in the presence of these currents, and he examines in detail three possible sources of internal work in the atmosphere, namely, ascending currents, variations of horizontal velocity as functions of time and place co-ordinates, and Lord Rayleigh's hypothesis of variation of horizontal wind velocity as a function of the vertical altitude co-ordinate. He also carefully considers the structure of the birds' wings, in comparison with those of the Handley-Page machine, and the effect of the flexibility of the quills on the aerofoil form in ascending and descending glides. Both from theory and from actual observation, it is found that the ascending air-currents in the higher regions of the atmosphere are greater in diameter than lower down, and from actual observation he contradicts Dr. Hankin's statements according to which birds are seen rising in descending currents. It would thus appear from Dr. Walker's observations that, in the region dealt with by Dr. Hankin, the atmosphere possesses sufficient internal energy to satisfy the conditions of "soarability" required by the latter observer. In regard to the violation of mechanical principles, both hypothetically by birds and actually by writers, we cannot do better than quote Dr. Walker's remark that . . . "it is strangely" (asterisk and footnote with references follow) "necessary to insist that it is as impossible to derive energy from a wind that is constant in time and space as it is from a perfect calm." To theories based on a denial of this principle the late Sir Hiram Maxim used to point out the enormous velocity of the wind due to the earth's rotation and its orbital motion about the sun, and he suggested that if writers believed in these theories, why did not they utilise this energy for the purposes of flight?

The recent records of gliding flight in the daily press afford ample confirmation of Dr. Walker's theories in regard to the quantity of *available* internal energy present in the atmosphere. When we read of aviators remaining for hours in the air under climatic conditions not widely different from those prevailing in Dr. Hankin's and Dr. Walker's investigations, and of 7 horse-power engines making long flights at a cost for fuel of not more than a penny a mile, we have reasonable prospects of realising a system of cheap transport largely superseding the use of wheels bumping over stony roads or iron bars placed end to end.

Apart, however, from the precariousness of the distribution of the necessary internal energy in space and time, a motorless aeroplane is in constant danger of being suddenly brought to rest relative to the air, or, more accurately, losing all headway, at which instant it has a vertical acceleration due to gravity, and the resistance to rotation (pitching, yawing, rolling) becomes technically describable as "a small quantity of the second order," thus approximating to the conditions assumed in the problem of rigid body rotation under no forces.

We are constantly reading of accidents which seem to suggest that they have arisen from this condition of affairs, even in the case of motor-driven machines which are at least equipped with a more adequate means of extricating themselves from this eventuality.

No system of aviation will ever be satisfactory, however, until backed up by a more thorough solution than we now have of the equations of motion of the "perfect aeroplane." Perfect fluids, perfect conductors and dielectrics, perfectly smooth bodies, perfect gases, and so on, are very familiar terms, but the "perfect aeroplane" has not yet figured in literature as such, though various formal representations have been proposed for it from the time of Lanchester's phugoid system down to the systems of Brodetsky and the present writer. These last systems reduce the study of the perfect aeroplane to the solution of a system of assumed and stated equations, in fact a problem in pure mathematics only.

If the conditions necessary for steady motion (under forces in equilibrium) and inherent stability are satisfied, an aeroplane will tend to assume a state of steady motion provided that the initial conditions represent a sufficiently small displacement from the steady state. But under widely different initial conditions it may tend to assume an altogether different motion, and, for example, it may sooner or later lose headway or crash to the ground, pitching over and over. We are thus led to considerations of *superstability*, an inherently *superstable* aeroplane being defined as one which, like a non-capsizing lifeboat, will tend to assume a state of steady motion whatever be the initial conditions of projection; failing that, to investigate the limits of superstability; in other words, the limiting initial conditions under which the machine tends towards instead of away from steady motion. It is clear that such an investigation will involve the search for periodic solutions of the equations of motion which, though difficult, should not be harder than many problems on which pure mathematicians have set their faces. In condition with lateral displacements a spiral gliding motion would represent one limit of superstability, but there are probably others which may or may not occur in practical applications. At present Dr. Brodetsky appears to be the only applied mathematician who has really made substantial advances tending in this direction.

It seems rather probable that further developments will involve the solution of integral equations.

Possible future applications to the location of aircraft are suggested by a paper by Dr. A. B. Wood and Capt. H. E. Brown on "A Radio-acoustic Method of locating Positions at Sea," read before the Physical Society on March 9, and the discussion thereon, in which Capt. Fowler, Major Tucker, and others took part. In this method a wireless signal is made at the same instant that a charge is fired into the sea, and the times of arrival of both signals are recorded at land stations, thus determining the distance of the ships from them. The method is obviously applicable to the sound ranging of aircraft in commercial aviation, but, as Mr. Smith remarked in the discussion, the captain of a vessel would certainly need to make the observations himself, and, up to the present, experiments on detection of acoustic signals, and especially echoes of sound signals, by means of apparatus carried on aircraft, have not been so successful as could have been wished. It is to be hoped, however, that experimental work on this subject will be continued, as the means hitherto at our disposal for location of aircraft leave much to be desired, especially if cross-country flights are to be effected at any considerable distances from the main air routes.

The possibilities of employing helium in airships are discussed by Capt. G. Arthur Crocco in the *Atti dei Lincei*, xxxii. (1) 2, 3. It is estimated that from the natural gas wells in the United States a supply of three million cubic metres per annum is obtainable, and taking twenty years as the life of a well, the cost works out at two dollars per cubic metre. This supply would not be sufficient to replenish the consumption of more than one airship in active continuous service on long-distance traffic under existing conditions, and Crocco considers in detail the different causes of loss and the means of reducing them within practicable limits. The author separates the consumption of gas into three categories, which he describes as "consumption of navigation," "osmotic diffusion," and "washing of the gas" necessitated by loss of purity, and due to endosmotic entry of air into the envelope accompanying the exosmotic diffusion of the helium. The annual losses of gas due to these three causes are in the ratio of 100, 10, 1, and it is estimated that if the first could be eliminated the annual loss of gas by an airship could be reduced to 20 per cent. of the total volume, and that a large fleet of commercial airships could be maintained in continuous working at a reasonable cost.

The "consumption of navigation" represents the amount of gas let out to compensate for the loss of weight of the fuel, and, as pointed out, this assumes serious dimensions in long-distance journeys where excessive buoyancy cannot be overcome by lowering the elevators. The necessity for this discharge of gas can be obviated in two ways, namely, by condensing the water in the products of combustion and by "thermic sustentation," and in his second paper Crocco examines the former method. It is estimated that 1000 grams of fuel contain 150 grams of hydrogen, which, combining with the oxygen of the air, give 1350 grams of water, so that by condensing this the gain of oxygen can be made to compensate for losses in other directions. The necessary superpressure to effect this condensation can be secured by means either of causing a back pressure in the motor or by separate compression. The paper contains formulæ and calculations of the amount of the superpressure required to effect the necessary condensation, and this of course is a function of the degree of saturation of the atmosphere. It is found that this only reaches a serious amount in the case of very hot and dry weather, such as in average climates only occurs on a few days in the year. Remembering that only 1000 grams out of 1350 have to be condensed, the author finds that the loss of power required for the purpose is not sufficient to interfere with the practical application of the method when the effects occurring exceptionally are reduced to annual percentages.

In a paper communicated through Prof. Levi Civita to the *Atti dei Lincei*, xxxi. (2) 1-2, Dr. E. Pistolesi employs moving axes to formulate the differential equations of motion of a fluid in the field of velocity produced by a screw propeller. In this way the problem is reduced to one of steady motion. The method is closely similar to one adopted many years ago in connexion with problems on the small oscillations of gravitating rotating fluids, with the difference that in applications of approximate methods the velocity components relative to the airscrew will not be small, but in certain cases it may be possible to regard as small the components relative to fixed axes set up by the motion of the screw.

Another hydrodynamical line of investigation which has recently come into prominence in connexion with the effects of skin friction on the resistances of aircraft is the theory of viscosity. This forms the subject of two papers in the *Atti dei Lincei*, xxxii. (1) 1, 2, by Dr. Umberto Cisotti, also communicated by Prof. Levi Civita, the first dealing with motion in canals and the second with damped waves.

The object of the present article has been to direct attention to papers published elsewhere than in the technical journals and periodicals, such as those of the Royal Aeronautical Society, the Aeronautical Research Committee, or the Institution of Aeronautical Engineers, all of which are replete with results of other important and valuable investigations.

Obituary.

Canon W. W. Fowler.

Canon William Weekes Fowler, Vicar of Earley, Reading, died on Sunday, June 3, at seventy-four years of age. He was suddenly taken ill in the vestry before the service, and died soon after service began. Having always been a man of untiring energy, we feel sure that he would have preferred to die in harness rather than to have endured any long illness.

Canon Fowler was the son of the Rev. Hugh Fowler, Vicar of Barnwood, Glos, and was born in January 1849. He was educated at Rugby, where he gained a scholarship for Jesus College, Oxford. He took a first in Classical Moderations, and a third in Lit. Hum.: he was ordained, and became a house master at Repton in 1873. In 1880 he was elected head-master of Lincoln School, where he remained for more than twenty years. Bishop King appointed him Canon of Welton Brinkhall in Lincoln Cathedral. He was Rector of Rotherfield Peppard, Oxon, in 1901–1904. In 1905 he became Vicar of Earley, in the gift of the Vicar of Sonning. In 1907 he was president of the Head-masters' Association, and for many years was an energetic member of the Reading Guardians.

Canon Fowler was best known in scientific circles as an entomologist, being a sub-editor of the *Entomologists' Monthly Magazine* from 1885 until the day of his death. He was secretary of the Entomological Society of London in 1886–1896, president in 1901 and 1902, and vice-president in 1903. He was a member of the Science Committee of the Royal Horticultural Society, and in 1906–1907 was a vice-president of the Linnean Society.

Besides writing numerous notes and articles on Coleoptera, Heteroptera, etc., in the scientific magazines, Canon Fowler's chief works were the volumes on Coleoptera for the "Fauna of British India," including the General Introduction, the Cicindelidæ and Paussidæ, published in 1912; the volumes on Hemiptera-Homoptera, with W. L. Distant, in the "Biologia Centrali-Americana," published in 1887–1909; a "Catalogue of British Coleoptera," with Dr. Sharp in 1893, and with Rev. A. Matthews in 1883; the "Coleoptera of the British Isles" in five volumes, published in 1887–1891, and a sixth supplementary volume, with Mr. H. St. J. K. Donisthorpe, published in 1913. He also published a number of text-books on the classics, etc., for use in schools.

Canon Fowler was a very broad-minded man, generous and unselfish, and was much beloved by all who knew him. He was always ready to help younger men with advice and entomological specimens, etc., and his death leaves a blank in the ranks of the older entomologists which will not easily be filled.

Horace Donisthorpe.

Dr. Hans Goldschmidt.

The inventor of the Goldschmidt thermite process, Dr. Hans Goldschmidt, died after a short illness on May 21, in Baden-Baden.

Hans Goldschmidt was born on January 18, 1861, in Berlin, where his father, in 1847, founded the chemical works of Th. Goldschmidt, of which he was the director until his death in 1873. Hans Goldschmidt studied chemistry at Leipzig, Berlin, Strasbourg and Heidelberg, where he graduated in 1886 under Robert Bunsen. After this he continued his studies in electro-chemistry and travelled in foreign countries; this widened his views on economic questions. In the year 1888 he entered, as a partner, the works of his father, in which his brother, Karl Goldschmidt, had taken the lead since 1882.

Goldschmidt's first technical achievement was the invention of an electro-chemical process for recovering the tin from white iron waste, which has found wide application in many countries. His name became famous in the year 1894, when he succeeded in reducing oxides by combustion with powdered aluminium, and by the tremendous heat of this reaction, metals of a high melting-point, such as chromium, vanadium, molybdenum, tungsten, and their alloys with iron and other metals, melt and can be produced in a pure state. As a by-product, corundum is formed, which can be technically utilised for grinding purposes. The thermite process found an even larger application by the use of mixtures of aluminium metal with iron oxide for welding together the ends of rails of tramways and for repairing broken machinery, especially of ships. Hans Goldschmidt also discovered a process for avoiding the formation of holes in iron castings and for improving steel castings by the addition of aluminium.

Hans Goldschmidt was one of the founders of the Bunsen Society for Applied Physical Chemistry, and was for many years its president. He was awarded the Elliot-Cresson-medal of the Franklin Institute. His high scientific standing and good nature will ensure for him a place in the history of technical chemistry and in the memories of his numerous friends both in and out of Germany.

We regret to announce the following deaths:

Prof. Heinrich Boruttau, a director of the Friedrichshain Hospital, Berlin, whose work was especially concerned with the relations of physics to medicine. He also worked on physiological chemistry and problems of nutrition. He died on May 15, aged fifty-four.

Dr. W. d'E. Emery, formerly director of laboratories and lecturer on pathology and bacteriology to King's College Hospital, on June 19.

Mr. E. J. Steegmann, for many years secretary to the Royal Commission on Human and Bovine Tuberculosis, on June 8, aged fifty-five.

Current Topics and Events.

The approaching twenty-fifth anniversary of Sir Ronald Ross's epoch-making discovery of the mosquito transmission of malaria is made the subject of a powerful letter in the *Times* advocating the establishment of a Ross Institute in London, to be called the Ross Clinique for Tropical Diseases. The letter is signed by the Marquess of Lansdowne and Lord Hardinge, ex-Viceroys of India, by a number of business men connected with the Tropics, and by presidents and directors of scientific societies at home and abroad. Among the latter are included the directors of the Pasteur Institutes of Paris and Brussels, of the Gorgas Institute in Panama, and of the School of Hygiene, Johns Hopkins University, the president of the International Health Commission of the Danube, and the Director-General of the United States Public Health Service. The object of founding a Ross Institute is twofold. On one hand, it is in honour of an Englishman to whom the whole civilised world and the British Empire in particular owe a debt of gratitude, and it is intended to be a public recognition of his services while he is still among us, and a lasting memorial to him after his death. On the other hand, it is to enable Ross, a man of genius, assisted by other experts in medical science, to exercise his special gifts in the initiation and continuation of researches into the still unsolved problems of tropical medicine and hygiene. It is to be clearly understood that the Ross Clinique is intended to supplement and not compete with the existing schools of tropical medicine. Its aim is research alone, for which there is plenty of room in the great capital of the British Empire.

In its issue for June 19 the *Times* reported the great outbreak of lava on the north-eastern flank of Etna, which occurred on the early morning of Saturday, June 16, and was already causing widespread devastation. Further details, with a map, have appeared in later issues of the *Times*, together with a report by Prof. Ponte, who has ascended the slope as far as possible. As in so many previously recorded eruptions on the slopes of Etna, the lava has broken out from several mouths arranged along a fissure, which in this case is near the crater of 1879. At the time at which this note is written, it is early to speculate as to the extent to which the flow may spread, and the experiences of Catania on the southern side, often repeated in historic times, indicate the magnitude and the vitality of the great reservoir that has played so important a part in the physiography of Pleistocene times. Charles Lyell, from 1830 onwards, roused an interest in Etna as one of the most appealing examples of earth-structures reared by forces now in action. A detailed map, on which dates are inserted, such as that published by O. Silvestri in his "Viaggio all' Etna" in 1879, shows how, layer by layer, the vast composite mass continues to be built up and maintained. The neighbourhood has now been evacuated, and the scenes of flight depicted in d'Annunzio's amazing film "Cabiria" are repeated in the tragedy of to-day. Activity is also reported in the small cones that are growing within the crater of explosion formed in Vesuvius in 1906.

The memorial portrait of Alfred Russel Wallace was unveiled at the Natural History Museum and presented to the Trustees on June 23. Wallace was born in 1823 and died in 1913, so that the presentation has appropriately taken place in the centenary year of his birth. Shortly after his death a committee was formed to collect funds for the memorial, which was to take two forms, a tablet in Westminster Abbey and a portrait in the Natural History Museum. The first was completed and placed in position in 1914, but the latter was deferred owing to the War and was only recently finished. Sir James Marchant, in offering the portrait to the Trustees, gave a short account of the formation of the memorial committee, and concluded by asking Sir Charles S. Sherrington, President of the Royal Society, to unveil it. In his address the latter alluded to the fact that much of the fruit of Wallace's expedition in the Malay Archipelago is incorporated in the Museum collections, and dwelt upon the happy circumstance of the juxtaposition of Wallace's portrait and of Darwin's statue, two men whose discoveries at the same moment and on the same theme were placed before the scientific world. Prof. E. B. Poulton, a co-worker of Wallace, spoke of his life and work, and testified to the generosity of his character and to the unselfish enthusiasm with which he encouraged and assisted the work of others. The portrait was accepted on behalf of the Trustees by the Archbishop of Canterbury, who undertook that it should receive the care that the Museum accorded to its treasures. He remarked upon the interest which students felt at seeing what manner of men they were who had made such great advances in natural science. The portrait, which is an extremely good likeness, was painted by Mr. J. W. Beaufort from photographs.

A writer under the most appropriate pen-name of Æolus has recently contributed to the *Wimbledon Borough News* two lengthy letters of protest against the by-pass road that is planned to run alongside the ground recently added to Wimbledon Common on the further side of Beverley Brook. While we sympathise with his love of a Nature unspoiled by the dust, noise, and smell of motor cars, we cannot forget that this road is only part of a scheme settled years before the War, and already modified in this area to meet the views of those who obtained the extension of the Common. A further scheme, already mooted by the John Evelyn Club for Wimbledon, which might well receive support, is to fence off part of this tract as a Nature reservation. Wimbledon is singularly rich in birds, and it is even possible that some of our wild mammals may yet linger in the district. If the Common Conservators could see their way to provide a sanctuary for them they would earn the thanks of all lovers of Nature.

Captain R. Amundsen has abandoned his projected flight from Alaska across the Pole to Spitsbergen. The *Times* reports that an official communication to this effect has been issued by the Admiral commanding the Norwegian fleet. The statement is made that a trial flight on May 11 proved very unsatisfactory. In full expectation of the flight being attempted in the third week in June, the Norwegian Government had sent the *Farm* to Spitsbergen with supplies, and the transport *Flint*, carrying three seaplanes, arrived at King's Bay in the middle of June. The seaplanes were to patrol the edge of the polar pack to the north and north-west of Spitsbergen in order to render assistance to Captain Amundsen and his pilot, Lieut. O. Omdal, in the case of any enforced descent. It was proposed, if the distribution of the pack rendered it advisable, to deposit supplies of petrol and food on the ice, each marked with a conspicuous beacon.

"National Baby Week," which is to be observed on July 1-7 under the auspices of the National Baby Week Council, 117 Piccadilly, W.1, brings into prominence the many problems of infant mortality. These problems have two phases which seem dependent upon biological conditions: (1) the comparatively high death-rate in the first month of life, and (2) the comparatively high death-rate of male infants as compared with female infants. In the year 1921, the most recent for which detailed figures are available, there were 1051 male births for every 1000 female births, while the deaths of male infants occurred at the rate of 92·85 per 1000 births and female infants at 72·16 per 1000. During the first four weeks of life, the "neo-natal" period, the death-rate was 40·01 for males and 30·27 for females per 1000 births. These ratios stand with little variation year by year, though during and after the War the ratio of male to female births —as was expected on an empirical basis from historical records alone—was slightly higher than the normal (104 males to 100 females). It would seem that this greater susceptibility to the strains of environment is characteristic of the male sex. The neo-natal death-rate, which has yielded but little to those influences which have proved so effectual in lowering the infant mortality rate as a whole (from 154 per 1000 births in 1900 to 77 in 1922), constitutes another difficult problem in public health. An interesting recent investigation (by post-mortems) into the causes of death in sixty-two cases of neo-natal mortality showed that while 73 per cent. were due to conceivably preventable conditions, the remaining 27 per cent. were due to malformations—a finding which might seem to indicate that neo-natal mortality may be but the expression in human life of Nature's trial and error—a biological interpretation which would, however, tend to discourage infant welfare discussions on this subject in the forthcoming "National Baby Week."

In the current number of the *Poetry Review*, Mr. Oliver C. de C. Ellis has a lively and cheering article attacking the fallacy that there is any opposition between poetry and science. He might very well have gone further than he has. It would be truer to say that the highest gifts in poetry are closely akin to, or even identical with, those required for the highest achievements in science. Some of the greatest poets, Dante, for example, have been masters of the science of their time, and Wordsworth, in a famous passage in the preface to his second edition of the "Lyrical Ballads," looks forward to a time when modern science, having entered into the mental equipment of all cultivated men, will inspire a new order of poetry, as philosophy and rural lore inspired Lucretius and Virgil and medieval science inspired Dante. Both orders of mental effort depend, as Mr. Ellis says, upon the imagination, but whereas the man of science imagines laws and relations of things which may be verified and used for guidance as to their own future action, the poet sees them in their relation to the human soul. In this sense the work of the man of science is objective and stands on the order of events; the work of the poet is subjective or moral, and depends for its appreciation upon a state of mind attuned to his own. "Poetry," as Wordsworth tells us, "is the wealth and fine spirit of all knowledge"; "it is the impassioned expression which is in the countenance of all science." And, one must add, that whereas science aims at pure truth, poetry, having this emotional content, aims also at giving pleasure. It implies a certain form and a certain emotional effect, though the substance must also be truth. It is the "first and last of all knowledge."

The British Mycological Society is organising a phytopathological excursion to Wye, in Kent, on Saturday, July 7. Those intending to take part in the excursion should communicate with Capt. J. Ramsbottom, at the British Museum (Natural History), South Kensington, S.W.7, by Wednesday, July 4.

According to the *Chemiker Zeitung* for June, Dr. Paul Knoller, lecturer and assistant at the University of Freiburg (Switzerland), has been appointed professor of mineralogy and petrography at Dayton University, Ohio.

Owing to the increase in the work of the Rothamsted Experimental Station, it has been decided to appoint an assistant director, and Dr. B. A. Keen, head of the Physics Department, has been selected for this position.

A circular tablet of blue glazed ware bearing the inscription "James Clerk Maxwell (1831–1879), Physicist, lived here," has been affixed to 16 Palace Gardens Terrace, Kensington, where Clerk Maxwell resided for a time, by the London County Council. Maxwell's occupation of the house probably dated from the latter part of 1860, immediately after his appointment to King's College, or the early part of 1861. The first reference to it in his biography by Campbell and Garnett is in a letter dated May 21, 1861. He resigned his appointment as from Easter, 1865, and left the house for good in March 1866 (*ibid.* p. 260).

AT a meeting of the Royal Society of New South Wales on May 2, the following officers for 1923-24 were elected:—*President*: Mr. R. H. Cambage. *Vice-Presidents*: Prof. C. E. Fawsitt, Mr. J. Nangle, Mr. E. C. Andrews, and Mr. C. A. Sussmilch. *Hon. Treasurer*: Prof. H. G. Chapman. *Hon. Secretaries*: Prof. O. U. Vonwiller and Mr. G. A. Waterhouse. *Members of Council*: Dr. C. Anderson, Sir Edgeworth David, Mr. W. S. Dun, Dr. R. Greig-Smith, Mr. Charles Hedley, Rev. E. F. Pigot, Mr. W. Poole, Mr. H. G. Smith, Prof. J. Douglas Stewart, and Prof. R. D. Watt.

THE David Livingstone Centenary Medal for 1923 has been awarded to Dr. T. Griffith Taylor, associate professor of geography in the University of Sydney, Australia. This medal, founded by the Hispanic Society of America and awarded by the American Geographical Society, is given "for scientific achievement in the field of geography of the southern hemisphere." Dr. Taylor has made notable contributions to Australian geography, applying the results of his physiographic and climatic studies to problems of settlement and human adaptation. He is the author of several works on Australia and of numerous communications appearing in Australian Government bulletins, and was senior geologist and leader of the western parties on the British Antarctic Expedition of 1910–1913 (Scott's last expedition), on which he has written "With Scott: The Silver Lining" (1915). It is anticipated that the medal will be presented on the occasion of the Second Pan-Pacific Science Congress, which meets in August and September in Australia.

ON June 10 two departments were opened for the public and visitors in the new premises of the Geological Museum of the Petrograd Academy of Science. One of the departments is devoted to the general osteological collection and contains among its exhibits remains of Indricotherium, a giant primitive rhinoceros-like mammal, from the Turgai Oligocene deposits (Indricotherium beds), north of the Aral Sea, recently described by Prof. A. Borissiak (Mém. Acad. Petrograd (viii.) xxxv. No). The other department, the so-called North-Dvina gallery, is devoted exclusively to the Upper Permian fauna, discovered by Prof. Amalitzky, and contains his types, some of them partly re-developed and re-described by the present curator of the gallery, Prof. P. Sushkin (*Comptes rendus* of the Petrograd Academy for 1921 and 1922).

ONE of the main functions of the Fuel Research Board is a survey and classification of the coal seams in the various mining districts by means of chemical and physical tests in the laboratory, supplemented where desirable by large-scale tests at H.M. Fuel Research Station, East Greenwich, or elsewhere. It is considered that the best way to carry out this work is by means of local committees, the personnel of which would include colliery owners, managers, representatives of the Fuel Research Board and of the Geological Survey of Great Britain, as well as of outside scientific interests. In this way local knowledge and experience is made available. The first of these committees has now been actively at work in the Lancashire and Cheshire area for nearly eighteen months, and the Board has recently decided to deal with the South Yorkshire area. The South Yorkshire Coal Trade Association and the Midland Institute of Mining, Civil, and Mechanical Engineers are co-operating in the work. The following committee has been appointed: Dr. C. H. Lander (chairman, *pro tem.*), Mr. J. Brass, Mr. Robert Clive (hon. secretary), Mr. H. Danby, Lieut.-Col. H. Rhodes, Prof. R. V. Wheeler, and Dr. Walcot Gibson.

THE annual general meeting of the Research Defence Society, on June 20, when Lord Knutsford presided, was well attended, and the necessary business was quickly done. Dr. Saleeby lectured on "Sunlight and Disease"; and showed lantern-pictures and films illustrating the past and present use of "the sun-cure": especially the amazing results which Rollier has obtained at Leysin; the downright cure, by light alone, of many fearful cases of tuberculosis. If the photographs and the films had not been there, the whole thing would have been incredible. The sun, that careful doctor, had faithfully recorded the work which he had achieved. Dr. Saleeby also spoke of the experimental research which is being pursued into the action of light on life: the relation of light to the storage of phosphorus, calcium, and vitamin A in the body, and so on: but we are still a long way from understanding these mysteries. In Great Britain, a measure of success has been gained at Sir William Treloar's Hospitals at Alton and Hayling Island, and at Queen Mary's Hospital, Carshalton. But what is the good of talking of "sun-cure" in this country, in this weather? It was a sunless day, near the end of a sunless May and June. Besides, in our great industrial cities we poison the air with smoke. Dr. Saleeby's pictures of Manchester and Sheffield were Ruskin's prophecies come true. Prof. Dreyer is working for a better tuberculin-treatment. Mr. Justice McCardie has spoken his mind on the contagiosity of a dusty house in which a consumptive patient had lived. People are learning more about tuberculosis. But, until we get finer summers, use smokeless coal, and abolish slums and overcrowding, we must not expect to repeat the wonders of Leysin in Great Britain.

ON April 6 Mr. G. R. Clarke, the Director-General of Posts and Telegraphs for India, read a paper to the Royal Society of Arts on postal and telegraph work in India. He pointed out that the present problem is not the erection of more wires to carry the increased traffic, but to increase the capacity of the existing wires by the use of multiplex high-speed instruments. Automatic telephone exchanges have proved a great success at Simla and Lahore, and many similar installations are in course of erection. Radio communication has not proved successful in India owing to the "atmospherics" making signalling impossible at certain seasons.

The research department, however, has perfected methods of eliminating the disturbances due to this cause, and so it is hoped that the radio method will be much more widely adopted in the future. During the last year postal and telegraph communication has been established with Tibet and Afghanistan. The Dalai Lama has given every encouragement to the establishment of communication between Lhasa and India. Afghanistan has not yet joined the Universal Postal Union; letters are stamped to India, and a charge is made on delivery, but the amount of this charge seems to be uncertain. In the discussion on the paper Colonel Edwards said that India offered the most wonderful possibilities in the way of air mail transport. For example, the journey from Calcutta to Rangoon took at present 3-6 days. If an air mail service were employed the time taken would be only 9 hours. Many similar cases could be cited. In England difficulties are caused by fog, but in India the only fogs are the few that occur during the monsoon.

WE have received from the Department of Agriculture and Technical Instruction for Ireland a copy of the catalogue of maps, memoirs, and sections published by the Geological Survey of Ireland. The list includes maps, etc., for the whole of Ireland: they are now to be obtained from the Ordnance Survey Office, Dublin. The one-inch map for the whole country is available in 205 sheets. Of the 16 sheets of the quarter-inch map only four appear to be published. There is a recent six-inch map of Dublin and surroundings. These maps are colour printed.

Our Astronomical Column.

VARIATIONS IN THE SPECTRUM OF θ^2 ORIONIS.—M. F. Henroteau directs attention (*Comptes rendus*, April 30, p. 1210) to the spectrum of the star θ^2 Orionis, which is of magnitude 5·17 and situated in the nebula of Orion (R.A. $5^h\ 30^m{\cdot}5$, Dec. $-5°\ 29'$, 1900), being of the B-type spectrum. In 1904 Prof. E. B. Frost discovered the star to be a spectroscopic double with a radial velocity of 140 km. In 1919 and 1920 M. Henroteau found that in addition to the broad absorption lines of hydrogen and other elements, there were super-imposed on them thin bright lines which gave a velocity less than that accorded by Frost. To verify this, Otto Struve of the Yerkes Observatory obtained several spectrograms in 1922, but these showed no evidence of bright lines. However, another spectrogram on March 2 of the present year displays these sharp bright lines. Thus we have a B-type star, not known as a variable, which intermittently presents bright lines, a phenomenon very rare in occurrence. What adds great interest to this particular star is that it is situated in the nebulosity of Orion, and this situation may account for the peculiarity. M. Henroteau proposes to make a special study of its spectrum.

COLOURS AND SPECTRA OF DOUBLE STARS.—Till recently the course of a star's evolution was considered to be defined by the sequence represented by types O B A F G K M, and the fact that the fainter components of binaries are often bluer than the brighter components was a source of much perplexity. One of the results of the "Giant and Dwarf" hypothesis was to afford a simple explanation of the observed facts, since among giants the blue stage is later than the red; and, conversely, the observed phenomena afford another strong argument for that hypothesis. Mr. Peter Doig has traced the bearing of these facts in two papers during the past year; now Mr. F. C. Leonard returns to it in Lick Obs. Bull. No. 343. He has photographed the spectra of a number of close pairs with a one-prism spectrograph on the 36-inch refractor, finding it possible to get separate spectra even with pairs only 1″ apart; where the magnitudes differed the brighter star was occulted by a screen for part of the exposure. In order to classify the spectra he also took spectrograms of several typical stars with the same instrument, since he notes that slit spectrograms differ systematically from the objective-prism series used at Harvard.

The resulting spectral differences of the components of the binaries were then correlated with absolute magnitudes, and with differences of magnitude and mass, the facts being displayed in a series of diagrams; he classifies stars not fainter than 1.0 mag. (absolute) as giants, the remainder as dwarfs; it is clearly shown that among giants the primary is redder, among dwarfs bluer. Once this law has been established it enables us to make estimates of the absolute magnitudes of stars of undetermined parallax. Further, the difference of spectral type increases as a rule with increasing difference of absolute magnitude or of mass, and there is hope that, by tabulating these differences in as many cases as possible, a clue will be obtained as to the relative duration of the stages of development corresponding to the various spectral types; such information would be of much use in cosmogony. The research also affords a proof that the less massive stars pass through their stages more rapidly than the massive ones; this was indeed generally assumed, but it has been questioned.

The cases of Sirius and o^2 Eridani are noted as anomalous, the discordance in magnitude being much greater than we should expect from the disparity in mass; Mr. Leonard suggests that in the latter case the mass-ratio should be reinvestigated; that of Sirius cannot be much in error.

THE RADIAL VELOCITIES OF 1013 STARS.—Messrs. W. S. Adams and A. H. Jay contribute to the April number (vol. 57, No. 3) of the *Astrophysical Journal* a catalogue of radial velocities which includes many of the results obtained in this line of work at the Mount Wilson Observatory during the past few years. The list is composed almost wholly of stars with spectra of types F, G, K, and M which have been observed not only for radial velocity but also for determinations of absolute magnitude and spectroscopic parallax. The spectrograms have been obtained at the Cassegrain focus of the 60-inch and the 100-inch reflectors, and the latter instrument was employed chiefly for stars fainter than the eighth visual magnitude. Single prism spectrographs with prisms of 64° angle and cameras of 18-inch focal length were used. The faintest star photographed was of magnitude 9·9, and 10 to 15 stellar lines have been measured on each spectrogram, and a list of those most commonly employed is given in the paper. The results here collected have already been used to some extent by Strömberg, Seares, and the authors in investigations of space velocities and the relationship of velocity to absolute magnitude and mass, but their publication makes them now available to all.

Research Items.

Function of the Spleen.—More than ten years ago Richet showed that dogs from which the spleen had been removed had to eat more than normal animals to keep their weight constant. In the *Comptes rendus* of the Paris Academy of Sciences of April 16 he states that spleenless animals when starved lose weight more quickly than the controls, and concludes that the organ diminishes denutrition; its normal function, useful but not necessary to the economy, being to slow down metabolism. These observations may possibly be correlated with those of Korenchevsky (*Journ. Path. Bact.* vol. xxvi., 1923, p. 387), who describes hypertrophy and hyperplasia of the germ centres in the spleen in pigeons with beri-beri caused by an inadequate diet of polished rice—perhaps an attempt to compensate for the severe failure of nutrition.

Palæocene Primates of the United States.—More than ten years ago a considerable collection was made in the Sweet Grass County, Montana, of fossils from the Fort Union Palæocene. The intervening time has been devoted to the cleaning and preparation of these, among which the mammalian remains appear to represent at least forty species belonging to not less than fifteen families and six or seven orders. The descriptions of these will be undertaken, order by order, and ultimately combined into a single monograph. The Primates form the subject of a memoir by J. W. Gidley (Proc. U.S. Nat. Mus., vol. lxiii. art. 1). Until now true Primates have not been reported in America from beds older than the Eocene, and these indicated that earlier forms must have existed, so that it is not surprising, although of the greatest interest, that they do occur in the Fort Union Palæocene, and that all thence are in general of a more primitive type. These early Primates belong to two families: Tarsiidæ, represented by four genera, of which three—Paromomys, Palæchthon, and Elphidotarsius—are new; and Plesiadapidæ, with one new genus—Pronothodectes. No representative of the Notharctidæ appears in the Fort Union collection. The author discusses the affinities and relationships of these various forms. He concludes that the early tarsiids as at present understood do not represent a natural group. It would seem, however, that within this group are to be found the ancestral stock which gave rise to the living Tarsiers; and possibly also the ancestral form whence ultimately sprang the aberrant lemur—Daubentonia—of Madagascar. The root group, or beginning of the Primates as a distinct order, has still to be sought in yet older formations.

Eocene Pelecypoda of Burma.—The fauna of the Eocene of Burma is especially rich in Gastropoda, but contains a lesser proportion of Pelecypoda. The former were placed in the hands of the late Mr. Vredenburg for description, while Dr. G. de P. Cotter has dealt with the latter (*Pal. Ind.*, New Series, vol. vii., mem. 2). Twenty-five species are described and figured, of which nearly all are considered to be new. They indicate that the Yaw stage, to which the bulk belong, is to be correlated with the Upper Eocene of Java and the Bartonian of Borneo. The accompanying plates are remarkably good.

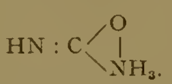
Soil Bacteria and Organic Antiseptics.—In an article in *Discovery* for June, Mr. P. H. Gray discusses the utilisation of organic antiseptics by bacteria of the soil. Phenol, cresol, toluene, and naphthalene applied to the soil disappear. This disappearance is due to the existence of bacteria in the soil which attack and destroy these compounds. Some 200 strains of antiseptic-decomposing bacteria have been obtained from over a wide area in Great Britain; they are able to grow in solutions containing the antiseptics and even to utilise these compounds as a source of energy. It is possible to increase the fertility of the soil by the addition thereto of a mild antiseptic. This destroys certain soil pests and disturbs the equilibrium between protozoa and bacteria in the soil, enabling the latter to increase, and the bacteria produce available plant food with an increase in fertility.

The Marine Element in the Fauna of the Ganges.—Dr. N. Annandale (reprint from Bijdragen tot de Dierkunde, K. Zool. Genootschap, Amsterdam, 1922, pp. 143-154) discusses the marine element in the fauna of the Ganges. He regards the Bay of Bengal, with its low salinity and gradual changes from salt water to fresh, as an exceptionally favourable starting-point for an immigration into fresh water on the part of marine organisms. An immigration of the kind has been in progress for a long period, and many adaptable euryhaline species are still attempting to establish themselves above the limits of tidal influence in fresh water. A very slight change either in the environment or in the constitution of the animals themselves would enable them to do so. The relict and euryhaline faunas of the Ganges represent different stages in this process of inland immigration, which has proved successful owing to the vigorous constitution of those organisms that have missed no accidental opportunity of establishing themselves in fresh water. In spite of superficial changes, a large proportion of both the relict and the euryhaline forms are of essentially primitive structure, or at any rate belong to ancient groups some of which have almost or completely disappeared from adjacent seas. In other words, fresh and brackish water have proved a last refuge for many marine species whose race in the sea was nearly done.

The Non-Mendelian Inheritance of Size Characters in Flower Petals.—Prof. R. R. Gates describes, in the *Journal of Genetics*, vol. 13, No. 1, March, the inheritance of petal size through four generations of reciprocal crosses between *Œnothera rubicalyx* and *Œ. biennis*. A more or less uniform F_1 generation is followed by wide segregation in F_2, not only between the size of petals in different plants, but even on the same plant and in some cases on the same flower. A close analysis of these flowers does not suggest frequency curves grouped around modes dependent upon different size factors, but rather haphazard distribution of sizes due to the failure of adjustment between different size tendencies inherited from the original cross. Such variation in size does not appear apart from the original cross, so that germinal factors are involved, but their representation is not possible, either in terms of normal Mendelian factors or in terms of the Galtonian curve for fluctuating variability. Prof. Gates suggests that the variable nature of these inherited tendencies, as exhibited within the individual, may arise through their partial dependence upon cytoplasmic characters of the parental forms.

The Oil Palm under Cultivation.—The oil palm, *Elæis guineensis*, occurs naturally in West Africa over an area lying between 12° N. and 12° S. of the equator. The fruit of the palm has an outer pulpy coat which contains some 50 per cent. oil and an inner kernel with about the same percentage of an oil of different composition. Both these oils are of commercial value, and G. G. Auchinleck, in Bulletin No. 62 of the Department of Agriculture, Ceylon, estimates that 300,000 tons of kernels and 100,000 tons of palm oil come on to the market annually. The French, English, and Belgians are in control in the various oil-producing areas of Africa, but the Dutch appear to be first in definitely undertaking the systematic plantation of the oil palm, some 28,000 acres being planted with this plant in Sumatra by 1922. If the somewhat uneven product and irregular supply from the palm's natural habitat can be replaced by a trustworthy product developed from a systematic plantation industry, the African palm-oil trade will meet with a formidable competitor. British planters in the East would probably do well to study Mr. Auchinleck's account of the oil palm and its product in this bulletin, and to watch the future history of the oil palms now planted at the Anuradhapura Experiment Station in Ceylon.

UREASE.—A powerful enzyme, which has the property of causing the rapid conversion of urea into ammonium carbonate, has been found in many plant tissues, especially seeds. That of the soya bean is the best known. Dr. W. R. Fearon, in the *Biochemical Journal* (vol. 17, No. 1, 1923), shows that what urease does is to split urea into cyanic acid and ammonia. He has isolated cyanic acid from solutions of urea under the action of the enzyme. The enzyme has no other action; cyanic acid in the presence of water rapidly undergoes spontaneous hydrolysis into carbon dioxide and ammonia. The facts can only be satisfactorily explained on the cyclic formula for urea put forward by Werner; that is,



The decomposition of urea by acids, alkalies, or heat proceeds along the same lines. We see also why urease does not decompose ethyl-urea or methyl-urea, not because of the nature of the enzyme, but because these substances do not yield cyanic acid.

VALENCY OF BORON.—We have received from the Koninklije Akademie van Wetenschappen te Amsterdam a reprint of an interesting paper on "The Valency of Boron," by Prof. J. Böeseken, from the point of view of atomic structure. He concludes that boron exhibits valencies of 3 and 5.

SEPARATION OF THE ISOTOPES OF MERCURY.—A detailed account of the partial separation of the isotopes of mercury by evaporation in vacuum in a large steel apparatus is given by Harkins and Madorsky in the March issue of the Journal of the American Chemical Society. The atomic weights of the heavy and light fractions differ by 0·1 unit. The partial separation is still a long and somewhat laborious process, but the authors state that they have designed an apparatus which would give the same separation in about thirty hours. The heavy and light fractions are still mixtures of isotopes, six of which, according to Aston, exist in the case of mercury.

WEATHER AT HONGKONG DURING 1922.—The *Monthly Meteorological Bulletin* for December 1922 contains "detailed results of observations made at the Royal Observatory, Hongkong, and the daily weather reports from various stations in the Far East," prepared under the direction of Mr. T. F. Claxton. The part for December also contains an annual summary of the Hongkong observations for the year 1922 and gives the mean and extreme values of the principal meteorological elements, with the normal values for the period 1884–1918. Tracks of the typhoons and principal depressions which occurred in the Far East during the year 1922 are shown on two plates. At Hongkong the barometric pressure during 1922 ranged from 30·445 in. during November to 29·174 in. during August. The air temperature ranged from 93·1° F. in August to 43·7° F. in November. The monthly mean was highest in July and lowest in January, the mean temperature for the two months differing by 22° F. For the thirty-five years the highest temperature observed was 97·0° F. in August 1900, the lowest 32·0° F. in January 1893. The total rainfall in 1922 was 69·44 in., of which 17·54 in. fell in August, and rain fell on 154 days. The average total rainfall for the thirty-five years is 83·83 in., the average total rain in the four months May to August being 55·13 in. The greatest prevalence of wind is from the east. Values of magnetic elements are given for the year; the means were Declination (west) 0° 21′·5, Dip (north) 30° 46′·0, Horizontal Force (C.G.S. Unit) 0·37279, Vertical Force (C.G.S. Unit) 0·22194, Total Force (C.G.S. Unit) 0·43386. No mention is made on the title-page of the Bulletin that the results for the year and the cyclone tracks, as well as the averages for thirty-five years, are given, and a casual reader might overlook this information, which is of primary importance.

EGYPTIAN PETROLEUM.—Heavy-grade Egyptian crude petroleum formed the subject of a paper by Mr. W. A. Guthrie read recently at the Institute of Petroleum Technologists. The oil chiefly discussed was the product of the well-known Hurghada (Rargada) wells, situated about 200 miles S.E. of Suez, on the western shore of the Gulf. This field was first developed in 1914, since when it has produced 1,201,868 metric tons of oil; its present output averages 3500 tons per week. Some proportion of the oil contains salt water up to 30 per cent., an emulsion which, though it has proved refractory to deal with, seems to respond to electrical dehydration treatment, a method not always commercially possible. The dry oil flashes below 45° F., and its s.g. ranges from 0·907 to 0·925. Its sulphur content varies from 0·5 per cent. to 2·22 per cent. (comparatively low), while it yields 10-11 per cent. asphalt and 7-8 per cent paraffin wax: hence it may be classed as a true mixed-base oil. Distilled in the ordinary way, the crude oil gives 8 per cent. benzine and 15 per cent. kerosene, the residue (above 290° C.) constituting 76 per cent. Both the benzine and kerosene can be refined to very high-grade products, while the residue is utilised for the production of solar or Diesel oil (43·2 per cent.), hard pitch (29·3 per cent.), and inferior fuel-oil. The inclusion of an appreciable quantity of paraffin wax in the pitch is considered by the author to be advantageous rather than deleterious to its use for road surfaces, since theoretically it should enhance chemical stability and render the material less liable to crumble or disintegrate under climatic variations or under ordinary wear and tear. The author dealt at some length with paraffin wax extraction, by no means an easy problem in this case, but this product actually finds little use within Egypt itself. One other interesting point mentioned in the paper was in connexion with the oil produced from the new field at Abu Durba, on the east shore of the Gulf; chemical and physical tests apparently show that this oil is an inspissated and oxygenated product of petroleum: it is of a very heavy asphaltic character and contains varying proportions of a waxy resin.

Museum Building at South Kensington.

THE latest chapter in the long history of museum building at South Kensington opened in 1909 when a large deputation of those interested in science and industry presented to the president of the Board of Education a memorial urging that the time had come for action with the view of providing proper housing for the Science Collections at South Kensington. The memorial, and the speakers who supported it personally, focussed the opinions of all the leading scientific and technical societies and institutions. Acting on the representations then made to him, the president of the Board of Education appointed in 1910 a "Departmental Committee on the Science Museum and the Geological Museum," with Sir Hugh Bell as Chairman. Three years later, the adoption of the report of that committee appeared to secure the early provision of adequate facilities for a well-directed advance in the usefulness of these museums.

Building operations were duly commenced, but were interrupted during the war period. Resumed later, they have made so little progress that representatives of the societies which originated the movement in 1909 have recently had occasion to consider the present position and to make a representation with regard to it. As the matter is one of wide interest, the following summary of its salient features may be of interest to those who are not familiar with the published papers that bear upon it.

THE SCIENCE MUSEUM.

For forty years the Science Collections have been developing on consistent lines. For more than twenty years they have been recognised as being, among national collections of the same field, the best museum collections in the world, but as having the meanest of museum buildings. It is now thirteen years since the appointment of Sir Hugh Bell's committee—a strong departmental committee of men versed in pure and applied science. That committee took careful measure of the possibilities and of the needs of the Science Museum, and formulated a well-considered and clear report upon the whole matter (Report, 1911, and Report, Part II., 1912).[1] This report received warm approval at all hands, and it was adopted by the Government as the basis for the development of the Museum. The first requirement to be met was necessarily the erection of adequate and worthy building accommodation.

In its report the committee quoted the exhibition space available in 1911 as 98,000 sq. ft. (94,000 sq. ft. in old buildings and 4000 sq. ft. in the new Western Hall), and said that buildings twice as large would be required for the then existing collections without the addition of a single specimen. The committee estimated at 265,000 sq. ft. the total exhibition space then required in new buildings, and recommended the provision of a building to occupy the ground available on the existing site, as shown on the accompanying plan (Fig. 1), this building to be erected in three successive sections, the eastern, the central, and the western blocks. The committee reported that the central as well as the eastern block would be required for the more immediate needs of the Museum.

In the programme for the replacement of the old buildings by a continuous building occupying the whole of the Science Museum site from Exhibition Road to Queen's Gate, three periods in the process are distinguished. The *first period* covers the erection of the eastern block; this is the present period. In the *second period*, when the new central block will be in process of erection on ground cleared by the demolition of the main part of the existing old buildings, the eastern block of the new building with the existing western galleries and western hall "will afford opportunity for exhibiting the collections made during the first period and for working up the

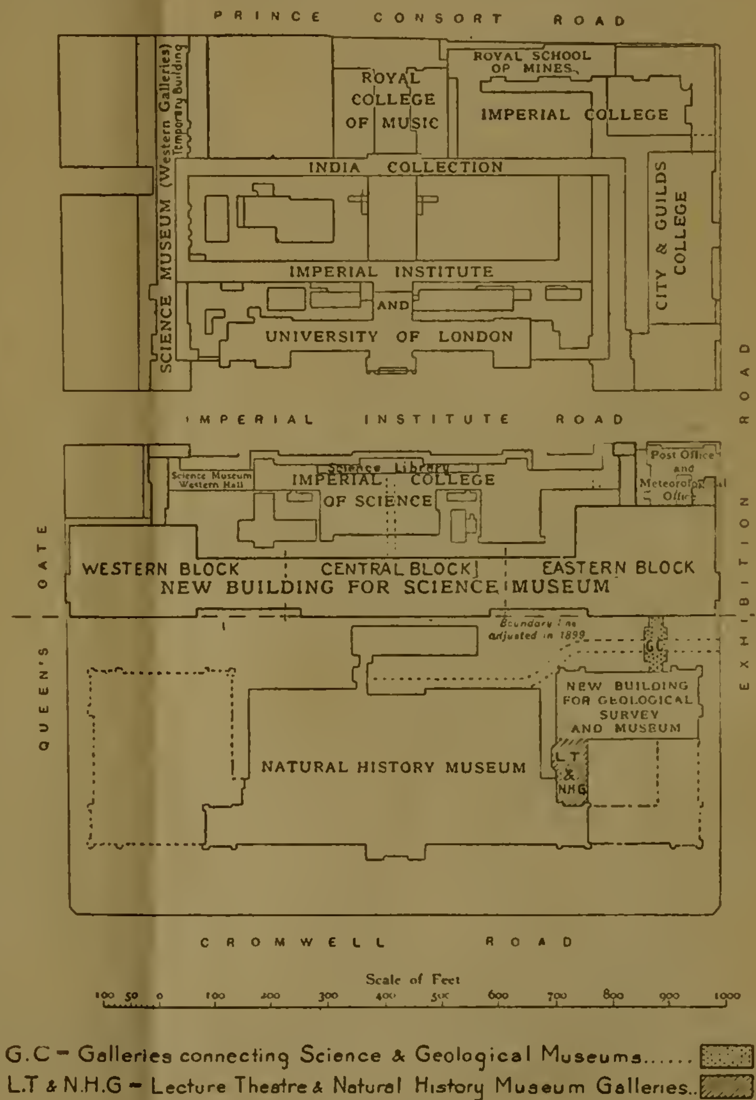


FIG. 1.

[1] Report of the Departmental Committee on the Science Museum and the Geological Museum, 1911, Cd. 5625; (Part II.) 1912, Cd. 6221.

collections in all departments." The close of the second period will see both the eastern and central blocks of the new building fully available for the uses of the Museum and for the development of its collections. The committee contemplated a pause in the building operations at this stage. It said that during the *third period*, which will last till the western block is built, "the new eastern and central blocks with the existing western galleries, will afford a total accommodation that may be expected to suffice for all requirements until there is a clear call for the western block."

The first section of the new building—the eastern block—was commenced in 1913. Then came the War: the shell of the building was put to other uses and continued to be so appropriated for some years after peace was declared. Building operations have now, however, been resumed on part of the block, and this first instalment of the new permanent quarters for the collections is expected to be completed by the end of 1924. It will provide, say, 75,000 sq. ft. of new exhibition space—only one half of the total set-out for the complete eastern block of the "Bell" report. Moreover, it appears to be contemplated that the existing Western Galleries, in which are housed the collections illustrating mathematics, astronomy, physiography, meteorology, physics (part), chemistry, metallurgy and mining, will be vacated about the end of the present year to make room for part of the War Museum collections.

The Western Galleries provide 33,000 sq. ft. of exhibition space, and as a part of the old building which provided 20,000 sq. ft. had to be demolished in 1913 to make way for the new eastern block, the total of the *old* exhibition space available in 1925 will be 53,000 sq. ft. less than that in use in 1911. The *new* space to be added in 1924 by part of the eastern block is 75,000 sq. ft., so that the net increase in 1925 as compared with 1911 will be only 22,000 sq. ft. Meanwhile, quite apart from additions to other sections, accommodation has had to be found for the two important new sections which illustrate respectively aviation and wireless telegraphy and telephony, and these alone already occupy more than 12,000 sq. ft.

For all practical purposes, on the programme as now understood, the Science Museum will be in 1925 no better off in the matter of exhibition space than it was in 1911: that is to say, it will be still so grossly overcrowded that the collections cannot possibly be examined in the way museum objects ought to be. In these circumstances the obvious practical step is to put in hand for completion not, as now, merely one half of the eastern block, but the whole of the block that is not at present in temporary occupation by the Museum. Better still would it be to provide other temporary accommodation for the sections of the collections there exhibited and to proceed with the completion of the whole block.

Indeed, there must be certainty of active and continuous progress with the building scheme as a whole, for not until the central as well as the eastern block is completed will the Science Museum have any appreciable increase of space for its steadily growing collections. Yet it is doubtful if there ever was a time when the progress of science and invention required so much of museum exhibition or when the Museum could do so much to spread intelligent appreciation of the achievements of science and of its applications in industry.

THE MUSEUM OF PRACTICAL GEOLOGY.

The terms of reference to Sir Hugh Bell's committee required the committee to consider and report upon the Geological Museum in Jermyn Street, as well as upon the Science Museum. On each it was to advise as to the purposes the collections should serve, the lines upon which they should be developed, and "as to the special characteristics which should be possessed by the new buildings which it is hoped will shortly be erected on the South Kensington site to house these collections."

As in the case of the Science Museum, so in that of the Geological Museum, the report with its appendices gives clear recommendations on these points. The committee shows the need for a larger building than the Jermyn Street site provides, and urges the advantages of bringing the Geological Museum into due relation with other museums at South Kensington. Yet ground has not been broken for a new Geological Museum building.

Now those passages in the report which deal with the Geological Museum are particularly helpful and hopeful, for it is evident that the committee gave special consideration to points affecting the co-ordination of the several national museums that are concerned with science, and that it saw the way to an effective and economical scheme by which, while each museum would preserve its individuality and its autonomy, its own organisation and responsible authority, all three—the Natural History Museum, the Museum of Practical Geology, and the Science Museum—might be grouped and worked so as to form jointly a complete and worthy national museum of science. The accomplishment of this ideal would be warmly welcomed by all workers in science no less than by students and the public at large.

The committee reported that the Geological Survey Offices and Library and the Museum of Practical Geology were cramped by the limitations of the building in Jermyn Street, and that if the necessary space could be allotted at South Kensington it would be of great advantage to have a building giving the required accommodation erected as part of the general scheme there. The committee pointed out that collections in the Science Museums represent the general principles of geology and geography by examples selected from all parts of the world, while the economic collections in the Museum of Practical Geology in Jermyn Street are arranged with special reference to the needs of the practical man and the technological student, and its stratigraphical collections deal specially with the geology of the British Isles. The committee added that if all these were housed in new buildings at South Kensington in communication with the systematic collection of minerals, and the palæontological collections arranged according to their natural affinities in the British Museum (Natural History), the series would represent at a single centre the whole field of geological science.

The committee further reported that the Trustees of the British Museum were willing that the building for the Museum of Practical Geology and the Offices and Library of the Geological Survey should be placed on the part of the site allotted to the Natural History Museum. The scheme provides that this building be erected in connexion with and as part, structurally, of the eastern extension of the Natural History Museum, when it comes to be built, and that it be brought into direct communication on its north side with the new Science Museum building by connecting galleries carried over the roadway which gives access to the back of the Natural History Museum. (See Fig. 1.)

The sketch plan submitted with the committee's report shows the new building for the Museum of Practical Geology and the Offices and Library of the Survey as a self-contained unit. This unit, however, communicates on the north with the Science Museum and its collections illustrating physical geology, physiography and geography, mining, metallurgy, and construction, while to the south it is in direct connexion with the mineral and palæontological collections of the Natural History Museum. The plan also shows in the related part of the Natural History Museum the position of a lecture room which the authorities of that Museum contemplate for joint use in connexion with their own Museum and with the Museum of Practical Geology.

There is no need to detail the many advantages of this scheme. They are obvious. It should be noted, however, that the limitations of space in the Jermyn Street building are no less harmful now than they were ten years ago. On the other hand, in the case of the geological section of the new buildings at South Kensington, financial considerations should not now present much difficulty, for the value of the Jermyn Street site would go far to balance the cost of providing the larger new building on the site designated for it.

It is worth while to quote here the concluding section of the 1911 Report of Sir Hugh Bell's committee:

"In other departments of knowledge, the British Museum and the Victoria and Albert Museum have set a high standard for the national provision of Museum facilities. In the domain of Science the requirements of most of the branches of Natural History are already admirably provided for at South Kensington in the Natural History Museum. In no way overlapping or duplicating the functions of these great institutions, but representing aspects of human activity which lie outside their scope, not less ample provision is necessary for those departments of knowledge, invention and discovery, the needs of which have been brought so vividly before us in our inquiry; and we are of opinion that no scheme for a national Science Museum can be regarded as satisfactory unless it provides the buildings necessary for affording to Science and the industries all the assistance a Museum can give. A Science Museum in which all branches of Physical Science, Pure and Applied, and the Scientific and Economic work of the Geological Survey shall be adequately illustrated in close proximity to the other great Museums at South Kensington will, we believe, be of incalculable benefit alike to intellectual progress and to industrial development, and will be recognised as an institution of which the country may well be proud."

Antarctic Geophysics.

THE two reports referred to below[1] are the records of the aurora observations and gravity determinations made during Capt. Scott's last south polar expedition, 1910–1913. They are both dated for 1921, but it was only in February of this year that they reached us.

The original plans for auroral observations on Capt. Scott's *Terra Nova* expedition included photographic determinations of the height of auroræ, using Prof. Störmer's method. This part of the programme unfortunately proved impossible to execute, owing to the lack of the necessary special lenses and photographic plates. The auroral spectrum also was not observed, so that the work accomplished consisted of visual observations, namely, sketches, brief descriptions, and times of occurrence of auroræ. These data are now summarised and discussed by Mr. C. S. Wright, himself a member of the scientific party. The sketches and daily log are not reproduced, but the plan of observation and the resulting data are described in general terms, discussed statistically, and finally considered in their theoretical bearing.

Observations were made at two stations, in what may be termed the Scott-Shackleton strip of the Antarctic coast. One was Cape Evans, 77·6° S., 166° E., and the other was Cape Adare, 71·3° S., 170° E. Both stations are thus within a few degrees of the south magnetic pole, but considerably farther from the pole of the earth's magnetic axis, Cape Adare being at the greater distance. The two stations are about 700 kilometres apart, and a horizontal plane through one station would, in consequence of the earth's curvature, pass over the other at a height of about 40 kilometres. Auroræ occur at heights of about 90 kilometres and upwards above the earth's surface, so that from either station, in clear weather, auroræ above, or even a little beyond, the other, would be visible low down on the horizon. The hills and mountains in the neighbourhood of Cape Evans obscure the free horizon in some directions, though the report does not indicate which these are, nor whether Cape Adare is similarly affected. This information, together with more detailed statistics as to the relative frequency of auroræ at different altitudes, would have added to the value of the report.

In many respects the auroral features at the two stations are strikingly dissimilar. Auroræ are far more frequent at Cape Adare than at Cape Evans, and also more distinguished by brilliance, colour, and motion. Cape Adare is therefore nearer to the region or belt of maximum auroral frequency than Cape Evans is. Moreover, the majority of auroræ visible from Cape Adare lie to the north, so that Cape Adare, and *a fortiori* Cape Evans, is situated within the belt. This has an interesting bearing on the size of the auroral belts; the Arctic auroral zone is generally supposed to have a radius of about 20°, and to be centred at the pole of the earth's magnetic axis. There is no very recent determination of the position of the pole, but it can scarcely have moved more than a degree or two from its position in 1885, the epoch of Adams's investigation. Cape Adare is 27° distant from this point, and as this angle is a lower limit for the radius of the belt, this radius would seem to be greater than was to be expected.

The auroræ visible from Cape Adare, since they lie to the north, must for the most part be less than 3° above the horizon of Cape Evans. Consequently the auroræ seen from the latter station must in the main be different from the former. They represent conditions some degrees within the belt, and they differ in number and brilliance from those near the belt. They appear most frequently in a direction slightly north of east, and least often in the west. Again, whereas the Cape Adare auroræ trend predominantly east and west, or rather from a little north of west to a little south of east, the Cape Evans auroræ show a marked avoidance of the east-west trend. In each case the trend is perpendicular to the direction in which auroræ are least frequently seen. Brightly coloured and quickly moving auroræ are rare at Cape Evans, but fairly common at Cape Adare.

Auroræ were seen at Cape Evans on about one day out of three when seeing conditions were favourable, and about twice as often at Cape Adare. At either station they usually appear first at a low altitude in the direction of maximum frequency, and move

[1] British (*Terra Nova*) Antarctic Expedition, 1910–1913. Observations on the Aurora. By C. S. Wright. (Published for the Committee of the Captain Scott Antarctic Fund.) Pp. viii+48. (London: Harrison and Sons, Ltd., 1921.) 7s. 6*d*. net.

upwards, approaching the station, sometimes passing overhead and, after an interval, vanishing while in the region of minimum frequency. The overhead passage was much more common at Cape Adare than at Cape Evans.

The auroræ show a well-marked tendency to occur most often in the early morning, round about 4 A.M. local time. A secondary maximum occurs at Cape Adare at 8 P.M., and a trace of it is apparent also at Cape Evans. In the afternoon the auroræ rarely pass overhead, but they are more often brilliantly coloured and of swift motion than those which occur in the morning. At times of maximum frequency the aurora is also generally of greatest extent.

In the magnetic report of the expedition, by Dr. Chree, the connexion between magnetic activity and the aurora has already been discussed; Mr. Wright here carries the discussion further. It is clear that there is some relation between the two phenomena, though it is not so evident as in latitudes farther from the pole, where auroræ are seen only rarely, and are always accompanied by magnetic storms. Mr. Wright shows, however, that there is a marked correspondence between the magnetic character of a period of several hours about the time of appearance of a brilliant aurora, and the intensity of the aurora; the relationship is much more close than that between the same two characteristics at individual hours. Some of the results of this report had been anticipated by Mawson's report (1908) on the auroral work of the Shackleton expedition, though the latter is not confirmed in all respects. The auroral station in the Shackleton expedition was not far from Cape Evans.

These valuable memoirs will become of still greater significance and importance if and when another south polar expedition conducts similar observations in a part of the Antarctic considerably different in longitude from the Scott-Shackleton region, but at a similar distance from the pole of the earth's magnetic axis.

Mr. C. S. Wright's report [2] on the gravity observations, for which he was responsible, made during the *Terra Nova* expedition, is a record of a most manful struggle against difficulties. It seems very regrettable that the instrumental equipment of the expedition was not of the highest quality, for observations in the Antarctic are sufficiently exacting even under the best conditions. As a matter of fact, some of the equipment for Mr. Wright's gravity work was very bad, particularly the old transit circle on which he had to rely for his clock rates.

Four series of observations were made at Cape Evans, the first two being made in a cave cut in snow-drift consolidated to ice. The cave being small, the temperature varied by 10° C. during the time of observation, due to the observer's presence; all the mirror and lens surfaces were frosted by his breath, and also the prisms, agate planes, and pendulums themselves. A fortnight's break in the series of observations for each determination of g was made in order to allow the mirrors to clear. Notwithstanding all the efforts made to meet these conditions, the first two series gave such discordant results that in the second year a change was decided upon.

Attempts were made to build a small observing hut of (full) petrol cases covered with rubberoid and canvas; the hut was to be heated artificially during the observations. Twice the nearly completed hut was demolished by blizzards, and when at last it was securely built and banked with snow, it had to be abandoned after some days' trial, as it was found impossible to maintain it at a workable temperature, or even to keep it free from drift snow. Finally, the photographic dark-room opening off the living hut was lent as an observing station. Two series of observations were made here, in July and August 1912; the last series was not so good as that made in July, probably owing to the whole hut being shaken by blizzards during the August determination. Rejecting the results obtained in the previous year, the mean value of g from the three pendulums used in 1912 at Cape Evans was 983·003 from the July series and 983·004 from the August series: the probable error of the final mean is given as 0·0023 cm./sec.^{2}. Commdr. Bernacchi, who on Scott's earlier expedition was faced with even greater difficulties in some respects, obtained the values 982·970, 982·979, and 983·025 from his three pendulums, at a spot fifteen miles farther south. These values may be compared with the standard value 981·292 at Potsdam, which was taken as the reference or base station for the gravity work, and where Mr. Wright received training and much help from Prof. Helmert and his staff at the Geodetic Institute.

Observations were also made at Wellington, Melbourne, and Christchurch, in the latter case both on the outward and return journey. The value of g had already been accurately observed at Melbourne by Hecker in 1904 and Alessio in 1905, who obtained accordant values 980·003; the value found by Mr. Wright was 980·009, the difference exceeding the sum of the probable errors in the two cases: no reason for the disagreement can be assigned. The observations at Christchurch, like those made there earlier by Bernacchi, were unfortunately not very successful or accordant. The observation at Wellington was the first that had been attempted there. The check observation at Potsdam at the end of the expedition agreed well with the initial determination made with the same pendulums.

Industrial Fatigue Research.

THE third annual report of the Industrial Fatigue Research Board (H.M. Stationery Office, price 2*s*. net) is even more interesting than those which have preceded it. It contains not only an account of the constitution, organisation, investigations, researches, external relations, and publications of the Board, but also nearly fifty pages of original contributions from five of its investigators—Mr. Farmer, Miss May Smith, Mr. Wyatt, Dr. Vernon, and Mr. Weston.

During its three years of activity the Board has published twenty-three reports—seven on general industrial problems, seven on the textile industries, five on the metal industries, two on the boot and shoe industry, one on the pottery industry, and one on the laundry trade. "More recently, however, and pending development of some scheme of actual co-operation with industries . . . the Board have tended to modify their original procedure, and have taken as their objective the study of certain general subjects, not confined to any one industry but of common interest to all, following up each subject along lines which experience shows to be most promising and dealing with it both by field investigation and by laboratory research."

The scientific committees under the Board accordingly comprise those for industrial health statistics, physiology of muscular work, physiology of the respiratory and the cardio-vascular systems, and industrial psychology. In addition to its five industrial committees, dealing respectively with the textile, metal, pottery and glass industries, and with industries specially affecting women, the Board has appointed two special committees, one concerned with Post Office work (more particularly the study of telegraphists' cramp), the other with Legibility of Type, in accordance with the recommendation of a committee "appointed by a Treasury Minute to select the best faces of type and modes of display for Government publication."

In this short notice it is impossible to do more than quote the titles of the interesting essays contributed to the report by the Board's Investigators; they are—"Some Considerations concerning Technique," "The Use of the Sample in Investigation," "Some Observations on Industrial Conditions, with Special Reference to Cotton Weaving," "Atmospheric Conditions and Industrial Efficiency," "Future Investigations in the Pottery Industry," "A Note on Machine Design in Relation to the Operative."

British University Statistics, 1921–22.[1]

THE most noticeable feature of the University Grants Committee's new blue-book is that it contains only 20 pages, whereas the returns for 1920–21 covered 391. The Committee proposes to issue a fuller publication on the old lines from time to time, say once in five years. In the intervals the public will be the more dependent for information on the Universities Yearbook. Oxford and Cambridge are not yet included in the returns, as their grants were "special emergency" and not regular grants. Excluding ex-Service students (8000 in 1921–22; 11,512 in 1920–21) the returns show, compared with those for the preceding year, increases of 2234, or 14 per cent., in the number of full-time men students, and 699, or 7 per cent., in the number of women students. The Committee points out that the numbers in England and Wales are about double what they were in 1913–14, and that the comparative smallness of the increase in Scotland (35 per cent.) was "no doubt due to the fact that the war found what may be called the 'university habit' already firmly established there by long tradition, assisted since 1901 by the operations of the Carnegie Trust."

Of the total number of full-time students, 93 per cent. had their homes within the United Kingdom, 58 per cent. within 30 miles from the university or college; of the remainder, 5 per cent. came from other parts of the Empire and 2 per cent. from foreign countries. Students from parts of the Empire outside the United Kingdom constituted 8 per cent. of the full-time students in London and 7 per cent. of those in Scottish institutions. Of full-time men students 6 per cent., and of women 28½ per cent., lived in Halls of Residence. The percentages of students in Halls of Residence in London, other parts of England, Wales, and Scotland were 11, 18, 23, and 5 respectively. Full-time students admitted for the first time in 1921–22 numbered 9249, including 3421 women; 52 per cent. were not less than 19 years of age, 28 per cent. were not less than 18, and 2⅔ per cent. were less than 17.

Three-fourths of the full-time students were following courses leading to first degrees, and 4½ per cent. were engaged in post-graduate study or research. Part-time students numbered 14,462, of whom 9455 were occasional students, 1126 were preparing for first degrees, and 2008 were graduate students or research workers. In addition there were 14,345 students taking courses not of a university standard.

Full-time students of medicine, including dentistry, numbered 11,612 (women, 2595)—nearly 32 per cent. of the total; 33 per cent. (men 5805, women 6252) were enrolled in faculties of arts, theology, law, music, commerce, economics and education; 2½ per cent. (men 758, women 123) were engaged in the study of agriculture, forestry, horticulture and dairying; and the remainder were equally divided between pure science (men 4295, women 1851) and technology (men 6019, women 68).

The number of first degrees obtained was 6352, including 2573 honours degrees; the number of higher degrees, 843.

The statistics of income were summarised and commented on in the article published in NATURE of May 26 on the Universities Conference. Of the expenditure (3,565,375*l.*), 10 per cent. was for administration, 49·3 per cent. for salaries of teaching staff, 13·4 per cent. for other expenses of departmental maintenance, 13·1 for maintenance of premises. Of income, 10·3 per cent. was from endowments, 2·7 per cent. from donations and subscriptions, 35·3 per cent. from parliamentary grants, 35·7 from tuition and examination fees. Recurrent grants from the Treasury amounted to 1,070,082*l.*, non-recurrent to 271,250*l.*, in addition to which there were special grants amounting to 499,400*l.* to provide retrospective superannuation benefit.

FULL-TIME STUDENTS IN VARIOUS FACULTIES IN 1913–14 AND IN 1921–22.

	London.	England, including London.	Wales.	Scotland.
All faculties—

* Excluding the institutions which, not being then in receipt of grants, were not shown in the returns for 1913–14.
† Including 718 in Imperial College, South Kensington.
‡ Including 649 in the University of Glasgow and 707 in the Royal Technical College, Glasgow.
‖ Including 62 at Armstrong College, Newcastle-upon-Tyne, 60 at the University of Leeds, and 176 (82 women) at University College, Reading.

University and Educational Intelligence.

ABERDEEN.—For a number of years the hospital accommodation of Aberdeen has been insufficient, and the city has now before it a bold and comprehensive plan for remedying this defect. Originating with the Aberdeen Medico-Chirurgical Society some three years ago, the scheme has been elaborated by a committee

[1] University Grants Committee. Returns from Universities and University Colleges in Receipt of Treasury Grant, 1921–1922. Pp. 20. (London: H.M. Stationery Office, 1923.) 3s. 6d. net.

representative of the various bodies concerned, including the directors of the Royal Infirmary, the directors of the Royal Hospital for Sick Children, and the University. It is proposed to utilise a site of more than 110 acres on the Town Council's properties of Burnside and Foresterhill, on the north-western outskirts of the city. The University on its part would build departments of medicine, surgery, midwifery, pathology, bacteriology, and pharmacology, with adjoining students' hostels. The teaching of these subjects would be removed from Marischal College, and the latter part of the medical course would be passed in immediate touch with the wards. The scheme has been in existence for about three years, but has not been pressed. The other bodies concerned having expressed their readiness to proceed, the matter is now before the Town Council. The difficulties in the way of the scheme are chiefly financial, a sum of about three-quarters of a million being involved. The advantages to the public served by the hospitals and to the teaching of medicine in the north of Scotland are incalculable.

CAMBRIDGE.—Dr. A. B. Appleton, Downing College, Mr. D. G. Reid, Trinity College, Mr. A. Hopkinson, Emmanuel College, and Mr. V. C. Pennell, Pembroke College, have been re-appointed demonstrators in anatomy. The Harkness scholarship has been divided between E. R. Gee, Trinity College, and W. D. West, St. John's College. Frank Smart prizes have been awarded to T. A. Bennet-Clark, Trinity College, for botany, and to A. D. Hobson, Christ's College, and L. H. Matthews, King's College, for zoology. The Wiltshire prize has been awarded to F. C. Phillips, Corpus Christi College.

At the recent conferment of honorary degrees on the Prime Minister, Viscount Grey, Lord Plumer, Sir Aston Webb, Mr. M. C. Norman, Prof. H. A. Lorentz, Dr. W. H. Welch, and Prof. N. Bohr, the Public Orator spoke as follows in introducing the three honorary graduates in science:

"Inter speculatores omnes venatoresque Naturae quos hodie physicos proprie vocamus, constat illum eminere quem iam ad vos duco. Admodum iuvenis Physicis professor constitutus, diu in Universitate Lugduno-Batava docuit, immo vero rude donatus adhuc docet, physicorum ipse Nestor. Multa linguarum scientia, multa rerum cognitione, miro ingenii acumine, talis est studiorum hortator, ut illis qui Naturae secreta explorant etiam si non adhuc penitus inveniunt verbo exemplo benignitate praecipue subveniat. Longam iam virorum seriem recolimus qui, post reformatam Ecclesiam et Lugduni constitutam Academiam, vitae Brittanicae Batavi lucem porrexerunt. Hodie lucis ipsius investigatorem honoramus qui nobis qua ratione inter se lux et vis electrica congruant et cohaereant exposuit. Si Academiae nostrae laudes hospiti nostro narrarem nonne verba illa primum arriperem, 'Hinc lucem'? et cum hospitem Universitati vestrae praesento, quid nisi eadem mihi succurrunt, 'Hinc lucem'? Duco ad vos Henricum Antonium Lorentz.

"Revocamus illum qui, apud Vergilium, augurio spreto, neglecta cithara, fama militari recusata,

ut depositi proferret fata parentis,
scire potestates herbarum usumque medendi
maluit et mutas agitare inglorius artes.

Eandem et hodie generis humani curam, eundem medendi amorem, easdem artes agnoscimus, sed non illum inglorium vocamus, qui vitam totam medicinae consecravit, qui discipulos usum illum plurimos docuit, qui non contentus translaticiam tradere scientiam secreta Naturae voluit ipse explorare et

venienti occurrere morbo.

Virum talem vobis praesento, Yalensem, in illa republica natum quae reipublicae normam dedit ampliori, multorum in Academia Baltimorensi doctorem, diu honoratum, diu amatum, necnon et Templi illius quod Novi Eboraci posuit Hygeae Propugnatrici Rockefeller, Flaminem Rectorem Archiatrum. Duco ad vos Willelmum Henricum Welch.

"Iterum inter nos praesentem salutamus alumnum et condiscipulum qui Danus, patre natus physiologo clarissimo, in rebus physicis ipse versatus, Angliam admodum iuvenis petiit, et ad Canum et apud Mancunienses et didicit et docuit. Illud laeti revocamus, quod apud Anglos primo investigavit quomodo re vera emittatur lux, quod cum patefecisset, atomi structura quae diu latebat magis intelligebatur. Hos tantos labores praemio Nobeliano coronatos quis mirabitur? sed ex eis quae scientiae speranda sint incrementa, quis divinabit? Quippe ad patriam reverso civium voluntate—quod ceteris gentibus exemplo sit!—facultas datur ut haec studia discipulis adiuvantibus libere prosequatur. Duco ad vos Niels Bohr."

EDINBURGH.—An anonymous donor has given the University a sum of 20,000*l*. to form the nucleus of a fund to provide a new Department of Zoology. In his letter to the Principal, Sir Alfred Ewing, the donor referred to the inadequacy of the present laboratories and to the serious disadvantages under which teaching and research in zoology are being carried on in Edinburgh, and stated that he hoped other support would be forthcoming so that the new Department might be erected in the near future.

The building in which the teaching of zoology is at present carried on forms part of the Old College, and was altered in 1882, so far as structural conditions would permit, in the endeavour to meet the needs of that time. Since then there has been a great development in the subject and in the methods by which it is taught, calling especially for more laboratory accommodation and better lighting, and in both these respects the present premises are wholly inadequate to meet the needs of the students—science and medical—and of the post-graduate workers in the Department. In addition to providing instruction for science students extending over four years, and for medical students in their first year, the work of the Department includes post-graduate courses in medical entomology, protozoology, and helminthology, for the diploma in tropical medicine and in public health. The accommodation in the existing premises, barely sufficient to meet the needs of forty years ago, has been hopelessly overtaxed during the last twenty years, and no alteration of the present building can remedy the defect. Strong hopes are entertained that the recent generous gift will be supplemented, and that the University Court will be able at an early date to proceed with the erection of the laboratories urgently needed for teaching and for research.

LEEDS.—Huddersfield Town Council has decided to make a contribution of 1000*l*. a year towards the maintenance of the University.

The following appointments have been made: Mr. George R. Ross to be lecturer in bacteriology, and Mr. R. Stoneley to be assistant lecturer in applied mathematics.

Prof. Jamieson has been appointed pro-vice-chancellor for a period of two years from July 1 in succession to Prof. A. Smithells.

LONDON.—At a meeting of the senate on June 20 the following appointments were made:—

Prof. F. Wood Jones, to the University chair of anatomy tenable at St. Bartholomew's Hospital

Medical College. Prof. Jones has been demonstrator and lecturer in anatomy at the medical schools in London and Manchester, and since 1919 he has been professor of anatomy in the University of Adelaide. He is the author of "Arboreal Man," "The Principles of Anatomy as seen in the Hand," and numerous other publications.

Mr. E. C. Williams, to the Ramsay Memorial chair of chemical engineering tenable at University College. Mr. Williams was awarded the Dalton chemical scholarship for research at Manchester, and he has since been on the scientific staff of the British Dyes, Ltd., and head of the department for the manufacture of intermediate products under the British Dyestuffs Corporation. Since 1921 he has been research chemist to the joint research committee of the University of Leeds and the National Benzol Association.

Dr. R. J. S. McDowall, to the University chair of physiology tenable at King's College. Dr. McDowall was lecturer in physiology at Edinburgh, and, since 1921, lecturer in experimental physiology and experimental pharmacology at Leeds. He is the author of publications on mammalian muscle, pulmonary circulation, and numerous other physiological subjects.

Mr. G. Stead, to the University readership in physics tenable at Guy's Hospital Medical School. Mr. Stead has been, since 1910, assistant demonstrator in the Cavendish Laboratory, Cambridge, and is the author of numerous publications embodying the results of research on the passage of electricity through gases.

The following doctorates were conferred: *D.Sc.* (*Engineering*): Mr. J. V. Howard (University College), for a thesis entitled "The Tension Test in relation to the Composition of Steel"; and Mr. S. L. Smith (Imperial College—City and Guilds College), for a thesis entitled "Mechanical Hysteresis and Tensile Deformation of Steel."

MANCHESTER.—The Sir Clement Royds memorial scholarship in chemistry of the value of 300*l.* is being offered to candidates born or resident in the county of Lancaster, preference being given to the county borough of Rochdale. Further particulars are obtainable from the Internal Registrar, to whom applications must be sent by, at latest, July 14.

Dr. H. S. Raper has been appointed Brackenbury professor of physiology and director of the Physiological Laboratories. Dr. Raper, who is at present professor of physiology and biochemistry in the University of Leeds, was engaged in research work during the War on protection against poison gas, and from 1918 was head of the Anti-Gas Department. He is at present retained by the War Office in an advisory capacity on physiological questions arising in connexion with chemical warfare.

The following additional appointments have also been made: Dr. T. M. Bride to be chemical lecturer in ophthalmology; Miss Irene J. Curnow to be assistant lecturer in geography; Mr. David Stewart to be assistant lecturer in anatomy; Mr. E. V. Ashcroft and Miss Eugenia R. A. Cooper to be demonstrators in anatomy; and Mr. W. H. Wood to be tutor and secretary to the Faculty of Medicine.

THE examination for the Aitchison memorial scholarship, value 36*l.*, covering the full-time day courses in technical optics at the Northampton Polytechnic Institute, extending over two years, will be held on September 25-26 next. It is open to candidates of both sexes. Full particulars can be obtained from the Hon. Secretary and Treasurer, Mr. H. F. Purser, 35 Charles Street, Hatton Garden, E.C.1.

APPLICATIONS for grants for 1924 from the Van 't Hoff Fund, which are made to investigators in the fields of pure and applied chemistry, must be sent before November 1 by registered post to: Het Bestuur der Koninklyke Akademie van Wetenschappen; bestemd voor de Commissie van het "Van 't Hoff-fonds," Trippenhuis, Kloveniersburgwal, te Amsterdam. A detailed account of the proposed use of the grant, and of the reasons on which the candidate bases his claim, should accompany the application. The amount available for 1924 is about 1400 Dutch florins.

THE Commissioners for the Exhibition of 1851 announce that Senior Studentships for 1923 have been awarded to the following: Dr. W. Davies, demonstrator and lecturer in chemistry at the University of Oxford; Dr. L. C. Jackson, science research scholar in physics of the Royal Commission of 1851, at the University of Leyden; Mr. J. H. Quastel, research student in bio-chemistry at the University of Cambridge; Mr. D. Stockdale, research student in metallurgy in the Goldsmiths' laboratory at the University of Cambridge, and demonstrator in the University Chemical Laboratory; and Mr. H. Williams, research student in geology at the University of Liverpool.

ON June 22, the Universities of Oxford and Cambridge Bill was before the House of Commons, and the second reading was agreed to without a division. It will be remembered that the Bill is a result of the report of the Royal Commission appointed in November 1919 to investigate financial and other conditions at Oxford and Cambridge. Under its provisions, two bodies of commissioners will be appointed, of which Lord Chelmsford and Lord Ullswater are to be the respective chairmen, to direct affairs in the Universities for five years. There is also provision for financial aid for each University; the Royal Commission suggested an annual grant of at least 70,000*l.* in addition to the 30,000*l.* already received annually by Oxford and Cambridge.

THE excessive prolongation of merely preparatory general education is trenchantly criticised in the annual report for 1922 of the Carnegie Foundation for the Advancement of Teaching. It is pointed out that the "High School" was intended originally to form for the common people of the country a college in which their sons and daughters might be prepared for various practical callings just as the college proper prepared its students for the learned professions. The high school and college offered in fact *parallel* modes of education. The high school gradually came under the complete domination of the academic colleges and universities until the former became, what it is in large measure to-day, a vestibule to the college, even though but a small number of its students proceed to college. There has resulted an "Educational pyramid" comprising 8 years in the elementary school (from age 6 to age 14), 4 years in the high school, and 4 years in college—in all 16 years of preparatory training in schools the primary purpose of which is assumed to be cultural. "The like of this is not to be seen in any other part of the world. . . . Without question 4 years can be dropped out of the programme with advantage to the cause of education and to the interest of the people and of their children. But this change also is clearly related to that conception of education which assumes that the beginning of education lies in the sincere learning of a few things rather than in the superficial acquaintance with many."

Societies and Academies.

LONDON.

Royal Microscopical Society (Industrial Applications Section), May 30.—Dr. A. Hutchinson in the chair.—H. B. **Milner**: The microscopical investigation of sands for various industrial purposes. The application of the petrological microscope to the discrimination of sands and allied rocks suited to various industrial requirements, such as glass manufacture, abrasives, ferrous and non-ferrous foundry work, silica-brick production, cement, mortar, concrete, brick and tile manufacture, and as a source of economically valuable minerals such as monazite and thorianite for incandescent gas mantles, etc., was discussed. The distinctive properties of sands for their proper utilisation in the arts can be determined by the microscope. The employment of the microscope should not be interpreted as a certain cure for all technical difficulties, but the full possibilities of the instrument are still unappreciated by the majority of manufacturers who employed refractory materials. Lines of microscopical research on refractory sands, particularly in connexion with silica-bricks, were suggested.

Aristotelian Society, June 4.—Prof. A. N. Whitehead, president, in the chair.—Sir Leslie **Mackenzie**: What does Dr. Whitehead mean by "event"? The word has a peculiar importance in his theory. It is intended to cover the fact that, on whatever theory we finally decide as to the nature of the physical world, that world cannot now be described or even discussed except abstractly if we confine ourselves to terms of space alone; for space and time have a common root, and, if we speak in terms of space alone, we can properly do so only in one of two ways: either we must use space as meaning space-time or simply as a second grade of abstraction. In either case it omits the essential point that the physical world is to be taken in terms of space and time in unity. At first sight, the word "event" seems to overstress the time element. The fact of a happening is thought of first in terms of time and not in terms of space. But it is something perceptible that happens, and if it took no time to happen, it would not be perceptible; for it would be nothing at all. Time, therefore, is of the essence of every happening. But equally there is no doubt that what happens physically happens in a space, it happens somewhere, and every physical happening must be thought of as also in space. Whether explicitly so understood or not, every event in the physical world is, therefore, a thing to be thought of as involving both time and space.

Geological Society, June 6.—Prof. W. W. Watts, vice-president, in the chair.—H. **Bolton**: On a new blattoid wing from the Harrow Hill mine, Drybrook (Forest of Dean). The wing is a right fore-wing of a new genus of blattoid, and of unusual size. The surface is densely chitinous, and crossed by a series of powerful well-branched veins, the cubitus being especially well developed, and much unlike any other known among the Coal-Measure blattoids. The insect probably occupied an intermediate position between the families Archimylacridæ and Hemimylacridæ. — C. E. **Tilley**: Contact-metamorphism in the Comrie area of the Perthshire Highlands. The thermal aureole of the Cairn Chois diorite-complex is divisible into (*a*) zone of biotite and (*b*) zone of cordierite, which rapidly passes into a zone of true hornfelses. In the Aberfoyle-Slate band, an additional outer zone (zone of spotted slates) is found; but no chemical reconstruction is apparent. The progression of metamorphism as here observed is that distinctive of kaolin-free slates subject to thermal alteration. The rocks of the hornfels zone—with a minimum width of 150 yards—show a wide range of composition. A classification of the silica-poor hornfelses is suggested, starting from a simplified system of four components. The mineralogical assemblages thus ideally determined can be alternatively developed from a consideration of the chemical changes incident on metamorphism of sericite-chlorite-quartz assemblages of the original rocks. Certain abnormal assemblages are considered as unstable. These, while not invalidating the hornfels classification adopted, serve to indicate that equilibrium in the inner contact-zone is closely approached rather than completely attained.

Linnean Society, June 7.—Dr. A. B. Rendle, president, in the chair.—H. **Sandon**: Some Protozoa from the soils and mosses of Spitsbergen obtained by the Oxford University Expedition.—J. D. F. **Gilchrist**: A form of dimorphism and asexual reproduction in *Ptychodera capensis*. C. E. **Moss**: The species and forms of Salicornia in South Africa.—J. **Burtt-Davy**: Geographical distribution of some Transvaal Leguminosæ. The Leguminosæ form the largest family of Transvaal Spermatophyta, as regards numbers of species, having about 100 species more than the Compositæ, and comprising nearly 10 per cent. of the recorded species of the flora. A large number of the genera have very few species. The greatest number of endemics generally occur in genera with the greatest number of species; and the species show great variation in range. Even in the same genus some range almost the length of the Continent. Classified according to their geographical range of distribution, the Papilionaceæ fall into five very distinct groups: (1) the South-western Cape Province element, (2) the Kalahari element, (3) the Rain-forest element of the eastern high mountains, (4) the Tropical African element, and (5) the Warm Temperate Plateau element. (4) and (5) account for 94 per cent. (306 species) of the total Papilionaceous flora and 123 are endemic to the Transvaal. Adding to these species those which range into the states bordering on the Transvaal but not beyond them, the number of endemics forms 78 per cent. of the population. Fifteen species (less than 5 per cent.) are common to the Transvaal and India, and five species are found in Madagascar. In connexion with the view that arborescent forms are the older types, it is noteworthy that, with one exception, possibly introduced, the arborescent and shrubby species of Papilionaceæ (only about twenty in all) belong to the Tropical African element, and about half of them belong to genera with few species. —C. E. **Moss**: Velaminous roots in terrestrial orchids. They are especially noticeable in the orchid genus Eulophia, abundant at the Cape (S.A.).

Physical Society, June 8.—Dr. Alexander Russell in the chair.—J. G. **Gray**: A general solution of the problem of finding the true vertical for all types of marine and aerial craft. The difficulties presented by this problem arise from the horizontal accelerations which result from the turning of vehicles. A gyroscopic pendulum to succeed must possess a real precessional period, or a virtual precessional period during turning motion of the vehicle on which it is mounted, which is measured in hours. Pioneer forms of Gray stabiliser comprise a single gyroscope, mounted with its axis normally vertical, and an erector connected rigidly to it; the whole is pivoted to a gimbal frame by means of two cross pivots. One form of erector consists of a circular track carried by the pivoted system, and so arranged that when the pivoted system is upright the track is horizontal. One, two, or more balls rotate on the track, each controlled by a pusher and a check carried by a member which rotates slowly (about 12 revolutions per minute) in the direction of spin of the gyroscope. When the system is upright the balls move round the track in contact with their pushers, and form a balanced system. When the system is inclined to the vertical the track is inclined to the horizontal, and each ball when ascending the slope of the track rests against its pusher, but after crossing the crest of the slope it is accelerated down the track and rests against its check. The motion of the balls relative to the pushers and checks results in the application to the pivoted system of an integral erecting couple. Such instruments possess an accuracy, for bombing purposes, amounting to one-eighth or one-tenth of a degree, or about 20 feet on the ground from a height of 12,000 feet. Later forms of Gray stabiliser set themselves into the true vertical even when the vehicles on which they are mounted are turning, and this holds for all speeds of turning. This result is obtained by constructing the apparatus so that a horizontal component of spin lies across the pivoted system, which is mounted so as to be pendulous with respect to the pivots. The direction of the horizontal spin, and its amount, are arranged so that when the vehicle turns there comes into existence a gyroscopic couple, applied about the fore and aft pivots, which is exactly equal and opposite to the so-called centrifugal couple applied to the pivoted system. Both couples are proportional to the angular speed at which the vehicle turns, and both change sign with that of the turning motion.

Zoological Society, June 12.—Sir S. F. Harmer, vice-president, in the chair.—N. A. **Mackintosh**: The chondrocranium of the teleostean fish *Sebastes marinus*.—R. I. **Pocock**: The external characters of the pigmy hippopotamus (*Chæropsis liberiensis*) and of the Suidæ and Camelidæ.—E. E. **Austen**: A revision of the family Pantophthalmidæ (Diptera), with descriptions of new species and a new genus. —Raymond **Dart** and C. W. **Andrews**: The brain of the Zeuglodontidæ (Cetacea), with a note on the skulls from which the endocranial casts were taken. —R. **Broom**: On the structure of the skull in the carnivorous dinocephalian reptiles.—Oldfield **Thomas** and M. A. C. **Hinton**: On mammals collected by Capt. Shortridge during the Percy Sladen and Kaffrarian Expedition to Orange River.

PARIS.

Academy of Sciences, June 4.—M. Albin Haller in the chair.—Charles **Richet**: The function of the spleen in nutrition. An account of some feeding experiments on dogs after removal of the spleen.—Gabriel **Bertrand** and Mlle. S. **Benoist**: A new sugar, procellose. Filter paper is converted into cellulose octacetate by the method of Maquenne and Goodwin, and the mother liquors from the crystallisation of this acetate worked up for the isolation of the new sugar, to which the name procellose is given. Its composition is $C_{18}H_{32}O_{16}$ and rotation $[\alpha]_D = +22°·8$ at 21° C.; its reducing power is half that of glucose. Its probable formula is given.—C. **Guichard**: Two triple orthogonal systems which correspond in such a manner that the first tangents to the two systems are reciprocal polars with respect to a linear complex. —Sir Richard Hadfield was elected corresponding member for the section of chemistry in succession to M. Paterno, elected foreign associate.—René Maire was elected corresponding member for the section of botany in succession to the late M. Battandier.—Jules **Drach**: Remarkable classes of W congruences.—Bertrand **Gambier**: The curves of Bertrand, and in particular, those which are algebraical.—MM. **Schouten** and **Struik**: A theorem of conformal transformation in differential geometry of n dimensions.—M. **Lainé**: The integration of differential equations.—Serge **Bernstein**: A property of integral functions.—Henri **Eyraud**: Multiple spaces and tensors.—M. **Chatillon**: The paramagnetism of cobalt sulphate in aqueous solution. An explanation of the divergent results of Cabrera and Trümpler on the coefficient of magnetisation of cobalt salts. With solutions prepared at ordinary temperatures, the results are independent of the concentration, but if the solutions are prepared hot and allowed to cool to the ordinary temperature, the atomic moment is a function of the concentration. —M. **de Broglie** and A. **Lepape**: The K absorption discontinuity of krypton and xenon. Krypton gave N = 36 (λ = 0·8648Å) and xenon N = 54 (λ = 0·3588Å). The last figure is approximate only.—L. **Bull**: A photographic technique for detecting minute deformations in rectilinear objects.—Adolphe **Lepape**: The quantitative measurement of radium emanation by the α-radiation. Corrections due to pressure and to the nature of the gaseous mixture. Corrections, generally neglected, should be applied to measurements of radium emanation: their importance depends not only on the variations of density and composition of the gas present in the condenser, but also on the dimensions of the latter.—Jean **Barbaudy**: The removal of toluene by steam.—A. **Boutaric** and Mlle. Y. **Nabot**: The influence of a third substance on the miscibility of phenol and water.—Marcus **Brutzkuo**: A contribution to the theory of internal combustion motors. Some theoretical considerations of the combustion of gases and liquids in engine cylinders derived from the application of the law of mass action.—Henri **Guinot**: A continuous method of dehydrating alcohol and certain organic liquids. A modification of the Young method for dehydrating alcohol, in which the benzene proposed by Young is replaced by trichlorethylene. The distillate separates into two layers, the lower layer containing only 2 per cent. of water and practically the whole (99 per cent.) of the trichlorethylene. This is returned to the still. —P. **Brenans** and C. **Prost**: The iodosalicylic acids. The 1.2.3 and 1.2.5 mono-iodide acids have been prepared, starting with aminosalicylic acids of known constitution: each of these has been transformed into the same 1.2.3.5 di-iodosalicylic acid.—A. **Blanchetière**: The action of dry heat on the alkaline earth salts of the carbamine acids.—L. **Cayeux**: The rôle of the crinoids in the history of the secondary oolitic iron minerals. The contribution of the remains of crinoids to the constitution of the oolitic iron minerals of the secondary epoch is of great importance.—Pierre **Bonnet**: The Neocretacian of Daralagœz (southern Transcaucasia).—P. H. **Fritel**: Two species of ferns new to the fossil flora of the millstone grit of Beauce (Aquitanian).—M. **Gruvel**: Some coral deposits on the western coast of Morocco. —L. **Éblé**: Magnetic measurements in the Paris basin. The values of the magnetic elements calculated to January 1, 1922, are given for 40 stations, ten of which are new.—R. de Montessus **de Ballore**: The methodical prediction of the weather. The results of a study of statistics given by Louis Besson in 1905.—J. **Rivière**: The variation of nocturnal temperature with a clear sky.—G. **Reboul**: The acoustic opacity of banks of clouds: application to the rapid determination of the thickness of a cloud layer.—Maurice **Lenoir**: The nucleolar material during the telophase of somatic kinesis in the nucleus in *Fritillaria imperialis*.—J. **Athanasiu**: Motor nerve vibrations in the animal series.—E. **Wollman** and M. **Vagliano**: The action of light on growth. A description of three sets of experiments on rats: the diet of the first set contained 5 per cent. of butter, and of the second and third sets 1 per cent. of butter. The rats were kept in the dark, but the third set were exposed to ultra-violet light from a mercury vapour lamp for 3 to 5 minutes each day. Other experiments were carried out in which the rats received only 1 per cent. of butter but were exposed to light. The growth of rats receiving only 1 per cent. of butter and exposed to daylight or to ultra-violet light was as rapid as those receiving the larger amount of butter and kept in the dark. If the food contained no butter, irradiation by the mercury lamp had no effect. Light alone cannot compensate for the absence of the fat soluble factor of growth.—Georges **Mouriquand** and Paul **Michel**: Some osteodystrophic factors and their action according to the species of animal. Dietic experiments, with deficiency of the C-vitamin, on rats and guinea-pigs show that these animals present marked differences in bone nutrition under the same conditions of food. The experiments will be extended to other species of animals, and it is pointed out that it is necessary to apply the results of feeding experiments with animals with much care, especially as regards man.—P. **Gillot**: The variations of some carbohydrate reserves in *Mercurialis perennis*. Maltose, which is always present in the reserve organs of this plant, undergoes variations comparable with those of the starch and saccharose: hence this sugar may be looked upon as a reserve substance of the same order as the other polysaccharides.—Georges **Tanret**: Some bases, of the type of tropacocaine, derived from pseudopelletierine.—E. **Kayser**: —The action of yeast on calcium lactate: the production of ethyl alcohol.—Alphonse **Labbé**: The critical zones of adaptation to the medium.—L. **Berland**: The origin of the spiders of New Caledonia. Of 150 species of spiders found, 93 species are confined to that island. The species are most probably of Malay origin in the Oligocene period.—René **Jeannel**: The evolution of the blind Coleoptera and the stocking of the caves in the mountains of Bihor in Transylvania.—Eugène **Lacroix**: The fundamental chitinous texture of the shell of certain Foraminifera. —Armand **Dehorne**: The interstitial cells in the testicle of annelids, Stylaria, and Lumbricus.—Maxime **Ménard** and **Saidman**: The action of the ultra-violet rays on superficial wounds. Details of 17 cases submitted to this treatment, of which 12 were cured and 3 improved.

SYDNEY.

Royal Society of New South Wales, May 2.—Mr. C. A. Sussmilch, president, in the chair.—C. A. **Sussmilch**: Presidential address. No volcanoes either active or dormant occur now in New South Wales, but there is abundant geological evidence to show that at many stages in its past history numerous large active volcanoes existed. Each subdivision of the Palæozoic era had its active volcanoes; during the Ordovician period submarine eruptions took place in the central part of the State. Later, volcanic activity appears to have been confined to the New England area, but here it occurred on a grand scale. A chain of active volcanoes extended from Port Stephens past Maitland, Musclebrook, and Scone, and from thence northwards to Currabubula, and active volcanoes occurred at Gloucester and on the Drake Goldfield. The lavas and tuffs poured out from these volcanoes aggregated many thousands of feet in thickness. In the succeeding Permo-Carboniferous period, when the great coalfields were being laid down, volcanic activity, while less intensive, was still present. In the Mesozoic era, the volcanic forces appear to have died out, and for several millions of years volcanic activity was unknown. In the succeeding Cainozoic era volcanic activity again asserted itself, and twice at least floods of basaltic lavas were poured out, submerging vast tracts of land, and completely covering up some of the then river valleys, thus preserving some of the deep leads afterwards worked for gold, tin, and gemstones. Towards the end of this era, a number of isolated groups of volcanic cones developed; these were the last eruptions to occur in New South Wales, and for the past million or so years volcanic activity has been entirely absent.

Official Publications Received.

Department of Commerce: Scientific Papers of the Bureau of Standards. No. 469: Directive Radio Transmission on a Wave Length of Ten Metres. By Francis W. Dunmore and Francis H. Engel. Pp. 16. 10 cents. No. 473: A Method for the Measurement of Sound Intensity. By J. C. Karcher. Pp. 105-111. 5 cents. (Washington: Government Printing Office.)

The Botanical Society and Exchange Club of the British Isles. Vol. 6, Part 5: Report for 1922. By the Secretary, G. Claridge Druce. Pp. 589-821. (Arbroath: T. Buncle and Co.) 10s.

Rhodesia Museum, Bulawayo. Twenty-first Annual Report, 1922. Pp. 18. (Bulawayo.)

Bergens Museum Aarbok, 1920-1921. 2 Hefte. Naturvidenskabelig Række. Pp. 96+71. (Bergen.)

Department of the Interior: Bureau of Education. Bulletin, 1922, No. 45: Status of Certain Social Studies in High Schools. By Harry H. Moore. Pp. 21. 5 cents. Bulletin, 1923, No. 12: Secondary Education in 1921 and 1922. By W. S. Deffenbaugh. Pp. 30. 5 cents. (Washington: Government Printing Office.)

State of Illinois Department of Registration and Education: Division of the Natural History Survey. Bulletin, Vol. 14, Art. 3: A Study of the Malarial Mosquitoes of Southern Illinois. By Stewart W. Chandler. 2: Operations of 1920. Pp. 23-32. Vol. 14, Art. 4: Changes in the Bottom and Shore Fauna of the Middle Illinois River and its Connecting Lakes since 1913-1915 as a Result of the Increase, Southward, of Sewage Pollution. By Robert E. Richardson. Pp. 33-75. Vol. 14. Art. 5: The Helminthosporium Foot-rot of Wheat, with Observations on the Morphology of Helminthosporium and on the Occurrence of Saltation in the Genus. By F. L. Stevens. Pp. iv+77-186+25 graphs+plates 7-34. Vol. 14, Art. 6: The Numbers and Local Distribution in Summer of Illinois Land Birds of the Open Country. By Stephen A. Forbes and Alfred O. Gross. Pp. 187-218+plates 35-68. Vol. 14, Art. 7: Coddling-Moth Investigations of the State Entomologist's Office, 1915, 1916, 1917. By Pressley A. Glenn. Pp. iv+219-289. (Urbana: Department of Registration and Education.)

Department of the Interior: United States Geological Survey. Bulletin 729: Oil Shale of the Rocky Mountain Region. By Dean E. Winchester. Pp. 204+18 plates. Bulletin 734: Deposits of Manganese Ore in the Batesville District, Arkansas, by Hugh D. Miser; with a Chapter on the Mining and Preparation of the Ores, by W. R. Crane. Pp. xi+273+17 plates. 45 cents. (Washington: Government Printing Office.)

Department of the Interior: United States Geological Survey. Water-Supply Paper 504: Surface Water Supply of the United States, 1919-1920. Part 4: St. Lawrence River Basin. Pp. iv+188. (Washington: Government Printing Office.) 20 cents.

Department of the Interior: United States Geological Survey. Professional Paper 131-F: Revision of the Flora of the Green River Formation, with Descriptions of New Species. By F. H. Knowlton. Pp. 133-182 +plates 36-40. Professional Paper 131-G: Fossil Plants from the Tertiary Lake Beds of South-Central Colorado. By F. H. Knowlton. Pp. 183-197 +plates 41-44. Professional Paper 131-H: The Fauna of the So-called Dakota Formation of Northern Central Colorado and its Equivalent in South-Eastern Wyoming. By John B. Reeside, Jr. Pp. 199-212+plates 45-50. (Washington: Government Printing Office.)

Queensland Geographical Journal (New Series). Vols. 36-37. Including the Proceedings of the Royal Geographical Society of Australasia, Queensland. 36th-37th Sessions, 1920-1922. Pp. iv+128. (Brisbane: Royal Geographical Society.)

Diary of Societies.

MONDAY, JULY 2.

ROYAL INSTITUTION OF GREAT BRITAIN, at 5.—General Meeting.

ARISTOTELIAN SOCIETY (at University of London Club), at 8.—M. Ginsberg: The Category of Purpose in Social Science.

FARADAY SOCIETY (at Chemical Society), at 8.—A. Ferguson: A Relation between Surface Tension and Density.—J. Grant and Prof. J. R. Partington: Concentration Cells in Methyl Alcohol.—U. R. Evans: The Law of Definite Proportions in the Light of Modern Research.—J. B. Firth: Determination of the Density of Charcoal by Displacement of Liquids.—F. G. Tryhorn and S. C. Blacktin: The Formation of Anomalous Liesegang Bands.

The Water in the Atmosphere.[1]

By Dr. G. C. Simpson, F.R.S., Director of the Meteorological Office.

THE dictionary definition of "saturation" is "the state of a body when quite filled with another," and it is usual to think of saturated air as air which is full of water vapour to such an extent that further water cannot be added without condensation taking place. This, however, is a wrong conception, for there is no limit to the amount of water vapour which air can contain at any temperature, provided that it is perfectly pure, except that ultimately the molecules of vapour will be so near together that there will be no distinction between vapour and liquid.

Air at 30° C. is said to be saturated when its vapour pressure is 31·51 mm. of mercury, but if to such saturated air we add water in sufficiently small drops it will be evaporated immediately and the liquid drops transformed into invisible vapour. If we could add drops with so small a diameter as $1{\cdot}6 \times 10^{-7}$ cm. the air would devour them with avidity until its vapour pressure was more than 126 mm., and then would be ready for more if smaller drops could be supplied.

The question of whether air can hold more vapour or not depends entirely on how the water is presented to it. If the water is presented with a flat surface, evaporation will take place until there is so much water vapour present in the air that as many water molecules return to the surface as leave it; the air is then saturated with reference to a flat surface of pure water. If the surface is curved—convex towards the air—more water molecules will leave each square centimetre of the surface than in the case of a flat surface; hence there must be more vapour molecules in the air before equilibrium is attained. Thus the saturation vapour pressure over a curved surface is higher than over a flat surface at the same temperature. On the other hand, if the water contains certain impurities—*e.g.* sulphuric acid, calcium chloride, and salts in general—less molecules leave the surface than in the case of pure water; hence a smaller number of molecules in the air will be sufficient to produce equilibrium over a solution.

In accordance with the usual practice we will describe air as saturated when the water vapour it contains is in equilibrium with a flat surface of pure water at the same temperature. This will define the saturation pressure at each temperature, and relative humidities will be given in terms of this saturation pressure.

It is well known that water can exist in the liquid state at temperatures far below the freezing point, and therefore water and ice may exist side by side over a large range of temperature. But the vapour pressure which is in equilibrium with ice at a given temperature is lower than that which is in equilibrium with supercooled water at the same temperature; that is, air is in equilibrium with ice at a relative humidity below 100 per cent.

Thus, according to our definition of relative humidity, the water vapour in air may be in equilibrium with water over a large range of relative humidities according to the physical state of the water present. The following tables give the relative humidity of air in equilibrium with pure water in the liquid and solid state.

Table I.

Relative humidity of air in equilibrium with water surfaces of various radii at 0° C.

Radius, cm.	Flat.	$1{\cdot}0 \times 10^{-3}$.	$1{\cdot}1 \times 10^{-5}$.	$2{\cdot}5 \times 10^{-6}$.	$7{\cdot}2 \times 10^{-7}$.	$1{\cdot}6 \times 10^{-7}$.
Relative humidity	100	100·00012	101	105	120	400

Table II.

Relative humidity of air in equilibrium with a flat surface of ice at various temperatures.

Temperature	0° C.	−10° C.	−20° C.	−30° C.	−40° C.	−50° C.	−60° C.
Relative humidity	100	91	82	74	67	61	55

Condensation at Temperatures above the Freezing Point.

It was in 1880 that Aitken first showed that condensation does not necessarily take place in air when its temperature is lowered below the dew point. He expanded carefully filtered air and found that no fog formed even when there was considerable supersaturation. Aitken was led to the conclusion "that vapour molecules in the atmosphere do not combine with each other, that before condensation can take place there must be some solid or liquid nucleus on which the vapour molecules can combine, and that the dust in the atmosphere forms the nuclei on which the water-vapour molecules condense."

Aitken invented a most ingenious instrument, easy to work and very transportable, by means of which it is possible to count the number of nuclei present in the air. Thousands of tests of the atmospheric nuclei have been made with this instrument at many places over the world, and nowhere has air free from nuclei been found. The number of nuclei is seldom less than 100 per c.c., while in most country places the nuclei rise to thousands, and in cities such as London and Paris the number may be so great as 100,000 to 150,000 per c.c.

The general explanation of these observations is as

[1] Discourse delivered at the Royal Institution on Friday, March 2, 1923.

follows. If there were no dust particles present the drops of water would have to be built up from aggregates of water molecules. Now the radius of a water molecule is 2×10^{-8} cm., therefore if a few molecules met together by chance they would only form a very small drop, which would be so small that it could not exist unless there was large supersaturation. For example, according to Table II. a drop having a radius of $7\cdot2\times10^{-7}$ cm. would require a supersaturation of 20 per cent., yet nearly 20,000 water molecules would be required to form such a drop. If, however, there were dust particles present the molecules of water would be deposited on them, and the radii of the initial drops would be so large that little supersaturation would be required to maintain them.

This explanation appeared to satisfy every one for a long time, but in recent years considerable doubt has begun to be expressed. Already, in 1885, Assmann had searched for the dust nuclei when cloud particles evaporated under the microscope, and had come to the conclusion that if any were present they must have a smaller radius than $2\cdot5\times10^{-5}$ cm.

In 1912, Wigand made the reverse experiment. He first took careful counts of the number of nuclei in the air, then he created large quantities of dust by beating carpets, blowing up large clouds of coal, coke, and ordinary dust by means of bellows. Although he made such large clouds of dust that it was extremely unpleasant to work in them, he could not find any increase in the number of nuclei in his condensation apparatus.

In 1910, A. Wegener directed attention to another difficulty. The distance one can see through the atmosphere depends on the number of dust particles present and their size. From measurements made at Ben Nevis it had been found, from a comparison between the transparency of the atmosphere and the number of nuclei measured in Aitken's instrument, that the damper the air the less the number of nuclei necessary in order to see the same distance. The observations gave the following result:

TABLE III.

Depression of the Wet Bulb.	Number of Nuclei present in 1 c.c. with a Constant Distance of Vision.
1·1-2·2° C.	$1\cdot25\times10^4$
2·2-3·9	1·71
3·9-5·5	2·26

This can only be explained if the size of the dust particles increases as the humidity increases, even when the humidity is still far below its saturation value. But this is not an effect which one would expect if the only function of the dust particles is to act as nuclei, for there would be no condensation on them until the air has reached its saturation point. At all humidities less than 100 per cent. the dust particles would remain dry and therefore of constant size.

From these and other observations meteorologists have been led to the opinion that condensation does not commence on dust particles, if dust is to be understood in the ordinary way, but on hygroscopic substances, and that Aitken's instrument does not measure the number of dust particles present but the number of hygroscopic particles.

A great deal of work has recently been done on this question, especially by Köhler in Norway. Working on a mountain in the extreme north of Norway, Köhler analysed the water obtained from the large deposits of rime which formed on the surroundings of his observatory. Rime is frozen cloud particles, and in this way he was able to determine the chemical contents of the actual cloud particles before they had had time to become contaminated. He found that calcium chloride was always present, and concluded that sea-salt obtained from the spray of the sea forms the true nuclei of cloud condensation. His results indicate that when the drops are extremely small there is sufficient salt present to reduce the vapour pressure to the same extent as the small radius of the drop increases it, thus allowing condensation to take place. Köhler is tempted to generalise his results and to contend that sea-salt is the main foreign substance on which condensation takes place. It is, however, not necessary to go so far as this, for there are many other sources of hygroscopic substances. Lenard and Ramsaner have shown that sunlight—probably only the ultra-violet part—acts on the oxygen, nitrogen, and water vapour of the atmosphere, producing very hygroscopic substances.

Large quantities of material capable of becoming condensation nuclei are produced by all processes of combustion. Thus the household fires and factory chimneys of centres of industry produce vast quantities of nucleus-forming material, chief of which is sulphurous oxide, SO_2. This, when illuminated by sunlight in the atmosphere, is a very hygroscopic substance capable of causing condensation in unsaturated air. It is estimated that in England something like 5000 tons of sulphur are burnt each day in coal fires, giving enough sulphur products to pollute the atmosphere from Land's End to John o' Groat's. Other products of combustion are also hygroscopic; thus it is not surprising that air from large industrial centres contains enormous quantities of nuclei.

It is not necessary for hygroscopic particles to be large in order for water to be deposited upon them. Their chemical affinity for water is sufficiently large to counterbalance the surface tension forces which cause small pure-water particles to evaporate unless there is supersaturation. A single molecule of a hygroscopic substance would probably be able to gather around itself sufficient water to make a drop large enough to grow by ordinary condensation. Thus, whereas the hygroscopic properties are important to build up a drop to a certain size, after that size has once been reached the hygroscopic attraction may cease through excessive dilution, but condensation will continue until the drop is in equilibrium with the surrounding vapour.

The ordinary small ion, in my opinion, takes no part whatever in meteorological processes. Before any deposition of water can take place on small ions, four-fold supersaturation is necessary in the case of negative ions and six-fold in the case of positive ions. We have absolutely no evidence of anything like these supersaturations in the atmosphere, and I have shown at some length, in a paper published in the *Philosophical Magazine*, that even in the case of thunder-storms, in which the conditions are by far the most favourable for the formation of supersaturated air, small ions take no part in the condensation. Further, we have no evidence that small ions act like hygroscopic substances; they do not appear to grow appreciably in size in saturated air, in fact they act like any other air molecule until four-fold or six-fold supersaturation is actually reached.

With regard to large ions (Langevin ions), these do appear from Pollock's work to grow with increase of humidity; but, as Pollock found that they do not form in pure air, these ions are probably nothing more than ordinary hygroscopic nuclei, with a small ion attached.

Without detracting in any way from the value of Aitken's work, we see that it is necessary to revise his conclusions, and to say that hygroscopic substances and not dust form the nuclei of condensation. I do not think that Aitken would have been surprised at this development of his work, for he clearly recognised the importance of salt particles as efficient nuclei.

Condensation at Temperatures below the Freezing Point.

When the temperature of the air is below the freezing point, condensation of the contained water vapour is a still more difficult problem, for there is very little experimental evidence to go upon. One thing is certain: owing to the small amount of vapour present, it is inconceivable that condensation will take place by the fortuitous meeting of molecules; some kind of nuclei therefore will be necessary.

According to experiments made on crystallisation from supersaturated solutions, we may conclude that crystallisation does not start readily on a perfectly spherical surface. An angular nucleus is necessary, and the nearer the angles are to those of the natural angles of the crystal the more readily will condensation take place. When sledging in the Antarctic with Captain Scott in 1911 we became enveloped in a fog during sunshine. On the fog opposite the sun we saw a white bow in the position usually occupied by a rainbow. This phenomenon can only be explained on the assumption that the fog was composed of small spheres; but the temperature was $-29°$ C. ($-21°$ F.). We are quite familiar with super-cooled water drops which have been formed when liquid drops are cooled from temperatures above to temperatures below the freezing point. In this case there was no part of the atmosphere within hundreds of miles of the place of observation in which the temperature was above the freezing point, and almost a dead calm existed at the time; hence these drops could not have formed at a high temperature and then been super-cooled.

The only explanation which appears possible to me is that in the clear air of the Antarctic there are no "dust" particles suitable for condensation available, but there are plenty of the hygroscopic molecules of which we have already spoken. With increasing humidity these hygroscopic molecules attract water from the air and form clusters of water molecules; but we know from colloidal chemistry that such clusters are in the spheroidal and not in the crystalline form. If this explanation is correct we have real liquid drops and the vapour pressure in the air must be that appropriate to a water surface—we may neglect the curvature of the drops, as their radii were probably of the order of 0·001 cm. But according to Table II. air at $-30°$ C. is saturated with reference to ice at a relative humidity of 74 per cent., hence in this case the air was heavily supersaturated with reference to the solid state. This accounts for the fact, recorded at the time, that "the fur of the sleeping-bags and the wool of sweaters became covered with hoar frost," for these substances formed excellent nuclei for the condensation of the water vapour direct into the solid state.

Support for this explanation is given by observations made by Wegener in Greenland. He describes how, in temperatures below $-40°$ C. with perfectly clear air, a strip of fog started at the house and extended for several kilometres in the direction of the wind. At such temperatures condensation takes place on water at 100 per cent. relative humidity, but on ice or solid nuclei at 67 per cent. The actual humidity was between these limits, therefore the air was not saturated with reference to the hygroscopic nuclei, but was supersaturated with reference to solid nuclei. There were, however, none of the latter present in the pure free air, but the air escaping from the hut was highly charged with solid nuclei, chiefly the products of combustion, and when this contaminated air mixed with the pure air condensation took place and the long strip of mist resulted.

This observation furnishes the explanation of an old-standing difficulty in meteorological optics. Cirrus and other very high clouds frequently exhibit a most beautiful colour effect, which has received the name iridescent clouds, as the clouds appear to be iridescent with colours like those of mother-of-pearl. If cirrus clouds are always composed of ice particles, as one has generally concluded on account of the low temperature of the atmosphere where they form, the colours cannot be satisfactorily explained; but if they are composed of water drops the explanation is easy. If water drops can exist at $-30°$ C. near the earth's surface, there is no longer any reason to postulate ice crystals for the cirrus clouds; and we may now say definitely that iridescent clouds prove that cirrus clouds are sometimes composed of spherical water drops. But it also proves that air, especially in the upper atmosphere, is frequently devoid of solid nuclei on which condensation can take place.

Haze.—Perfectly pure air is almost completely transparent to visual light waves, and if the air were always pure we should see distant objects through air almost as clearly as through a vacuum. But the air is never pure; there are always more or less particles of foreign matter present. The action of these particles is two-fold: first, they reduce the amount of light reaching the eye from distant objects; and, secondly, in the day-time they scatter the general light of the sky and so send to the eye extraneous light which reduces the contrast between distant light and dark objects on which visibility depends. Generally this foreign matter consists of a mixture of solid ponderable particles and hygroscopic molecules. The latter in perfectly dry air would be practically invisible, but when loaded with water in a humid atmosphere they add to the obscurity of the atmosphere.

The amount of obscurity will therefore vary with the amount of solid matter and with the humidity of the air. Haze is due to this kind of obscurity, and varies in intensity from the slight obscurity of polar regions, which depends almost entirely on the hygroscopic particles, to the dense obscurity of a dust storm in tropical regions, which is due almost entirely to solid particles.

Mist.—When the temperature of air falls, the humidity increases until the saturation point is reached. The diameters of the hygroscopic particles grow, but even in saturated air the amount of water extracted is not great, and if there is little solid matter present the obscurity is not marked. But if the temperature falls below the dew point the hygroscopic particles are sufficiently large to form excellent nuclei for condensation, and relatively large amounts of water are deposited for small falls of temperature.

Real condensation has now commenced, and the obscurity changes from that of haze to that of mist. It has been a common practice to record atmospheric obscurity as haze when there is a noticeable difference between the readings of the wet- and dry-bulb thermometers, and as mist when the readings are the same. This, however, is not a true criterion, for the air can be saturated without condensation, while mist cannot be formed until water has been condensed on account of a fall of temperature after the dew point has been reached. The whole process of the formation of haze and mist is continuous, and in practice it is practically impossible to say when haze becomes mist, although extreme cases are easily distinguished. Nevertheless haze and mist are fundamentally different, for haze owes its origin to foreign matter, and the small amount of water associated with hygroscopic nuclei, while mist is due to an actual precipitation of water from vapour to liquid.

Fog.—There is, however, no fundamental difference between mist and fog: in most cases fog is only a dense mist, and the density at which mist becomes fog is a matter of definition. It is now the practice of the London Meteorological Office to limit fog to the obscurity in which objects at one kilometre are not visible.

When mist and fog are formed in fairly clear air they are white. On the other hand, if the air contains a large quantity of impurities, such as carbon particles from imperfect combustion, the mist particles absorb the impurities and become themselves dark-coloured. In this way are formed those dense fogs in London which are likened to pea soup. It was originally thought that the density of a London fog was due to the fact that the smoke of the city provided an unusually large number of nuclei on which condensation could take place, thus offering a temptation to the air to deposit its moisture which it could not resist. As a matter of fact, there are always sufficient nuclei in the purest air in England to allow of the formation of fog whenever the meteorological conditions are suitable. The relationship between smoke and fog is peculiar, and may be said to be accidental. The meteorological conditions which are necessary for the formation of fog are such that while they last smoke cannot get away either vertically or horizontally from the place of its origin. Above the fog there is a temperature inversion which effectively prevents all upward motion of either air or smoke, while fogs over the land usually form in calm air. Thus during a fog practically all the smoke which London makes is kept over it and within a few hundred feet of the ground. This smoke, combined with the deposited water, can, as we all know, produce such an obscurity that midday is as dark as midnight. The total abolition of smoke from London would not reduce the occasions on which mist and fog occur, but many fogs would remain mists, and we should never have a "London particular."

For the formation of mist and fog it is necessary that the temperature of the air should continue to fall after the dew point of the air has been reached. The extent of the fall below the original dew point determines the density of the obscurity, neglecting for the moment the effect of impurities. This cooling can be brought about in several ways, of which only two are of real importance. Fogs may be caused by warm air blowing over a cold sea or a cold land surface, and the method by which the temperature of the air is then reduced on account of turbulence was first explained in a brilliant paper by G. I. Taylor, which has become a meteorological classic. The fogs of London are, however, almost entirely due to the loss of heat from the lower layers of the atmosphere into a clear sky above. The air radiates its heat, its temperature falls, and condensation takes place as already described. Other methods of fog formation, such as the mixing of warm and cold air, are of secondary importance and never give rise to more than patchy local mists or light fogs.

Clouds.—Adiabatic cooling plays no part in the formation of mists and fogs, because the pressure changes in any given layer of the atmosphere are relatively small and slow. Appreciable adiabatic cooling can take place only when air is raised in the atmosphere, and then the cooling may be large and rapid.

When air not saturated rises in the atmosphere its temperature is reduced by about 1° C. for every 100 metres of ascent. When the ascent is carried far enough the dew point is reached, after which any further rise will cause condensation on the nuclei present. As the ascent is carried beyond the point of condensation more and more water is deposited, with a consequent increase in the size of the drops. This is the manner in which clouds are formed, and there are very good reasons for saying that it is the only way. Thus there is a fundamental difference between the method of formation of clouds and fogs: fogs form without any ascent of the air, while clouds are never formed without it. Thus it is not correct to describe clouds as fogs of the upper atmosphere.

The very sharp line of demarcation between the air under a cloud and the cloud itself needs explanation. There is no slow transition between the clear air and the cloudy air, as one would expect if clouds were due to the gradual increase in the size of drops from small nuclei to relatively large cloud particles. We must picture the hygroscopic nuclei collecting more and more water around them as they rise with the ascending current, owing to the increase in relative humidity. But when saturation is reached they are still very small, say about $1 \cdot 1 \times 10^{-5}$ cm., that is, they are smaller than the wave lengths of light (5×10^{-5} cm.), and therefore cannot be directly observed, and produce little obscurity in the air, which still appears relatively clear. Drops of this size need supersaturation to grow, but we see from Table I. that only 1 per cent. supersaturation is necessary. They are, however, unstable, for as they grow they need less supersaturation. Thus as soon as the air is sufficiently supersaturated to be in equilibrium with the nuclei the slightest further rise causes the drops to grow very rapidly to the size in which they are in equilibrium with saturated air. The height at which this change occurs is the height of the base of the cloud.

Rain.—Before we are able to form a clear idea of the processes which give rise to rainfall it will be necessary to consider the laws of the fall of water drops through the air.

It is well known that in a vacuum all bodies fall at the same rate with a constant acceleration, so that their velocity constantly increases. When, however, bodies fall through a resisting medium, such as air, they more or less quickly reach such a velocity that the resistance of the air equals the pull of gravity, after which they fall with a constant velocity, which is different according to the density and shape of the falling bodies.

Experiments have been made to determine the rate of fall of water drops through air at atmospheric pressure, and the following "end velocities" have been found.

Table IV.

Radius, cm.	Velocity calculated by Stokes, cm./sec.	Velocity observed by Schmidt, cm./sec.	Velocity observed by Lenard, cm. sec.
0·0005	0·3	..	..
0·001	1·3	..	..
0·005	32	..	..
0·010	126	..	..
0·020	..	180	..
0·030	..	270	..
0·040	..	340	..
0·050	..	393	440
0·100	..	577	590
0·150	..	692	690
0·175	..	740	737
0·225	..	..	805
0·273	..	..	798
0·318	..	..	780

Three important points are to be noticed about these results.

(*a*) The extremely small velocities with which small drops fall. The average radius of the drops in clouds from which rain is not falling is approximately 0·001 cm. Such particles, according to our table, would fall only at the rate of a little over a centimetre a second.

(*b*) As the drops get larger the rate of fall tends to a constant value of about 8 metres a second.

(*c*) Drops for which $r = 0{\cdot}25$ cm. have the most rapid fall, larger drops fall more slowly.

Lenard has given the reason for (*c*). He showed that the friction on the air causes deformation of the drops, so that instead of retaining the shape of spheres they become flattened out, thus presenting an increased resistance to the air through which they are falling. This deformation becomes appreciable when the radius of a drop is about 0·2 cm. and then increases rapidly as the drop grows larger. When the radius is about 0·25 cm. and the drop is falling at the rate of 8 metres a second, any further increase in volume produces a greater flattening, and instead of the velocity being increased it is slightly decreased. When the size of the drop is such that if it were not flattened it would have a diameter of about half a centimetre, $r = 0{\cdot}25$ cm., the drop becomes very unstable, and all drops larger than this quickly break up into a number of smaller drops, which of course fall more slowly. This means that raindrops can never fall through air at a greater velocity than 8 metres a second. Small drops fall slower than this, and large drops flatten out as soon as they are falling at 8 metres a second, and then soon break up into smaller drops.

In the above all the velocities have been given for air at normal pressure. If, however, the pressure is less, all the results are the same, except that the velocities must be increased in the proportion $\sqrt{B}/\sqrt{P}$, in which B is the normal pressure and P the actual pressure.

Dines has found that in Europe the quantity of vapour in air is always very small. If the whole water vapour in the atmosphere on an average summer day were precipitated it would only give a total rainfall of 0·80 in. The greatest amount ever measured on a summer day in Europe would only give 1·5 in. of rain, and of course the quantity is much less in winter. How then can we have rainfall of several inches of rain in the course of an hour or so? The answer is simple: the ascending currents which are necessary to cause precipitation carry with them their own water vapour to supply the rainfall. An ascending current of air which is saturated at 10° C. (50° F.) needs only an upward velocity of 1 metre a second to carry with it sufficient vapour to give a rainfall of more than 1 inch per hour, so that there is no difficulty in explaining the greatest rate of rainfall ever experienced in the tropics.

There are many ways in which the air is caused to rise in the atmosphere; ascending currents up to many metres a second are possible, and do occur in the atmosphere. Let us think of air rising at about 10 cm. per second, which is the order of the upward velocity of the air in depressions. At a certain height cloud particles form as already described. These have a radius of about 0·001 cm. and fall relatively to the air at 1·3 cm. per sec., hence they are carried upwards with the air, but the base of the cloud remains at the same height because new cloud particles are constantly being formed at that height. As the air rises the cloud particles grow in size, because water is being condensed on them, and they lag more and more behind the air. Drops with a radius of 0·002 cm. are falling as rapidly as the air is rising, and therefore remain stationary, while drops of 0·007 cm. are falling at the rate of one metre a second, and therefore fall through the rising air and appear at the earth's surface as rain. It is obvious that this process will continue as long as the ascending currents continue, and in this way we get the continuous steady rain with which we are so familiar in this country.

The rate of rainfall will increase as the upward velocity of the ascending air increases until the upward velocity becomes greater than 8 metres a second. When this occurs no water can fall through the ascending air for the reason already explained. All water condensed in such an upward current—and it will be a very large amount—is carried upwards until the upward air velocity falls below 8 metres a second, as it is bound to do at some height owing to lateral spreading out. Here water accumulates in large amounts. It is the sudden cessation of the upward velocity in such an ascending current which gives rise to the so-called cloud-bursts, for when the sustaining current stops the accumulated water falls just as though the cloud had literally burst.

The accumulated water while it is suspended in the air is constantly going through the process of coalescing into large drops, which at once become deformed and broken up again into small drops. Every time a drop breaks there is a separation of electricity, and this is probably the chief source of electricity in a thunderstorm. This explains why thunder-storms are associated with heavy rainfall and do not occur in polar regions where there is no rain.

Hail.—I have already explained how the small liquid cloud particles are carried upwards with the ascending air, but as the air rises its temperature constantly falls, and there must come a point in the ascent when the temperature falls below the freezing point. The cloud particles do not immediately turn into ice. As a matter of fact it is not an easy matter to freeze perfectly pure water, and water can remain liquid at temperatures far below the freezing point. Observations made on mountains and in balloons and aeroplanes have proved conclusively that cloud particles remain liquid at temperatures so low as −20° C. How far small drops can be super-cooled before they solidify we do not know, but super-cooled drops are in a very unstable state. From Table II. we see that at −20° C.

ice forms when the relative humidity over water is 82 per cent., which means that if water and ice are simultaneously present the relative humidity of the air relative to the ice is 121 per cent., *i.e.* it is 21 per cent. supersaturated. Thus if a few drops become converted into ice they are in a highly supersaturated atmosphere, and so will grow rapidly at the expense of the water drops. Meteorologists generally consider that $-20°$ C. is about the limit at which large water particles can exist without changing into ice.

Let us consider a region in the atmosphere through which there is an ascending current of air. The air is supposed to have a temperature of 20° C., and a relative humidity of about 50 per cent. at the ground. As the air rises, at first its temperature is reduced by 1° C. for each 100 metres of ascent. Hence by the time it has risen 1000 metres its temperature will have been reduced to 10° C., and it will have reached its dew point. Here the cloud level begins. As it rises still further its temperature continues to decrease, but not so rapidly as before, because the condensation of water vapour releases the latent heat of vaporisation. It reaches 0° C. at a height of 3000 metres. Hence the region between 1000 and 3000 metres contains only drops of water. As the air rises above 3000 metres the temperature falls still lower, but the water particles do not freeze at once, they remain super-cooled. We may assume that at $-20°$ C., which is reached at about 6000 metres, the super-cooled drops solidify and the remaining part of the cloud above this level is composed of snow alone.

There will not be a sharp division between the region of super-cooled water and the region of snow. For a certain distance ice crystals and super-cooled water will be mixed together. Such conditions are very unstable, and from considerations of the vapour pressure alone the ice particles grow rapidly, because the vapour over super-cooled water is highly supersaturated with respect to ice. In addition, the slightest contact between ice and super-cooled water causes the latter to solidify at once. The original ice particle will therefore quickly grow in size and, if the ascending current is not too large, will commence to fall. It has, however, to fall through 3000 metres of super-cooled water drops, and in doing so grows appreciably in size. As each super-cooled water particle strikes the ice it solidifies, and also imprisons a certain amount of air, so that by the time the ice particle reaches the bottom of the super-cooled region it is simply a ball of soft white ice without any sign of regular crystalline structure.

If the descent through the super-cooled region has been fairly rapid the temperature of the ice ball will be considerably below the freezing point when it arrives in the region where the temperature is 0° C., and the cloud particles are not super-cooled. As it continues its way downwards it receives a considerable addition of water: in the first place, by direct deposition, because it is colder than the air; and, secondly, by collision with the water particles. This water covers the surface of the cold ice ball with a uniform layer of liquid which quickly freezes into clear solid ice, with little or no imprisoned air. Finally the ice escapes from the bottom of the cloud, and falls to the ground as a hailstone.

When hailstones are split open to show their internal structure we can nearly always see the inner soft white mass of ice which was collected while the stones were in the super-cooled region, surrounded by a layer of clear transparent ice formed by the freezing of the water deposited when the stone was passing through the non-super-cooled region.

This simple explanation of the formation of a hailstone was not considered satisfactory at first, because it was considered that hailstones produced in this way must necessarily be small. Trabert calculated that if a hailstone started to fall from a height of 2 kilometres, and swept up all the water it met on its way down, its radius would grow only by 2 millimetres. But Trabert left many things out of consideration, as pointed out by Wegener. In the first place, he started his hailstone much too low in the atmosphere: he should have started it from a height nearer 8 kilometres than 2. Secondly, he neglected the effect of the ascending currents. We know that there are violent ascending currents during thunder-storms, in which alone hailstones are formed. The ascending currents may be so violent that even large hailstones will not be able to fall through them, but they are all the time falling rapidly relatively to the air, and therefore sweeping water out of it.

The velocity with which a hailstone falls through still air at atmospheric pressure is

$$v = 1246\sqrt{r} \text{ cm./sec.}$$

If, therefore, the velocity of the ascending current were 10 metres per second, the hailstone could not commence to fall until it had a radius of 0·64 cm. It would then commence to fall very slowly as its size grew larger, but it would all the time be moving relatively to the air at a greater rate than 10 metres a second. Thus the effective height through which it would fall would be very great in comparison with the actual height.

It must also be remembered that with such an ascending current no water could fall in the form of rain; all the water would be retained in the cloud, the water content of which could be very large indeed, thus giving large quantities of water to be swept up by the hailstone. When we also take into account that a hailstone is generally very much colder than the surrounding saturated air, so that the deposition of moisture on it from the vapour would be large, there is no difficulty in explaining the size of all ordinary hailstones.

It must not be considered, however, that an ascending current is steady. Just as we have gusts and lulls in horizontal winds, so we have increases and decreases in the velocity of ascending currents. Thus a hailstone which has penetrated into the lower part of the cloud might be blown upwards and so go through the whole process again. In this case we should have a layer of white ice deposited around the clear layer, around which again there would be another layer of clear ice. In fact, if a hailstone is held by the ascending currents near to the region where the temperature is 0° C., it might well be carried up and down between the regions where the water is super-cooled and where it is not several times. We should then have several concentric layers of clear and white ice, and a broken stone would have the appearance of an onion. Such cases are not at all uncommon.

For the formation of hailstones two conditions must be fulfilled.

(*a*) The clouds must extend through a great vertical height so that the three regions of water particles, super-cooled particles, and snow are extensive and well developed.

(*b*) There must be violent ascending currents, otherwise the stones would fall too rapidly to grow to a large size.

These conditions are best fulfilled in warm regions, for there violent ascending currents are most easily developed, and the condensation starts at a relatively high temperature, so giving regions of water particles and super-cooled water particles of great depth. These are the reasons why hailstones only occur during the summer in temperate regions, and why the most violent hailstorms and the largest hailstones are found in tropical regions.

Soft Hail.—If the temperature at the ground were much lower than in the case just considered, the region between the bottom of the cloud layer and the zero isothermal would be much reduced. It is in this region that the hailstone receives its coat of clear transparent ice. The hailstones which then fall would be relatively small, and consist only of the soft white balls appearing in the centre of the more complete hailstones.

Falls of soft hail of this nature are quite common in the winter in Europe and in the hills of India; there are frequently falls of soft hail during the winter and spring in Simla. The reason is clear, for in Europe the temperature of the ascending current is so low that the freezing point is reached almost at the bottom of the cloud, while in Simla the clouds form over the plains, and Simla itself is so high that the region in which water particles exist is mainly below the station. Thus the hail which falls in Europe during the winter and in the hills of India falls almost immediately out of the region of super-cooled water particles, and therefore has had no opportunity for building up a layer of transparent ice.

The form of these soft hailstones is most instructive. In most cases they are like cones with a hemispherical base. It is clear from this form that as they have fallen through the super-cooled region they have struck the water particles on their under sides. This has caused the bases to grow, and the cone above is really the shape of the stream-lines behind the enlarged base. A stone which has once commenced to have this form will retain it throughout, for the cone acts as a kind of tail and tends to keep the base always at right angles to the relative air motion.

Snow.—Snow which forms over an ascending air current in which water particles first form will probably have solidified cloud particles for nuclei. Whatever the nuclei may be, as soon as the initial crystals are formed further condensation takes place exactly as in the precipitation of water, but the vapour condenses directly into the solid state without first going through the liquid state. The crystals of water are hexagonal prisms, and water in the crystalline state in the atmosphere shows all the wonderful shapes that this form of crystallisation can take. Having once started, the crystals may grow either along their central axis, giving rise to long thin prisms, or along their six axes to form hexagonal plates.

Sometimes the growth is uniform, so that the result is a perfect hexagonal plate, at others the growth along the axes is more rapid than in the space between; this gives rise to stars, having a beautiful feathery appearance. The actual crystals vary in size, from minute crystals which can scarcely be seen by the naked eye to plates a quarter of an inch in diameter. In cold regions the crystals are small, because there is little water vapour present from which they can grow. In the Antarctic during the winter, when the temperature was always near or below 0° F., only the smallest crystals were seen, so small that they were almost like dust.

When crystals form at temperatures near the freezing point they grow to their largest size. When the air is full of large crystals frequent collisions take place. The crystals become interlocked and bundles of many separate crystals are formed; these produce the ordinary snowflakes which, on account of their size and weight, fall relatively rapidly. It is to these latter that the term snow should be applied. With this restriction, snow occurs only when the temperature is near the freezing point.

The Interior of a Star.[1]

By Prof. A. S. Eddington, F.R.S.

On December 13, 1920, the angular diameter of a star was measured for the first time in history with an apparatus devised by Prof. A. A. Michelson. Hitherto every star had appeared as a mere point of light, and no test had been able to differentiate it from a geometrical point. But on that eventful evening a 20-foot interferometer constructed at the Mt. Wilson Observatory was turned on the star Betelgeuse, and the measurement revealed that this star had a disc $\frac{1}{20}$ of a second of arc in diameter—about the size of a halfpenny 50 miles away. The distance of Betelgeuse is known roughly (unfortunately it cannot be found so accurately as the distances of many stars), so that we can convert this apparent size into approximate actual size. Betelgeuse is not less than 200 million miles in diameter. The orbit of the earth could be placed entirely inside it.

The stars are thus not limited to objects of comparatively small bulk like the sun; there are among them individuals truly gigantic in comparison. We can add another step to the astronomical multiplication table—a million earths make one sun; ten million suns make one Betelgeuse. This is a comparison of volume, not of amount of material. It leaves open the question whether, in order to obtain one of these giants, we should take the material of ten million suns rolled into one, or whether we should take the material of the sun and inflate it to ten million times its present size. There is no doubt that the latter answer is nearer the truth. Betelgeuse, I admit, contains more matter than the sun (perhaps 50 times as much); but in the main its vast bulk is due to the diffuseness with which this material is spread out. It is a great balloon of low density, much more tenuous than air, whereas in the sun the material is compressed to a density greater than water.

Whether the star is one of these balloon-like bodies or whether it is dense like the sun depends on the stage of its life at which we catch it. It is natural to think that the stars gradually condense out of diffuse material, so that they become denser and denser as their life-history proceeds. We can now see in the heavens samples of every stage in the development of a star. The majority of those seen with the naked eye are in the early diffuse state; that is not because these young stars are really more numerous, but because their great bulk renders them brighter and more conspicuous. What I shall have to say about the inside of a star refers chiefly to the young diffuse stars—the *giant stars* as they are called. The reason is that we understand much more about the properties of matter when it is in the condition of a perfect gas than when it is condensed; although the difficulties of treating a dense star like the sun are not insuperable, we have naturally made the most progress with the easier problem of giant stars.

Internal Temperatures.

We only observe the physical conditions at the surface of a star, and at first it might seem impossible to learn anything about the conditions in the interior. Consider, for example, the question of temperature. The nature of the light received from Betelgeuse teaches us that the temperature is 3000° C.—not an extravagantly high temperature judged even by terrestrial standards. But this refers, of course, to the layer near the surface from which the observed light is coming; it is just the marginal temperature of the furnace affording no idea of the terrific heat within. I shall not attempt to explain in detail how we manage to calculate the inside temperatures; but I can perhaps show that there is a clue which can be followed up by appropriate mathematical methods.

Elasticity is a well-known property of a gas, familiar to everybody through its practical application in the pneumatic tyre. What gives the gas its elasticity or expansive force is its heat, that is to say, the energy of motion of its molecules hastening in all directions and continually tending to spread apart. The greater the heat the greater the expansive force. Now at any point inside the star a certain condition of balance must be reached; on one hand we have the weight of all the layers above pressing down and trying to squeeze closer the gas inside; on the other hand we have the elasticity of this inside gas trying to expand and force the upper layers outwards. Since neither one thing nor the other happens and the star remains practically unchanged for hundreds of years, we must conclude that these two tendencies just balance. At each point the elasticity and therefore the heat has to be of the exact amount needed to bear the weight of the layers above. That is the principal clue by which we determine how much heat there must be at various depths inside the star.

The internal temperature depends on the particular star considered, but it is generally from 2 to 20 million degrees at the centre. Do not imagine that this is a degree of heat so vast that ordinary conceptions of temperature have broken down. These temperatures are to be taken quite literally. Temperature is a mode of describing the speed of motion of the ultimate

[1] Discourse delivered at the Royal Institution on February 23.

particles of the matter. In a mass of helium at ordinary temperatures the average speed of the atoms is rather less than 1 mile per second; at 4 million degrees it is 100 miles per second. This is a high speed, but not a speed to feel uncomfortable over. Sir Ernest Rutherford describes atoms of helium moving at the rate of 100,000 miles a second. I cannot vie with him. I usually find that my physical colleagues are rather disappointed with our jog-trot atoms in the stars.

Material and Ætherial Heat.

We must imagine then a typical giant star as a mass of material with average density about that of air swollen to at least a thousand times the bulk of the sun. The atoms of which it consists are rushing in all directions with speeds up to 100 miles a second, continually colliding and changing their courses. Each atom is being continually pulled inwards by the gravitation of the whole mass, and as continually boosted out again by collision with atoms below. The energy of this atomic motion constitutes a great store of heat contained in the star; but this is only part of the store. The star contains a store of another kind of heat—ætherial heat, or æther-waves like those which bring to us the sun's heat across 90 million miles of vacant space. These waves also are hastening in all directions inside the star. They are encaged by the material, which prevents them leaking into outer space except at a slow rate. An æther-wave making for freedom is caught and absorbed by an atom, flung out in a new direction, and passed from atom to atom; it may thread the maze for hundreds of years until by accident it finds itself at the star's surface, free now to travel through space indefinitely, or until it ultimately reaches some distant world, and perchance entering the eye of an astronomer, makes known to him that a star is shining.

The possession of this double store of heat is a condition which we do not encounter in any of the hot bodies more familiar to us. It is a new phase of matter beyond the reach of laboratory experiment, although happily the theory is so simple that there cannot be much uncertainty as to behaviour. It is true that a red-hot mass of iron contains a little of this ætherial heat in addition to the heat comprised in the motion of its molecules, but it is less than a billionth part of the whole. Only in the giant stars does the ætherial portion rise to importance. A red-hot metal emits ætherial heat, but it keeps no appreciable store; it converts the material heat into this form as it is required for use. The star rejects this hand-to-mouth method; and although it is continually changing elements of heat from one form to the other, it keeps a thousand years' supply always in readiness and emits its radiation by leaking ætherial heat from the store. In older theories this feature was not realised; it was supposed that convection currents must exist continually bringing up hot matter from the interior to replace the surface-matter which had radiated and cooled. Now it is seen that the difficulty is rather in the other direction—how does the star dam back the store of æther-waves so that they do not escape from it faster than we observe? This change of view has necessitated modifications of the older theories of Lane and others, and has on the whole considerably simplified the problem.

In the hot bodies of the laboratory the heat is almost entirely in the material form, the ætherial portion being insignificant. In the giant stars the heat is divided between the two forms in roughly equal amounts. Can we not imagine a third condition in which this time the heat is almost wholly ætherial, the material portion being insignificant? We can imagine it, no doubt; but the interesting, and I believe significant, thing is that we do not find it in Nature.

Light Pressure.

You have heard of the pressure of light—that light actually has mass and weight and momentum and exerts a minute pressure on any object which obstructs it. A beam of light or æther-waves is like a wind, a very minute wind as a rule; but the intense ætherial energy inside the star makes a strong wind. This wind distends the star. It bears to some extent the weight of the layers overhead, leaving less for the elasticity of the gas to bear. That, of course, has to be taken into account in our calculation of the internal temperatures—making them lower than the older theory supposed. Just as æther and matter share the heat-energy between them, so the ætherial wind and the material elasticity share the burden of supporting the weight of the layers above. We are able to calculate the proportions in which they share it. To a first approximation the same proportion holds throughout nearly the whole interior, and the proportion depends only on the total mass of the star—not on the density or even on the chemical composition of the material. Moreover, in order to make this calculation we do not need any astronomical knowledge; all the constants in the formula have been determined by the physicist in his laboratory. We need to know the average molecular weight of the material, but I shall tell you later how we are able to fix that approximately in spite of not knowing what elements to expect in the star's interior; that happens to be one of the benefits of dealing with very high temperatures.

Let us imagine a physicist on a cloud-bound planet, who has never heard tell of the stars, setting to work to make these calculations for globes of gas of various dimensions. Let him start with a globe containing 10 grams, then 100 grams, 1000 grams, and so on, so that his *n*th globe contains 10^n grams. They mount up in size rather rapidly. No. 1 is about the weight of a letter; No. 5, a man; No. 8, an airship; No. 10, an ocean liner; after that comparisons are difficult to find. The following table gives part of his results:

No. of Globe.	Ætherial Pressure.	Material Pressure.
30	0·00000016	0·99999984
31	0·000016	0·999984
32	0·0016	0·9984
33	0·106	0·894
34	0·570	0·430
35	0·850	0·150
36	0·951	0·049
37	0·984	0·016
38	0·9951	0·0049
39	0·9984	0·0016
40	0·99951	0·00049

It is obvious why I omit the rest of the table; it consists of long strings of 0's and 9's. But for the 33rd, 34th, and 35th globes the table becomes interesting; and then lapses back into 9's and 0's again. Regarded as a tussle between æther and matter to control the situation, the contest is too one-sided to be interesting, except just from Nos. 33 to 35, where something more exciting may be expected.

Now let us draw aside the veil of cloud behind which our physicist has been working and let him look up into the skies. He will find there a thousand million globes of gas all of mass between the 33rd and 35th globes. The lightest known star comes just below the 33rd globe; the heaviest known star is just beyond the 35th globe. The vast majority are between Nos. 33 and 34. just where the ætherial pressure begins to be an important factor in the situation.

It is a remarkable fact that the matter of the universe has aggregated primarily into units of nearly constant mass. The stars differ from one another in brightness, density, temperature, etc., very widely; but they all contain, roughly, the same amount of material. With a few exceptions they range from ½ to 5 times the mass of the sun. I think we can no longer be in serious doubt as to the general cause of this, although the details of the explanation may be difficult. Gravitation is the force which condenses matter; it would if unresisted draw more and more matter together, building globes of enormous size. Against this, ætherial pressure is the main disruptive force (doubtless assisted by the centrifugal force of the star's rotation); its function is to prevent the accumulation of large masses. But this resistance, as we see, only begins to be serious when the mass has already nearly reached the 33rd globe; and if indeed it is efficacious, it will stop the accumulation before the 35th globe is reached, because by then it has practically completely ousted its more passive partner (material pressure). We do not need to know exactly how strong the resistance must be in order to prevent the accumulation, because, when once the resistance begins to be appreciable, it increases very rapidly and will very soon reach whatever value is required. All over the universe the masses of the stars bear witness that the gravitational aggregation proceeded just to the point at which the opposing force was called into play and became too strong for it.

Ascending and Descending Temperature Stages.

It was shown by Homer Lane in 1870 that as a gaseous star contracts its temperature will rise. Betelgeuse is typical of the first stage when the temperature has risen just far enough for the star to be luminous. It will go on contracting and becoming hotter, its light changing from red to yellow and then to white. But evidently this cannot go on indefinitely. When the condensation has proceeded far enough the material will be too dense to follow the laws of a perfect gas. A different law then begins to take control. The rise of temperature becomes less rapid, is checked, and finally the temperature falls. We can calculate that the greatest temperature is reached at a density of about ¼ to ⅓ that of water. The sun is denser than water, so that it has passed the summit and is in the stage of falling temperature. So long as the temperature is rising the brightness of the star scarcely changes. It is becoming hotter, but smaller. Calculation shows that the increased output of light and heat per square metre of surface, and the decreased area of the surface, very nearly counteract one another, so that the total output remains fairly steady. But on the downward path the falling temperature and diminishing surface both reduce the light, which falls off rapidly between the successive stages or types which we recognise. That is entirely in accordance with what is observed to happen.

Taking any level of temperature, a star will pass through it twice, once ascending and once descending. In the main we have been in the habit of classifying stars according to their surface temperature, because it is on this that the spectral characteristics of the light, its colour, and the chemical elements revealed, chiefly depend. But that classification mixes together stars from an early ascending stage and from a later descending stage. For example, a star like Betelgeuse just beginning its career is put in the same class with a dense red star which has run its course and reached its second childhood. They are both red stars of low temperature, and that was good enough for the early attempts at classification. Sir Norman Lockyer always stoutly maintained the existence of the ascending and descending series; but he was almost alone among spectroscopists in this. He did not actually succeed in separating the ascending and descending stars though sometimes he came very near to the right criterion. We owe to Russell and Hertzsprung the actual separation. They discovered it not by spectroscopy, but by measuring the absolute brightness of stars; the greater brightness of the ascending stars, due to their large bulk, easily distinguishes them from the descending stars, at any rate in the low-temperature groups. At the highest temperatures the two series merge into one another.

The disentangling of the two series, and the recognition of the true sequence of stellar evolution, is probably the most revolutionary and far-reaching of recent discoveries in stellar physics. It began to oust the older view about 1914, and it is worth noticing that the discovery was made from observations coming under the province of the older astronomy and not what is generally called astrophysics. The data were parallaxes, proper motions, double star orbits, etc. The spectroscopists had been misled as to the order of evolution, and it was left to the rival branch of astronomy to show the way; but they were not to be outdone for long. Adams and Kohlschütter have found an easy spectroscopic method for distinguishing the ascending and descending stars. Although our main purpose now is to grope in the interior of a star, perhaps we may emerge at the surface for a moment to consider what is the difference of surface condition of a diffuse and condensed star, respectively, which enables the spectroscope to distinguish between them.

Surface Conditions.

The state of the outermost layers of a star can, it would seem, be influenced by two factors only, (1) the intensity of the stream of radiant energy crossing through them and (2) the intensity of gravitational attraction holding them to the star. The former is measured by the effective temperature, so that we have the two variable factors, temperature and gravity. The spectrum presumably will vary as the conditions governed by these factors vary. We must not expect to be able to classify the spectra accurately in a single sequence; they can vary in two directions. The ordinary classification depends principally on the temperature factor; we may call this the longitudinal sequence. Adams's new method aims at disentangling the transverse sequence corresponding principally to the gravity factor. We may say that his method is really a way of finding the value of gravity at the surface of a star, although it is not yet possible to put the value into actual numbers. Clearly, gravity will be smaller in the diffuse stage than in the dense stage on account of the greater distance from the centre to the surface.

The effect of lowering gravity is to make the density smaller at corresponding temperature. This introduces an important change in the state of the gas, namely, ionisation. At moderately high temperatures the atoms begin to lose one or more of their most loosely attached electrons, a process called ionisation. Ionisation is facilitated by low density and prevented by high density. The theory of ionisation in stellar atmospheres has been chiefly worked out by M. N. Saha, who has arrived at many interesting results. Here we need only remark that the ionised atoms give rise to different spectra, which have long been distinguished from the spectra of the neutral atoms. The lower density in the atmosphere of diffuse stars should strengthen the "enhanced" lines due to ionised atoms, compared with the "arc" lines due to neutral atoms. The difference in general is not very large, but the atoms of certain elements for which the conditions are most critical, are specially sensitive to the change of density. This is the criterion which Adams and Kohlschütter found empirically, and it distinguishes quite easily the ascending and descending series. To a limited extent it also distinguishes the larger and smaller stars within the same series.

Although the stars begin to shine on reaching a temperature of about 3000° and return to this temperature at the close of their luminous existence, they do not all climb the temperature-ladder to the same height. The more massive stars climb higher than the light stars. We can to some extent calculate the height to which they will go; but I am afraid the figures at present are very uncertain, though there is hope of improving them before long. The sun's surface temperature is now about 5900°; I do not think that it ever went higher than 6600°; it had not sufficient mass to go beyond. Sirius, nearly 2½ times as massive as the sun, has climbed to 11,000°, and at the moment is practically at its maximum, having only just turned downward. Still hotter stars like Rigel are known, and these must be more massive still. At the other end of the scale a star of mass less than 1/7 of the sun would not be able to reach 3000°, and could scarcely be luminous; but in any case such small masses would be formed very seldom, for the reason explained earlier in this lecture. It is a well-known fact that hot stars on the average are more massive than cool stars; we see that this is accounted for by the smaller stars being weeded out as the temperature-standard is raised.

Atoms and Electrons.

We have hitherto pictured the inside of a star as a hurly-burly of atoms and æther-waves. We must now introduce a third population to join in the dance. There are vast numbers of free electrons—unattached units of negative electricity. More numerous than the atoms, the electrons dash about with a hundred-fold higher velocity—corresponding to their small mass, which is only 1/1850 of a hydrogen atom. These electrons have come out of the atoms, having broken loose at the high temperature here involved. An atom has been compared to a miniature solar system; a composite central nucleus carrying positive charge corresponds to the sun, and round it revolve in circular and elliptic orbits a number of negative electrons at comparatively large distances corresponding to the planets. We know the number of satellite electrons for each element; sodium has 11, iron 26, tin 50, uranium 92. Our own solar system with 8 revolving planets represents an atom of oxygen. The thermodynamical theory due mainly to Nernst permits us to calculate roughly how many of these break loose under given conditions of temperature and density; and in a typical star a large proportion of them must have become free.

This condition solves for us our chief difficulty as to the molecular weight of stellar material. We need to know it in order to perform our calculations as to the state of the star; and at first sight it might seem hopeless to arrive at the molecular weight without knowing the elements which constitute the bulk of the material. But suppose first that the temperature is so high that all the satellite electrons have broken away. An atom of sodium will have separated into 12 particles, namely, 11 electrons and 1 mutilated atom; its atomic weight 23 is divided between 12 independent particles, so that the average weight of each is $23/12 = 1{\cdot}92$. Next take iron: the atomic weight 56 is divided between 27 particles; average 2·07. For tin we have 119 divided by 51; average 2·34. For uranium, 238 divided by 93; average 2·56. It scarcely matters what element we take; the average weight of the ultimate particles (which is what we mean by the molecular weight) is always somewhere about 2. If only the stars were a bit hotter than they actually are, it would make our task very easy. Unfortunately, they are not hot enough to give complete separation, and the actual degree of separation will depend on the temperature of the star, thus introducing a difficult complication. Generally at least half the electrons are detached and the molecular weight must be taken as between 3 and 4. I hope that the theory of this dissociation of electrons will be improved, because at present it is the chief bar to rapid progress with the theory of stellar constitution. It is a great help to know that the molecular weight is between 3 and 4; but we have reached a stage when it is becoming necessary for progress to know it for each star within much closer limits.

Brightness and Mass.

We pictured a physicist on a cloud-bound planet who was able from laboratory data to predict how large would be the masses into which the material of the universe must aggregate. Let us now set him a harder task. We inform him that we have observed these masses of gas, and, choosing one equal, say, to his 34th sphere, we ask him to predict how brightly it will shine. I have already mentioned that the star keeps practically the same brightness so long as it is a perfect gas ascending in temperature, so it should not be necessary to give the physicist any data except the precise mass. To use the same plan as before, we imagine a series of lamps of 10 candle-power, 100 candle-power, 1000, and so on; and his task is to pick out which lamp in this series corresponds approximately to the star. I believe that it is now possible for him to perform this task and to pick out (correctly) the 31st lamp. But for this purpose it is not enough that he should know all about the heat stored in the interior of the star; the brightness of the star depends on the rate at which the æther-waves are leaking out, and that introduces a new subject—the obstructive power of the material atoms which dam back the radiant flow.

Another name for this obstructive power is *opacity*. A substance which strongly obstructs the passage of light and heat waves is said to be opaque. The rising temperature towards the centre of the star urges the heat to flow outwards to the lower temperature level; the opacity of the material hinders this flow. The struggle between these two factors decides how much light and heat will flow out. We have calculated the internal temperature-distribution, so that we know all about the first factor; if then we can observe the outward flow which occurs, that should settle the value of the second factor—the opacity. The outward flow is capable of observation because it constitutes the heat and light sent to us by the star.

One of the troubles of astronomy is that our information about the stars is so scattered. We know the mass of one star very accurately, but we do not know its absolute brightness; we know the brightness of another but not its mass; for a third we may have an accurate knowledge of the density but nothing else. For Sirius, Procyon, and α Centauri our knowledge is fairly complete and accurate; but not any of these are giant stars in the state of a perfect gas, and they are therefore useless for the present discussion. But within the last year we have been fortunate enough to obtain complete and very accurate information for one of the giant stars, Capella. This is another of the benefits which astronomy has derived from Prof. Michelson's interferometer method of observation. The brighter component of Capella (which is a double star) has a mass 4·2 times that of the sun and a luminosity 160 times greater. We can use these facts to calculate the opacity of Capella in the way I have described; it turns out to be 150 in C.G.S. units. To illustrate the meaning of this, let us enter Capella and find a region where the density is that of the terrestrial atmosphere we are accustomed to; a slab of this gas only 6 inches thick would form an almost opaque screen. Only $\frac{1}{20}$ of the radiant energy falling on one side would get through to the other, the rest being absorbed by the gas.

Absorption of X-rays in Stars.

It seems at first surprising that 6 inches of gas could stop the æther-waves so effectively; but we might have anticipated something like this from general physical knowledge. We give different names to æther-waves according to their wave-length. The longest are the Hertzian waves used in wireless telegraphy; then come the invisible heat-waves; then light-waves; then photographic or ultra-violet waves. Beyond these we have X-rays, and finally—the shortest of all—the γ-rays which are emitted by radioactive substances.

Where in this series are we to place the æther-waves in the interior of a star? It is solely a question of temperature, and the æther-waves at stellar temperatures are those which we call X-rays—more precisely, they are very "soft" X-rays. Now X-rays, and soft X-rays especially, are strongly absorbed by all substances. The opacity which we have found in Capella is of the same order of magnitude as the opacity of terrestrial substances to X-rays measured in the laboratory. The following table shows a few of the laboratory results compared with the astronomical value for Capella:

Wave-length (Å).	Absorption-coefficient (opacity) in			
	Aluminium.	Iron.	Silver.	Capella.
0·5	2	14	10	...
0·95	11	80	72	...
1·1	21	125	86	...
1·3	31	205	152	...
2·3	136	...	...	...
10	...	...	...	150

We have been performing an investigation of the absorption of X-rays in a star, parallel to investigations on the same subject made in the laboratory. In one respect the physicist has a big advantage because he can vary the material experimented on, whereas we have to be content with the material, whatever it is, composing the stars. But, as you see from the table, the physicist is also interested in finding how the absorption changes for different wave-lengths. We can follow him in this, and even do better than him, because he is restricted by certain practical difficulties to a narrow range of wave-length, whereas we can explore a range of wave-length covering a ratio of at least 10 to 1, by using stars of different temperatures. It is true that our results are not yet very accurate; we have only one star, Capella, for which a really good determination is possible, but for other stars rough values can be found. The terrestrial results indicate an extremely rapid change of absorption for slight alterations of wave-length (as is seen from the table); the astronomical results, on the contrary, give a nearly steady absorption-coefficient. We cannot yet detect certainly whether it increases or decreases with wave-length; at any rate there is nothing like the rapid change shown in the foregoing table. This profound discrepancy between astronomical and laboratory results leads us to inquire more deeply into the theory of absorption in a star. It will be found that there is a good reason for it.

We have been taking advantage over our cloud-bound physicist by having a preliminary peep at an actual star. We are not going to allow *him* to do that. He must not use astronomical observations to determine the opacity, but must be able to predict the astronomical value either from pure theory or from terrestrial experiments. This study is of special interest because it plunges us at once among those problems which are most exercising practical physicists at the present time. We started to explore the interior of a star; we shall presently find ourselves in the interior of an atom.

It is now generally agreed that when æther-waves fall on an atom they are not absorbed continuously. The atom lies quiet waiting its chance and then suddenly swallows a whole mouthful at once. The waves are done up in bundles called quanta and the atom has no option but to swallow the whole bundle or leave it alone. Generally the mouthful is too big for the atom's digestion, but the atom does not stop to consider that; it falls a victim to its own greed—in short, it bursts. One of its satellite electrons shoots away at high speed, carrying off the surplus energy which the atom was unable to hold. The bursting could not continue indefinitely unless there were some counter-process of repair. The ejected electrons travel about, meeting other atoms; after a time a burst atom meets a loose electron under suitable conditions and induces it to stay and heal the breach. The atom is now repaired and ready for another mouthful as soon as it gets the chance.

From this cause a big difference arises between absorption of X-rays in the laboratory and in the stars. In the laboratory the atoms are fed very slowly; the X-ray bundles which they feed on can be produced by us only in small quantities. Long before the atom has the chance of a second bite it is repaired and ready for it. But in the stars the intensity of the X-rays is enormous; the atoms are gorged and cannot take advantage of their abundant chances. The consumption of food by the hungry hunter is limited by his skill in trapping it; the consumption by the prosperous profiteer is limited by the strength of his digestion. Laboratory experiments test the atom's skill in catching food; stellar experiments test how quickly it recovers from a meal and is ready for another. That is why the absorption follows a different law in the two cases.

Capture of Electrons.

To predict the stellar absorption-coefficient we must accordingly fix attention on the rate of repair of the burst atoms. The atom is wandering about advertising a vacancy for an electron, and numbers of ejected electrons are rushing about on holiday. Many electrons will come up, look at the situation, and go off again. How is the atom to trap the electron into taking up the situation? I will give you the solution of this problem which I am inclined to think fairly probable, though I have not found many who agree with me. We may compare the electron to a stray planet entering the solar system from outside, bearing in mind, however, that the planets (satellite electrons) must be supposed to repel the invader, and the sun (positive nucleus) attracts it. Dynamics teaches us that, provided no actual material collision occurs, the intruder will scarcely ever be captured, but after stirring up things a little will retreat again towards infinity. There are exceptions, as when the sun and Jupiter conspire to capture a comet, but these would be very rare in the conditions corresponding to an atom. In some cases the intruder would turn the tables by carrying off a regular planet, thus compensating for the occasions when it was itself captured. Probably, as regards repair of the atom, as much harm as good would be done on the average.

More delicate persuasion being of no avail, there seems nothing left but for the atom to secure its electron by brute obstruction. For this reason I take the view that usually the capture of an electron occurs through its running against the positive nucleus of the atom. This nucleus has a highly complicated structure, the iron nucleus, for example, consisting of 86 distinct charges arranged in some kind of equilibrium. If by accident an electron runs full tilt into this packed mass, it will agitate it and lose energy in so doing; it will rebound, no doubt, but with smaller velocity insufficient to carry it out of the sphere of attraction of the atom.[3] By a process of exclusion this seems the only method consistent with dynamical laws by which the atom can secure the electron needed for its repair. Therefore I have concluded that the actual electron trap is none other than the positive nucleus—a region at the centre of the atom known to be about 10^{-12} cm. in radius. It must be remembered that the nucleus attracts the electrons and will sweep into the trap many which were not initially aimed at it.

This theory has been adversely critised mainly on the ground that it is entirely accordant with the laws of dynamics. At first sight that might not seem a grave objection; but we have got so used to the atom behaving in a way which violates the classical laws, that any theory which does *not* violate them is liable to be viewed with suspicion. While admitting that there are uncertain possibilities in the mysterious region in the interior of an atom, we must note that the present problem belongs to a class of investigations in which the usual dynamical laws are applied by physicists, often with much success. It concerns the motion of a free electron—not yet forming part of any permanent quantised system—a problem which occurs in the theory of conduction of electricity in metals, in thermionic phenomena, and in the scattering of α- and β-particles. In these problems physicists are accustomed to assume (rightly or wrongly) that the classical laws of dynamics are observed, and we have only followed their (good or bad) example. In particular in Rutherford's experiments on scattering, the classical laws of force are found to hold good almost to the boundary of the nucleus itself. There seems to be a fair presumptive evidence that our stellar problem should be attacked in the same way; although we admit that unknown circumstances may intervene.[4]

The strong point in our favour is that this theory

[3] The kinetic energy at the moment of collision with the nucleus is enormously greater than the kinetic energy before entering its sphere of attraction; so that a very small *proportionate* change of kinetic energy by collision would wipe out the original energy of the electron. The imperfect elasticity of the collision is a dynamical consequence of the complex structure of the nucleus. A collision of two simple charges may be perfectly elastic, except that that would apparently prevent a hydrogen nucleus from ever recovering its electron.

[4] While the fast-moving particles undoubtedly penetrate the atom in the way we have assumed, it is held by some that slow-moving electrons (as in the stars) are turned back at the surface. The idea seems to have originated at a time when the positive charge of the atom was thought to be a large sphere coextensive with it; and it seems out of keeping with modern views. It is ignored in current theories of conduction of electricity. Even if it were conceivable that a neutral atom could so ward off an electron, the strongly positive atoms in the stars could scarcely exclude it.

actually does give a value of the absorption-coefficient agreeing with astronomical observation. Thus for Capella the calculated value is 110 as compared with the observed value 150. There are certain doubtful factors which permit of the result being varied by a factor 2 or possibly 3; and we lay no stress on the precise accordance. But it appears to be possible to predict on this hypothesis the brightness of a star of known mass like Capella to within a magnitude, which amply solves the problem proposed to our physicist on the cloudy planet. It may be added that the theory also explains why the absorption in giant stars is nearly independent of the wave-length; but that is a more elementary result which becomes apparent as soon as we realise that the problem is concerned with the rate of repair of the atoms; many alternative theories of the conditions of repair would lead to the same conclusion.

Source of Stellar Energy.

The store of ætherial heat and the store of material heat in the star may be compared to the accumulators of a power station. We have not yet discovered the dynamos. The accumulators would run down in a few thousand years if they were not replenished. What is the source of the energy maintaining (and during the ascent of temperature increasing) this internal store? We believe now that the source is sub-atomic energy. One theory is that inside the star the simpler elements are gradually being built up into more complex elements, and energy is liberated in the process; a more drastic view is that matter is being entirely annihilated, setting free the whole of its energy of constitution. Taking the first theory, the most conspicuous known case is in the formation of helium from hydrogen. We do not know how to make helium from hydrogen, but we know that it is so made; we know also that 0·8 per cent. of the mass disappears in the process, and this must be the mass of the energy—æther-waves—liberated when the change occurs. Æther-waves weigh very light, and the energy available from this source is colossal. If 5 per cent. of the star consists of hydrogen which turns into helium as a first step in the formation of the higher elements, that would provide energy sufficient for all reasonable demands.

We might perhaps expect that the earliest stars would consist almost entirely of hydrogen, the evolution of the higher elements having little chance of beginning until the interior became hot enough to stimulate the process. But a difficulty arises here. For astronomical reasons it seems impossible to admit that even the earliest stars contain more than a very moderate proportion of hydrogen. I have referred to the fact that our calculations have been practically independent of the chemical constitution of the star; but one reservation ought to have been made—*provided it is not made of hydrogen.* Hydrogen gives results differing widely from all the other 91 elements.

To assume hydrogen as the material would in most cases destroy the general accordance of theory and observation; indeed it is a way of realising the goodness of this general accordance to note how it disappears when hydrogen is substituted instead of a normal element. I think, therefore, that the process of element-building from protons and electrons must have begun before the stellar stage is reached. This is a curious detached piece of knowledge to have come across in exploring the interior of a star—to be able to deny that it is mainly composed of hydrogen though any of the other 91 elements may be present to any extent; and it is still more curious that hydrogen should be the element which we were tempted to build the stars with, so that this apparently random denial hits the mark.

Admixture of hydrogen diminishes the proportion of ætherial energy and ætherial pressure, and so permits gravitation to aggregate larger masses. The occasional formation of stars of exceptionally large mass (20 to 80 times the sun's) may be due to the accidental prevalence of hydrogen in the region where they originated—that is to say, the material was in a more primitive state as regards evolution of the elements.

We need not be greatly concerned as to whether these rude attempts to explore the interior of a star have brought us to anything like the final truth. We have, I think, been able to recognise some of the leading factors participating in the problem and to learn how many varied interests are involved. The partial results already attained correspond well enough with what is observed to encourage us to think we have begun at the right end in disentangling the difficulties, and we do not anywhere come against difficulties which appear likely to be insuperable. The fact is that gaseous matter at very high temperature is the simplest kind of substance for a mathematical physicist to treat. To understand all that is going on in the material of a desk, for example, is a really difficult problem almost beyond the aspirations of present-day science; but it does not seem too sanguine to hope that in a not too distant future we shall be able to understand fully so simple a thing as a star.

New Methods of Crystal Analysis and their Bearing on Pure and Applied Science.[1]

By Sir William Bragg, K.B.E., F.R.S.

It is one of the most fascinating of all studies to trace back the properties of the substances that we see round about us to the manner and the details of their underlying structure. There are in the world, or indeed the universe, a certain number of different kinds of the atoms of which all things are made. We know of rather more than ninety in all. The science of radioactivity has brought to our notice atoms distinguished by special powers of emitting radiations, but the list is not really increased thereby. Everything we see round about us, or are aware of when perhaps we cannot see, is built up by joining together these atoms in various ways: and all the properties of substances, their infinite complications, powers, and beauties, are associated with the properties of the atoms even before construction is begun. It is surely no wonder that we try to find out how this is done.

Chemistry itself has its origin in this quest. One of its early successes was the explanation—incomplete, no doubt—of the part played by oxygen in the act of burning or rusting. As chemistry has grown to its present magnitude all its findings have related to the part played by this or that atom or combination of atoms in determining the properties of various substances. The methods of chemistry are founded on the study of the behaviour of crowds. The smallest portion of any substance handled in the laboratory contains billions of atoms; and the properties of the individual are inferred from the treatment of gross aggregates. The chemist mixes together two liquids in certain proportions, observes, tests, and weighs the results; and he infers that atoms already grouped in certain combinations are ready to change to fresh groupings. From his weighings he finds the proportions in which the atoms break with one another and recombine. He observes and measures their readiness to change partners. Sometimes the exchange is so rapid that energy is liberated with explosive violence. Sometimes it is so slow that it must be hurried, either by the application of warmth or by other means, the quaintest of which is the action of a catalyst, a third body which promotes a new grouping without being finally concerned in it; as the chaperone of bygone days effected the introduction between two people anxious to meet each other and then effaced herself.

The science of radioactivity takes up the study of the atom in a totally different way. It finds that sometimes atoms are endowed with movement so rapid that the individual has enough energy to make its own mark. In the spinthariscope of twenty-five years ago Sir William Crookes showed the separate and visible flashes which were made when a succession of helium atoms, shot out from radium, struck a phosphorescent screen. Each impact made its little flash of light just as when a pebble is dropped at night into a phosphorescent sea. This is a typical experiment belonging to the science of radioactivity, typical in that it deals with the individual and not with the crowd. In this science there is very little concern with the combinations of atoms. It leads more to a study of the nature of the internal structure of the atom: that is why if we wish to understand the atom's inner mechanism we turn to the work which J. J. Thomson, Rutherford, Aston, and others are doing. The new methods with which I deal here attack the question from yet another aspect, based on the recognition of the properties of crystals on one hand and of X-rays on the other.

A crystal that has grown without disturbance presents surfaces of brilliant polish which make with each other angles of characteristic and invariable magnitude. Sometimes one face grows abnormally as compared to others, on account, it may be, of some disposing cause in the circumstances in which the crystal was formed, but in crystals of the same substance the angles between corresponding faces are always exactly the same. There are not, usually, many different kinds of faces on a crystal. Often on careful examination it is found that there are not more than three or four. If we examine specimens of the same crystal which seem at first sight to differ in form, we find that the difference is nothing more than an unequal development of the various types of face. An outward presentment so simple as this must imply a like simplicity in internal design. There must be a unit of pattern which contains but few atoms and, repeated again and again through space, makes up the whole crystal. The idea has long been familiar to the crystallographer, but he could not push the corresponding interpretation to its limits: he had no clue to guide him, no methods of examining the actual details of the design. The reason of the failure is not difficult to understand: the details were too fine to be distinguished under the most powerful microscope. Nor is this a mere question of a lack of technical skill which might be removed at some future time. It will never be possible to see the arrangements of atoms in a crystal.

When we say that we see any particular thing, what we really do is to observe some change which the thing has made in the light waves which reach our eyes after they have been reflected or scattered or in

[1] Sixth Trueman Wood Lecture, delivered at the Royal Society of Arts on January 24.

some other way affected by the thing that is seen. This means that the thing itself must be comparable in size with the wave-length of light. We could not expect to gather from the behaviour of a breaker as it rushed up the beach information as to the size and form of the individual grains of sand over which it had passed. We might expect, however, to be able to gather information as to the extent of a reef from observation of the degree to which it had stilled the waves that traversed it before they reached the shore. Now, the diameter of an atom is quite a thousand times less than the length of the light-waves which affect our eyes. Consequently it is out of the question that we should ever see it in the sense that we can see small objects even under the microscope. A very simple way to realise this point is to consider that the atoms form part of the very lenses of the microscope; and, if we tried to increase our power of microscopic vision by redesigning the optical arrangement, the lenses would have become, so to speak, granular and have lost their optical properties long before we were able to "see atoms by their aid." The fact is that light-waves are adapted for ordinary seeing, and that by the microscope we have stretched their proper range some thousands of times. Nothing that we can ever do with ordinary light will give us the magnification of a hundred million times, which is what we require if we are to study the atoms themselves. We want a new sort of light of immensely finer quality than ordinary light; and we have been fortunate enough to find this in the X-rays. X-rays are simply a form of light the wave-length of which is ten thousand times shorter than that of the light with which we see in the normal way.

There is one more point to be made clear before we can realise how the combination of X-rays and the crystal has opened up a new vista. Although the X-ray is so fine in structure that it can really be affected by the individual atom, the magnitude of that effect is too small to be of any use: it is here that the crystal helps us. We remember that there is in the crystal a perfectly regular repetition of some simple pattern or combination of atoms. When X-rays sweep over them, whatever effect one of the units has, all its fellows have also; and so on the whole there is a combined action big enough in its results to be detected by instruments designed for the purpose. In somewhat the same way, to take an example, each tiny furrow on a piece of mother-of-pearl is of the right order of width to have an effect on the light which is reflected by the whole piece, but the magnitude of one such effect is not enough to make an impression on our eyes. However, on the surface of the pearl there are many thousands of such furrows very like one another and running more or less in the same direction, and what one furrow does the others do also. It is this combined or multiplied action which so affects the light as to give the beautiful play of colour associated with mother-of-pearl.

Now we have all the factors essential to the new methods: the X-rays for fineness of vision and the crystal for combination in the action of the atoms upon the X-rays. It is not necessary now to go into further details; it is only needful to realise that there is an instrument called the X-ray spectrometer in which the reaction between the X-rays and the atomic arrangements enables us to study the form and size and disposition or structure of the atomic patterns of the crystal.

Every crystal is in a way a long avenue down which we can look and see at the far end of it the most primitive groupings of the atoms. The wonder is that we should be able to look so far, that the structure of the crystal should be so finished and so unvarying from first to last that our observation of a crystal big enough to handle should tell us no more and no less than the properties of the one little unit of pattern. If the diamond in a ring were increased to the size of the earth the individual carbon atoms would only be about as big as tennis balls. Yet so faithful is the information which X-rays and crystals give us that we can compare, and indeed measure, the distances from atom to atom with an error less than 1 part in 1000. This new power, which is surely wonderful enough, we naturally apply to the further elucidation of the problem which I described at the beginning. We try to find out, by fresh means, the relations between the properties of substances and the nature of the atomic structures of which they consist.

It might be objected that a crystal is something special and that most bodies do not show the perfect crystalline form. The difficulty is apparent, not real. In the first place, far more substances are crystalline than would be supposed, and actually every substance would more naturally develop into a perfect and characteristic crystal than into any other form. The crystal is the natural condition. Bodies which seem to us to present no crystalline appearance at all are often aggregates of minute crystals jammed together miscellaneously or held like a mush in a semi-liquid matrix. Often, again, as in the case of liquids, the various atoms and molecules have not had time nor peace enough to arrange themselves as they would. Even if many of the substances in the behaviour of which we are most interested, such as iron and steel, are far in form from the perfect crystal, yet we may expect to arrive in the end at an understanding of their structure by the separate examination of the few definite forms of crystal of which, as we know well, the whole mixed mass is compounded.

We may now go on to consider individual cases. It is, perhaps, natural to a new form of inquiry to deal with particular instances of its application as they have been so far made, rather than to attempt broad generalisations. As we consider each case let us look at it from the point of view already emphasised. Let us try to see how the properties of the whole crystal depend strictly upon and are, indeed, an index to the properties of the atoms and atomic combinations of which it is made.

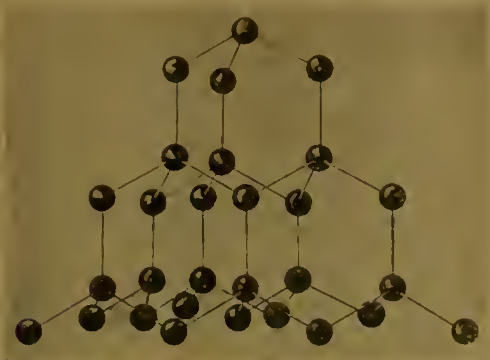

FIG. 1.—Diamond; showing how each carbon atom, represented—only diagrammatically—by a black ball, lies at the centre of gravity of its four nearest neighbours.

The diamond is, perhaps, the best to begin with. Its unique qualities dispose us to expect a structure which is equally distinguished, and so it turns out to be. The structure is figured in the accompanying sketch (Fig. 1). It may look at first sight somewhat complicated, but when it is examined closely it is found that the whole story is told in one sentence. Each atom has four neighbours regularly disposed about it. In other words, the four make a regular tetrahedron, and the first atom is at the centre of it. In the arrangement so determined by X-ray analysis we recognise at once an agreement with one of the most important deductions of the chemist, the so-called tetravalency of the carbon atom, which means a tendency to associate itself with its neighbours by four bonds of equal strength. The hardness and strength of the diamond are based on the simplicity and regularity of this tetrahedron arrangement, and in addition on the strength of the tie between atom and atom. We find that atoms are fastened together by bonds of two or three different types; the one here illustrated is the strongest of all. Every atom, we know nowadays, consists of a central core, which is positively electrified, and of a sufficient number of negative bodies of a second kind called electrons to balance the positive charge on the core. The diamond is an example of many cases where neighbouring atoms share electrons and build them each into their own structure. It is somewhat analogous to the sharing of party-walls by the houses of a terrace. Yet it can be seen that the structure is obviously weaker in certain directions than in others. Such are the horizontal planes in the figure. These are called the cleavage planes. The diamond-worker takes advantage of the fact, using it skilfully instead of grinding. An excellent example is to be found in the exhibit of the Crown Jewels in the Tower, where the manner of cleaving one of the great diamonds is shown. There is a second plane of cleavage, which is only used by workmen of the greatest skill, as it is much more difficult to bring off the operation successfully. It is at right angles to the plane of the first kind. The tetrahedral form of structure is often reproduced in the form of the whole diamond, though no one, I believe, knows exactly why the faces of the tetrahedron are often rounded. This does not mean that the layers of the atoms are curved, but simply that they lie on one another like a series of steps. A structure so tightly bound together is brilliantly clear from the optical point of view.

There is another form of carbon crystal, that of graphite or black lead, the properties of which seem so different from those of the diamond that it is difficult to believe they are of the same element and, moreover, of much the same construction. One common feature is of great interest, namely, the existence in both cases of layers of atoms arranged in hexagonal pattern. It is difficult to express in words, but the illustration (Fig. 2) will make it clear. Each atom is still bound to three

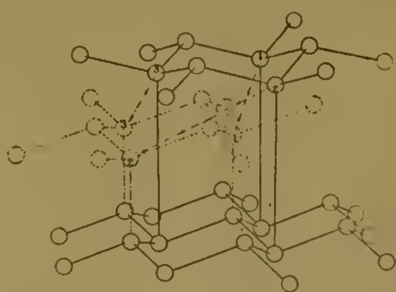

FIG. 2.—The fine lines of the diagram show the structure of graphite. By moving the top layer to the position shown by the broken lines the diamond structure is obtained.

of its neighbours by the same strong ties as before, but the fourth is broken and a weaker, lengthier connexion is substituted. All this is reproduced in the outward appearance of graphite. Its crystals are badly formed, but are more or less in hexagonal columns, which split up with the greatest ease into thin leaves at right angles to the column axis. So easy, indeed, is this cleavage that the pounding of a mass of graphite in a mortar is ludicrously ineffective. The leaves simply multiply themselves more and more. One leaf slides on another very easily, yet the atoms in each leaf hold well together. It is the combination of these qualities that gives to graphite its lubricating powers. If you slip on the black-leaded hearthstone, it is because some of the layers which are sticking to the sole of your shoe slide on others which cling to the stone. I do not know that you can find a better example of the relation between the external features of a crystal and its elementary structure. One change has converted the hard diamond into the soft, slipping graphite, and it is easy to see that the results are exactly what one would expect from the nature of the change.

Now we may pass on to another structure which is much like that of the diamond, namely, that of ice (Fig. 3). The fundamental element of the design is again the fact that an atom, oxygen in this case, is surrounded symmetrically by four other atoms of like kind; the latter making a regular tetrahedron of which the former is the centre. But there is this difference between diamond and ice: that in the latter case an atom of a second type, namely, hydrogen, is inserted between every pair of oxygen atoms. Thus, the immediate neighbours of each oxygen are four hydrogens. As every hydrogen has only two oxygen atoms as neighbours, there are twice as many hydrogens as oxygens in the structure. That is, of course, in agreement with the known composition of water.

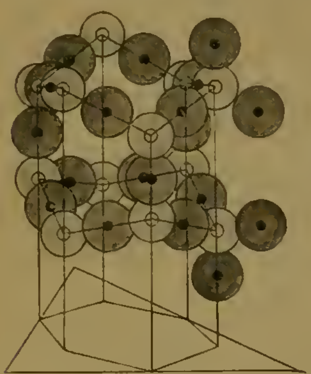

FIG. 3.—Ice. White spheres represent oxygen atoms, and the black spheres hydrogen: enough of each kind are drawn to show the hexagonal nature of the crystal. Each black ball lies between two white: each white touches four blacks, but in two cases only, on the right of the diagram, the full number, four, is put in. The distance between the centres of two neighbouring oxygens is known with accuracy, but it is not known how much of the intervening space is occupied by the hydrogen.

Here, also, as in diamond and graphite, are to be found layers in which the atoms are arranged in a hexagonal pattern. Arctic explorers have described a hexagonal structure in the ice-floes; the block breaking up into hexagonal vertical columns resembling the pillars of the Giant's Causeway. But the most beautiful ice-crystals are found in the snowflakes or in the frost figures on the window. The forms are of an intricate delicacy based always on the hexagon and on the angle of 60°. In the model which is illustrated the foreshadowing of the sixfold symmetry is shown. The featheriness of the snow is the outward expression of the lightness of the pattern, which resembles lace rather than a continuous structure. It is clear that the atoms could be packed more tightly, and that must have something to do with the fact that when ice is compressed it tends to melt. It is not easy to understand why the atoms join together in this of all possible ways. It is evident that particular points in the structure of one atom are linked up with corresponding points in the structure of another. Such considerations have, no doubt, to do with the internal structure of the atoms themselves,

It is a curious fact that when a tetrahedral structure is found, as in the cases of diamond and ice, there is an alternative with respect to one of the details. By a slight structural change somewhat difficult to describe in words, the tetrahedral arrangement of the diamond becomes the usual hexagonal arrangement of ice. Mr. Whipple has directed my attention to a paper written about a hundred years ago, in which the author describes ice-crystals of peculiar form which he had found on the wooden bridge of Queen's College, Cambridge. It is possible to make out from the description that in this case the ice had grown as a diamond would do: the effect is described as one of great beauty and brilliance.

There is one feature of the carbon structures which is of great interest. The hexagonal ring of six atoms is to be found both in diamond and graphite. Now, a whole branch of chemistry of first-rate importance is concerned with the examination of substances of which such a ring forms the essential element of design. When an atom of hydrogen is attached to each atom of carbon the ring with its fringe is the molecule of benzene. The ring is an extraordinarily persistent combination.

Organic chemists have learnt that they can detach at will one or more of the hydrogens, replacing them by somewhat more complicated groups, such as the pair of oxygen and hydrogen atoms called the "hydroxyl group," or the "nitro group," consisting of one nitrogen and two oxygens, and so on. In this way an immense number of different substances are formed of widely varying properties. They occur in the work of the dye chemists, in the manufacture of explosives, in the study of living organisms, and, in fact, constitute a most important class of bodies. Chemists have inferred the existence of these rings by reasoning processes of really wonderful accuracy and power. It is natural to suppose that the ring which we find in our structures is the very ring which has been the concern of the organic chemist.

We have tried to put this idea to the test, and so far, I think, with success. We can measure this ring in the diamond. It is just one hundred millionth of an inch across, and we can make good estimates of the enlargements that must result from such substitutions for the hydrogens as I have already described. We can then measure the space which the rings, modified or not, occupy in the organic crystal, and we get a very satisfactory fit (Fig. 4).

We have, for example, estimated the size and form of the molecules of naphthalene and anthracene on the assumption that they consist, respectively, of two benzene rings, and three benzene rings, in line; in accordance with chemical evidence. We have found, by X-ray analysis, the size and form of the unit cells (Fig. 6); a simple calculation shows that two molecules have to be packed into the cell in each case; the crystals, it should be observed, are isomorphous.

Fig. 4.—Showing mutual relations of three naphthalene molecules and parts of others. Letters are attached to all the carbon atoms of one molecule; hydrogen atoms completing this molecule are attached at A B C D G H I J.

It is found that the molecules pack into place very well, if they are arranged as in the sketch of Fig. 4. The figure refers to naphthalene, but the modification required for anthracene is readily conceived; and, indeed, it appears that the cell in one case is exactly as much longer than in the other as would be expected considering that the anthracene molecule contains one more ring than the naphthalene. Here again we may see in the structure of this little unit of naphthalene, which contains two double rings, everything that foreshadows the properties of the whole crystal. Why is the substance so light? Because the structure is so lace-like and there are so many empty spaces. Why does it break up so easily into thin flakes? Because the molecules lie side by side somewhat like corn bent by the wind, and their side-to-side attachments differ from those that are end to end: the latter break more easily and the substance naturally splits up into layers, each of which is like a velvet pile, the fibres of which represent the molecules. Why does the substance melt so easily? Because *all* the attachments of molecule to molecule are feeble and break up under disturbances due to heat. And so we may go on. If we attach a hydroxyl group to the side of the molecule we see the fibres of the pile open out sideways. If we attach it at the ends, we find the fibres grow longer; the two substances formed in this way are well known in the dye industry.

We have recently been examining the crystalline form of a number of the organic substances, and have learnt something of a very interesting system which governs the packing. It holds for all crystals apparently, but is very plain in the organic field. There are two stages in the process of the formation of the crystal from the original atoms. First of all, the atoms are grouped into companies which the chemist calls "molecules." Chemistry has concerned itself largely with the study of the molecule, and particularly with the molecule in the free state, as in a liquid or a gas. In the second stage the molecules, retaining their composition if not their exact form, are packed together to make the crystal pattern: it is this stage which is the subject of our present considerations, and can be analysed by the X-ray methods. Take a simple example:—Two atoms of hydrogen and one of oxygen make up the water molecule. It is a company of atoms strongly tied together in an alliance which stands much rough treatment. The molecules can exist in a state of independence as steam or water vapour: in a condition of semi-independence they associate themselves together as water. We know how much care has been given to the study of the water molecule in both these states. Now, in the second stage the molecules are arranged side by side and end to end to form the crystal of ice. It has been necessary to take away much of their motion in order to induce them to take the new form. They are no longer running hither and thither, twisting and spinning with the energy of their motion. They lie more quietly now, still quivering, no doubt, but tied together so that they can no longer change appreciably their relative positions. They are now the crystal to be investigated by the new methods: the result is shown in Fig. 3, already described.

We find that when the molecules are packed into the crystal pattern—and they do not seem to suffer much in the process—they are put together just as anyone would try to pack a box with objects all alike in shape but individually of irregular or, one might say, of awkward form. How would you pack a box full of boots? You would naturally put them in pairs, the right boot over the left in the familiar way. It is just such methods of packing that are followed in a crystal. It is convenient to illustrate by means of models. Here are a number of wooden "shoes" which are to represent molecules without symmetry in their form. Take four of them and put them together in the manner illustrated (Fig. 5). The result is a pattern which possesses a certain amount of symmetry,

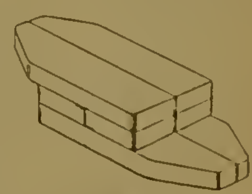

Fig. 5.—Arrangement of the four "shoes" showing the mutual orientation but not the mutual positions of the four molecules usually found in a monoclinic prismatic crystal such as benzoic acid or phthalic acid.

the same, in fact, as that of the boxes in Fig. 6. This is a very convenient form for packing, and it appears that a majority of known crystals pack together in this way. All of them show the symmetry that might

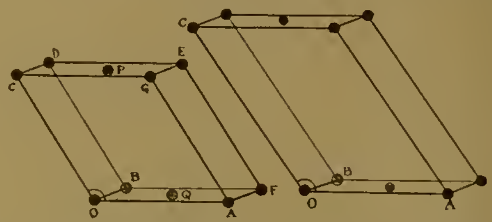

FIG. 6.—Unit cells of naphthalene and anthracene drawn to the same scale (10^8 to 1). It is apparently usual for cells of this kind to contain four molecules, but in these two cases they contain two only; that is because the molecules have some symmetry of their own. The molecules shown in Fig. 4 fit into the naphthalene cell. If the unshaded molecules be supposed to be placed with one end at Q, its general lie is parallel to OC. The two shaded molecules of Fig. 4 would then be placed with their ends at B and F. The anthracene molecule is like that of naphthalene except that there are three rings in a line instead of two: the axis OC is correspondingly larger.

be expected. They are exactly alike on either side of a dividing plane: in other words, they are exactly like their reflection in a mirror. They have, too, an "axis of symmetry"; a half turn about the axis brings no apparent change. Fig. 7 is an illustration

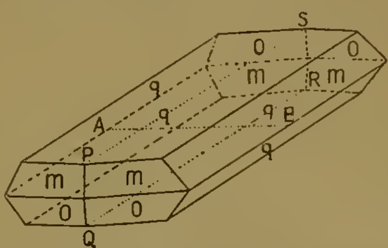

FIG. 7.—Phthalic acid, a monoclinic prismatic crystal possessing a plane of symmetry PQRS, and an axis of digonal symmetry AB, but there is no plane of symmetry through AB. Faces marked by the same letter are alike. The mutual orientation of the four molecules in its unit cell is that of the shoes in Fig. 5.

of a crystal of this kind. The X-ray methods show us that there are four molecules in the unit of pattern, and that they are arranged in the manner described

It is very interesting to observe the result of a different arrangement. Sometimes a set of four are arranged as in Fig. 8, like two pairs of shoes back

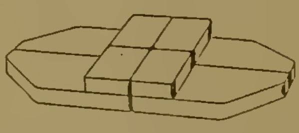

FIG. 8.—The relative orientations but not the relative positions of the four molecules in the crystal unit cell in resorcinol.

to back. The top and bottom are now unlike, but there is a greater symmetry in other directions. We have recently examined a crystal substance, resorcinol, which is built on this pattern; its external form is shown in Fig. 9. The fundamental molecule is a benzene ring in which two hydrogens have been replaced by two hydroxyl (oxygen-hydrogen) groups. The crystal shows clearly different forms at its two ends, the difference of which is shown in another very interesting way. If the crystal is warmed, one end of it becomes positively electrified and the other negatively. We have been able to go some way to the actual determination of the relative positions of the molecules: the results are shown in Fig. 10. There are two sets of planes perpendicular to the axis, which in the crystal occur alternately. In each plane there are two types of molecule, counting difference of orientation as difference of type. The plain lines in the diagram show the arrangement of the two types lying in the plane of the paper, and are marked A and D. One of them can be obtained from the other by a revolution through 180° in the plane. They are joined by long and by short lines, the former containing the oxygens of the hydroxyl groups. The arrangement of the next plane, above or below the first, is shown by the dotted lines: the molecules in this plane can be obtained from those in the first by reflections, with proper translations, across planes that are perpendicular to the paper and cut it in lines parallel to either of the sides of the rectangle. The arrangement is clearly governed by the necessity of fitting the molecules together so as to accommodate the hydroxyl attachment.

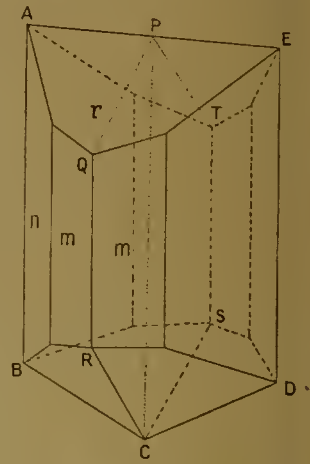

FIG. 9.—Resorcinol, a rhombic pyramidal crystal, having two planes of symmetry, AEDCB and PQRCST, and an axis of digonal symmetry PC.

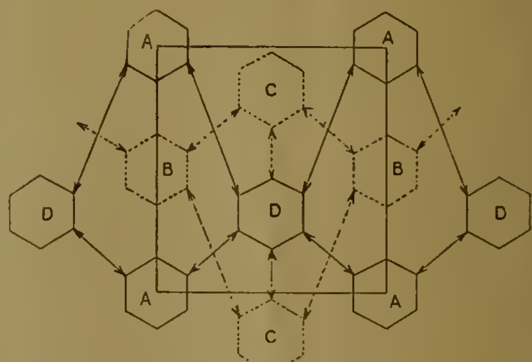

FIG. 10.—Probable arrangement of molecules in resorcinol.

Another case of great interest and importance is the two-molecule cell, the two being exactly alike. How would you pack a box with boots all right-footed or all left-footed? You cannot find a way of packing which will make the result symmetrical on either side of a plane. Neither do you find a crystal, built on such a basis, to have right and left symmetry. The crystal of tartaric acid, investigation of the properties of which established the fame of Pasteur, is an excellent

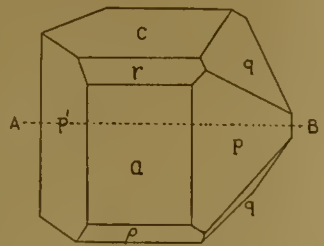

Fig. 11.—Tartaric acid, a monoclinic sphenoidal crystal, having an axis of digonal symmetry, AB, and no other axis or plane of symmetry.

example. Its peculiar form is shown in Fig. 11. A recent publication by Mr. Astbury gives the proof that there are two molecules in the unit cell. Their mode of arrangement in terms of "shoes," which are of one kind only, is shown in Fig. 12. The arrange-

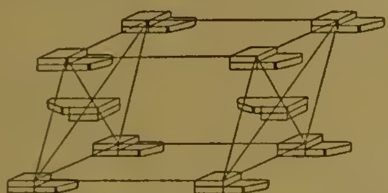

Fig. 12.—Arrangement of "shoes" of one kind only representing the arrangement of molecules in tartaric acid.

ment of the atoms in one molecule, represented in Fig. 12 by one shoe, is shown in Fig. 13. A model of the crystal is shown in Fig. 14; and diagrammatic representations of the atoms in two adjacent molecules are given in Fig. 15 (*a*) and (*b*): one of these figures is right-handed and the other left. The most striking

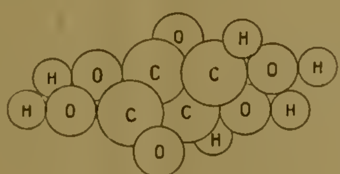

Fig. 13.—Molecule of tartaric acid.

physical property of the crystal is its power of rotating the plane of polarisation of light which traverses it. It has long been guessed that there must be some spiral arrangement in the structure: and this is beautifully confirmed in the model. There are, in fact, two spirals. This is somewhat unexpected, but it explains in a delightful way a property which has been obscure. One of the spirals is in the interior of the molecule itself and is certainly permanent when the crystal is dissolved. That accounts for the fact that tartaric acid in solution is "active," that is to say, can exercise its rotatory power. But the second spiral is a twist brought in by the necessity of fitting

Fig. 14.—Tartaric acid. The small balls represent hydrogen atoms, the larger black balls oxygen, and the largest two grey and two black balls carbon. Scale of the model is 10^8 to 1.

the molecules in their places. It is a peculiarity of the crystal structure, not of the molecule: it is a right-handed screw if the first is a left-handed screw, and *vice versa*. Also it appears to be more powerful in its effect on the light; so that when the tartaric acid

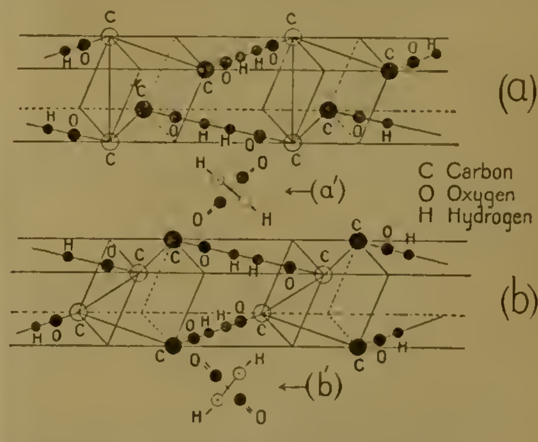

Fig. 15.—Tartaric acid; (a) and (b) represent two molecules end to end; (a') and (b') show corresponding cross-sections with the side attachment. The two sets of figures are right and left to each other.

as a crystal rotates light in one sense, in solution it rotates light in the opposite sense. Here, again, the intricate effects of the whole crystal are directly referred to structural details.

It is to be observed that in this case there could be no question of the existence in the crystal of two molecules related to one another as right to left. For the mirror reflection of a right-handed screw is a left-handed screw, and the whole effect depends on a want of balance. In this case also there is a plane of cleavage, passing through the points where the molecules join each other end to end.

Quartz is another example of a crystal possessing rotatory power, and like tartaric acid it contains a special element in its construction. The X-ray

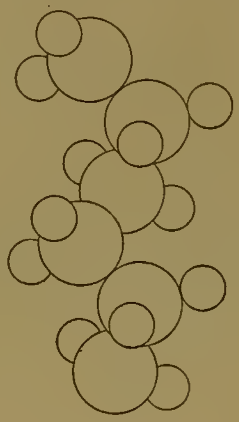

Fig. 16.—Spiral construction in quartz: large balls silicon, small balls oxygen.

methods make this very clear, and give us also some indications as to the structural system. In the model shown in Fig. 16 the large balls represent the atoms of silicon and the smaller those of oxygen. The spiral character of the fundamental crystal is beautifully manifested in its outward form. The illustration (Fig. 17) shows the two possible forms of the crystal,

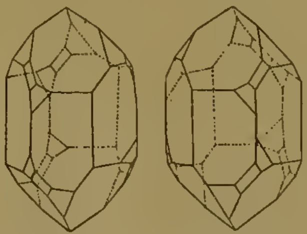

Fig. 17.—Right- and left-handed quartz.

right-handed and left; a certain set of small faces gives to each crystal a spiral appearance.

These various examples have been given as illustrations of the tasks which the new method of crystal analysis undertakes. They belong to a new field of research, akin to chemistry in that they seek to refer the properties of substances to the nature of the elements of construction. Chemistry has, however, concerned itself in the main with the relatively free molecules of liquids and gases: here we deal with the properties of the solid. Our concern is to explain the strength and elasticities of materials, their power of conducting electricity and heat, their electrical properties, optical properties: all these characteristics and many more, in terms of the structure as revealed by the X-ray analysis. Here are, we may say, the contributions of the method to pure science.

It is natural to say something of the possible application to applied science. The properties of solid materials are of such fundamental interest to all arts and crafts that any new insight into their origin is necessarily important. But, at the same time, applications of science to industry are always unexpected in nature and time. What we have now to do from the purely scientific side lies plain before us: how and when any result will have practical value cannot be foreseen.

Much attention has been given to the immensely interesting problems of the crystallisation of iron and steel. Westgren in Sweden, Bain in America, and others, have done good work on the structure of the various forms of iron, α, β, γ, and δ.

In Great Britain, the effect of the crystalline form on the strength of a material has been examined by G. I. Taylor and Miss Elam in the case of the beautiful aluminium crystals of Prof. Carpenter. The crystals are very easy to deform because certain planes of easy slip traverse the whole crystal, and these planes are always the first to give way. The X-rays show the structure of the crystals and the position of the planes. When the large crystals are broken up into smaller, oriented in all ways, the material becomes stronger because in whatever way a stress is brought to bear some of the crystals are ready to bear it.

Kaolinite, which can be examined, though in the form of a very fine powder, shows clearly a crystalline structure: by the same methods it can be shown that the structure disappears when the temperature is raised to a certain point. These facts were, at least in part, anticipated by the scientific branches of the pottery industry: but this method provides a useful confirmation, and further investigation promises to be very interesting. Calcined at 900° C., a new crystalline structure appears: and when the temperature has been sufficiently raised, the X-rays show that sillimannite has formed.

Such examples are mere pointers in a direction in which we may hope there will be a great movement in time to come. Our first aim is to develop the new methods as pure science. A broad, straight road opens out before us, and the going is good. As we travel along it we shall, doubtless, find many side turnings leading to useful applications, but we must not expect them until we are right opposite to them. Our first and obvious duty is to travel down the high-road as far as it will take us.

Leitz

NEW MICRO-PROJECTION EQUIPMENT

WITH SPECIAL COLLIMATOR OF GREAT LIGHT TRANSMITTING POWER

(For use with any microscope)

Owing to the exceptional high degree of correction in the illuminating system, a brilliant and sharp image is obtained with an arc lamp taking only 4·5 amps.

The illumination is sufficient to project objects under polarised light, and various accessories can be supplied for this purpose.

Descriptive pamphlet on request.

OGILVY & CO.

(British Agents for E. Leitz)

18 BLOOMSBURY SQ., LONDON, W.C.1.

Optical and Mechanical Repairs to any make of Microscopical Apparatus executed on the Premises.

Seeing is Believing

In nature there are many things happening that even its closest students can hardly believe true.

A pair of Ross Binoculars is one of the most essential items in a naturalist's outfit. They will reveal the habits and ways of birds and animals in a way that is little short of wonderful.

No other Binoculars will give you such illumination and detail, two most essential factors, as those made by Ross.

Send for copy of illustrated booklet with introduction by Mr. Cherry Kearton, the world-famous naturalist.

ROSS LTD.

CLAPHAM COMMON, LONDON, S.W.4.
Showrooms at 13-14 Great Castle Street, Oxford Circus, London, W.1.
