2. A soft pulse which is strikingly slow in relation to the temperature.
3. An enlarged spleen (not necessarily palpable).
4. A fever lasting upwards of a week to fourteen days.

Now if a case can be observed from the onset, and a temperature chart kept from the commencement, it is comparatively simple to say at the termination of the disease that the patient has probably had either mild typhoid or paratyphoid fever, but unfortunately this is rarely possible. Of course by the tenth or twelfth day there will probably be spots or enlargement of the spleen, or other unequivocal evidence, but there may not be anything so helpful, and it is then that a careful history is so important. A typical case to treat as a suspect would be somewhat as follows:

A Typical Case.

The patient reported sick eight days previously with headache, pain in the limbs, and constipation. On questioning he will admit that for three or four days before reporting sick he had been off his feed and felt generally out of sorts, with a distinct tendency to shiver at odd times, and very probably there will have been about forty-eight hours' looseness of the bowels, perhaps not amounting to true diarrhoea, before he actually was ill enough to go sick. On examination the patient may very likely look a trifle lethargic, and may cerebrate somewhat slowly. His tongue will show dorsal furring, with pink or red edges and tip, but may be quite moist. The abdomen may be a trifle tumid and elastic. There may be vague discomfort in it, or even tenderness under the left costal margin. The splenic dullness will probably be elicited more readily than in a normal individual.

The stools will be constipated and the bowels only opened with enemata. The temperature will be about 101° or 102° at night, with a morning remission of about 2° or more. The pulse will be 70-80, of small volume, and very compressible. There may or may not be an occasional rhonchus in the chest. The patient himself will probably say that he is "in the pink."

Such a case is likely to be paratyphoid fever, and should be treated as such.

COMPLICATIONS AND SEQUELAE.

It is possible for paratyphoid fever to show all the complications and sequelae which are found in typhoid fever. There is, however, a marked difference, both actual and relative, in the frequency with which they occur in the two diseases.

They will now only be described in so far as they are liable to affect the clinical aspect of paratyphoid fever.

Bronchopneumonia and meteorism are perhaps the commonest complications of typhoid fever. Capillary bronchitis, or bronchopneumonia, has not occurred in more than 4 per cent. of our paratyphoid cases. While rare in both para A and para B, it seems relatively more common in the latter. Meteorism, due to paralytic distension of the large intestine, is very rare indeed, and has only occurred in some of those unusual toxic cases closely resembling typhoid infection. The rareness of this complication is surprising when one considers the tendency of para B to cause severe and extensive inflammation of the large gut.

Haemorrhage, on the contrary, seems almost as common in para B as it is in typhoid fever. Severe haemorrhage occurs in about 5 per cent. of all cases of para B, and was solely responsible for the death of one case, while it was a contributory cause in four other fatal cases. In two not fatal cases it was quite copious, but did not seem to affect seriously the patients' general condition. It is far less frequent in para A, occurring only in about 1 per cent. of cases. In para B it is liable to occur at a definitely earlier date in the disease than in typhoid fever.

Perforation (a distressing accident which no one can foresee or guard against) has occurred in 3 cases of para B and in 1 case of para A—that is to say, in about 1 per cent. of all cases of paratyphoid fever.

Thrombosis of the femoral vein occurred in 3 out of 100 cases of para B and once in a series of 50 cases of para A. A mild otherwise average case seems quite as liable to this complication as one of the more severe variety. It seems to begin at a relatively earlier date in the disease than it does in typhoid fever. Of 4 cases the left femoral was involved three times and the right once.

Amongst the other complications and sequelae that have been met with are:

Relapse,	Suppurative orchitis,
Recrudescences of fever,	Neuritis,
Pleurisy,	Meningismus,
Empyema,	Mental weakness in convalescence,
Abscess of lung,	Periostitis,
Pericarditis with effusion,	Pyelitis,
Tachycardia,	Cholecystitis,
Laryngitis,	Abscess of spleen,
Tonsillitis,	Peritonitis without perforation of the bowel,
Otitis media,	
Parotitis,	

We would like to call particular attention to what seem to be two definite idiosyncrasies of paratyphoid B:

The first is a tendency (of which mention has already been made) to involve the large gut, and secondly, the special liability to pus formation. The former peculiarity is shown by the fact that the three perforations which have so far occurred in our para B cases were all situated in the large intestine—namely, one in the sigmoid, one in the appendix, and one in the descending colon. Also, it is the usual thing at necropsies on cases of paratyphoid B to find the caecum and the colon as far as the splenic flexure severely affected, and in three or four cases the solitary follicles have been extensively involved nearly as far down as the rectum.

The second tendency of para B—namely, that to pus formation—is evidenced by the occurrence of the following complications. Three cases of suppurative orchitis, two cases of splenic abscess, one case of empyema, one of periostitis of a rib, one of abscess of the liver, one of abscess of the lung, and the case of suppurative peritonitis above

mentioned, all occurring in the course of paratyphoid B. The bacillus paratyphoid B was recovered from two of the cases of orchitis, both the splenic abscesses, and from the abscesses of the liver and the lung, and from the pus around the rib.

Relapses, Etc.

The disinclination of the temperature of paratyphoid A finally to settle has already been noticed. Sudden recrudescences of the temperature both during and after the primary period of pyrexia are fairly common in both para A and para B, but especially in the former. In para A these rises are liable to be associated with rigors, which occurred in 4 of the 50 cases. Over 25 per cent. of all cases of para A show one or more of these recrudescences, and half of these show two or three such rises (Chart 5). Similar rises, which have not, however, been associated with rigors, occur in about 15 per cent. of the para B cases. The duration of these pyrexial bouts is usually about three days.

Relapses—that is to say, more serious and prolonged rises of the temperature, associated with more or less of a return of the original symptoms, and frequently fresh enlargement of the spleen and reappearance of spots—occur in from 6 per cent. (of the B cases) to 10 per cent. (of the A cases). The relapse usually lasts from six to ten days. Examples of such cases are seen in Charts 3 and 6.

Irregularities of the Pulse.

Some interesting irregularities of the pulse are met with. Troublesome tachycardia, leading to prolonged convalescence, occurs in about 5 per cent. of the cases, being decidedly more common in para A. Bradycardia is still more common, but seems to be a favourable feature. It is especially frequent in para B, occurring in over 10 per cent. of the cases, sometimes starting before the temperature has settled. Lieutenant Marris has suggested that some of the cases of tachycardia are due to disturbances of the splanchnic vasomotor control, and certainly the application of a wide elastic belt has been found to do good in a number of them. He has also examined with the polygraph other cardiac irregularities, such as heart-block, auricular fibrillation and auricular flutter, which would appear to be by no means infrequent, but which are only temporary disabilities. It will be seen that the period of convalescence is sometimes attended by quite interesting clinical problems.

Mortality.

The death-rate of paratyphoid fever is very low compared with that due to *B. typhosus* infection. The mortality of para B is a little over 4 per cent. and that of para A under 1 per cent. It is hoped in a further paper to refer more fully to the fatal cases and to describe the morbid anatomy and *post-mortem* appearances.

A *post-mortem* examination has been made in all the fatal cases except one. The causes of death in paratyphoid B have been as follows:

- One case from profuse hæmorrhage.
- Three cases from severe toxæmia combined with severe hæmorrhage.
- Two other cases from sheer toxæmia.
- One case from gangrenous pneumonia.
- Three cases from perforation.
- One case from abscess of the spleen with peritonitis.
- One case from peritonitis without perforation.
- One case died after drainage of a localized abscess in the region of the caecum (? appendicular in origin), and showed abscesses in the liver and also an abscess in the lower lobe of the right lung.
- Two cases died of intercurrent or associated disease, namely, one from lobar pneumonia and one from cerebro-spinal meningitis. This last was the only one in which no *post-mortem* examination was made, but during life the *B. paratyphosus* B was isolated from the blood and the meningococcus from the cerebro-spinal fluid, thus definitely proving the coexistence of the two diseases. In all the other cases the *B. paratyphosus* B was isolated from the bile, and in many of the other cases from the spleen as well. Only one case so far has died in this hospital of

paratyphoid A fever. This was a rather severe case in which a paratyphoid ulcer of the appendix perforated, causing general peritonitis.

ROUTINE OF DIAGNOSIS.

In the preceding remarks we have endeavoured to indicate the clinical phenomena which should lead a case to be classed as "suspected paratyphoid"; we will now mention briefly the routine measures which must be adopted in order to place the diagnosis of such a case on as sure a basis as is possible.

A positive diagnosis can be made in one of two ways. First, the specific bacillus may be recovered from the blood, faeces, or urine of the patient, and secondly, evidence may be discovered in his blood that he has acquired, or is acquiring, an immunity to a specific infection.

1. *Cultivation of Bacillus.*

Before accepting the identity of any bacillus it must conform rigidly to certain cultural characteristics, it must agglutinate with the appropriate high-titre immune serum, and it must satisfy the specific "absorption" tests first advocated by Castellani. If these requirements are not all rigorously exacted there will be many instances of faulty diagnosis, especially in the case of bacilli isolated from the stools.

The recovery of a bacillus from the blood is, unfortunately, not practicable so often as could be wished, for the bacillæmia of paratyphoid fever is often very transient, and cases are frequently not seen until too late.

The attempt should, however, always be made, for the bacilli may be present in the blood as late as the twenty-third day. It is best to do the venepuncture when the temperature is at its highest, and for this reason the evening is probably better than the morning; 5 c.cm. of blood should be removed from a vein and placed into about 10 to 15 c.cm. of sterilized ox-gall. This is incubated at body temperature for twelve hours before plating out, and re-inoculated and replated for the next three days. In a like manner, unless one is dealing with a carrier, the bacilli are most often found in the faeces and urine during the height of the disease. Hence it is advisable to send for examination three or four specimens of both faeces and urine during the first week that the patient is under observation; more can be sent later if the clinical phenomena continue to indicate a positive diagnosis.

2. *Agglutination.*

The second method of diagnosis is to search for the visible evidence of the immunity which the patient must have acquired or be acquiring if he has or has recently had the infection, and is of course the old Widal agglutination reaction. The only satisfactory method is to examine the blood for the specific agglutinins of typhoid, paratyphoid A and paratyphoid B on at least three separate occasions at intervals of four or five days, the first occasion being on the day of admission.

In each case the end-point, that is to say, the maximum dilution of serum in which agglutination occurs, is noted, and it is found that the strength of agglutination follows a definite curve in any recent infection. The macroscopic method is employed, standard emulsions of the micro-organisms must be used, and the result must be read after a constant interval has elapsed, which interval experience has shown to be sufficient for complete agglutination to take place. The technique and the correct interpretation of the resulting curves (especially in the case of typhoid fever where protective inoculation has been practised) are much more difficult matters than might be expected from the short description we have given, but the method adopted in this hospital is that elaborated and published by Captain Dreyer, professor of pathology in the University of Oxford.

In conclusion, we would say that, in view of the constant leucopenia which is present in all enteric group infections, a routine enumeration of leucocytes should be undertaken in all cases, though, of course, this does not help in the absolute diagnosis of paratyphoid fever.

We have not found the diazo reaction to be of diagnostic value in paratyphoid fever, since it appears to be absent or equivocal in all except the most severe cases.

CASE I.
Typical mild, short paratyphoid A with thirteen days' pyrexia.

Chart 1.—Case I.

On admission (seventh day): No distress, sallow complexion, soft small pulse, dry brown tongue, firm easily felt spleen in

a normal looking abdomen. A few typical spots. Stools "typhoid." Blood culture grows para A. No agglutination with *Bacillus paratyphosus A*.
Fourteenth day: Feels well. Spleen just felt, no spots; agglutination with *Bacillus paratyphosus A*, 1 in 100.

CASE II.

Mild but prolonged case of paratyphoid A, with thirty days' pyrexia. The patient was cheerful and quite undistressed from the thirteenth day onwards with nothing suggestive of a "typhoid" appearance. Blood culture on the tenth day of illness grew *B. paratyphosus A*.

On admission (thirteenth day): Sallow complexion, looks seedy but quite bright mentally. Soft, good volume pulse, more rapid than usual; moist, slightly furred tongue, abdomen negative and spleen not enlarged. A few big, well raised paratyphoid spots. Bowels constipated.

Thirty-fifth day: Feels and looks well. Many big spots. Chart shows well a characteristic "spikiness."

CASE III.

Rather severe paratyphoid A with pyrexia of average length (twenty days), but followed by relapse of fifteen days. Blood culture showed *B. paratyphosus* on sixth day of disease and on seventh day of relapse (thirty-third day).

Chart 3.—Case III

Sixth day: Flushed, very lethargic, very soft pulse, dry tongue with a yellow dorsal fur, a tender "doughy" abdomen, spleen enlarged to percussion, a few typical spots,

Fourteenth day: General condition markedly improved. No spots. Spleen not felt. There were no fresh signs during relapse, which patient bore

Chart 4.—Case IV.

well without return of previous severe symptoms. Note the typical "spiky" temperature chart.

CASE V.

Typical mild paratyphoid A with seventeen days' pyrexia.

On admission (ninth day): A little flushed, but otherwise fairly normal appearance. Good volume, but soft pulse. Dry tongue with brown fur in centre. Abdomen negative. Spleen not found enlarged. Several typical spots. Stools (microfilm): Blood culture grows *B. paratyphosus A*. This case ran a typical mild non-toxic course without wasting or distress. The chart shows a typical regularity of the temperature.

CASE VI.

Paratyphoid A of average severity in which the temperature reached normal on the twenty-third day. The pulse was rather more rapid than is usual, and there was some tachycardia in convalescence. The chart shows a rather characteristic disinclination of the temperature finally to settle.

On admission (thirteenth day): Looks flushed and heavy and is disinclined to talk, but is quite clear when roused. Pulse soft and diastolic; tongue dry, rough, and furred; abdomen negative except tenderness in left flank, but the spleen is not made out enlarged. Bowels constipated. Blood culture shows *B. paratyphosus A*. The general condition rapidly improved.

CASE VII.

Paratyphoid A, severe up to third week and necessitates for great irregularity in temperature associated with rigors, and for a relapse with dry plenury. The primary period of pyrexia lasted twenty-six days. Blood culture taken before admission showed *B. paratyphosus A*.

On admission (thirteenth day): Flushed "typhoid" appearance, but mental condition good. Pulse small and very soft. Paratyphoid A, severe up to third week and necessitates for great irregularity in temperature associated with rigors, and for a relapse with dry plenury. The primary period of pyrexia lasted twenty-six days. Blood culture taken before admission showed *B. paratyphosus A*.

Tongue dry and furred in centre. Abdomen a little distended. Spleen palpable. A few typical spots were present. "Typhoid" stools.

CASE VII.

Typical short paratyphoid B showing rapid rise of temperature at onset and quick fall to normal on the ninth day. At the time of onset the patient was in hospital for bruises, the result of a shell explosion. He was up and about, when he felt cold, had headache and pains in the back, and next day his temperature was 103°. He had a discharge from the ear, and it was thought at first that this local condition accounted for the fever. He was seen by one of us on the eleventh day, and sent in as probably paratyphoid.

Chart 7.—Case VII.

On admission (eleventh day): Feels and looks fairly well. The pulse is slow and soft; tongue moist, but has brown fur; the abdomen is negative, and the spleen is not found enlarged. A few spots are present. Bowels constipated. Strong agglutination of *B. paratyphosus B.* Both stools and urine on this day were found to contain the para B organism.

Chart 8.—Case VIII.

CASE VIII.

Typical rather severe case of paratyphoid B, running rapid course with eleven days' pyrexia. On admission (sixth day): Flushed and looks feverish, but is quite clear mentally. Pulse slightly dicrotic; tongue dry, with thick, dirty white fur; the abdomen "full," and spleen not enlarged. A few developing spots are present. Bowels constipated. Blood culture negative. Strong agglutination with *B. paratyphosus B.* A blood culture taken before admission grew *B. paratyphosus B.* The patient made a quick convalescence.

Chart 9.—Case IX.

CASE IX.

A severe toxic case of paratyphoid B, which began to improve rapidly at end of second week, the temperature reaching normal on the eighteenth day.

On admission (eighth day): Flushed, looks toxic, muttering, a little tremulous; is too ill to get history. The pulse is of big volume and very soft. The tongue is dry, with yellowish-

CASE X.
Typical mild paratyphoid B, in which the temperature reached normal on the seventeenth day.

CASE XI.
Very mild non-toxic case of paratyphoid B.

On admission (tenth day): The patient looked debilitated, but otherwise nothing abnormal was found, and the blood culture and serum reactions were negative. During the next few days the temperature rose, and blood was again taken on the fifteenth day, and this time grew *B. paratyphosus B.*, and the serum strongly agglutinated *B. para-*

Chart 11.—Case XI.

typhosus B. By this time, however, the stools sent for examination on the day of admission had grown *B. paratyphosus B.* also. There were at no time any definite physical signs. Presumably the patient had a mild, brief attack, accounting for the normal temperature and the organism in the stools, on the tenth day, and the febrile period occurring in this hospital, during which the organism was grown from the blood, was a relapse.

CASE XII.

Mild case of paratyphoid B fever showing but intermittent type of pyrexia.

On admission (fourteenth day): The patient looks poorly and feels weak. The pulse is of small volume and soft. The tongue is dry with brown fur. The abdomen is sunken, and

the spleen not enlarged. Several spots seen. Bowels constipated. Blood culture negative. Stool culture grew *B. paratyphosus B.*

Chart 12.—Case XII.

Twenty-fifth day: Fresh crop of spots. Spleen felt enlarged and remained so until thirty-first day. Uninterrupted convalescence.

brown fur. The abdomen is not distended, and the spleen is felt. There are many big, well-raised spots. Bowels constipated. Diagnosed as severe paratyphoid B fever. Blood and stool cultures both grew *B. paratyphosus B.*

Twelfth day: Continues severe, with rapid grunting respiration, is restless and flushed, and has a dicrotic pulse.

Fifteenth day: Better. Quiet and undistressed. The patient continued rapidly to improve, and made a good convalescence.

RECENT BACTERIOLOGICAL EXPERIENCES WITH TYPHOIDAL DISEASE AND DYSENTERY.

BY
J. C. G. LEDINGHAM, M.B., D.Sc.,

AND

W. J. BENFOLD, M.B., D.P.H.,

BACTERIOLOGISTS TO THE KING GEORGE HOSPITAL.

WITH NOTES ON THE PROTOZOAN PARASITES IN THE EXCRETA.

By H. M. WOODCOCK, D.Sc.,

HONORARY PARASITOLOGIST TO THE HOSPITAL.

(From the Bacteriological Department of the King George Hospital, Waterloo, S.E.)

ONE result of the extension of hostilities to the Near East has been the opportunity afforded to the medical profession at home of studying on a fairly extensive scale certain infectious diseases not with only sporadically in time of peace. During the past two months (that is, since the middle of August, 1915) this hospital has admitted from the Dardanelles area a considerable number of cases presenting a recent history of acute dysentery with the classical symptoms of tenesmus and frequent evacuations of blood and mucus. In the great majority of these cases the stools on admission had either regained their normal character or were for a varying time after admission persistently loose, unformed, or semifluid. In a small minority of cases the disease at the time of admission still continued in a subacute or chronic form, with constant or intermittent discharge of blood and mucus in the dejecta. Simultaneously with these admissions of convalescent or subacute cases of dysentery there has been a succession of cases of typhoidal disease, in the main due to *B. paratyphosus A*. The bacteriological supervision of these cases, necessitating, on the one hand, the examination of numerous samples of excreta, and on the other, the carrying out of blood cultures and serological tests for purposes of diagnosis, has been no light addition to the ordinary routine of a bacteriological department attached to a hospital of 1,600 beds.

We venture to communicate the following notes on our bacteriological experiences, solely in the hope that they may be of interest and perchance of service to others working in similar fields and possibly under less advantageous surroundings.

EXAMINATION OF FAECES.

In the first place, it may be advisable to detail briefly our routine technique for the bacteriological examination of stools, urine, and blood, and for the performance of serological tests with the serums of patients.

When large numbers of stools have to be dealt with, the development of rapid and reliable methods of identification is of paramount importance, otherwise reports are apt to get in arrears, and confusion is likely to reign in the laboratory. Further, it is to the interest of the clinician that bacteriological diagnosis should be forthcoming at the earliest possible moment. The technique for faeces examinations here detailed is that to which we have been led by gradual modifications of the scheme with which we commenced operations, and it has proved very satisfactory.

ESSENTIALS.

1. MacConkey's bile-salt-lactose-neutral-red-agar.
2. Mannite peptone water containing Durham's tube.
3. Thoroughly tested specific agglutinating serums of high potency for *B. typhosus*, *B. paratyphosus A*, *B. paratyphosus B*, *B. enteritidis* Gaertner, *B. dysenteriae* Shiga, and *B. dysenteriae Y*. These serums we obtain from the Lister Institute.

The following dilutions of these serums are made with carbollized saline (0.5 per cent. carbolic in normal saline) and kept in bulk preferably but not necessarily in the cold chest.

1. P.G. mixture containing in equal parts, *Paratyphosus A* serum (1 in 66), *Paratyphosus B* serum (1 in 66), and *Gaertner* serum (1 in 65). Concentration of each in final mixture 1 in 200.
2. P.T. mixture containing in equal parts, *Paratyphosus A* serum (1 in 66), *Paratyphosus B* serum (1 in 66), and typhoid serum (1 in 66). Concentration of each in final mixture = 1 in 200.

3. *Y* serum diluted 1 in 100, or 1 in 200.
4. *Shiga* serum diluted 1 in 100, or 1 in 200.
5. *Paratyphosus A* serum diluted 1 in 200.
6. *Paratyphosus B* serum diluted 1 in 200.
7. *Typhoid* serum diluted 1 in 200.
8. *Gaertner* serum diluted 1 in 200.

STEPS.

Portion of faeces emulsified in broth and allowed to stand on bench for an hour. One or two drops from the upper layers of the fluid are spread on the bile-salt-agar plates.

Next Morning.—Pick off several non-lactose colonies (discrete colonies wherever possible) and inoculate each colony into mannite and into ordinary broth. The number of colonies taken off will depend on many factors: for example, (1) the number of white colonies present, (2) the appearance of the colonies, (3) the clinical symptoms of the case if known, (4) the appearances of the stool.

Evening of Same Day.—After at least five hours' growth, examine the broth tubes, preferably with the dark ground microscope, and record motility or non-motility. At the same time inoculate an agar slope from each broth tube.

Second Morning. The mannite tubes are examined and the results acid and gas, acid only, or no change recorded on the corresponding agar slopes.

1. If acid and gas and motile, test the corresponding slope with P.G. mixture. A loop of culture is emulsified in 4 or 5 c.c.m. of saline. Equal parts of this emulsion and the P.G. mixture are placed in a small "agglutination" test tube and kept at 37°C. Examine the tube every hour and note if agglutination is taking place. If so, test the corresponding emulsion with *Paratyphosus A* serum, *Paratyphosus B* serum, and *Gaertner* serum separately (one dilution of each giving 1 in 400 in the final mixture). If agglutination takes place with *A* serum but not with *B* or *Gaertner* serum the emulsion may then be tested up to the full titre of the serum.

2. If acid and gas and non-motile, no further steps need be taken, but it must be remembered that a positive motility is final, while a negative result may leave a certain element of doubt, in which case it is wise to treat the culture as in 1. The extra labour is small.

3. Acid only and non-motile. Test with the P.T. mixture. Many paratyphoid strains give little or no gas in the sugars they normally ferment, and for this reason it is necessary to treat all cultures giving acid only in mannite and motiles as possible paratyphoids as well as typhoids. If agglutination occurs, test further with *A*, *B*, and *T* serums separately.

4. Acid only and non-motile. Test with "Y" serum.

5. No acid and motile. Discard for the time being, or, if time permits, test further to determine whether the culture is Morgan's No. 1 *Bacillus* or a member of the *Proteus* group.

6. No change on mannite and non-motile. Test with *Shiga* serum.

The emulsions are arranged in a test rack according as they have to be tested with P.G. mixture, P.T. mixture, Y serum, etc. Equal volumes of serum (say from the stock P.G. mixture) are placed in small "agglutination" tubes by aid of a large-bored capillary pipette with rubber teat and fiducial mark, delivering about 0.4 c.c.m.

Similar volumes of the corresponding emulsions are added by means of the same pipette, which is cleansed (between each operation) by boiling water from a beaker. As mentioned above, the tubes, after being placed in the incubator, should be examined every hour or so, and any that have reacted should be further tested if necessary. No negative results should be recorded, however, until the following morning, when the final readings are made.

NOTES WITH REGARD TO THE METHOD.

There has never been the slightest difficulty in differentiating *B. paratyphosus A*, *B. paratyphosus B*, and *B. Gaertneri* by the specific serums. Absorption methods have never been necessary. As will be mentioned below, we have so far isolated only one member of the mannite-fermenting group of *B. dysenteriae* (Flexner-Y) which has agglutinated to the full titre of our "Y" serum. Organisms probably belonging to this group but inagglutinable by the specific serum are set aside for later examination at leisure. In view of the high specificity frequently met with in this group with respect to agglutination by specific serum, it is highly probable that we may be dealing with a group which can only be differentiated by a serum prepared by immunization with one or more of their number.

The *Shiga* strains we have obtained have all been agglutinated in high dilution by the specific *Shiga* serum 1 in 1,500 to 1 in 4,000. In the presence of decisive agglutination tests, confirmatory fermentation tests may with confidence be deferred to a more convenient time.

The following extract from our ledger is given to illustrate the method in practice:

Index No. 899.
Name, H.
Date, October 13th.

Particulars of Faeces.—Fairly stiff yellow stool. No blood or mucus seen.
Microscopic Examination.—No blood or mucus. No flagellates or smoochae.

MacConkey Plates.—A few suspicious colonies.

Cultures Picked Off.

A. Mannite—Motility + Discard.
B. Mannite + Motility + P.T. (+ + +); A 400 (+ + +); B. 400 (0), T. 400 (0).
C. Mannite + Motility + Reacted similarly to B.

B finally taken up to 1 in 3,200.

Report, *B. paratyphosus* A.

Technique for Blood Culture in Typhoidal Cases.

10 c.cm. blood from an arm vein are taken; 5 c.cm. are inoculated into a tube containing about 10 c.cm. of pure egg bile. The other 5 c.cm. are placed either in a flask of ordinary broth or in a mixture in equal parts of bile and broth.

The bile tube is examined next morning (hanging drop under dark ground microscope). If a motile organism is seen the bile is plated out on MacConkey's medium, or (preferably) an agar slope may be plentifully inoculated with the bile and a culture obtained for agglutination purposes next morning (or possibly the same evening). The bile tubes should be examined for at least four days, as we have on several occasions recovered *B. paratyphosus* A on the fourth day while apparently negative on the third. Before being finally discarded, all bile tubes should be plated out.

Ordinary broth has been most unsatisfactory. In many cases the broth has remained sterile while the bile tube has given positive results.

Technique for Widal Tests in Cases of Typhoid, Paratyphoid, and Dysentery.

The macroscopic method is used, small test tubes being required.

Standardized emulsions of *paratyphosus* A, *paratyphosus* B, *typhoid*, *typhoid*, *Shiga*, etc., are made by emulsifying twenty-four-hour agar slopes in normal saline containing 1 in 1,000 formalin in the case of *paratyphosus* B, which is emulsified in *half-normal saline* containing formalin. These emulsions are standardized to a certain opacity corresponding to about 2,000 millions per c.cm. The tubes are placed in the incubator at 37° C. for at least two hours and then kept on the bench till next morning, when the final reading is taken and recorded. The reading is made in the first instance from the appearance of the sediment examined under a strong light and eventually controlled by microscopic examination of the shaken-up mixture (the tube being rolled a definite number of times between the hands). A capillary tube is inserted into the highest dilution and a drop therefrom removed to a slide, then a drop from the next highest, and so on. The row of drops is then examined without any coverslip under the low power of the microscope.

CASES OF PARATYPHOID FEVER.

CASE 1.—O—y. Admitted August 23rd with fever which lasted till September 7th. *B. paratyphosus* A was recovered from the blood on August 26th.

Agglutination.—September 10th: r. A, 1 in 40 (+ + +), 1 in 80 (+), 1 in 160 (0); r. B, 1 in 40 (+), 1 in 80 (0).

CASE 2.—E—s. Admitted August 26th with fever which lasted till September 17th. The patient had a relapse which lasted from October 2nd till October 14th. *B. paratyphosus* A recovered from the blood on August 27th.

Agglutination.—September 10th: r. A, 1 in 40 (+ + +), 1 in 80 (+), 1 in 160 (+ +); 1 in 320 (+), 1 in 640 (trace); r. B, 1 in 40 (0).

CASE 3.—W—s. Admitted August 23rd. Pyrexia on August 24th which lasted till September 14th. Relapsed September 13th. Temperature normal on October 1st. *B. paratyphosus* A recovered from the blood on August 31st.

Agglutination.—September 10th: r. A, 1 in 40 (0), 1 in 80 (0); r. A of Case 4, 1 in 40 (0), 1 in 80 (0); r. B, 1 in 40 (0).

CASE 4.—H—n. Admitted August 24th. Pyrexia from August 28th to October 6th; exacerbation from October 6th to October 29th. *B. paratyphosus* A was recovered from the blood on September 1st; and *B. dysenteriae* Shiga from the blood on October 11th. (See Case 14 in Dysentery series.)

Agglutination.—September 8th: r. A, 1 in 40 (+), 1 in 80 (0), October 12th: 1 in 40 (+), 1 in 80 (0), 1 in 160 (0); r. A (homologous), 1 in 40 (+ +), 1 in 80 (trace), 1 in 160 (0); r. Shiga, 1 in 40 (trace), 1 in 80 (0); r. Shiga (homologous), 1 in 40 (0), 1 in 80 (0).

CASE 5.—O—a. Admitted August 27th with slight fever. Normal on September 17th; relapse September 19th to Sep-

tember 26th. *B. paratyphosus* A recovered from the blood on September 21st to October 17th.

Agglutination.—September 10th: r. A, 1 in 40 (+ + +), 1 in 80 (+), 1 in 160 (0); r. A of Case 4, 1 in 40 (+ +), 1 in 80 (+), 1 in 160 (0); r. B, 1 in 40 (0).

CASE 6.—C—s. Admitted August 23rd. Pyrexia from September 1st to September 10th; since normal. *B. paratyphosus* A recovered from the blood on September 4th.

Agglutination.—September 10th: r. A, 1 in 40 (+), 1 in 80 (0); r. B, 1 in 40 (+ +). End-point not reached.

CASE 7.—W—n. Admitted August 23rd. Pyrexia from September 8th to 22nd. Since normal. *B. paratyphosus* A recovered from the blood on September 11th.

Agglutination.—September 11th: r. A, 1 in 40 (0), 1 in 80 (0); r. B, 1 in 40 (0), 1 in 80 (0).

CASE 8.—B—t. Admitted August 23rd. Pyrexia from September 11th to October 9th. *B. paratyphosus* A recovered from the blood on September 15th, and from the pus of a testicular abscess on October 21st in pure culture.

CASE 9.—F—t. Admitted September 16th with pyrexia which lasted till October 7th. *B. paratyphosus* A recovered from the blood on September 19th.

Agglutination.—September 27th: r. A, 1 in 40 (trace), 1 in 80 (0); r. B, 1 in 40 (0), October 5th: r. A, 1 in 40 (0); r. B, 1 in 40 (0); r. T, 1 in 40 (+ +), 1 in 80 (+), 1 in 160 (trace).

CASE 10.—A—r. Admitted September 16th. Pyrexia from September 21st to October 17th. *B. paratyphosus* A recovered from the blood on September 23rd.

Agglutination.—October 9th: r. A, 1 in 40 (trace), 1 in 80 (0); r. B, 1 in 40 (0), 1 in 80 (0), 1 in 160 (+ +), 1 in 320 (+), 1 in 640 (trace). (Zonc effect.)

CASE 11.—S—r. Admitted September 22nd. Pyrexia for six days before admission; normal on October 16th. *B. paratyphosus* A recovered from the blood on September 23rd, and from the faeces on the following day.

Agglutination.—September 27th: r. A, 1 in 40 (+ + +), 1 in 80 (+ + +), 1 in 160 (+ +); end-point not reached; r. B, 1 in 40 (+), 1 in 80 (0).

CASE 12.—T—v. Admitted September 10th. Pyrexia from September 13th to October 1st. *B. paratyphosus* B recovered from the blood on September 23rd.

Agglutination.—September 27th: r. A, 1 in 40 (+ + +), 1 in 80 (+ +), 1 in 160 (+), 1 in 320 (0); r. B, 1 in 40 (+ + +), 1 in 80 (+ +), 1 in 160 (+ +); end-point not reached. October 9th: r. A, 1 in 40 (+), 1 in 80 (0); r. B, 1 in 40 (+ + +), 1 in 80 (+ +), 1 in 160 (+ +), 1 in 320 (+ +), 1 in 640 (+ +), 1 in 1280 (trace); r. T, 1 in 40 (+ +), 1 in 80 (+), 1 in 160 (+), 1 in 320 (+), 1 in 640 (0).

CASE 13.—M—e. Admitted September 16th with fever which lasted till October 2nd; normal since. *B. paratyphosus* A recovered from the blood on September 21st.

Agglutination.—September 27th: r. A, 1 in 40 (0); r. B, 1 in 40 (0), October 5th: r. A, 1 in 40 (0); r. B, 1 in 40 (trace), 1 in 80 (0); r. T, 1 in 40 (+ +), 1 in 80 (+ +), 1 in 160 (+ +), 1 in 320 (+), 1 in 640 (+), 1 in 1280 (0).

CASE 14.—M—y. Admitted September 5th with fever which lasted till September 21st. Severe relapse October 2nd to 27th. *B. paratyphosus* A recovered from the urine on October 6th, and from the blood on the following day.

CASE 15.—D—1. Admitted September 12th. Pyrexia September 22nd to October 7th. Slight relapse October 22nd to 26th. *B. paratyphosus* A recovered from the blood on October 1st.

CASE 16.—M—n. Admitted September 26th. Pyrexia from September 30th to October 21st. *B. paratyphosus* A recovered from the blood on October 3rd.

CASE 17.—M—n. Admitted September 13th with fever, which lasted till September 24th; since normal. Blood culture negative on September 15th. *B. paratyphosus* A recovered from faeces on September 14th.

Agglutination.—September 21st: r. A, 1 in 40 (+ + +), 1 in 80 (+ + +), 1 in 160 (+ + +); end-point not reached; r. B, 1 in 40 (0), 1 in 80 (0), 1 in 160 (0); r. T, 1 in 40 (trace), 1 in 80 (0).

CASE 18.—F—v. Admitted September 6th. Pyrexia September 8th to 19th. *B. paratyphosus* A recovered from faeces on September 16th.

CASE 19.—R—n. Admitted September 26th. Pyrexia October 3rd to 17th. *B. paratyphosus* A recovered from faeces on September 28th.

CASE 20.—C—k. Admitted September 26th with pyrexia which lasted till October 7th. Blood culture negative on October 2nd. *B. paratyphosus* A recovered from faeces on September 28th.

Agglutination.—October 9th: r. A, 1 in 40 (+), 1 in 80 (trace), 1 in 160 (0); r. B, 1 in 40 (0); r. T, 1 in 40 (+), 1 in 80 (+), 1 in 160 (trace), 1 in 320 (0).

CASE 21. H—J. Admitted September 9th. Pyrexia September 20th to October 13th. *B. paratyphosus* B recovered from faeces on September 25th.

Agglutination.—October 7th: r. A, 1 in 40 (+ +), 1 in 80 (+), 1 in 160 (0); r. B, 1 in 40 (0), 1 in 80 (+ +), 1 in 160 (+ +), 1 in 320 (+), 1 in 640 (+), 1 in 1280 (trace). Note initial inhibition zone.

CASE 22. G—B. Admitted September 16th. Had dysentery in August with blood and mucus. Slight diarrhoea on admission, with fever which lasted till September 27th. *B. paratyphosus* A recovered from faeces on September 23rd.

Agglutination.—September 27th: r. A, 1 in 40 (0); r. B, 1 in 40 (0), 1 in 80 (0); r. Shiga, 1 in 40 (+ +), 1 in 80 (+ +), 1 in 160 (+), 1 in 320 (0).

CASE 23. H—N. Admitted September 16th. Pyrexia September 18th to October 13th. Blood culture negative on September 25th. *B. paratyphosus* A recovered from faeces on October 13th and 15th.

Agglutination.—October 9th: r. A, 1 in 40 (+), 1 in 80 (+), 1 in 160 (0); r. B, 1 in 40 (0), 1 in 80 (0), 1 in 160 (0); r. T, 1 in 40 (+), 1 in 80 (+), 1 in 160 (trace), 1 in 320 (0).

CASE 24. C—N. Admitted September 9th. Pyrexia September 12th to 20th; relapse September 30th to October 22nd. Blood culture negative on September 18th. *B. paratyphosus* A recovered from faeces on October 11th.

Agglutination.—October 5th: r. A, 1 in 40 (0), 1 in 80 (0), 1 in 160 (0); r. B, 1 in 40 (0), 1 in 80 (0), 1 in 160 (0).

In the following the diagnosis rests so far on serological data.

CASE 25. N—B. Admitted August 23rd with fever which lasted till September 8th; relapse September 17th to October 8th. Blood culture negative on August 26th.

Agglutination.—September 10th: r. A, 1 in 40 (+ + +), 1 in 80 (+ +), 1 in 160 (+), 1 in 320 (0); r. B, 1 in 40 (0), 1 in 80 (0).

CASE 26. C—E. Admitted August 23rd with fever: normal September 1st; relapse September 23rd to October 6th. Blood culture negative on August 26th.

Agglutination.—September 8th: r. A, 1 in 40 (+ + +), 1 in 80 (+ +), 1 in 160 (+); limit not reached; r. B, 1 in 40 (+), 1 in 80 (0).

CASE 27. B—R. Admitted August 27th with fever which became normal on September 13th. Pyrexia again from September 14th to 18th; since normal. Blood culture negative on August 31st.

Agglutination.—September 10th: r. A, 1 in 40 (+ +), 1 in 80 (+), 1 in 160 (+ +); limit not reached; r. A, of Case 4, 1 in 40 (+), 1 in 80 (0); r. B, 1 in 40 (0), 1 in 80 (0).

CASE 28. B—T. Admitted August 30th with fever which lasted till September 20th. Blood culture negative on September 1st.

Agglutination.—September 1st: r. A, 1 in 40 (+ +), 1 in 80 (+ +), 1 in 160 (+), 1 in 320 (0). September 10th: r. A, 1 in 40 (+ +), 1 in 80 (+), 1 in 160 (0); r. B, 1 in 40 (0), 1 in 80 (0).

CASE 29. G—M. Admitted August 30th with acute fever which lasted till September 10th; since normal. Blood culture negative on September 2nd.

Agglutination.—September 10th: r. A, 1 in 40 (+ +), 1 in 80 (+ +), 1 in 160 (0); r. B, 1 in 40 (0), 1 in 80 (0).

CASE 30. F—R. Admitted August 8th with pyrexia which lasted till September 1st. Blood culture negative on August 10th.

Agglutination.—September 5th: r. A, 1 in 100 (+ + +). Not taken further.

CASE 31. P—P. Admitted August 50th with slight fever (convalescent case). Blood culture negative on September 6th.

Agglutination.—September 10th: r. A, 1 in 40 (+ +), 1 in 80 (+), 1 in 160 (0); r. B, 1 in 40 (0), 1 in 80 (0).

CASE 32. T—S. Admitted August 23rd with fever which lasted till September 1st; since normal.

Agglutination.—September 7th: r. A, 1 in 40 (+ + +), 1 in 80 (+), 1 in 160 (0); r. B, 1 in 40 (0), 1 in 80 (0).

CASE 33. G—M. Admitted September 3rd with slight fever (convalescent case). Blood culture negative on September 7th.

Agglutination.—September 10th: r. A, 1 in 40 (+ + +), 1 in 80 (+ +), 1 in 160 (+); limit not reached; r. B, 1 in 40 (+), 1 in 80 (0).

CASE 34. N—S. Admitted August 26th with fever complicated by wound. Blood culture negative on September 7th.

Agglutination.—September 10th: r. A, 1 in 40 (+ + +), 1 in 80 (+), 1 in 160 (0); r. B, 1 in 40 (0), 1 in 80 (0).

CASE 35. E—E. Admitted September 5th with fever; nine days of fever before admission; fever lasted till September 30th. Blood culture negative on September 8th.

Agglutination.—September 9th: r. A, 1 in 40 (+ +), 1 in 80 (+), 1 in 160 (0).

CASE 36. II—S. Admitted September 9th with very slight pyrexia which continued till September 17th; history of fever previous to admission. Blood culture negative on September 11th.

Agglutination.—September 11th: r. A, 1 in 40 (trace), 1 in 80 (0), 1 in 160 (0); r. B, 1 in 40 (+ +), 1 in 80 (+ +), 1 in 160 (+), 1 in 320 (0).

CASE 37. V—E. Admitted August 30th. Had dysentery, with blood and mucus, in Gallipoli. Blood culture negative on September 2nd.

Agglutination.—September 10th: r. A, 1 in 40 (0), 1 in 80 (0), 1 in 160 (0); r. B, 1 in 40 (+ + +), 1 in 40 (0); not taken further. September 14th: r. B, 1 in 40 (+ +), 1 in 80 (+ +), 1 in 160 (+), 1 in 320 (0).

CASE 38. K—Y. Admitted September 10th with slight fever (convalescent case). Blood culture negative on September 15th.

Agglutination.—September 21st: r. A, 1 in 40 (+ +), 1 in 80 (+ +), 1 in 160 (+), 1 in 320 (0); r. B, 1 in 40 (+ +), 1 in 80 (+ +), 1 in 160 (+); not taken further.

CASE 39. P—N. Admitted September 10th with very slight pyrexia (convalescent case). Blood culture negative on September 15th.

Agglutination.—September 21st: r. A, 1 in 40 (trace), 1 in 80 (0), 1 in 160 (0); r. B, 1 in 40 (+ +), 1 in 80 (+ +), 1 in 160 (+); not taken further.

CASE 40. R—N. Admitted September 10th. No high temperature (convalescent case). Blood culture negative on September 15th.

Agglutination.—September 21st: r. A, 1 in 40 (0), 1 in 80 (0), 1 in 160 (0); r. B, 1 in 40 (+ +), 1 in 80 (+ +), 1 in 160 (+), 1 in 320 (0); r. T, 1 in 40 (+ +), 1 in 80 (+).

CASE 41. M—E. Admitted September 5th. Pyrexia from September 8th to September 28th. History of a previous fever in Malta. Blood culture negative on September 15th.

Agglutination.—September 21st: r. A, 1 in 40 (+ +), 1 in 80 (+ +), 1 in 160 (0); r. B, 1 in 40 (0), 1 in 80 (0).

CASE 42. I—E. Admitted September 9th with fever which continued till September 23rd.

Agglutination.—September 16th: r. A, 1 in 40 (0), 1 in 80 (0), 1 in 160 (0); r. B, 1 in 40 (+ +), 1 in 80 (+ +), 1 in 160 (+); limit not reached.

CASE 43. W—L. Admitted September 10th. Pyrexia September 11th to 23rd. Blood culture negative on September 16th.

Agglutination.—September 21st: r. A, 1 in 40 (trace), 1 in 80 (0); r. B, 1 in 40 (+ +), 1 in 80 (+ +), 1 in 160 (+), 1 in 320 (0); r. T, 1 in 40 (+ +), 1 in 80 (0), 1 in 160 (0).

CASE 44. P—R. Admitted September 10th with fever which lasted till October 11th. Relapse October 12th to 19th. Blood culture negative on September 17th.

Agglutination.—September 21st: r. A, 1 in 40 (+ +), 1 in 80 (+ +), 1 in 160 (+), 1 in 320 (0); r. B, 1 in 40 (+ +), 1 in 80 (+ +), 1 in 160 (+), 1 in 320 (0).

CASE 45. F—R. Admitted August 28th. Pyrexia from September 9th to 26th.

Agglutination.—September 21st: r. A, 1 in 40 (+ +), 1 in 80 (+ +), 1 in 160 (0); r. B, 1 in 40 (0), 1 in 80 (0), 1 in 160 (0).

CASE 46. M—R. Admitted September 16th with fever which lasted till October 5th. Blood culture negative on September 16th.

Agglutination.—September 21st: r. A, 1 in 40 (+ + +), 1 in 80 (+ + +), 1 in 160 (+ +); limit not reached; r. B, 1 in 40 (+ +), 1 in 80 (+ +), 1 in 160 (0); r. T, 1 in 40 (+ +), 1 in 80 (+ +), 1 in 160 (+). October 5th: r. A, 1 in 40 (+ +), 1 in 80 (+ + +), 1 in 160 (+ +), 1 in 320 (trace), 1 in 640 (0); r. B, 1 in 40 (+ + +), 1 in 80 (+ + +), 1 in 160 (+ +), 1 in 320 (+), 1 in 640 (trace), 1 in 1280 (0).

CASE 47. D—N. Admitted August 20th. Pyrexia September 10th to 19th; since normal. Blood culture negative on September 13th.

Agglutination.—September 21st: r. A, 1 in 40 (+ +), 1 in 80 (+ +), 1 in 160 (+ +); limit not reached; r. B, 1 in 40 (+ +), 1 in 80 (0), 1 in 160 (0).

CASE 48. S—E. Admitted September 16th with slight irregular fever, which lasted till October 5th.

Agglutination.—October 1st: r. A, 1 in 40 (+ +), 1 in 80 (+ +), 1 in 160 (trace); r. B, 1 in 40 (0), 1 in 80 (0), 1 in 160 (0); r. T, 1 in 40 (+ +), 1 in 80 (+ +), 1 in 160 (+), 1 in 320 (trace), 1 in 640 (0).

CASE 49. C—S. Admitted September 26th with pyrexia, which lasted till October 20th. Blood culture negative on October 2nd.

Agglutination.—October 3rd: r. A, 1 in 40 (0), 1 in 80 (0), 1 in 160 (0); r. B, 1 in 40 (+ +), 1 in 80 (+ + +), 1 in 160 (+ + +), 1 in 320 (+ +), 1 in 640 (0); r. T, 1 in 40 (+ +), 1 in 80 (+ +), 1 in 160 (+ +), 1 in 320 (trace), 1 in 640 (0).

CASE 50. G—S. Admitted September 16th. Pyrexia September 25th to October 11th; since normal. Blood culture

negative on October 6th. *E. dysenteriae* Shiga isolated from faeces on October 18th.

Agglutination.—October 15th: r. A, 1 in 40 (0), 1 in 80 (0); r. B, 1 in 40 (0), 1 in 80 (+), 1 in 160 (0). October 22nd: r. A, 1 in 40 (0), 1 in 80 (0), 1 in 160 (0); r. B, 1 in 40 (trace), 1 in 80 (0), 1 in 160 (0); r. Shiga, 1 in 40 (1), 1 in 80 (0), 1 in 160 (0).

CASES OF ENTERIC FEVER.

CASE 1.—R.—s. Admitted September 16th with pyrexia, which continued till October 21st. *B. typhosus* recovered from the blood on September 16th.

Agglutination.—September 27th: r. A, 1 in 40 (0), 1 in 80 (0), 1 in 160 (0); r. B, 1 in 40 (0), 1 in 80 (+), 1 in 160 (0); r. T, 1 in 40 (0), 1 in 80 (0), 1 in 160 (0). October 2nd: r. A, 1 in 40 (0), 1 in 80 (0), 1 in 160 (0); r. B, 1 in 40 (0), 1 in 80 (0); r. T, 1 in 40 (0), 1 in 80 (0), 1 in 160 (0). October 5th: 1 in 40 (0), 1 in 80 (0); r. B, 1 in 40 (0), 1 in 80 (0); r. T, 1 in 40 (0), 1 in 80 (0), 1 in 160 (0). October 11th: 1 in 40 (0), 1 in 80 (0), 1 in 160 (0). October 18th: 1 in 40 (0), 1 in 80 (0), 1 in 160 (0). October 25th: 1 in 40 (0), 1 in 80 (0), 1 in 160 (0).

CASE 2.—M.—d. Admitted September 11th. Pyrexia September 11th to 17th; normal September 18th to 22nd; very acute fever September 22nd to October 10th; normal since. *B. typhosus* recovered from the blood on September 25th.

CASE 3.—M.—d. Admitted August 30th with symptoms pointing to necrotic endocarditis. *B. typhosus* and streptococci recovered from the blood on September 2nd. Death took place on September 6th. At the autopsy the Feyer's plaques were congested and inflamed, but no actual necrosis was found in the gut. The mesenteric glands were enlarged and acutely congested. The spleen weighed 121 oz., and was soft and diffused. The gall bladder was healthy; there were no calculi. Left ventricle greatly hypertrophied. Cusps of aortic valve united together from old endocarditis. No recent vegetations. There was also a discharging wound on the left shoulder.

REMARKS WITH REGARD TO THE CASES RECORDED ABOVE.

It may be well to point out, in the first instance, that diagnosis only has been our object—in fact, our only possible object. When the blood culture was positive no further work was necessary, but in a certain number of cases we have made careful serological tests in order to obtain some estimate of the reliability of the latter for diagnostic purposes. As a rule the agglutination test was not performed until some days or perhaps a week (or more) had elapsed after the positive or negative blood culture.

Of the first group of 24 cases in which the causative bacillus was recovered from the blood, faeces, or urine, it will be observed that 8 or 9 cases gave little or no agglutination with the corresponding organism. The remainder, however, gave as a rule very definite reactions with the organism found to be the infecting agent.

Titres so high as 1 in 320 have been obtained in *paratyphosus* A infections, but a definite reaction even in 1 in 40 is to be regarded as significant in these A infections. Normal serums in our experience have given no reaction with *B. paratyphosus* A in this dilution.

In *paratyphosus* A cases also the serum has rarely given a group reaction with *paratyphosus* B. On the other hand, in the few *paratyphosus* A cases in which the typhoid *Widal* has been tested (Nos. 9, 13, 17, 20, 23) this has proved to be very low except in one case (No. 13), where agglutination of *B. typhosus* was obtained up to 1 in 640 dilution. (All cases, so far as could be ascertained, had been inoculated against enteric fever.)

B. paratyphosus B was recovered from two cases only (Nos. 12, 21). In case No. 12 the serum was tested on two occasions, when very high titres with *paratyphosus* B were found. There was also—at least on the first occasion—a very definite group reaction with *B. paratyphosus* A, which, however, had apparently in great part disappeared before the second test. This phenomenon may be analogous to that noted recently by certain Continental workers who have recorded positive typhoid *Widals* in the early stages of bacillary dysentery. As the dysentery *Widal* became established the group reaction tended to disappear. With regard to the second group of cases (25 to 50), in which the diagnosis has rested on serological data, 15 (namely, 25, 26, 27, 28, 29, 30, 31, 32, 33, 34, 35, 41, 45, 47, 48) were almost certainly cases of *paratyphoid* A fever, 8 (namely, 36, 37, 39, 40, 42, 43, 49, 50) almost certainly *paratyphoid* B fever, while 3 (namely, 38, 44, 46) were either A or B, or mixed infections. In this latter group of three only the recovery of the actual causative agent or agents would effectively clear up the diagnosis. Apparently, however, many of these cases came in during the convalescent stage, when blood culture

was not likely to yield positive results. In 5 cases (namely, 40, 43, 46, 48, 49) the typhoid *Widal* was tested, but only in 2 (namely, 48, 49) was a well-marked positive reaction evident. Three cases only of enteric fever have occurred, *B. typhosus* being recovered from the blood in all. Case No. 3, which came to autopsy, has been already referred to. In case No. 1 the serum was carefully titrated against *paratyphosus* A, *paratyphosus* B, and *B. typhosus* on two occasions. A remarkably strong typhoid reaction was obtained on the first occasion with distinct evidence of group reaction with A and B (especially the latter). On the second occasion this group reaction had completely disappeared, while the specific typhoid *Widal* remained at the same high level.

On the whole we are strongly of opinion that the serological test in typhoid disease, while of the greatest service in practical diagnosis, should be employed only as a second string when bacteriological methods have failed to reveal the causative agent. To this object, namely, the isolation of the causative bacillus from the blood or excreta, chief attention should be directed. For statistical purposes, there can be no doubt that the best evidence is that derived from positive bacteriological findings.

No doubt the value of the serological test, and more particularly the interpretation of the same in doubtful cases, might be greatly improved by repeated titration of the serum from the commencement of the disease onwards, but a routine of this scope does not come within the realm of practical diagnosis, and moreover may fail entirely to detect the real nature of pyrexias during which (possibly because they are of short duration and small intensity) agglutinin development in measurable or significant degree fails to take place. A more detailed analysis of the results is for the moment deferred.

Mixed Infections.

The question of mixed infections, or rather of secondary infections, occurring during the convalescent or possibly carrier stage of the first infection, demands notice. Most of the *paratyphoid* cases have come in with a history of dysentery. Where typhoid disease and dysentery are simultaneously prevalent, the occurrence of post-dysenteric *paratyphoid* fever or post-*paratyphoid* dysentery is to be expected.

In Case 22, which gave a history of dysentery, *B. paratyphosus* A was recovered from the faeces. The patient's serum did not agglutinate A or B, but gave a very marked reaction with the Shiga bacillus. In Case 50 also, although the serum gave a significant agglutination with *paratyphosus* B, the organisms recovered from the stools were *E. dysenteriae* Shiga and *E. enteritidis* Gaertner.

Case 4, in which Shiga was obtained from the blood during a so-called relapse in the course of a definitely diagnosed *paratyphoid* A fever, was probably also one of post-dysenteric *paratyphoid* in a person who had become a dysenteric (Shiga) carrier. From another case—not listed—of convalescent dysentery whose serum agglutinated Shiga in high dilution, *B. paratyphosus* A has recently been recovered in the faeces.

Cases of this kind will doubtless tend to increase, and they demand careful bacteriological attention, both from the point of view of science generally and preventive medicine in particular. In the absence of further data it is impossible to discuss the matter further at this stage.

BACILLARY DYSENTERY.

A large number of convalescent cases of dysentery have arrived with few or no symptoms. The stools were examined, as a rule, only once (and with generally negative results), and the patients were not retained in hospital. Among these admissions, however, were a few subacute or chronic cases either still passing blood and mucus or soft fluid unformed motions with or without mucus.

From 15 cases of this kind *B. dysenteriae* Shiga has been recovered. (See list of cases below, with notes regarding the appearance of the motions.) Agglutination tests have been performed in most of these cases with the stock Shiga strain and occasionally with the homologous organism also.

Apparently, during convalescence, very high titres may be expected.

One case only of *Flexner's* dysentery occurred, the

infection running its course from start to finish in the hospital. It lasted only a few days, and was heralded by high fever and the passage of blood and mucus.

As mentioned above, samples of stools have been examined, from which organisms probably belonging to the mannite-fermenting group of *B. dysenteriae* have been recovered, which do not agglutinate with the specific Y-serum available. The only case of dysentery which ended fatally soon after admission, and which showed intense enteritis of the large bowel at autopsy, was probably due to infection by a member of this group. From the bloody and mucoid stool before death, and also from the colon at autopsy, organisms of this type were recovered. Their consideration must remain over for the present.

The following list of cases, with particulars of the nature of the stools and the organisms isolated, is appended.

CASES OF BACILLARY DYSENTERY.

(Subacute or Chronic and Convalescent Cases.)

CASE 1.—I.—A. Admitted July 27th. Diarrhoea eight weeks before admission. No history of blood and mucus before admission. Mucoid stool of July 27th showed microscopically: Blood, pus, catarrhal cells, *Lambda intestinalis* (inactive), and cysts of the anaerobic *B. dysenteriae* Shiga recovered in almost pure culture. Two other samples on the same day had similar features, except that there was much less pus and blood and far more food detritus, muscle fibres, and innumerable bacteria.

A sample taken on July 29th was apparently pure mucus. Microscopically: Numerous flagellato cysts were found. *B. dysenteriae* Shiga again recovered.

Sample of July 30th: Quite different from previous samples. Soft creamy stool not containing blood or pus, but numerous actively motile flagellates (*Lambda* and *Macrostoma*).

July 31st: Pure mucus stool. No flagellates seen. Some *Lambda* cysts present.

August 1st: Mucus stool, with pus and little blood. No active flagellates or cysts seen. *B. dysenteriae* Shiga recovered.

August 2nd: Greenish grumous stool, containing undigested muscle fibres, very few pus cells, and innumerable bacteria. No active flagellates.

August 3rd: Greenish-yellow mucoid stool. No motile flagellates seen. *Macrostoma* cysts present.

August 4th: Creamy stool like that of July 30th. Swarming with flagellates.

From the grumous and creamy stools, which contained food residues and many bacteria, *B. dysenteriae* Shiga could not be recovered.

Blood count on August 2nd:

Red cells	4,350,000
White cells	16,000
Differential count:			
Small lymphocytes	3.7 per cent.
Large lymphocytes	9.4
Large mononuclears	8.1
Plasma cells	1.3
Polymorphonuclears	76.9
Eosinophiles	0.3

Agglutination.—October 18th: r. Shiga, 1 in 40 (+ +), 1 in 80 (+), 1 in 160 (0); v. Shiga (homologous), 1 in 40 (+ +), 1 in 80 (trace), 1 in 160 (0).

The serum of the patient gave only a trace of agglutination with the homologous Shiga in 1 in 10 (performed July 29th).

This patient is still in hospital (October 28th), and is slowly putting on weight after a period of considerable emaciation.

CASE 2.—S.—r. Admitted August 23rd. Dysentery started with blood and mucus three months before admission.

First sample of August 24th: Like fluid blood with mucus. No flagellates present. *B. dysenteriae* Shiga recovered.

Second sample of same day: Fluid brownish grumous material containing numerous flagellates. *B. dysenteriae* Shiga recovered. *E. paratyphosus* B recovered.

August 25th: Stool containing blood, mucus, and pus, but no flagellates. *B. dysenteriae* Shiga recovered.

Agglutination.—September 23rd: r. Shiga, 1 in 20 (+ + + +), 1 in 40 (+ + + +), 1 in 80 (+ + + +), 1 in 160 (+ + + +); not taken further; v. B, 1 in 40 (+), 1 in 80 (trace), 1 in 160 (0). October 18th: r. Shiga, 1 in 40 (+ + + +), 1 in 80 (+ + + +), 1 in 160 (+ + + +), 1 in 320 (+ + + +), 1 in 640 (+ +), 1 in 1280 (+ +), 1 in 2560 (0); v. Shiga (homologous), 1 in 40 (+ + + +), 1 in 80 (+ + + +), 1 in 160 (+ + + +), 1 in 320 (+ +), 1 in 640 (0). This patient is slowly convalescing in hospital.

CASE 3.—D.—t. Admitted September 16th. Diarrhoea started on August 22nd. Blood appeared in the dejecta eight days after commencement of illness. The acute symptoms were over about September 11th. On September 18th the patient passed a watery stool containing mucus, but no flagellates or amoebae. *B. dysenteriae* Shiga recovered.

Agglutination.—September 23rd: r. Shiga, 1 in 20 (+ + + +), 1 in 40 (+ + + +), 1 in 80 (+ + + +), 1 in 160 (+ +), 1 in 320 (0).

CASE 4.—W.—e. Admitted September 9th with slight diarrhoea and some abdominal pain. Dysentery apparently began about June 10th. On September 14th the patient passed a

formed normal solid stool. *B. dysenteriae* Shiga recovered. Probably carrier case.

Agglutination.—September 23rd: r. Shiga, 1 in 20 (+ + + +), 1 in 40 (+ + + +), 1 in 80 (+ + + +), 1 in 160 (+ +). Not carried further.

CASE 5.—R.—s. Admitted September 27th. Dysentery with blood and mucus started at the end of August. Slight diarrhoea present on admission. On September 18th passed a yellowish semifluid stool containing some mucus. No flagellates or amoebae seen. *B. dysenteriae* Shiga recovered.

Agglutination.—September 23rd: r. Shiga, 1 in 20 (0), 1 in 40 (+ + + +), 1 in 80 (+ + + +), 1 in 160 (+ +). Not taken further. Note initial inhibition zone.

CASE 6.—F.—b. Admitted September 13th. Dysentery commenced on August 10th, with blood and mucus. He has frequently passed a stool since admission. Subacute case. Sample of September 22nd: Semifluid, brownish-yellow stool with a little mucus. No flagellates or amoebae. *B. dysenteriae* Shiga recovered.

Agglutination.—September 23rd: v. Shiga, 1 in 20 (+ + + +), 1 in 40 (+ + + +), 1 in 80 (+ + + +), 1 in 160 (trace).

CASE 7.—P.—k. Admitted September 26th. Sick for a month previous to admission. Diarrhoea still present on admission and some abdominal pain. Sample of September 28th: Greenish-yellow mucoid stool. No flagellates present, but some amoebic cysts (probably *E. coli*). *B. dysenteriae* Shiga recovered.

Agglutination.—October 12th: r. Shiga, 1 in 40 (+ + + +), 1 in 80 (+ + + +), 1 in 160 (0); v. Y, 1 in 40 (+ + + +), 1 in 80 (+ + + +), 1 in 160 (0).

CASE 8.—W.—h. Admitted September 13th. Dysentery began in hospital on October 1st; ten motions on that day, with blood and mucus, and a temperature of 104°; watery diarrhoea, for a few days afterwards. Acute dysentery with blood and mucus, lasting only a few days. Sample of October 2nd: Fluid stool with much blood and mucus and pus. No flagellates. *B. dysenteriae* Y recovered.

Agglutination.—October 12th: r. Shiga, 1 in 40 (0), 1 in 80 (0), 1 in 160 (0); v. Y, 1 in 40 (+ +), 1 in 80 (0).

CASE 9.—W.—e. Admitted September 26th. Dysentery began at the end of August with passage of blood and mucus. Some diarrhoea and abdominal pain still present on September 30th. Convalescent case. Sample of September 30th: Brownish-yellow loose stool. No flagellates or amoebae. *B. dysenteriae* Shiga recovered.

Agglutination.—October 12th: r. Shiga, 1 in 40 (+ + + +), 1 in 80 (+ + + +), 1 in 160 (0); v. Y, 1 in 40 (+ + + +), 1 in 80 (+ +), 1 in 160 (0).

CASE 10.—Admitted September 23rd. Diarrhoea for two months previously. Blood and slime appeared in the motions about September 12th. Convalescent case. Stools occasionally loose, and slight abdominal pain. Sample of September 28th: Liquid soap character containing mucus. No flagellates, amoebae, or blood. *B. dysenteriae* Shiga recovered.

Agglutination.—October 12th: r. Shiga, 1 in 40 (0), 1 in 80 (0), 1 in 160 (0); v. Y, 1 in 40 (+ +), 1 in 80 (0).

CASE 11.—M.—w. Admitted October 11th. Dysentery with passage of blood and mucus commenced on August 12th. Diarrhoea with mucus still present on admission. Convalescent case. Sample of October 11th: Loose yellow mucoid stool. No blood or pus. Some cysts of *E. coli*. *B. dysenteriae* Shiga recovered.

Agglutination.—October 18th: r. Shiga, 1 in 40 (+ + + +), 1 in 80 (+ + + +), 1 in 160 (+ + + +), 1 in 320 (trace), 1 in 640 (0); v. Shiga (homologous), 1 in 40 (+ + + +), 1 in 80 (+ + + +), 1 in 160 (trace), 1 in 320 (0).

CASE 12.—B.—v. Admitted September 26th. Dysentery began on August 16th. Convalescent case. Sample of October 20th: Stiff dark brown stool. No blood or mucus. No active flagellates, but a few *Macrostoma* cysts. *B. dysenteriae* Shiga recovered.

Agglutination.—October 22nd: r. Shiga, 1 in 40 (+ + + +), 1 in 80 (+ + + +), 1 in 160 (+ + + +), 1 in 320 (0); v. B, 1 in 40 (+ + + +), 1 in 80 (+ + + +), 1 in 160 (0); v. A, 1 in 40 (+ +), 1 in 80 (0), 1 in 160 (0).

CASE 13.—G.—s. Convalescent case (see No. 50 of Paratyphoid series). Sample of October 18th: Loose yellow slightly mucoid stool. No blood, but numerous *Lambda* cysts. *B. dysenteriae* Shiga recovered, also *E. enteritidis* Gaertner.

CASE 14.—H.—n. (See No. 4 of Paratyphoid series.) *B. paratyphosus* A was recovered from the blood of this case on September 1st (about the fifth day of pyrexia). An exacerbation of pyrexia (so-called relapse) occurred on October 6th, and on October 11th a blood culture yielded *B. dysenteriae* Shiga in pure culture. This case was, in all probability, one of post-dysenteric paratyphoid A fever.

CASE 15.—D.—y. Admitted October 8th. Dysentery with blood and mucus began at the end of May. Slight diarrhoea since admission. Sample of October 22nd: Loose yellow stool containing mucus and pus, but no blood. *B. dysenteriae* Shiga recovered, also *E. enteritidis* Gaertner.

REMARKS ON CASES REPORTED ABOVE.

It will be noted that the stool from which the specific organisms were recovered, was not invariably of the typical mucoid variety with blood. In several cases the stool was of the watery order, with or without admixture of mucus, and in two cases at least the stool was normal and formed. This point is, of course, by no means new, but it has a distinct bearing on the preventive medicine and the carrier question in relation to bacillary dysentery. This, however, we do not propose to discuss here for lack of relevant data. The general carrier question in relation to bacillary dysentery is fully discussed elsewhere.³ All that we can definitely say at present with regard to the carrier question in relation to our cases is that the specific organism has been isolated at periods varying from one to four months after the onset of the infection. Case No. 14, in which *B. dysenteriae* Shiga was recovered from the blood during a pyrexial exacerbation in the course of paratyphoid A fever, deserves notice. So far as we can ascertain, this finding is unique. *B. dysenteriae* "Y" has recently been recovered from the blood during life in a series of cases with obscure clinical picture (partly typhoid-like, partly dysentery-like) by Ghon and Roman,² and the explanation suggested by these authors was that the cases were really dysentery carriers secondarily infected with enteric.

The dysentery organism had succeeded in invading the blood stream, perhaps owing to the disordered condition of the bowel. In our case there is little doubt that the patient was a dysentery carrier secondarily infected by *B. paratyphosus* A. The patient had suffered severely from diarrhoea previous to his attack of paratyphoid fever. During the pyrexial exacerbation there was no return of blood and mucus in the dejecta.

No cases of amoebic dysentery have been met with (see section on flagellates, etc.). Several patients have been admitted with a history of having had injections of emetine. In no case, however, have motile forms or cysts of *E. trayingana* been detected.

The question of flagellate dysentery is discussed in the next section.

To the resident medical officers of the hospital we are greatly indebted for their cordial co-operation.

INTESTINAL PROTOZOAN PARASITES PRESENT IN THE FÆCES.

Up to the time of writing, protozoan parasites have been found in the faeces of 26 cases. In several instances more than one kind of parasite occurred at the same time. The following is a list of the parasites observed:

Parasite.	No. of Cases.
<i>Lamblia intestinalis</i> (active and/or encysted) ...	7
<i>Macrostoma mesnili</i> active ...	6
<i>Trichomonas hominis</i> (active) ...	3
<i>Ceromonas hominis</i> (active and encysted) ...	1
Active flagellates, not specifically determined probably <i>Macrostoma</i> or <i>Trichomonas</i> ...	4
Encysted cysts ...	5
<i>Entamoeba coli</i> cysts ...	6
<i>Blastocystis hominis</i> ...	5

As there are very few records in England of these human intestinal parasites, it may be of service to give a

few notes with regard to them, particularly as they are likely to be met with in the examination of faeces in cases of dysentery or diarrhoea among soldiers home from the Dardanelles or France.

The examination is best made by taking up a very small quantity of the faeces on a platinum loop and mixing it well with a drop of sterile saline (0.5 per cent.), sufficient in amount to run under a cover-slip. The faeces must be well diluted, otherwise cysts especially are apt to be overlooked. The faeces should be examined as freshly as possible, because after four or five hours most of the active flagellates become motionless, degenerate and die. If the sample is kept in an incubator, at blood temperature, a few individuals will usually remain sluggishly motile for some hours longer. A convenient and rapid way of making a permanent preparation is as follows: A thin smear of the faeces, diluted as above, is made in the same manner as an ordinary blood film. The slide is immediately placed in a stain tube containing at the bottom a small quantity of 4 per cent. osmic acid solution + a drop of glacial acetic for fixation, and is left in for about ten seconds. Allow the smear to dry in air and then put in absolute alcohol for a quarter of an hour to harden.

Wash with tap water and stain with Giemsa (1 drop to 1 c.c.m.) for twenty minutes or so. Rinse with tap water. The smear must be fixed before drying, otherwise the active flagellates, which are soft and plastic, will be round and flattened, and usually unrecognizable as such.

Lamblia intestinalis (Fig. 1, A-D).—The active individual has a characteristic and unmistakable appearance. In shape it is like a flattened pear, with a broad, rounded anterior end and a taper-

ing hinder extremity. As is well known, there is a large saucer-like depression or concavity on the ventral side, in the anterior part of the body, by which the creature applies itself to the intestinal cells. This depression is best seen when the flagellate turns over on its side in moving. The creature does not change in shape at all—that is, it is not amoeboid. In stained preparations the double arrangement of the organellae is seen—two nuclei, four pairs of flagella, and two axial rods (axostyles). In Fig. 1, B, the karyosomes of the nuclei have come out well, but in Fig. 1, A, the nuclei have stained uniformly, as generally happens with Giemsa, though all these flagellates have karyosomatic nuclei. The cysts are frequently present in the stools when no active forms can be found. They are elongate-ovoid and slightly smaller than the active forms. Even in life four nuclei can generally be made out; also, in early cysts, remains of the flagella and axostyles. In stained preparations (Fig. 1, C and D) apparently all the cysts contain four nuclei (that is, two pairs), and there can be little doubt that cyst-formation is preceded by conjugation of two individuals. The protoplasmic contents are sometimes shrunk away from the cyst membrane.

Macrostoma (syn. *Tetranitius* n.p.p.) *mesnili* (Fig. 1, E and F). This flagellate is slightly smaller than *Lamblia*. The body is pear-shaped but not flattened, and it generally possesses a tail process; it is capable of altering its form to some extent, and in faeces which have been standing for some time the body form may have become quite irregular. Contrary to what is the case in *Lamblia*,

Fig. 1.—A and B, *Lamblia intestinalis*, active forms; C and D, cysts of same; E and F, *Macrostoma mesnili*; G, *Trichomonas hominis*. × 2000.

the protoplasm of *Macrostoma* is usually vacuolated, some of the vacuoles containing ingested food masses. At the anterior end is a large, conspicuous cytostome or oral groove, inside which one of the four flagella, rather shorter than the other three, invariably lies. This flagellum, by its vibration, produces a constant flickering inside the cytostome. The single nucleus is situated quite at the anterior end of the body, and the flagella originate close to it. Even with the precaution of first fixing the smear, these parasites are too often rounded and flattened (cf. Fig. 1, F), though the flagella can usually be made out; after drying alone, before hardening, nothing is seen but a shapeless mass of protoplasm, with a large nucleus. There cannot be the slightest doubt that the parasite found by Castellani in dysenteric stools in Ceylon, and regarded by him as an entirely new type of organism ("Entoplasma") was one of these flagellates, probably a large form of *Macrostoma*. Cysts which may have belonged to this form have been seen very rarely. They were ovoid, but smaller than *Lambli*a cysts, and showed a single (?) dull nuclear area, somewhat nearer one end of the protoplasm.

Trichomonas hominis (Fig. 1, G).—The body is usually pear-shaped, but may be rounded. This form can be distinguished by its jerky, irregular movements, and by the conspicuous undulating membrane running along one side. The vigorous action of this membrane often produces waves of the peripheral protoplasm, passing down the side of the body, from before backwards. The membrane ends posteriorly, and its flagellar border is continued as a short free flagellum. Three anterior free flagella are present, which can be made out in sluggish individuals. In the stained individual of Fig. 1, G, the curved wavy line on the right is the attached flagellum, which terminates freely to the left. The inner line running roughly parallel with the attached flagellum is the so-called axial line, marking the base of the membrane. The shorter curved line on the left starting from the nucleus, is the single axial rod; in life this projects backwards, forming a stiff tail to the body. Up to the present the cysts of this form have not been observed.

Cercarion hominis.—Only on one occasion has an infection—a very slight one—with this flagellate been observed. A single active individual was found; it was very amoeboid, but the main flagellum could be seen vibrating freely, thus distinguishing the creature from an amoeba. A scanty number of cysts were present. These are spherical, with finely granular contents. They are slightly larger than the other flagellate cysts, but distinctly smaller than an *Entamoeba* cyst; there is only a single nucleus in the cyst, not always clearly visible. This form is a true human parasite, distinct from the coprozoic form, *C. longicauda*, which passes through the bowel in the encysted state and is only active in faeces (cf. the case of water Amoebae and parasitic Entamoebae).

Coccidian Cysts.—Human coccidiosis has always been regarded as a very rare and exceptional occurrence. In the faeces of 5 cases

bodies have been found which are in all probability coccidian cysts (Fig. 2, A and B). They were usually scanty, but in one case not infrequent, five or six cysts being quickly found in one fresh preparation. The cyst is ovoid, with rather narrow ends. The membrane is definite and firm, but rather thin. The size of the cyst is very generally about 32 by 14 microns. It is thus little more than half the size of any human nematode ova, according to textbooks of parasitology; on the other hand, the dimensions are well within the limits of those given for the cysts of coccidia which have been described from man. Further, the contents of the cyst appear quite different from those of eggs. The cyst contains either one or two protoplasmic masses, larger or smaller respectively, which are full of large refringent granules, strongly resembling the characteristic reserve food granules of

coccidian oocysts. More than two masses have never been observed—that is to say, this does not appear to be the segmentation process of an egg. Nor have any worms been found in a single case. The two masses, resulting, doubtless, from the division of the single larger one, represent most probably two sporoblasts, which will become the sporocysts. For some reason or other no further development has ever been observed in cysts taken from faeces, after the latter have been kept for a day or two. The coccidian is apparently of the *Isospora* type rather than the *Coccidium* type, which has four sporocysts; a species of *Isospora* is known to occur frequently in cats and dogs. There has been so far no opportunity of determining whether this coccidian infection is restricted to the intestinal epithelium or whether it also invades the liver.

Blastocystis hominis.—This peculiar parasite, which has been known only a few years, is usually regarded as allied to the fungi (Ascomycetes) rather than to the protozoa. It has been undoubtedly the cause of much confusion, and has been mistaken for resting or resistant stages of different flagellates—for example, *Trichomonas* or *Macrostoma*. In one case, where the stool was very watery and of a clayey colour, enormous numbers of this parasite were present. Different stages of *Blastocystis* are seen in Figs. 3, A and B. The body is spherical, motionless, and in the earlier stages shows a large vacuole; frequently, in fact, the body appears to be nearly all vacuole, there being only a narrow rim of protoplasm enclosing it. The vacuole is clear, and not fatty or oily in appearance. The limiting membrane of the body is thin and delicate, and does not resemble the cell wall of a fungus. The parasite is probably more closely allied to the protozoa than to the yeasts or blastomycetes. At first there is only a single nucleus, lodged in the rim of protoplasm. With increase of size the nucleus divides, the two daughter nuclei pass to opposite sides of the body, and simple binary division may take place. Or nuclear multiplication may continue, and the vacuole may diminish and tend to disappear as such. This condition probably leads to multiple fission. Resistant stages, or cysts, have not yet been observed.

Entamoeba coli.—Up to the present no cases of infection with *Entamoeba tetragena* (the cause of amoebic dysentery) have come under notice. In several cases, however, the cysts of *E. coli* have been found in the faeces, usually in scanty numbers, but once or twice fairly numerous. Active forms have not been observed at all. The cyst of *E. coli* is usually spherical (Fig. 4), but may be ovoid. It is considerably larger than any of the flagellate cysts, and is further distinguished from the latter by the fact that the membrane is thick, with a well marked double contour. By careful focussing, moreover, many nuclei, appearing as small rings slightly clearer within than the surrounding protoplasm, can be made out. Practically all the cysts in which the nuclei could be clearly made out had from six to eight nuclei, the latter being the normal complete number. This fact, of course, is usually given as a definite diagnostic character distinguishing *E. coli* cysts from those of *E. tetragena*, which have four nuclei as the complete normal number. All the evidence obtained so far supports the view that *E. coli* is non-pathogenic, and a distinct form from *E. tetragena*.

Fig. 3.—*Blastocystis hominis*: A, with a single nucleus; B, with two. $\times 2000$.

Fig. 2.—Coccidian cysts: A, containing a single protoplasmic mass; B, with two masses (sporoblasts). Drawn from life. $\times 1000$.

14 microns. It is thus little more than half the size of any human nematode ova, according to textbooks of parasitology; on the other hand, the dimensions are well within the limits of those given for the cysts of coccidia which have been described from man. Further, the contents of the cyst appear quite different from those of eggs. The cyst contains either one or two protoplasmic masses, larger or smaller respectively, which are full of large refringent granules, strongly resembling the characteristic reserve food granules of

Fig. 4.—Cyst of *Entamoeba coli* with eight nuclei. Drawn from life. $\times 1000$.

Pathogenicity.

With regard to the question of the pathogenicity of the above flagellates, the data so far to hand afford only slight indications. Of late years, several Continental workers have recorded cases of "flagellate-dysentery" (the flagellates being usually *Lambli*a or *Trichomonas*),

which have been chronic, giving rise to continued diarrhoea, often with blood and mucus in the stools, and proving refractory to ordinary methods of treatment. These cases have been regarded as not due to bacillary or amoebic dysentery, but precise evidence as to the absence of the former is usually lacking. The present series of cases is complicated by the fact that, in the majority of them, one or more types of pathogenic bacteria have been obtained. Blood, mucus, and pus stools have occurred only in two cases, from both of which Shiga's bacillus was recovered. On other occasions, where loose stools have occurred, at times slightly mucoid but with no blood or pus, Shiga has either been obtained or, where not actually recovered, the patient's serum has subsequently given the agglutination reaction. Or, again, some other organism—for example, *B. paratyphosus A*—has been present. In several cases, in fact, the patients appear to have been infected with several different organisms, bacteria and protozoa. It is quite possible that the bacterial infection and the disturbance caused by it have favoured the establishment of the protozoan infection, whatever this has been.

Nevertheless, there is a residuum of cases, where loose diarrhoeal stools have occurred, containing flagellates or their cysts, where no evidence of pathogenic bacteria has been obtained. Where active flagellates are present the motions are nearly always loose or thin and creamy or bright yellow in colour, the latter being markedly the case with stools containing *Trichomonas*. This parasite has occurred in diarrhoeal stools from one patient at intervals over eighteen days, after which it apparently died out. Up to the present this form has not proved persistent or refractory. *Lamblia* is probably a more important cause of intestinal derangement, and this can be readily understood when the essential parasitic character of this form and the situation it occupies are borne in mind. The following is the record of one of three very similar cases of infection with this parasite, uncomplicated (now) by the presence of any other pathogenic organism. In the instance in question, the active forms have never been seen in the stools examined; this fact shows the importance of the recognition of the cysts.

- W s. Admitted September 26th, 1915.
- September 28th. Pasty yellow stool; fair number of *Lamblia* Cysts.
- October 13th. Loose, slightly mucoid stool; no blood or pus; some *Lamblia* cysts.
- October 22nd. Pasty, olive-green stool; very numerous *Lamblia* cysts.
- October 30th. Thin, soup-like, greenish-brown stool; no blood or mucus; numerous *Lamblia* cysts.

The presence of cysts in such numbers indicates, of course, a heavy intestinal infection with the active forms. During this period the patient has suffered from chronic diarrhoea; during the night before the last sample was examined, for instance, he had five thin or loose motions. Prior to admission, the patient, who came from Gallipoli, had a history of six weeks' dysentery and diarrhoea, with blood and mucus in the stools during the first two or three weeks. During this early period he had three or four injections of emetine. Probably, therefore, the patient had amoebic dysentery, which was entirely cured by the emetine, for neither Entamoebae nor their cysts have ever been found in the stools. The emetine had apparently, however, no effect upon the *Lamblia*. French workers strongly recommend turpentine (terebenthine) in cases of persistent diarrhoea due to these flagellates. It is hoped to obtain further information upon this subject as time goes on.

1. Medusham and Arkwright: *The Carrier Problem in Infectious Diseases* (Typhoid). 1912. 2. *Wien. Klin. Woch.*, 1915, pp. 579, 630.

ACCORDING to the New York Medical Record, the field service of the American Ambulance in Paris during the first eleven months of its activity transported 57,000 wounded from the front. The number of automobiles now employed in this service is about ninety, and, in addition, twenty machines are attached to the hospital at Neuilly. One supply and one staff machine accompany each of the units in the field, themselves composed of from ten to twenty-five cars. There have been no deaths among the drivers of the field ambulance, although they go very near to the fighting lines and are frequently under heavy fire. More cars are added to the field equipment as the fund grows. The number of beds in the hospital at Neuilly has been increased from 175 to 600.

NOTE ON THE TETRAVACCINE: TYPHOID, PARATYPHOID A, PARATYPHOID B + CHOLERA.

BY PROFESSOR ALDO CASTELLANI, M.D., PHYSICIAN, II AND VI (LADY PORTER'S) MILITARY HOSPITALS, SROPLJE, SERBIA, AND RALPH W. MENDELSON, M.D., MEMBER OF THE AMERICAN RED CROSS SANITARY COMMISSION, SROPLJE, SERBIA.

It may be of interest to put on record the somewhat extensive experience we have had in Serbia with the tetravaccine: typhoid + paratyphoid A + paratyphoid B + cholera, one of the combined vaccines prepared and used for several years in Ceylon by one of us.

Technique of Preparation.

This is identical with that used by one of us previously, and already published in various papers. It may, however, be of advantage to describe it again briefly.

The growth of typhoid cultures is washed off with sterile 0.85 per cent. salt solution, to which 0.5 per cent. carbolic acid has been added; the emulsion so obtained is stored at room temperature (18 to 20 C.) for twenty-four hours, and then standardized. To standardize it the germs are counted by using a Thoma-Zeiss apparatus, and sufficient carbolic salt solution is added to bring the number of germs down to 2,000 millions per cubic centimetre. The standardized emulsion is tested for sterility. The same procedure is carried out with paratyphoid A and paratyphoid B cultures, these two emulsions being also standardized to contain 1,000 million germs per cubic centimetre. The above procedure is also carried out with cholera, the emulsion of which, however, is standardized to contain 4,000 million germs per cubic centimetre. The four standardized emulsions when found sterile are mixed together in equal proportions, and the vaccine will therefore contain per cubic centimetre:

Typhoid	500 million
Paratyphoid A	250 "
Paratyphoid B	250 "
Cholera	1,000 "

Of this mixture 0.5 to 0.6 c.c.m. are given under the skin of the arm the first time, and the same amount a week later; A third dose, also $\frac{1}{2}$ c.c.m., given two weeks after the first, is of advantage, but not essential for practical purposes.

The Peptone Water Method.—Owing to the scarcity of agar at one-time in our laboratory we prepared a certain amount of vaccine with peptone water in the following way. Large bottles were filled with peptone water containing 1 per cent. peptone and 0.75 per cent. sodium chloride, and sterilized. Some of the bottles were then inoculated with typhoid, others with paratyphoid A, others with paratyphoid B, and others with cholera. The cholera bottles are kept in the incubator at 35 C. for twenty-four hours. The bottles inoculated with typhoid, paratyphoid A, and paratyphoid B were incubated for forty-eight hours, as the growth of *B. typhosus* and allied germs is slow and scanty in such a medium. We found by experience that with the peptone water we used and with the strains of germs we had, provided the bottles were kept in the incubator exactly the stated period of time and temperature, the number of germs was, for practical purposes, nearly constant. The cholera bottles will contain approximately 3,800 to 4,000 million cholera vibrios per cubic centimetre and the typhoid and paratyphoid bottles will contain approximately 900 to 1,000 million per cubic centimetre. The peptone water cultures were then mixed in the following proportions:

Typhoid	2 parts
Paratyphoid A	1 part
Paratyphoid B	1 part
Cholera	2 parts

To this was added $\frac{1}{2}$ per cent. carbolic, which is sufficient to sterilize the vaccine in a very few hours. We may say at once that the results obtained with this vaccine as regards agglutination, etc., appear to be very

similar to those obtained with the carbolized agar culture vaccine, though whenever possible we prefer to use the latter.

Experimental Work on which the Preparation of the Tetravaccine and other Mixed Vaccines is Based.

The preparation of tetravaccine, as well as other combined vaccines, is based on the experimental work of one of us carried out in 1901 and 1902,¹² when it was demonstrated that if an animal (rabbit) was inoculated with two or three species of bacteria, agglutinins and immune bodies for all the germs were elaborated, provided a sufficient minimum quantity was given, the amount of agglutinins and immune bodies elaborated for each germ being nearly the same as in control bodies inoculated with only one species. It was also demonstrated that when immunization is obtained by a single inoculation, the amount of agglutinins and immune bodies elaborated is not in proportion to the amount of culture injected, provided a sufficient minimum dose be used. A series of rabbits inoculated with 2 c.cm. of typhoid culture gave the same average agglutination limit and the same amount of immune bodies as a series of rabbits inoculated with 4 c.cm. In rabbits no good results were obtained, as a rule, by inoculating more than three species of bacteria.

Facsimile of label.

But more recent experiments have shown that in rabbits the tetravaccine—typhoid, paratyphoid A, paratyphoid B, and cholera, induces protective substances for the four germs in the rabbit.

Blood Examination of Rabbits Inoculated with the Tetravaccine.

The particulars of the investigation will be given in a future more complete paper. Here we will limit ourselves to the statement that according to our researches the blood of the inoculated rabbits developed agglutinins for the four germs, and that the amount of agglutinin developed for each germ was not distinctly less than in rabbits inoculated with monovaccines. Porcelli, using Castellani's tetravaccine, has come to the same conclusion.¹³

Number of Individuals Inoculated and Technique of Inoculation.

The number of individuals inoculated by us with the tetravaccine amounts to 50,000, and more than 120,000 by colleagues, among whom we would like to mention Colonel Randon, who has very ably organized such vaccination for the civil population, also on a very large scale, and Dr. Boricki, who has now started the preparation of the tetravaccine at the Government Pasteur Institute of Nish. The method for preparing the arm for inoculation was simple. At first we took elaborate means to scrub the arm thoroughly with soap and water, drying, and then painting with tincture of iodine; but when inoculating at the rate of several thousand a day, we found it impossible to spend the time necessary for this procedure, and depended entirely upon the iodine alone, with excellent results.

The reactions were usually very mild and consisted usually of a small area of redness, a slight local temperature and some tenderness. General reactions were very seldom complained of, and when inquired into revealed a

slight headache and a general inaptitude. These particulars were carefully looked into in all cases upon the second inoculation.

It seems hardly permissible to elaborate upon the technique of inoculation, yet with continued practice one acquired a skill that almost assumes the dignity of an art. We have found it possible when everything is going right to inoculate at the rate of 400 an hour. The left arm is chosen, the skin over the insertion of the deltoid, and a quick stab, as though one were shaking a drop of ink from a pen, results in placing the point of the needle at the exact depth. The syringe is held in the right hand between thumb and index finger, while the tip of the ring finger is placed just above the point of the needle, acting as a check to the force applied. No after-treatment such as massage or sealing the puncture is used.

Blood Examination of Individuals Inoculated with the Tetravaccine.

We have examined the blood of more than 100 individuals inoculated with the tetravaccine for agglutinins. In ten we studied the agglutination curve for several weeks. We propose giving the particulars with all the tables referring to this subject in a future more complete paper. We are limited here to giving a table containing the results obtained in three individuals in whom the observations were carried on for six weeks.

	<i>B. paratyphosus A</i> ...	1,200	1,150	1,200	1,100	1,150	1,100
	<i>B. paratyphosus B</i> ...	1,100	1,200	1,150	1,150	1,100	1,100

The individuals inoculated with the tetravaccine produce a very large amount of agglutinins for typhoid, a fairly large amount of agglutinins for paratyphoid A and paratyphoid B, a certain amount for cholera, which varies between the limits 1:20 and 1:150. Comparing the results with those obtained in control individuals inoculated with typhoid, paratyphoid A, paratyphoid B, and cholera, we find that the amount produced is not distinctly smaller. The tables referring to all the cases, including the controls inoculated with monovaccines, will be published in a later more complete paper.

Statistics.

We are not in a position now to give any elaborate statistics, but we may say that so far, in the inoculated troops, typhoid, paratyphoid A, and paratyphoid B have been practically absent. The very few cases reported—without any death—have mostly been proved to be cases of intermittent or remittent subtertian, there being in the country now an extremely severe epidemic of malaria. As regards cholera, no cases have been reported, but the disease is not now present in Serbia.

CONCLUSIONS.

1. The preparation of the tetravaccine (typhoid, paratyphoid A, paratyphoid B, and cholera) as well as other combined vaccines is based on the experimental work carried out by one of us in 1901, when it was demonstrated that animals inoculated with more than one species of bacteria, within limits, developed agglutinins and immune bodies for all the species injected, the amount of such bodies being not distinctly inferior to that observed in control animals inoculated with one species only.

2. The inoculation of the tetravaccine is harmless. We have had no septic or other accident in any of the more than 50,000 men we have inoculated, this entailing more than 100,000 injections, nor have we heard of any untoward

accident observed by colleagues who have inoculated in Serbia more than 120,000 men with the tetravaccine. We have never observed any really serious reactions, either local or general, the inoculated persons being as a rule able to attend to their duties in from twenty-four to forty-eight hours after injection.

3. The inoculated persons develop protective substances for the four germs: typhoid, paratyphoid A, paratyphoid B, and cholera. The amount of agglutinins present for each of the four germs is practically the same as in control individuals inoculated with typhoid, paratyphoid A, paratyphoid B, and cholera monovaccines.

4. We are of the opinion, as stated in previous publications, that the tetravaccine should be used as a matter of routine to inoculate the troops taking part in the present war, greatly exposed as they are to the four diseases, typhoid, paratyphoid A, paratyphoid B, and cholera. Its use renders it possible to give a contemporaneous protection for the four maladies by a simple and rapid procedure.

As we have already received numerous requests and inquiries from many quarters, and as the time at our disposal makes it impossible for us to supply the vaccine to all who ask for it, it may be mentioned that the tetravaccine is now prepared on a large scale by Mulford and Co., of Philadelphia, and can be obtained from them.

PARATYPHOID "A" FEVER.

BY

A. H. SAFFORD, D.P.H.LOND.,
MAJOR, R.A.M.C.

ALTHOUGH paratyphoid fever has been recognized for several years, and during the last three or four years has become of considerable importance in India, especially as affecting the British troops, it appears seldom to be recognized by civilian practitioners, and not much attention been paid to it outside the army. This is no doubt due to the fact that few textbooks give more than a brief sketch of the disease.

The following notes are based on over a hundred cases which I have personally observed and in which the *Bacillus paratyphosus A* was isolated in each instance, either from the blood, urine, or faeces.

Definition.—A septicaemia caused by the presence of the *Bacillus paratyphosus A*, causing a remittent type of fever of about twelve days' duration.

Incubation.—From ten to fifteen days.

Chart to illustrate a severe case of paratyphoid A fever followed by a relapse. B, Blood culture positive.

Immunity.

In India race seems to bear no relation to immunity, for although the organism has been more frequently isolated from Europeans than from Indians this is due chiefly to failure in taking the necessary steps for its isolation among the latter. From five blood cultures from Indians I have isolated *B. paratyphosus A* on two occasions and *B. typhosus*

once. It appears to be more common among men than women, but no definite statement on this can be made at

Chart to illustrate a typical case of paratyphoid A fever. B, Blood culture positive.

present owing to the excess of male over female population in the army in India. One attack protects against a second. I have never seen or heard of a second attack. As might be expected, antityphoid inoculation gives no protection against paratyphoid.

Bacteriology.

A Gram-negative motile bacillus is present which agglutinates with high titre paratyphoid A serum, and by the absorption test can remove the agglutinins.

Reactions.

	24 Hours.	48 Hours.	10 Days.
Glucose ...	Acid + gas +	Acid + gas +	The same as after 48 hours' incubation.
Lactose ...	No change	No change	
Cane sugar ...	No change	No change	
Mannite ...	Acid + gas +	Acid + gas +	
Dulcitol ...	No change	Acid + gas +	
Inulin ...	No change	No change	
Neutral red agar	Gas + fluorescence -	Gas + fluorescence -	
Litmus milk	Acid + clot -	Acid + clot -	
Indol ...	Nil	Nil	

Symptoms.

The onset is as a rule insidious, there being a general feeling of lassitude and loss of appetite. There is complaint of headache (frontal and occipital), pain in the back and limbs, and chills. A rigor seldom occurs. The

headache becomes very severe and the patient suffers from insomnia for the first few nights, but when once the headache is relieved sleep returns. There is constipation and the tongue is coated with a yellowish-brown fur except the tips and edges, which are clear. The temperature varies considerably with the severity of the case, but is generally 101° to 102°, or even higher at nights, and 99° to 101° in the morning. There is generally defecescence, the fever lasting about twelve days.

The pulse-rate is slow in comparison with the temperature. This is a very diagnostic sign, and often gives one a clue to the real nature of the disease during the first few days.

The pulse-rate is often described as being rapid in this disease, but careful observation of my own cases and a study of a large number of charts from various stations in India entirely disproves this.¹

In a few cases there is initial bronchitis or tonsillitis, and epistaxis sometimes occurs.

A rash may be present during the first few days, but

I have seen so many varieties and also so many cases in which no rash appeared that I do not consider the presence or absence of a rash any aid to diagnosis.

Tenderness or even pain over the gall bladder is a common symptom. There is often an initial enlargement of the spleen but seldom of the liver.

By the end of the first week the headache is relieved and there is marked improvement in the general condition of the patient; this is in marked contrast to the case of true typhoid. Although the fever continues a few days the patient feels quite well, and is anxious for an increase of diet or even to be allowed to get up.

Complications and Sequelae.

A relapse is fairly common, and usually begins within seven to ten days after the cessation of the initial attack, but seldom runs the full course, lasting five to seven days. Haemorrhage is rare, but blood-tinged mucus is sometimes passed. Perforation is extremely rare, but has been recorded. Phlebitis and cholecystitis appear to be the most common complications, the former occurring more often than in typhoid.

The mortality is very low, and is generally placed at 1 per cent., but even this figure is, I think, too high.

Convalescence is slow: considering the comparatively short duration of the fever there is marked debility and anaemia.

Treatment.

The case should be isolated and treated on general lines, as a case of typhoid.

Beyond relieving the headache and constipation little can be done except careful nursing. For the relief of the headache small doses of aspirin are useful, and for the first night or two hypnotics may be used. An initial dose of castor oil should be administered if the case is seen early; if not enemata should be given. The pain over the gall bladder is seldom excessive, and can generally be relieved by hot fomentations.

The diet should consist entirely of milk or milk-when during the fever and be very gradually increased. Too early feeding is, in my opinion, the cause of most cases of relapse.

Diagnosis.

Little reliance can be placed on Widal's reaction as an aid to diagnosis, as the agglutinins are very feeble—seldom higher than in a dilution of 1 to 40 during the disease, and are frequently entirely absent.¹ They appear to be highest at about the twenty-second day of the disease, by which time the patient is convalescent. The most rapid and satisfactory method of arriving at a diagnosis is by blood culture, but it is essential that the blood should be drawn within the first five or six days of the disease. I have recovered the bacillus from the blood as late as the ninth day, but this is uncommon. A bottle containing 20 c.cm. of sterile ox bile should be inoculated with 5 c.cm. of blood from the vein. This is best done with an all-glass syringe which has been sterilized by dry heat or hot oil at a temperature of 140 C. The syringe should not be sterilized with antiseptics. The further stages in the isolation of the organism must be carried out by an experienced bacteriologist. Failing isolation from the blood, the urine and faeces should be daily examined. The disease varies considerably in intensity from the ambulatory type, which is fairly common, to the typhoid type. The fever in this type lasts three or four weeks, but even in this severe type the "typhoid state" is seldom, if ever, seen.

An intermittent type of temperature sometimes occurs.

THE TREATMENT OF AMOEBIC DYSENTERY.

BY

GEORGE C. LOW, M.A., M.D.,

ASSISTANT PHYSICIAN, SEAMEN'S HOSPITAL, ALBERT DOCK;
LECTURER, LONDON SCHOOL OF TROPICAL MEDICINE, ETC.

RECENTLY many cases of dysentery have been coming home to England from Gallipoli and other places abroad, and as a result people who have little or no experience of this symptom-complex of disease are called upon suddenly to treat them. Naturally the results in many instances are not very satisfactory, and, in the hopes that some information on the subject may help any practitioners so situated in the future, I propose to give a brief account of the up-to-date treatment of one of the commonest forms of this disease. Since Rogers proposed the use of emetine for amoebic dysentery I have treated many cases, both in private and in the Seamen's Hospital, by this drug, and the method of administration now given is therefore based on actual experience and is one that will be found useful and efficacious in actual practice. Other ways of giving the drug I have no doubt may prove equally successful—at any rate, in the hands of experts—but there are certain points that must be carefully followed if success is to be obtained.

Space will not permit of a dissertation on all the varieties of dysentery met with. It is sufficient to say here that there are bacillary forms of the disease, protozoal forms, and helminthic. Of these the one termed amoebic comes under the protozoal group, and is caused by a parasite termed the *Entamoeba histolytica*. The cases of dysentery that have recently reached England from the Dardanelles have, at least in the vast majority of cases, been bacillary or of some undetermined type, and certainly have not been amoebic.

The administration of emetine to such is useless, as this drug is only specific for the form of dysentery caused by the *Entamoeba histolytica* just mentioned, and by its improper use in cases not due to such parasites negative results are first obtained, and the drug is brought into disrepute. The first thing to do in dealing with a case of dysentery is to determine its type, and for this purpose the faeces must be carefully examined for protozoal and other parasites. To detect pathogenic amoebae is not difficult, at least to the expert, but there are pitfalls the unwary may easily fall into, especially if one has not had sufficient practice in examining stools. *Lambliæ* cysts, *Blastocystis*, vegetable cells, and desquamated cells from the bowel are easily mistaken, and such mistakes are serious, as they may condemn a patient to a long course of emetine for no purpose whatsoever. Still more difficult, at least in the vegetative stages of the parasites, is the distinction between *Entamoeba coli*, a harmless amoeba, and the *E. histolytica*, the harmful one. In the tropics and abroad generally the former is very common, and there is no reason why mixed infectious with both should not occur. The distinction between the two lies in the hands of the expert, but the broad rule generally adopted now is, if a patient is passing blood and mucus—that is, has signs of definite dysentery and has amoebae present—the case may be looked upon as an amoebic one and treated accordingly. Later on, when the case becomes chronic or passes into the stage of the true carrier, cysts appear, and these can be differentiated from each other by their size and the number of their nuclei.

Having then diagnosed the case properly—a most important thing—the next thing is to treat it, and this is done by emetine hydrochloride in varying doses and amounts. The drug may be administered in one of three ways: (1) Intravenously; (2) subcutaneously or intramuscularly; or (3) by the mouth.

As regards intravenous injections, I have had no occasion to use them, but there is no reason why they should not be employed in fulminating or in moribund cases where time is precious. The most usual method of administering emetine is subcutaneously or intramuscularly. Subcutaneous injections often give rise to a considerable amount of pain and stiffness, and to avoid this some give them deep into the muscles similarly to quinine. There seems to be an idiosyncrasy in some individuals, a man I lately treated having considerable trouble—pain and stiffness—after his injections, whether

THE Pan-American Medical Congress, at its seventh meeting, held in San Francisco in June, passed a resolution requesting the president to organize a Pan-American Committee on Medical Education to include one representative from each American country. The committee is to investigate the status of medical education and medical practice in the different countries; and to consider the feasibility of a system of exchange professorships between American universities. Its report is to be communicated to the national medical organizations of the countries represented, and a final report is to be submitted to the eighth Pan-American Medical Congress.

they were given subcutaneously or intramuscularly. These symptoms did not disappear for several days, and in two injections given in the loose cellular tissue of the abdominal wall slight haemorrhages occurred as well as a considerable amount of redness at the site of the injection. This happened, though every care was taken to sterilize the skin, syringe, and needles, and the ampoules came from the usual source. At the same time as this two other patients had similar injections, both subcutaneously and intramuscularly, without the least trouble. The stiffness and pain in the case just mentioned definitely prevented the patient having full use of his arms for several days, and this possibility must be borne in mind in giving injections to people who are up and about. As a rule now I give the injections intramuscularly, avoiding giving a second one near a place where one has been previously given, until all signs have disappeared. Even with large doses no sickness is produced by the injections.

As regards giving the drug by the mouth, the method has the disadvantage that sickness may be produced. Provided the drug is retained, however, it acts quite as efficiently as by injections, and I know of one case where it did better. When administered by this route one gives it in keratin-coated tablets at night when the patient has gone to bed, taking the same precautions as one used to do with the old ipecacuanha treatment. I have tried this method fairly extensively and find that one of three things happens: (1) Either the patient has no sickness at all. (2) He may be sick for a night or two and then get quite accustomed to the drug, or (3) it may make him sick every time.

In acute cases in bed injections are best. In chronic cases with slight local lesions that one does not wish to keep in bed, or for some reason finds it inconvenient to inject, then the mouth method may be employed.

Another objection has been raised to the keratin coated tablets, and that is that they may not dissolve and may be passed unchanged per rectum. This has not been my experience, but it is a possibility. If there is any suspicion of it, as evidenced by the case not improving as he should, the stools can be washed and the tablets searched for.

The salt usually employed, as already stated, is emetine hydrochloride. Recently I tried another preparation for Dr. Balfour, made by Burroughs, Wellcome and Co., named methyl emetine. Though larger doses of this can be employed, it does not seem to be any more efficient than the hydrochloride, but one would need to try it on further cases before deciding finally.

The dose of emetine hydrochloride I now usually employ is 1 grain for each injection, two of these being given a day, morning and night, for the first two or three days if the case is a bad one with much blood, mucus, and pain; or if not, only once a day. After that 1-grain injections are administered every night until a total of 12 grains in all has been given. By this time all blood and mucus should have disappeared from the stool, and amoebae should no longer occur. Not uncommonly about the fifth or sixth day of treatment a moderate degree of looseness of the bowels, or in some instances a definite diarrhoeic condition, is met with. This may be due to the emetine itself, similarly to what one got and aimed at in the old ipecacuanha treatment, and it does no harm. After the cessation of the drug the stools become solid, of a normal consistence, and no blood or mucus is seen on their surface. They should be carefully searched for amoebae, and if these return or if mucus and blood appear again a second course of emetine will be required. This does not, as a rule, require to be so prolonged as the first, and may be given again in 1-grain doses every night until 6 grains in all have been taken. Third courses are practically never necessary. In my experience larger doses than those mentioned are not required. If all symptoms of dysentery have not disappeared by the time the 12 grains are taken, then the diagnosis is in all probability at fault, and the condition is due to some other cause than the entamoeba. With such doses toxic symptoms do not occur, but it is quite possible that if the drug is given in larger individual doses and kept up over long periods of time such might appear. As has been pointed out, there is no necessity for this, excessive doses not being required. The action of the drug on the vegetative or living stage of the amoebae is very rapid, the parasites quickly disappearing, as do also the

blood, and mucus, and other symptoms. In addition to the emetine treatment, acute cases of dysentery are, of course, kept strictly in bed and on a strict diet. At first only milk or liquid diet in the shape of whey and weak soups are allowed; then, as the symptoms subside, milk puddings may be substituted, these in turn being followed by a further increase until pounded white fish and chicken are reached. No alcohol is permitted at any time. After treatment, during convalescence, and for at least four to six months afterwards, the patient must be kept on a simple white meat diet with plenty of milk, no beef, coarse vegetables, curries, spices, alcohol, or things of that sort being allowed. In addition to diet, chills and wettings must be very carefully guarded against. Relapses of amoebic dysentery, even after very careful treatment, are frequent, and it is only by taking the greatest precautions and care that these may be avoided.

Often chronic cases of amoebic dysentery present themselves for treatment. The symptoms depend upon the amount of bowel involved and the character of the lesions present. Blood and mucus to a certain extent are generally present in the stools, or all that may be found is some looseness of the bowels, with two or three actions a day, or slight diarrhoea. In this latter type of case the only reason for suspecting dysentery is the presence of the specific parasite, often now in the cystic or resting stage. These cases act as true carriers and are dangerous to other people, the cysts being the infective agent that passes the disease on from one person to another. Such cases may require to be isolated. It has been stated that emetine has no effect upon the cysts and does not cause them to disappear. In a case Dr. Wenyon and I recently studied carefully this was not so. Injections of emetine in 1-grain doses daily quickly caused them to vanish, and they have not reappeared again up to date (some months later). The treatment of these chronic cases and carriers is the same as for the acute ones. It may not be necessary to confine them so strictly to bed or even to keep them in bed at all, but they should be put through a similar course of emetine and be dieted in exactly the same way. In addition to amoebic manifestations of the bowel, the liver may be involved and an abscess may threaten to form. Here, again, emetine works in a most miraculous manner, and if applied in the doses mentioned above may completely abort all the symptoms. Since its introduction the chances of averting suppuration have increased enormously, and fewer cases of abscess of the liver now come to the operating table.

Though practically all cases of amoebic dysentery respond quickly to emetine treatment, there is a small residuum—in which there has been no doubt of the correctness of the diagnosis—which does not, symptoms continuing and amoebae, vegetative or cystic, being still found in the stools. Such cases require further careful study to explain this anomaly.

In all the stages of the treatment of the disease it is of fundamental importance that the stools should be carefully looked at every day. There is no other way really of being certain how the drug is acting unless this is done. Where obtainable, flat glass stool dishes will be found very useful. One can examine the faeces then without removing the glass top and so avoid the horrible smell so many of these stools have. In addition to these macroscopic examinations, careful microscopic ones must also be carried out at least every second or third day.

In many instances physicians send samples of such stools to experts for diagnosis. In such a case it is not necessary to send the whole stool, all that is required being a small portion in a small glass bottle. Only practice in the microscopic examination of stools will make perfect. Students who have passed through the tropical schools are now supposed to possess this proficiency, but one must impress upon the home doctor, who has not had similar chances, that the subject is by no means an easy one and that there are many sources of fallacy.

Finally a word of warning as to the significance of flagellates in the faeces. Though this has nothing to do with amoebic dysentery or its treatment, yet in the search for entamoebae in the faeces they are sure to be met with, and as a matter of fact the cystic stages of some of these are often mistaken for amoebae. Three of the commonest intestinal flagellates are *Lambia intestinalis*, inhabiting the small intestine in its upper parts, *Trichomonas*

intestinalis and *Tetramitus mesnili*, inhabiting the large bowel. These, of course, have been known to tropical workers, and not only known but studied for years. Some have suggested that they cause diarrhoea, but on the whole the consensus of opinion is that they are harmless. They certainly are to many individuals, who may harbour them (*Lambia* at least) for long periods of time with no symptoms, but that, of course, does not preclude the possibility of their becoming pathogenic under certain unknown conditions. It is very improbable that they ever produce dysenteric symptoms; in fact, one may say they never do. The fact of them being found in dysenteric stools, as they have been recently, in many instances in cases coming to London from Gallipoli, simply means the patients have had a double infection, the dysentery being due to Shiga's or Flexner's bacillus, paratyphoid bacilli, or other bacterial causes.

It may even be that the flagellates flourish better in a bowel already damaged, but careful examinations of apparently healthy individuals in the tropics would tend to negative this, as sometimes the heaviest infections seem to occur in people with no bowel symptoms whatsoever. If they are harmless there is no special necessity to destroy them by treatment. In a case of *Lambia* infection Dr. Wenyon and I recently studied—the case that had *Entamoeba histolytica* cysts—we tried emetine and other drugs. Emetine had no effect whatsoever, while beta naphthol though causing a diminution of the parasites did not completely destroy them, and after the drug was stopped they became as numerous as ever again. As already emphasized, emetine has no effect on bacillary dysentery. The treatment of this disease is quite a different one, being chiefly carried out by diet, salines and sorbents, and the diagnosis of this type is purely a bacteriological one, similar to that of typhoid and paratyphoid fever.

ON A CASE OF SEPTICÆMIA TREATED BY INTRAVENOUS INJECTION OF EU SOL.

J. LORRAIN SMITH, BY JAMES RITCHIE,
M.D., F.R.S., M.D.,
PROFESSOR OF PATHOLOGY; PROFESSOR OF BACTERIOLOGY;

AND

THEODORE RETTIE, D.Sc.,

RESEARCH ASSISTANT UNDER THE MEDICAL RESEARCH COMMITTEE,
(Report to the Medical Research Committee from the Department
of Pathology, University of Edinburgh.)

Preliminary Note.

In the paper on the antiseptic action of hypochlorous acid which was published in this JOURNAL on July 24th, 1915, by Lorrain Smith, Murray Drennan, Rettie, and Campbell, it was shown that 5 c.cm. of esol can be injected intravenously into rabbits without harmful effect. In the paper referred to the name "esol" had been given to an aqueous solution of free hypochlorous acid of 0.5 per cent. strength, prepared by shaking up 25 grams of a mixture of equal parts of chloride of lime and boric acid in 1 litre of water and subsequently filtering. For intravenous injection 8.5 grams of common salt per litre are added. Since July we have made further observations, and find that 25 c.cm. can be injected intravenously in the rabbit without harm, and in one case as much as 45 c.cm. were given—that is, an amount equal to a quarter or half of the total blood volume.

The possibility of applying this method to generalized septic conditions was offered by a case of puerperal septicæmia which was sent into the Royal Maternity and Simpson Memorial Hospital, Edinburgh. The following is a summary of the clinical account of the case:

Mrs. M., aged 27, 4 para, delivered without assistance of a female child on October 5th. When the maternity nurse arrived she found the patient sitting by the fire with the baby in her lap. Placenta had not come away but was expelled naturally shortly afterwards. The progress was normal till the fourth day when, though the patient had not complained, she was found to have a rise of temperature. The prexia continued, and on the sixth day had reached 103 F. with a pulse-rate of 126. The breathing was rapid and shallow, with a short suppressed cough and some pain on the right side of the chest. On examination there was a suspicion of bronchial breathing

over a small area in the right base. The patient was removed to the hospital, where a diagnosis of puerperal septicæmia was made, the lung condition being looked on as secondary and slight in extent. On the day following admission the temperature was normal for a few hours, but this was followed by a steady rise till three days later it reached 103.4 F., pulse 145, respirations 38. The patient's condition was looked on as exceedingly grave and the prognosis hopeless. At Sir Halliday Croom's request we undertook treatment with esol.

In view of the animal experiments we decided to begin with a dose of 100 c.cm. Dr. R. W. Johnston exposed the median cephalic vein, and we injected with a transfusion apparatus 100 c.cm. of esol into it, made up in normal saline, and warmed to 37 C.; the injections took five minutes. The temperature was rising at the time of the operation, and continued to rise for an hour thereafter, when it reached 106 F. It then fell continuously for twelve hours till it reached 96 F. Stimulants were administered, and the temperature slowly rose again. When it reached 101 about twenty-four hours after the first injection, another dose of 100 c.cm. of esol was injected. The temperature ceased to rise, and continued for four days between 99 and 101, and then fell to normal, where it remained for five days.

The patient then developed pelvic cellulitis, and the temperature rose again to 102, and continued to show an evening rise to this point for eight days, after which it fell again to normal. The cellulitis was regarded by Sir Halliday Croom as a purely local condition.

On the day following the second intravenous injection intravenous douching with esol was applied, and also on the subsequent day. This was the only other treatment employed to combat the septic condition itself.

REVIEW OF THE CASE.

There seems no reason to doubt that this was a typical case of puerperal septicæmia in the ordinary acceptation of the term, and, further, that there was every likelihood of a fatal result, and this was the opinion of Sir Halliday Croom and other members of the staff. Cultures from the interior of the uterus yielded a *Streptococcus pyogenes* which was fatal to mice. Cultures from the blood, however, were sterile, so that in all probability life was threatened mainly by the toxic effects due to absorption from the local foci.

The immediate effect on the temperature due to the injections of esol may be regarded as evidence of the action of the hypochlorous acid on the circulating toxin. This view of the case is confirmed by the subsequent temperature disturbance caused by the parametric inflammation.

This case is published at the earliest possible moment because of its bearing on the treatment of septicæmia among the wounded soldiers.

The method is obviously a safe one if carried out with caution and on the lines indicated above.

It has not been possible to determine the maximum quantity of esol which can be injected with safety into the human subject. Since 100 c.cm. is a small fraction of the blood volume we consider that it is possible where repeated doses are given that this amount might be cautiously increased. On the other hand, to judge from our animal experiments, large amounts may diminish the coagulability of the blood and cause hæmolytic.

In a case of malignant endocarditis with pneumonia which is still under treatment we have demonstrated that the 80 to 120 c.cm. esol can be injected without harm.

The success which has followed the treatment of gas gangrene by local applications of esol in Captain John Fraser's hands, taken along with the above observations, suggests that the method of intravenous injection may be expected to give favourable results in cases of general septic infection in the field, gas gangrene, tetanus, and other kindred conditions characterized by toxæmia.

This case was under the care of Sir Halliday Croom, and we beg to express our thanks to him for permission to publish an account of the clinical observations.

REFERENCE.

BRITISH MEDICAL JOURNAL, October 9th, 1915.

The first medical congress of Ecuador, organized by the College of Medicine of Guayaquil, was held in that city from October 9th to the 16th. Among the subjects discussed were the climatic conditions of Ecuador, the special features of typhoid and malarial fevers as seen in various parts of that country, the means of preventing the spread of epidemics, the medical botany of Ecuador, and a scheme for the compilation of a *Pharmacopœia Ecuatoriana*, and the practice of medicine in Ecuador.

A Lecture

ON WOUND INFECTIONS AND THEIR TREATMENT.

DELIVERED WITH DEMONSTRATIONS AT THE OPENING OF AN EXHIBITION OF SURGICAL APPLIANCES FOR THE TREATMENT OF THE WOUNDS HELD AT THE ROYAL SOCIETY OF MEDICINE FROM OCTOBER 8TH TO 14TH.

By COLONEL SIR ALMROTH E. WRIGHT, M.D., F.R.S., C.B.,

A CONSULTANT PHYSICIAN TO THE EXPEDITIONARY FORCE IN FRANCE. (From the Research Laboratory attached to No. 13 General Hospital, Boulogne-sur-Mer.)

(Continued from p. 476.)

PART III.

Physiological Action of Strong Salt Solutions.

IN connexion with the physiological action of strong salt solutions—and when speaking of strong salt solutions I have in view those containing about 5 per cent. of salt—we have to consider primarily the effect produced upon leucocytes. And we have to distinguish between the case where the strong salt comes into direct application, and the case where it comes into operation from a distance.

In the former case—both in pus and blood—the leucocytes are broken down; and, in pus, evidence is obtained of a setting free of trypsin. In other words, strong salt solutions acting on a medium containing leucocytes will promote auto-digestion, and provide a nutrient substratum which will, as soon as the excess of salt is removed, favour the growth of microbes.

To study the effect of strong salt solutions acting from a distance we centrifuge blood in an emigration tube or cell;¹ let it clot; superpose our 5 per cent. salt solution; allow time for the salt to diffuse; and then incubate at 37 C.

Fig. 12.—We have represented in A and B the lower portion of the white and the upper portion of the red clot obtained by centrifuging blood in one of Emery's cells. The white corpuscles only are shown in the figure. In A strong solution has been imposed upon the free surface of the white clot. In B physiological salt solution has been imposed. The appearances are described in the text.

Fig. 12, A, shows the picture that we then get; and I add for comparison Fig. 12, B, showing the picture obtained when we impose upon the blood, instead of 5 per cent., 0.85 per cent. salt solution. In each case we have: below, the red corpuscles; and above these, the layer of leucocytes; and above these again, the white clot. In A, where the 5 per cent. salt solution has been imposed, we have practically no wandering out of the leucocytes into the white clot. We have instead a tightly packed and sharply margined band of leucocytes intervening between the red and white clots. Below this we see a good many leucocytes which have, as it seems, travelled back from the leucocytic layer into the red clot. In other words, we have here, instead of positive chemiotaxis as in B, paralysis, and presumably also negative chemiotaxis. There would seem to be little doubt about the negative chemiotaxis; for in companion tubes or cells, treated in every other respect than the salt solution as exactly alike, the white corpuscles have all been by the centrifugalization separated out from the red. It will be appreciated in connexion with Fig. 12, A, that the elements of the blood

¹ The cell referred to is a special form of cell devised by my fellow-worker, Captain d'Este Emery, and made by fitting together two pieces of glass slide with paraffin wax.

have, first by the mechanical force of the centrifuge, and secondly by the chemical stimulus of the strong salt solution, been disposed in what I have called the "kakotropic" arrangement—that is, the blood fluids are in front, and the leucocytes behind. The import of this in connexion with the conduct of the wound will presently appear. For the moment let us merely put it down upon our tablets that it would seem to follow from what we see in Fig. 12, A, that we have in strong salt solution an agent which would be capable of arresting all suppurative processes.

Effect of Strong Salt Solution on the Condition of the Wound and the Microbic Infection.

The effect of strong salt solution on the wound will, of course, be the resultant of its physical and physiological effects; and there will be in addition an effect exerted directly upon the microbes.

This last may very quickly be dealt with and disposed of. Percentages of 2 per cent. will begin to inhibit, and 5 per cent. solutions will completely arrest, the growth of pyogenic microbes. In other words, undiluted 5 per cent. salt solution will by itself—and this is to be borne in mind in connexion with proposals to combine this with carbolic acid—prevent any growth of microbes in the wound.

Let us, however, turn—for this is of more moment—to the effect exerted by the hypertonic salt solution on the condition of the wounds. And we may take the case of hypertonic solution applied to a sloughing or indurated wound. Now coming, as it will here, into direct application upon leucocytes, the strong salt solution will break these up, and set free trypsin and favour auto-digestion; and, coming into operation at the same time on the walls, it will promote an outflow of fluid. The effect of this will be to loosen and separate the sloughs, to disperse the induration, and finally to give us—always provided that the concentration of the salt is maintained—a wound in which muscles and connective tissue lie before us as bare and clean, and as free from pus, as meat exposed on a slab at the butchers'. Moreover, impression preparations will show that the surface lymph is practically free from leucocytes, and that the sero-saprophytic microbes have disappeared, leaving behind only a few staphylococci or streptococci. This complete result is, as a matter of fact, only rarely seen—for applied in the ordinary way on a pad of lint or gauze, the hypertonic solution is by the outflow of lymph very rapidly diluted.

But whether we have before us the complete, or only the incomplete, result, we have a wonderful improvement upon the state of the wound before treatment. None the less, the prospect for the future is not quite reassuring. In point of fact, we have here lying open and naked before us all the lymph spaces; and, moreover, the elements of the lymph are disposed in the "kakotropic arrangement"—the fluid elements which furnish a favourable culture medium in front, and the leucocytes which would be capable of combating the streptococci behind; and at any rate, so far as the superficial lymph spaces are concerned, there would now seem to be nothing to prevent microbial invasion save only that we have here an outflowing current.

But if the salt which has been absorbed into the tissues were no longer carried away, or if the saline solution outside were now to be diluted, the tide might easily turn and flow inward. In short, we see that we have made a successful advance, but that we must, before we can congratulate ourselves, advance a great deal more.

Our experiments in connexion with the bactericidal power of the whole blood tell us that our next step must be. If we want to keep the streptococci at bay, and destroy them, we must get the elements of our lymph into the agathotropic order; in other words, we must now bring forward our leucocytes. Our studies on emigration tell us how this is to be done. We shall have to substitute for our 5 per cent. 0.85 per cent. saline solution.

Effect of Physiological Salt Solution.

It will in connexion with physiological salt solution be unnecessary to go much into detail with respect to its physical and physiological action. All that requires to be emphasized is that 0.85 per cent. salt solution, which we call normal or physiological, is normal and physiological

only with respect to its tonicity. It has, of course, a much higher content in sodium chloride than the blood fluids, and will, when placed in contact with these, send into them sodium chloride, exchanging this against other salts. It is to this different salt content that we have to ascribe the physiological action which 0.85 per cent. salt solutions exert when superimposed on centrifuged blood. Fig. 12, n, has shown us what then invariably happens. The white corpuscles—and in particular the polynuclear white corpuscles—are carried forward by a chemiostatic movement in the direction of the free surface upon which the physiological solution has been imposed. And precisely the same occurs in the wound. After the lapse of a few hours the perfectly bare wounds which are obtained by treatment with strong salt solution begin to clothe themselves with a grey film. And when we make impression preparations we find on the surface of our cover-glasses a layer of beautifully well-preserved polynuclear white corpuscles. In other words, the elements of the lymph are now in the agathotropic arrangement; and microbes if found at all are only very few in number.

This marks another great step in advance. It is, however, as we shall presently see, one that falls very far short of a final conquest over the infection. But for the moment let us turn aside and see what will happen when hypertonic salt solution is applied to a clean, or, as the case may be, a suppurating wound, and is then diluted. We shall see our new data dovetailing perfectly with the old.

To study the sequence of events where a hypertonic salt solution is spontaneously diluted with outflowing lymph, we carefully clean the surface of a granulating wound. We then bring down upon it—and I owe this piece of technique to my fellow worker, Lieutenant H. H. Tanner—a lymph cup such as is shown in Fig. 13, fastening it

Fig. 13.

down securely upon the skin by strips of adhesive plaster. We now introduce a measured quantity of hypertonic solution into our lymph cup, and then from time to time remeasure and sample the fluid. During the first hour or more only a lymphagocytic effect is produced. The fluid in the cup increases in quantity—in an experiment I have in mind the original 3 c.cm. of 5 per cent. salt solution increased in three hours to 5 c.cm.—but the fluid remains quite limpid. After that a leucocytogenic effect begins to manifest itself. First a few, and then more and more leucocytes emigrate into the fluid in the lymph cup; and the streptococci, which in the first phase of the experiment may have been fairly numerous, gradually decrease until it is difficult to find them.

To study what will happen when 5 per cent. salt solution is brought into operation upon a suppurating surface and is afterwards diluted, we take a sample of pus, mix it with 5 per cent. salt solution, and then place it in the incubator. We then dilute with sterile water until we have brought down the content in salt to 0.35 per cent., and then we incubate for a further period of hours. After the expiration of that period we find—and we may put this down to the setting free of trypsin from the cells broken down by the strong salt solution—a much more luxuriant growth of microbes than in a control sample incubated for the whole period with physiological salt solution.

Reverting now to our wound which was treated with physiological salt solution, you will remember that we had there a position won but not consolidated; and, if events were now allowed to take their course, the leucocytes which had been drawn up to the surface, and in particular, perhaps, those which had done service in the destruction of microbes, would not long maintain their vitality, for

the conditions which prevail on denuded surfaces are, as we have seen, uncoagulative to leucocytes. Now just as soon as the first leucocytes die and break up and set free their trypsin, all those in the neighbourhood become involved in the same ruin, and this provides for any microbes that have survived or come in from outside in an eminently favourable culture medium. After this we have very soon upon our wound surface in the place of an almost extinguished infection a luxuriant culture of microbes; and though no doubt it might be possible, by instituting continuous irrigation with physiological salt solution, still to hold on, our position cannot really be consolidated by anything except the restriction of the infected surface and the final closure of the wound. In other words, that as soon as we have practically conquered the infection surface we ought, as I said in an earlier section of this lecture, to proceed immediately to secondary suture of the wound.

TREATMENT BY VACCINES.

Treatment by vaccines would have hardly any meaning in connexion with antiseptic treatment; but it is, as a moment's consideration will make plain, very intimately linked up with phylagocytic treatment. For, once we have made up our minds that an infection will have to be fought by the protective powers of the organism, it will be reasonable to look round and see whether the protective powers of the organism generally cannot be reinforced. And it will also occur to the mind that not only the blood fluids could be reinforced in protective substances but also chemiostatic sensibility of the leucocytes could be so altered as to give a more vigorous emigration response. If this were secured, the leucocytes would not only come more rapidly and more effectively into action, but they would come into action in the whole theatre of infection, instead of, as in the case where salt solutions are applied, only in those regions into which the salt is conveyed by diffusion.

Having seen where vaccine therapy fits in, we have next to consider how and upon what principle we shall select from the bacterial flora of the wound those microbes which ought to be combated by vaccines. The principle here is quite clear: we ought to direct our attention to those microbes which are least easily killed by the protective elements of the blood. That will mean that we ought to put into our vaccine primarily the streptococcus and the staphylococcus, for these belong to the class of serophytes; and in the second instance the bacillus of Welch and the *Bacillus proteus*, for these belong to the class of imperfect serophytes, microbes which will, provided we make a sufficiently heavy implantation, establish themselves and then grow luxuriantly in the blood. Let me explain that whenever in the following I speak of a vaccine for bacterial infections of wounds I shall have in view either (a) a vaccine containing streptococci and staphylococci obtained from wounds, or (b) a vaccine which contains in addition to these the bacillus of Welch.

The question of the vaccine settled, the next question is at what stages in the wound infection we can find specially favourable opportunities for the use of vaccines. The first of these specially favourable opportunities will present itself immediately after the wound has been received. The patient is here just entering upon his incubation period; and it may quite well make all the difference to him if he is, now, before the microbes which have been carried into his tissues grow out, enabled to kill them. I hold very strongly—and there would be no difficulty at all in arranging for this—that every wounded man should be inoculated as soon as he reaches the first-aid post. A second, and also very favourable, opportunity of achieving definite good by inoculation would present itself at a later stage, in those cases where the streptococcus, or the bacillus of Welch, or the two acting in conjunction, establish a footing in the tissues, and begin to spread there. I am thinking, of course, of the early stage of erysipelas, cellulitis, or gaseous emphysema, where we have, as the case may be, the beginnings of an inflam-

² Both varieties of vaccine are available in all military hospitals. The first under the designation "antistreptococcal vaccine," the other that of "antistaphylococcal vaccine." If an autogenous vaccine were to be made for a particular patient one would determine the microbes which menaced him by taking a sample of his pus and making, as described in the first portion of this lecture, progressively smaller implantations of this into his serum or blood by the method of pro-culture, or two-haem-culture, and then using for the vaccine those microbes which grew most readily in the blood.

matory blush on the skin, or the beginnings of induration, or it may be that purplish mottling of the skin which heralds gaseous gangrene.

And the employment of vaccine would also be specially opportune when we address ourselves to the partial or complete secondary suture of the wound. For the conditions are here analogous to those which obtained when the original wound was received—analogue in the respect that we have in both an implantation of microbes into the depth; and analogous also in the respect that success or failure will hinge upon the rapidity and effectiveness with which the protective elements of the blood are brought to bear upon the implanted microbes.

But to all this it may be objected that we have here merely plausible theoretical considerations; and that what is required is direct evidence establishing the utility of inoculation.

Let me therefore consider with you how far it would be possible here to procure probative evidence; and for the sake of those who attach superior authority to clinical evidence, let us begin with this.

A comparison of what would be procurable in connexion with antiseptic inoculation with what has been procured in connexion with antityphoid inoculation will here clear up certain points for us. The first of these is, that once a man has been inoculated against typhoid, events will take their course unaffacted by outside interference. In other words, if an inoculated man comes into contact with infection, and the typhoid bacillus effects a local lodgement in him, nobody comes and interferes between the organism of the patient and the invading microbe. Moreover, when the invading microbes are successfully disposed of, there will not remain open any door to after-infection. The exact reverse will hold of antiseptic inoculation.

Here there will be all sorts of interference, useful or, as the case may be, harmful, at the point where the microbes have effected a lodgement; and the wound will remain open to further infection from outside, and in particular it may readily be reinfected in the course of operative interference. By reason of this it will, if the wound becomes septic, be impossible to tell whether the responsibility lies with the microbes originally implanted, or whether these were killed off, and we are in presence of an after-infection. Enough will have been said to show that it will be quite out of question to procure in the case of antiseptic inoculation trustworthy statistical data such as are available in connexion with typhoid.

Precisely the same will hold true in the case of antiseptic inoculation undertaken as a preliminary to secondary suture of the wound. For here everything will depend on the operative skill of the surgeon and on the scientific preparation of the cases. And the only judgement which will have value will be that of the surgeon who has actually followed the cases; and, again, his opinion will have value only if he have experience also of cases of secondary suture undertaken without inoculation.

There remains the third class of case, that where vaccine is employed to abort an incipient infection of tissues. Here, again, statistical proof will be unattainable. When, however, a sufficient number of separate observers shall have experimented with the vaccine, using control, and shall have formed each his own experimental judgement, we shall have evidence which will really have probative value. But experimental judgements of that kind are not yet available in sufficient number.

For the present, therefore, there is not—nor will there ever be, except only in connexion with the last class of case—anything to carry conviction to that type of man who puts aside what he calls "theory" and demands everywhere proof and certainty.

But, while we have in these matters no certainty—and let us not regret it overmuch, for certainty is like the stick without the dog to the blind man who wants "to get a move on"—we have here all that an exacting mind could require in the way of inferential evidence of the value of immunizing response in wound infections. Such evidence is furnished by the fact that patients who make only very indifferent immunizing response suffer from long-continued pyrexia, and their wounds heal slowly, and they not infrequently develop serious complications, in particular in the form of spreading infections and metastatic infections of joints. The direct reverse holds of patients who are making satisfactory immunizing

response. Their wounds heal rapidly; and they never give cause for a moment's anxiety. Now, such immunizing response as we see here safeguarding the patient is, in the case of healthy men—and I reckon as healthy men all who are not suffering from autoinoculations and fever—readily obtainable by the inoculation of vaccines.

I have now completed what I have to say about the different ways of treating wound infections; and you will have appreciated that, while antiseptic treatment stands apart, the three other methods are closely interlinked—forming together a complete system of phylacagogic treatment. Let me now draw the threads together, and put before you in outline a scheme which might serve as a basis for the treatment of wound infections.

Before that, however, let me just pause to express my gratitude and indebtedness to my fellow-workers in these researches on the treatment of wounds, and in particular to Captain S. W. Patterson of the Australian Medical Service, to Captain d'Este Emery, and to Lieutenant A. C. Inman and Lieutenant H. H. Tanner. And I have at the same time to express my grateful acknowledgement to the authorities of the Army Medical Service, and to Colonel W. l'Estrange Fames, C.B., of the Australian Hospital, and, above all, to the Medical Research Committee for placing the services of these officers at my disposal.

SCHEME FOR THE PHYLACAGOGIC TREATMENT OF WOUND INFECTIONS.

It will be convenient for the ordering of this scheme of treatment to follow the wounded man from the "first-aid post" back through the whole system of hospitals.

Treatment in the First-aid Post.—Here, after hæmorrhage has been arrested and the wound has been cleaned and bandaged and splints have been fitted, it will be well to give a prophylactic injection of "antigangrene vaccine," this being, as already explained, a vaccine containing the streptococcus, and staphylococcus, and bacillus of Welch. For this injection nothing in the way of apparatus would be required beyond a syringe in a metal case and the vaccine in a rubber-capped bottle. From this last the vaccine would be drawn off as required through the rubber cap sterilized with lysol or other antiseptic. To sterilize the skin at the point inoculated is, in connexion with injection of vaccine, a work of supererogation.

There would follow upon the inoculation a rapid immunizing response which would, one is entitled to anticipate, in a bullet wound perforating only tissues, extinguish the infection, and would in other wounds do the same in those regions where the physiological conditions were not too unfavourable.

Treatment in the Field Ambulance.—I would suggest that the work of the field ambulance, which is—except in the case of the wounded who are too ill to move—restricted to mere washing and sterilizing operations, to the application of clean, dry dressings, and to the injection of tetanus antitoxin, should be extended to the performance of simple operations for the excision of the projectile and foreign bodies, and the procuring of efficient drainage. And I would suggest that all wounds, with the exception of those which promise to get well of themselves, should be treated with hypertonic salt solution. These suggestions are dictated by the consideration that where a wound will, if left to itself, certainly become septic, we ought, at the earliest possible moment, both to remove extraneous substances which contain microbes, and provide for a free outflow of lymph from the whole internal and external surface of the wound.

Concerning the operative procedures for the procuring of drainage it will suffice to say that they ought to give sufficient access to permit of loops of sterile bandage, previously steeped in a solution of 5 per cent. sodium chloride and 0.5 per cent. sodium citrate, being carried down into the wound to serve as wicks.³ The introduction of the bandages ought to be preceded by a syringing out of the wound with the aforesaid solution, and the free ends of the bandage ought to be carried out from the wound to be inserted between plies of lint well soaked in the same solution, and folded over so as to form a thick pad. Finally, one or two tabloids of salt ought to be

³File here the author's Memorandum on the Employment of Bandages for the Draining of Wounds, BRITISH MEDICAL JOURNAL, October 16th, 1915, p. 554.

planted in between the back layers of the pad, and over the top of all ought to come a layer of impervious protective tissue. This method of dressing ought to be applied also to the open funnel wound. In the case of "gougged-out" or "punched-in" wounds of soft tissues the wicks of bandage would, of course, be dispensed with.

This will be the place to elucidate two points which come up for consideration everywhere when hypertonic salt solutions are used as lymphagogic agents. The first has reference to the concentration of the salt, the second to the addition of citrate of soda.

In connexion with the concentration of the salt all strengths from that of sea water—corresponding to about 2.5 per cent. of sodium chloride—to a saturated solution—corresponding to 30 to 40 per cent. of sodium chloride—have been used in the wound; and the stronger the salt solution the greater the lymphagogic effect. But as the concentration of the salt increases, treatment will be more and more painful until with saturated, and nearly saturated, salt solutions we get escharotic effects with intolerable burning on the wound surfaces; while on the skin there is produced severe irritation followed by bacterial infection. The strength of the salt solution must therefore be kept within limits. Where we have freshly cut edges of skin, and, as in the flapless amputation, nerve fibres exposed in the wound, it will be unjustifiable to employ more than 5 per cent. of salt; and even then it will be well to protect the cut edges of the skin with a thin coating of vaseline. When, on the contrary, we are dealing with comparatively insensitive granulation tissue, or with quite insensitive sloughing surfaces, we may, with a view to achieving more rapid results, employ somewhat stronger solutions. But even with sloughing wounds it will be better not to go beyond 10 per cent. of salt. Again, when we use a wet pack of salt solution, it will be well to protect all the skin in the neighbourhood with a coat of vaseline. And finally, when we use, as suggested above, tinctures of salt to keep our salt solution up to strength, in despite of outflowing lymph, care must be taken to prevent the solid salt coming into contact with the wound surface.

Passing now to the question as to when citrate of soda should be employed in combination with hypertonic salt solutions, it may be explained that the purpose of the citrate is to prevent the lymph coagulating in the siphon bandages and on the walls of the wound. I may point out, in connexion with this, that while 5 per cent. salt solution will, as already Alexander Schmidt showed, prevent clotting, it will not, as my fellow worker, Lieutenant A. C. Inman, has shown, prevent clotting in blood that is mixed with pus. Such blood is, however, prevented from clotting by 5 per cent. salt mixed with 0.5 per cent. of citrate of soda. The practical rule, therefore, will be to add citrate of soda when we are confining the discharge and may be dealing with pus; and to omit the citrate as unnecessary when we are irrigating and washing away any pus.

Treatment at Casualty Clearing Stations.—As the patient is transported farther and farther back from the front, and x-ray and other equipment becomes available, it becomes possible to undertake more extensive operations for the procuring of drainage, and for the removal of the projectile and extraneous substances, as well as for resection of hopelessly infected tissues. But we have always in connexion with operations upon a patient who has to be transported farther, to consider not only the practicability of the operation, but also that of keeping the patient under close observation sufficiently long after we have operated. It must be remembered here that the wound infection is always the important factor to keep in view, and that the period which is occupied in transport will generally represent for the patient a period of retrogression; and the set-back will generally be proportionate to the duration of the journey. During transport drainage will, unless this can be prevented by wet salt packs applied under protection, be interrupted; the wound may become "lymph-bound," and then cellulitis or gas gangrene may supervene. Or, again, if the wound has arrived at the suppurative stage, the discharges will be confined and become tryptic, and corrupt.

This will, of course, apply retrospectively as well as prospectively, so that in every hospital which receives patients from the front its work will consist largely in efforts to regain for the patients ground lost upon their journey. In particular the induration of the walls of the

wound will require to be dispersed, and relief will have to be obtained for the wounds that are lymph-bound.

Treatment at Hospitals at the Base.—Operative work will here be called for in connexion with two classes of cases. First there will be cases of spreading infection in the tissues—cellulitis and gaseous gangrene—which have manifested themselves during transport. These will require treatment by free incision supplemented by hypertonic salt solution. Further, there will be operations postponed from the casualty clearing stations—postponed either because of pressure of work or for the patient's sake, to give him the benefit of special equipment or special operative skill available at the base, and in conjunction with this the longer hospital stay which is there permissible.

The longer hospital stay will, when it can be secured, allow of quite important progress in the conduct of the wound infection. It will then be possible to embark upon, what I may call, the full programme of phylacagogic treatment.

In this programme we first irrigate with a hypertonic salt solution until we have restored the tissues to their natural condition, and are dealing with a more surface infection, and only with serophytic bacteria. We then irrigate with physiological salt solution till we have extinguished, or all but extinguished, the surface infection. And we then undertake, in one, or in a series of successive operations, secondary suture of the wound.

The essential features of these three linked procedures have already been explained, but the details remain to be worked out. The following practical points may, however, be emphasized.

Lymphagogic Irrigation.—The irrigation and drainage of the wound may with advantage be conducted by the methods which form the subject matter of the demonstrations already referred to (see Footnote 3). The solution which I would suggest for use is a 5 per cent. solution of sodium chloride, boiled, and kept at a temperature of 37° to 40° C. Irrigation with this solution ought to be continued *ad dic in diem* until the desired result is obtained. If we fail in this we have probably some retention of pus in inaccessible spaces, and these ought to be opened up. Whether irrigation ought to be continuous, or whether it ought to be continued for only a few hours at a time, remains to be determined.

Leucocytagogic Irrigation.—Our therapeutic solution will here normally consist of boiled physiological salt solution. It, however, remains to be determined whether in those cases where secondary suture is for any reason impracticable, it may not be better to substitute for physiological salt solution some such fluid as Ringer's solution or Locke's solution (without the sugar), whose salt content will more nearly resemble that of the blood—such a fluid, though as a leucocytagogue not so good as physiological salt solution, might quite as well prove more favourable to the growth of connective tissue and epithelium.

There remain over now two general questions with regard to which an explanatory word must be said. The first relates to infections of joints and serous cavities which are shut off from the exterior; the second, to the employment of antiseptics and antiseptic precautions in connexion with operative interference and the various manipulations and procedures undertaken in the wound.

Treatment of Infections in Unopened Joints and Serous Cavities.—The complete programme of lymphagogic treatment, leucocytagogic treatment, and secondary suture is, of course, a programme for open wounds. But lymphagogic treatment will be superfluous where we have a purely surface infection in a closed cavity. And the question of secondary suture will not come up, unless we have first opened up widely—a method of treatment which is, at least in infections of the knee-joint, of very doubtful wisdom. There remains accordingly of our programme only the irrigation with physiological salt solution, and in combination with this effective drainage. In the particular case of a knee-joint infection the fluid could be supplied through one needle and be carried off through another. Or the fluid might be carried in through a fine rubber tube inserted in a very small incision. And the fluid might be allowed to find its own way out, or it might be carried out by a siphon of sterile bandage inserted through a small counter opening and carried down to a vessel of water standing on the floor.

Employment of Antiseptics and Resort to Antiseptic Precautions in Connection with the Wound.—The employment of antiseptics and the taking of antiseptic precautions in connexion with all operations and manipulations in wounds is governed by the consideration that the patient will have made immunizing response only to those microbes which the projectile carried into the wound, and to those contained in the vaccine—those being *ex hypothesi* those present at the outset in every wound. To all other microbes the patient will, except only so far as the increase of his antitryptic power may protect him, be fully susceptible. From this it follows that we shall, if we neglect any antiseptic precaution, be running the risk of superadding to the already subsisting infection another infection; and in hospital we shall be running the risk of transferring infections from patient to patient. Herein, then, lies the justification for prescribing the prophylactic employment of antiseptics and antiseptic precaution, and in particular the use of sterile instruments and sterile gloves in connexion with the dressing of patients, and in association with this the sterilization of all bandages and salt solutions used in the wound.

CONCLUDING REMARKS.

I pass in conclusion—for in the end one's thoughts always take that direction—to the problem as to whether it would not be possible for the researches I have detailed to bear fruit in a wider sphere than that represented by the present audience and those who will perhaps read this discourse.

You see that my mind is here set upon those questions of organization concerning which I ventured to say something when lecturing here some six months ago.⁴ Let me to-day again break ground for you by indicating that there are included in the Army Medical Service in reality three different services—a Service of Administration; a Service of Sanitation; and a Service for the Treatment of the Sick and Wounded. And let me again, in connexion with the last mentioned, ask you to remember that it is staffed almost exclusively by medical practitioners joining for the war; and that the civil profession is by consequence specially responsible for its efficiency. Now, if that is so, it then must be for the civil profession a duty of special obligation to see that whenever, in the practically unexplored field of wound infections, any new knowledge is gained, that new knowledge shall be brought into application in all military hospitals.

At the beginning of the war the outlook, so far as it related to the wounded, was, I think, somewhat as follows:

It was realized that all sorts of surgical operations in which life would be at stake would have to be undertaken; and that these would, under the conditions that existed, fall to new-joined junior medical officers with very little operative experience. There were, therefore, sent out to the theatre of war a certain number of eminent surgeons.

Here at the very outset we see recognition of the fact that the rank and file of new-joined medical officers will require—and, moreover, will very gratefully accept—skilled help and supervision.

There were two alternative ways of supplying help and supervision.

The one was to associate the eminent surgical experts with the Medical Service of the Army in the capacity of consulting surgeons. To do so, was not to follow the precedent of civil life: for in civil life the operating surgeon is not consultant and adviser to the operating general practitioner. Nor was it to follow the precedent of the army. But, at any rate, that was the course that was adopted.

The other and, I think, the better alternative would have been to have made those who now function as surgical consultants integral elements in the army machine; to have entrusted to them the selection of the operating staff in the hospitals in their administrative unit; and then to have made them directly responsible for all operative treatment in those hospitals.

All this touches, but only indirectly, the particular point in organization I want you to consider.

What seems to me specially required is the organization of all that department of treatment which lies outside the sphere of the operating surgeon, or at any rate the sphere

of the operating theatre. Before the war it was generally held about this department of treatment—let me call it for short “the conduct of the wound infection”—that all that would be required would be: to drain the wound, by making an opening at the most dependent point; then to wash out with antiseptics; and finally, to apply dressings. And it was held—and no doubt correctly—that for the proper carrying out of the antiseptic washings and dressings any doctor who was on the *Medical Register* or any trained nurse would suffice.

Now the wind has swept this all away, and it has come home to everybody that every wound is infected and that the infection is the really serious element in wounds. Coming on the top of this, practically everybody has become aware that the antiseptic system has—so far as the treatment of the wound infection is concerned—completely broken down. So finally it comes to this, that the progress of knowledge has fled away from the ordinary medical officer everything, other than the knife, which he was relying upon for the treatment of bacterial infections of wounds.

And though here and there he may have substituted for the antiseptic hypertonic salt solution, that is, as we have seen, only to take one item out of the programme of bringing the protective elements of the body to bear upon the infection; and what is required is the complete programme. Now to carry out the complete programme it will be necessary to stop every moment and think; and it will be necessary also to verify every step; and to make as occasion requires new departures. Now to stop every moment and think, is not given to everybody; and to verify, and as occasion may require rectify, one's course in combating a bacterial infection involves thinking in terms of microbes and protective substances and antitoxinulations and vaccines, and involves also a certain acquaintance with laboratory technique.

So that I have the conviction that a newly-joined medical officer, supposing him left completely without supervision and help, would more easily perform successfully all the surgical operations that might be required of him than conduct satisfactorily the treatment of a wound infection.

If that is so—and it is for you to judge whether it is so—what follows is that it will be necessary to provide in connexion with the conduct of the wound infection the same kind of aid and instruction as is provided in connexion with operative surgery.

And what holds true with respect to the organization of the one, will hold true also with respect to the other. For the conduct of the wound infection, which we are here considering, one would wish to have in each large administrative unit a responsible head disposing of a staff of men with both laboratory and clinical experience, who would be deputed one to each hospital to exercise supervision as “a physician in charge of wounds” over all that department of treatment which lies outside the sphere of operative surgery.

And I would emphasize that it would be just as necessary in the case of the “physician in charge of wounds,” as in the case of the “surgical specialist,” to confer such rank as would make it possible effectively to direct the operations of the medical officers working in the wards.

ACCORDING to the *Boston Medical and Surgical Journal*, Scandinavian immigrants do not survive in the Southern United States, where their former settlements have entirely disappeared, whilst those in the northern States are thriving. Albinism is markedly frequent in the German and Scandinavian races. The Greeks are subject to various forms of infantilism, especially arrested sexual development, and are particularly prone to spinal meningitis. The Armenians and Syrians are susceptible to sporadic typhus and trachoma. Spanish, Portuguese, and Basque shepherds readily contract anthrax. Italians, who age prematurely, have a marked tendency to arterio-sclerosis, while pellagra, hookworm, malaria, rickets, and osteomalacia are common amongst them. Italian emigrants are very liable to tuberculous diseases. Turks suffer badly from parotitis. Tuberculosis is killing out the red Indian. Diabetes is so common among the Jews that its increase in New York keeps pace with the free immigration of European Hebrews. The admixture of Jews with the physically dominant races in the States has produced a fine type relatively free from the recessive characteristics of Aryans and Semites.

Memoranda:

MEDICAL, SURGICAL, OBSTETRICAL.

TWO CASES OF DYSENTERY IN CHILDREN DUE TO *B. DYSENTERIÆ* OF FLEXNER TYPE.

I publish these cases with the object of drawing attention to the dysenteric origin of some of the cases of infantile diarrhoea occurring in this country.

It was shown by Bainbridge and Bulfield (1911) that *B. dysenteriae* (Flexner type) was one cause of epidemic infantile diarrhoea in England. Four of the twelve children attacked in the outbreak they described had blood in the motions. Marshall (1909) had previously described one fatal case of dysentery from which he isolated the same organism. Similar observations have been made in Denmark, the United States of America, and elsewhere.

The position in reference to summer diarrhoea of infants is probably this: There is one type of diarrhoea accompanied with blood in the stools, which may occur in infants, and is due to the *B. dysenteriae* (Flexner or Shiga), while there is a second type of acute choleric character, without blood in the stools, associated in this country with the bacillus No. 1 of Morgan.

The two cases I desire to report occurred in my own family, and had the following clinical histories.

CASE I.

P., a girl aged 3½ years, woke up on the night of June 12th-13th, 1915, in a state of delirium. The delirium continued the whole of the following day. Marked diarrhoea and vomiting set in at 7 a.m. on the same day. The motions at the commencement were green and watery, but rapidly became slimy, and contained a considerable quantity of blood.

The temperature on this first day of illness was: 11 a.m., 103.8; 2.30 p.m., 102.8; 6 p.m., 103.2. The treatment was dietetic, while tepid sponging was needed to lower the temperature and diminish the delirium.

Second Day.—The motions, which were very frequent (over a dozen), contained mucus and blood and were intensely foul-smelling. The temperature was normal throughout the day. Delirium had abated, the patient had intervals of restlessness and drowsiness. Thirst was marked. Small doses of grey powder were given.

Third Day.—The patient was much better; blood and mucus were still present in the motions, however.

Fourth Day.—Motions still slimy in character, but no blood present.

Sixth Day.—Motions formed and natural in character.

CASE II.

The infant sister of the first case was attacked on June 20th. This case was afebrile, and no delirium occurred. On the first day of the disease the child passed six motions, the later ones containing blood and slime. The motions were of a similar character the second day. No blood was present on subsequent days. The case was exceedingly mild; the child objected to lie in bed throughout the whole period.

Bacteriological Findings.

A sample of faeces from the first case containing blood and slime was plated on MacConkey's medium on June 13th. The next day the plates showed one-third of the colonies to be non-lactose fermenters; four such colonies were inoculated on to agar and tested on the ordinary media with the following results:

	First Day.	Seventh Day.
Glucose	Acid only	Acid only
Cane sugar	No change	No change
Dulcitol	No change	No change
Lactose	No change	No change
Mannite	Acid only	Acid only
Milk	Acid	Alkaline
Broth	Cloud, non-motile rod	Indol positive
Agar	Dysenteric-like growth	—

The strain was completely agglutinated by a Y serum in dilution 0.1 in 2,560, and slight agglutination occurred at 1 in 5,120 dilution. This was the end titre of the serum. The patient's serum definitely agglutinated her own

organism on the fourth day of the disease in a dilution of 1 in 80 and slightly at 1 in 160.

The first blood-containing motion of the second case was similarly examined. Only one non-fermenting colony appeared on the MacConkey plate, which colony, however, proved to be a genuine *B. dysenteriae* of Flexner type. On testing this new strain against the Y serum it agglutinated also to the full titre of the serum.

Bacteriological Department,
Lister Institute.

W. J. PENFOLD.

A NOTE ON THE "IRRITABLE HEART" OF SOLDIERS.

THE somewhat remarkable character of our observations and the urgency of the problem with which they deal is our reason for giving them publicity at the present stage of their progress.

Of soldiers admitted to our beds at University College Hospital for the special purpose of investigation, and sent to us with the diagnosis of "cardiac strain" or "disordered heart action," a large group isolates itself.

They are men in whom the following prominent symptoms have arisen either gradually or suddenly, in some during the period of training, in others while serving actively in the trenches: Aching or sharp pain over the region of the heart, sometimes radiating but rarely severe, and breathlessness and palpitation on the slightest exertion, are the rule. So also is a sense of fatigue or exhaustion with effort; and oftentimes giddiness, occasionally proceeding to actual fainting, may be present.

On examination the heart's action is vigorous, the apex beat often forcible and covering a wider area than is normal. The limits of dullness are not usually increased; no murmurs are heard as a rule, but a systolic murmur may be present at base or apex. The pulse-rate is increased, often notably, and is peculiarly susceptible to posture and exercise. The blood pressure may show a notable fall as the patient passes from the lying to the upright posture. In many subjects there are other evidences of vasomotor instability—coldness and blueness of hands and feet or a prominent *tache*.

For the moment we exclude from this group all such cases as give a past history of rheumatic fever, chorea, or syphilis. In a number of the included patients, on the other hand, there is a history of throat affections or intestinal troubles.

The group is well defined, and in our view the symptomatology suggests, not primary cardiac mischief, but disturbances of function resulting from toxic absorption or actual infection. We have systematically examined eleven patients from this point of view, and in ten of them have found that streptococci (in two cases, staphylococci) are present in the urine; as a rule the organisms are found at the first examination; in other patients several such examinations are required. We take the view that we are dealing with an infection of the blood with organisms of a low grade of virulence and that these are filtered out in the urine, for the urine contains no pus cells, and, in a number of the patients, the organism has been recovered from the blood itself.

The source of the infection, its relation to local mischief, such as may occur in throat or gum sockets, and the relation of the infection to the symptomatology, are subjects which we propose to consider more fully at a later date.

THOMAS COTTON,
THOMAS LEWIS,
F. H. THIELE.

London, W.C.

* Working under the Medical Research Committee.

A RADIUM INSTITUTE on the lines of that which has been at work in London for some years will, it is announced, be established in New York. The institute will consist of a hospital for the treatment of cancer and other diseases by the external and internal use of radium, and laboratories for the study of radium.

THE number of patients treated during 1914 in the Royal Northern Sea-bathing Infirmary, Scarborough, was 590. They included 34 Belgian soldiers (22 wounded and 12 sick), 44 British soldiers from the Expeditionary Force (23 wounded, 9 sick, 2 injured, and 10 frost-bitten), and 6 seamen from a patrol trawler. The Red Cross Society supplied rclags of most willing and capable workers.

Reports of Societies.

DISCUSSION ON PARATYPHOID FEVER.

At a meeting of the Section of Medicine of the Royal Society of Medicine on November 9th, the President, Dr. A. E. GARRON being in the chair, Sir BERTRAND DAWSON, in opening a discussion on paratyphoid fever, said that he would base his remarks on experience gained in a stationary hospital in France. The amount of enteric fever met with in the war had been small; there had been only 1,365 cases in France, and 910 of these were examples of paratyphoid fever. Its existence was due to carriers; no general sources of food supply had been infected, and no epidemics had occurred. The smallness of the number was not due entirely to improved sanitation or to inoculation, but in part to the fitness of the troops. Like typhoid, paratyphoid began as a septicæmia and subsequently invaded the viscera. At the hospital under consideration 18 patients had died from paratyphoid infection; 14 *post-mortem* examinations had been made when death followed infection with paratyphoid B, and one after infection with paratyphoid A. In the last, a condition of the intestines was found closely resembling that of true typhoid. Death had followed perforation at the base of the appendix. Of the paratyphoid B cases, both the small and large intestines were affected in 2, the small intestine alone in 4, the large intestine alone in 8. In both the latter perforation at the base of the appendix had occurred. The mesenteric glands were invariably enlarged and hyperæmic, and often hæmorrhagic. Splenic abscess occurred twice, and in one case an abscess was found at both poles of the organ. In one case the sole lesion found was a splenic abscess, the pus from which contained the organism. Nothing noteworthy was found in the liver in 11, but in others abscesses had followed portal pyæmia. Pleural effusion was met with in one of the cases. Gangrenous bronchopneumonia was found in 2, in one of which a cavity resulted. In another an abscess of the right lung followed one in the liver. There was little in the aspect of the patient suggestive of serious illness, as was seen in typhoid in the un inoculated. There was less chance of death or of complications, and patients got well more quickly with paratyphoid. A case might begin very badly and then damp down to continue as a lower grade infection, thus differing from typhoid. Broadly speaking there were no great distinctions between typhoid and paratyphoid. Most cases began gradually, but a sudden onset occurred in about 30 per cent. The initial features were those of typhoid. Diarrhoea was met with in about half of the patients; the remainder were constipated. Splenic enlargement was detectable clinically in about 50 per cent. The abdomen was flat, not protuberant. The spots, though resembling those of typhoid, were occasionally larger with less regular margins. The rash was profuse in a few cases, morbilliform in two. The pulse-rate was of great importance from the points of view both of diagnosis and prognosis. It was slow in relation to the temperature, and in 80 per cent. of the cases averaged under 90. If the rate remained below 100, it gave a sense of security as to the outcome of the case. The more severe the infection the more the rate tended to rise in relation to the temperature, but no such inference could be drawn if the temperature were below 100° F. He referred to the occurrence of tachycardia, and more rarely of bradycardia, during the subsidence of the fever. In a case of moderate severity the fever persisted for about twenty-one days; in many it fell far short of that duration; and in severe cases the course was prolonged and indefinite, simulating typhoid, though of more favourable portent. In diagnosis most reliance could be placed on laboratory methods. The value of the agglutination test was enhanced by Professor Dreyer's technique. The blood culture was often negative, and that of the stools positive in only a few cases. Diagnosis on clinical evidence alone was often impossible. Negative agglutination tests were not so reliable as positive results. If there was strong evidence on clinical grounds a negative Widal reaction should not lead to the abandonment of the diagnosis. Mild cases were often lacking in distinctive features. Convalescence quickly followed a few days of mild pyrexia. Thirty per cent. of all cases admitted as suspicious turned out to be negative. One group of these

indefinite cases displayed symptoms of abdominal disorder, a second displayed "rheumatic" symptoms, whilst in a third an unhealthy condition of the gums was especially prominent. One such group had been termed "trench" fever, though it was not specially connected with trenches, and was probably no new disease. He would prefer the name "infective gastro-enteritis" pending further investigation. The symptoms were often slight, beginning with headache and lassitude, and causing the patient to lie up on the third or fourth day. Other symptoms were a dirty tongue, nausea, vomiting, and abdominal discomfort, especially in the upper part of the abdomen; constipation was the rule. The fever often reacted normal by the tenth day. No doubt many cases of "trench" fever were diagnosed as paratyphoid, but he was confident that the conditions were distinct. In some cases jaundice supervened. The condition was sometimes called "influenza," but its onset was gradual, there was no catarrh of the upper air-passages, and convalescence was quicker. Catarrhal jaundice might obscure paratyphoid infection. If the onset were sudden, paratyphoid might resemble influenza very closely, but it was important to realize that gastro-intestinal influenza was not so common as was often thought, and many cases so diagnosed belonged to the group of infective gastro-enteritis. Paratyphoid was probably commoner in civil practice than was generally recognized, and the moral was that a blood culture should be made if headache and fever were accompanied by a slow pulse.

Professor DREYER said that the bacteriology of enteric fever fell under three main heads: (1) the bacteriology of the active disease; (2) the bacteriology of carriers; (3) prophylaxis. The bacteriological diagnosis of paratyphoid was of two kinds—the recovery of the microbe from the blood, stools, urine, etc., and the immunity reactions, especially agglutination. The bacillæmia was of very short duration, especially in paratyphoid A. Bacilli disappeared from the stools relatively soon, except in the case of paratyphoid B. Of 100 cases of enteric fever, including all three varieties, all proved by the recovery of the bacteria, in 30 per cent. the bacteria could be isolated from the blood; in 20 per cent. they could be recovered from the stools in typhoid and paratyphoid A, but in between 70 per cent. and 80 per cent. in paratyphoid B, if repeated examinations were made. In ordinary typhoid the disease could be detected by agglutination in 100 per cent., in paratyphoid B in 100 per cent., but in paratyphoid A only in 95 per cent. For the detection of paratyphoid A a 1 in 10 dilution was sufficient for practical purposes. Co-agglutination, which had been so much discussed, need not be regarded; if agglutination occurred to more than one variety, it was to be explained by a mixed or rather superadded infection. The error in the agglutination test was not more than 1 per cent. It could be used in the case of inoculated men. The absolute figure was of no value, but rather the curve plotted out as the result of a series of tests. If the disease were present a rise or drop in the curve occurred during its progress, whilst if the agglutination were due to previous inoculation it showed only a very gradual decline. The agglutination reached its maximum on the twentieth day. In paratyphoid A, a first attack only produced a small quantity of agglutinins, whilst in the relapses they equalled in amount those met with in typhoid and paratyphoid B. The great resistance to typhoid found among our troops be ascribed to antityphoid inoculation. Many slight cases occurred, however, which did not come under observation. There existed a certain group of fevers which did not respond to bacteriological tests. It must be anticipated that the amount of typhoid among inoculated men would increase, for the proportion of the inoculated was greater than during the early stages of the war. It was an important question whether a degree of immunity could be obtained against the paratyphoid infections. The evidence was strong that inoculation against paratyphoid did not lead to susceptibility to true typhoid. Castellani had shown that immunity could be conferred at the same time against different infections, and Professor Dreyer thought it better to inoculate simultaneously against typhoid and paratyphoid, than first to inoculate against one and then the other. He had experimented in this way, and by mixed inoculation had obtained a markedly increased resistance to paratyphoid. The amount which he had employed was 1000 million typhoid bacilli, 500 million paratyphoid A,

and 500 million paratyphoid B. given in two equal doses. This had not led to those who had been so inoculated being placed *hors de combat* to a greater extent than if antityphoid inoculation only had been given. In some cases this treatment had produced marked resistance to one or two of the varieties of infection, and in others to all three. The only way to prevent spread of the disease was by the segregation of carriers, detected by examination of the faeces and urine. He had become convinced that the method of separation of the organism by actinic rays had no special advantage over the usual methods.

Sir W. HERRINGHAM said that the onset of "trench" fever was often quite sudden. The condition began to be prevalent about June, and was now clearing off. He did not ascribe its occurrence to the trenches. Even when the examination was thoroughly carried out the attack could not be proved to be due to paratyphoid in a large majority of the cases. Fever of a two or three days' duration often occurred in bouts, with intervals of two days or more between them. He could draw no distinction between cases which relapsed every few days and those with a normal interval of ten days. In a few other cases the temperature provided a "hog-backed" chart and was not relapsing in type. How the infection was conveyed was under investigation.

The discussion will be continued on Tuesday, November 23rd, at 5.30 p.m.

Reviews.

GUNSHOT INJURIES OF BONES.

In his book on *Gunshot Injuries of Bones* Mr. HENRY GROVES, who is Lecturer on Surgery in the University of Bristol, and now holds a commission in the R.A.M.C., has confined himself to a discussion of the treatment of fractures of the shafts of the long bones. As he announces in his preface: "While the time has not yet come for the formulation of final conclusions about war wounds, it is fully ripe for the emphasis of certain general principles."

The opening chapters are devoted to a discussion of the physiology of bone in relation to repair, and of its pathology as affected by the presence of sepsis. In this latter connexion the author remarks upon the rarity of massive necrosis in relation to gunshot injuries, and expresses an opinion that when it does occur injudicious surgery has usually been a contributory factor. Captain Hey Groves is quite certain that any extensive operative exposure of bones, or drilling into the marrow cavity, will quickly produce the necrosis which so rarely results from a mere gunshot accident. This pronouncement from a surgeon of experience is opportune at the present moment, and will find abundant confirmation from workers both at home and abroad. The author asserts that there is a marked natural tendency for septic comminuted fractures to undergo repair, and when infection has ceased to become aggressive, the repair is rather more rapid than in simple bone injuries. Repair may be aided by timely immobilization and extension, but will be prevented by faulty treatment such as the removal of comminuted fragments of bone, or by operations interfering with the blood supply. These conclusions are sound, and should be remembered. The removal of loose pieces of bone is a prolific source of non-union, and the after-history of cases plated in the presence of sepsis shows that even if there seemed to be an immediate benefit, it was not a lasting one. Inquiries made by the author of several surgeons who have received these cases after plating operations have resulted in depressing stories of failure; he tells us, indeed, he did not hear of a single success. While the author admits that speedy relief of pain may follow plating due to immobilization, which may be helpful to dressings and early transport, he places against these possible advantages the probability of extensive opening up of soft tissues and bone marrow to infection, the liability to increased comminution, the danger of causing extensive necrosis, and even the ultimate loss of

¹ *Gunshot Injuries of Bones*. By F. W. Hey Groves, M.D., M.S. Lond., F.R.C.S. Eng. Grafton R.A.M.C. (T.). Oxford War Printer, London; H. Frowde, Hodder and Stoughton, 1525. (Figs. 810, 119, 128; 56 figures, 3s. 6d. net.)

the limb. This is a vital issue, for it is possible, apart from open operation, to obtain in all cases immediate fixation allowing of easy dressing. Although the author would retain loose pieces of bone connected with the shaft, he would remove such if found in the neighbourhood of joints, because, if left, they might prove obstructive to mobility.

Early and thorough intervention are advocated in the case of an infected wound, followed by unobtrusive attention. Immediate enlargement of the wound is advocated by counter openings, and even free incisions through apparently healthy tissues. The author discards the ordinary longitudinal incisions, and advocates transverse or cruciform incisions across the great muscles through half their thickness; by this means the wound will keep gaping until healing takes place. The arguments for this procedure do not seem to be convincing, and there are many obvious and urgent objections to it. The author prefers wire wound loosely in spiral form to a rubber tube for drainage, and favours a constant stream irrigation. He summarizes the principles of treatment of compound fracture by insisting on thorough drainage, extension in the correct direction, semiflexion of joints, free access to the wound, the avoidance of voluminous dressing and bandages which he calls "mummification," and early movement of the joints.

The question of extension is fully discussed, and certain types of apparatus advised; it is recommended that after applying an over-extension, 20 lb. of weight should be applied to the femur, 12 lb. for the tibia and fibula, and 8 lb. for the bones of the arm. The extension should be applied in a direction opposed to the muscular pull. Continuous extension by a spring, or weight and pulley, is preferred to fixed extension. Early stroking, as advised by Lucas-Championnière, is recommended, and acts by "producing a degree of anaesthesia by a series of light hypnotic passes." It is not intended, the author asserts, to act on the lymph or blood flow.

Plaster is very properly condemned as foul and filthy. The chapter on fractures of the femur introduces no new principle; the disadvantage of the Liston and Hodgkin's splints are emphasized. Objection is taken to the Thomas splint because, among other reasons, of the painful counter pressure of the ring on the perineum. The author, however, has modified this splint for transport purposes, and the ring is so shaped and padded, if judged by the illustration, that one can quite understand a tragedy in the perineum.

Special methods of operative attack are discussed, such as Codivilla's transfexion pins, horse-shoe screw clamp, and the author's double transfexion apparatus. These methods can only rarely come under consideration, and never in the presence of sepsis.

The book closes with a very excellent chapter on bone grafting—a method which, before the war, was much discussed, and at a later date will be largely practised. Its employment should be postponed in the light of recrudescence supuration.

We have much pleasure in recommending this little book to surgeons. Its appearance is opportune, and it reflects in a concise and lucid way the mind and the practice of a thoughtful surgeon.

LIEUTENANT-COLONEL FAICHNIE, R.A.M.C., in a paper on the recent decline of enterica in India, prepared for publication in July, 1914, concludes that inoculation has undoubtedly increased immunity, and has had a great effect on the prevalence of the disease in India. Opinion as to how this has actually been brought about varies in the importance it attaches to infection by flies and by carriers. Colonel Faichnie considers that the excrement of faecal-bred flies is the more important factor, because in so many instances the absence or presence, decrease or increase, of typhoid bears a direct relation to the number of faecal-bred flies. He cannot see any corresponding relation between the number of carriers and cases of enteric. He believes that faecal-bred flies give a reasonable explanation of the peculiarities of Indian typhoid, and that the large number of cases cannot be explained by the theory of direct infection, although he does not assert that direct infection and other causes have never given rise to typhoid fever. This suggestion as to the importance of the part played by faecal-bred flies is interesting, but the incidence of the disease in countries where water carriage systems are in force cannot be explained in this way.

British Medical Journal.

SATURDAY, NOVEMBER 13TH, 1915.

DYSENTERY AND WAR.

As was to be expected, accounts of the occurrence of epidemic dysentery are coming in from the various armies, and this week we publish a paper of great interest from the Bacteriological Laboratory of the King George Hospital, Waterloo, which throws considerable light on the nature of the dysenteries which have attacked the British forces in the Near East.

Epidemic dysentery in the field is liable to be the starting point of widespread disease amongst civilian populations owing to the return of dysentery carriers among the invalided and disbanded soldiers; a clear idea, therefore, of the type or types of the disease affecting the soldier is of vast importance from the standpoint of preventive medicine. The clinical condition we call dysentery may arise from many causes. It may be bacillary or protozoal in its origin. The bacillary type may be due to Shiga's bacillus, or it may be due to one of the several members of the Flexner group. The protozoal type is chiefly due to the *Entamoeba histolytica*, but possibly it may also be due to flagellates—for example, *Lamblia intestinalis*, and to ciliates—for example, *Balantidium coli*.

Up to the present time epidemic dysentery in England has chiefly affected asylum populations; with one exception all the asylum epidemics which have been investigated have been shown to be due to the *B. dysenteriae* of Flexner type. In addition to the asylum cases a small outbreak of dysentery, due to Flexner's organism, occurred in London in 1911, and evidence is accumulating that this bacillus is much more important as a cause of dysentery in England than has been generally believed. Shiga's bacillus has been reported as the cause of epidemic dysentery in Scotland, and also in one English asylum. Small outbreaks also have occurred in other institutions in addition to asylums, and amongst civilian populations. For example, the small epidemic amongst children which occurred in London in 1911, was found to be due to *B. dysenteriae* (Flexner). Such cases in children are probably not at all uncommon even in this country, and the presence of blood and mucus in the dejecta should immediately suggest the dysenteric character of the malady and the necessity for careful therapeutic and hygienic measures. Summer diarrhoea as we know it in London is not accompanied by the passage of blood and mucus, except possibly in a few cases, and *B. dysenteriae* has not been found in association with it. On the other hand, certain forms of summer diarrhoea in America and Denmark which have been associated with dysenteric motions have been found to be due to *B. dysenteriae*, whereas the choleraic or toxæmic forms unaccompanied by blood and mucus have not been associated with the presence of this bacillus. It is probable that cases of bacillary dysentery, perhaps of only slight severity and duration, are liable to be overlooked, and their true nature therefore missed. Most writers incline to the view that infections by the Shiga bacillus are liable to be more severe and more protracted than Flexner-Y infections, and in

this country, as we have already indicated, the Flexner-Y bacillus seems to have been the main cause of the recorded cases, both in institutions and outside.

We have no evidence that protozoal dysentery in epidemic form has occurred hitherto in England, and it is certain that the bulk of the cases seen here are imported; little is known as to the extent of the danger of these imported protozoal cases to the civil population.

The experience of Ledingham, Penfold, and Woodcock appears to show that the cases returning from Gallipoli and still excreting the specific organisms are chiefly infected by *B. dysenteriae* Shiga, while in a smaller number *B. dysenteriae* Flexner, *Lamblia intestinalis*, and also other flagellates are present. None of the cases they examined showed the *Entamoeba histolytica*, though it has been reported from the Eastern Mediterranean. This apparent discrepancy may, however, be due to treatment by emetine at the seat of war and on the voyage home. This experience is somewhat different from that of Remlinger and Dumas, who have been investigating the type of dysentery prevailing amongst the French in the Argonne, where apparently the large majority of the cases are due to the *B. dysenteriae* "Y" of Hiss and Russell; this organism is a member of the Flexner group. Rumpel has recently examined a small sample of cases from the German army of the west front, and these he likewise found to be due to a bacillus of the Flexner type. Cases due to the bacillus of Shiga have, however, been reported from the Austrian side.

These outbreaks of dysentery in the armies raise many important problems for the sanitarian and the clinician. The carrier problem in the case of dysentery is of great importance, and, although numerous researches have been devoted to the subject, opinions appear to vary greatly as to the duration of the period during which the specific organisms remain in the body after cessation of symptoms. In bacillary dysentery a period of three months has usually been given as a working basis for the sanitarian, but Simon's observations make it probable that this period is too short. Simon examined in 1909 near Strassburg 70 soldiers who had been attacked by bacillary dysentery in 1908. Of these 70 soldiers, 4 were still found to be carriers, and one of these 4 was subsequently shown to carry the infection for over 600 days. In 1909 he examined also 84 healthy carriers detected during the epidemic of 1908, and found that no fewer than 13 of them continued to carry the *B. dysenteriae*.

It is a matter of great difficulty to determine when an individual has ceased to carry. Probably three or four negative examinations made in the course of the two or three weeks after the last positive result, are necessary before the bacteriologist is able to declare that an individual is free from suspicion. Such a rule would certainly not err on the side of undue stringency.

On the other hand the exigencies of war sometimes ride rough-shod over sanitary regulations, and it appears highly desirable that the carrier, and indeed all convalescents, should be trained to observe such a high standard of personal hygiene that they may with a good conscience enjoy almost unrestricted freedom. It is somewhat remarkable that none of the recent papers referring to dysentery in the different armies deals with the healthy carrier. The term is not a good one, as there is little doubt that these so-called healthy carriers have suffered from diarrhoea in some form so mild that it

has been overlooked or ignored. It is well known that *B. dysenteriae* is the infective agent of certain forms of catarrhal diarrhoea not necessarily associated with blood and mucus in the stools. There is much evidence to show that in epidemic seasons many of the infected patients do not show blood and mucus in their stools, but appear to suffer rather from slight catarrhal diarrhoea. These cases, from the standpoint of prophylaxis, require the same strict supervision as the fully-developed dysenterics; this group may really include many of the cases classed by Simon as healthy carriers. It is reasonable to believe that the danger of the carrier varies directly as the number of bacilli he is excreting; on that account, therefore, the relapsing carrier, who probably excretes as many bacilli as the primary cases, is a serious source of danger. Dissemination of the disease appears to depend chiefly on defective personal hygiene, hence its prevalence in asylums and its liability to spread amongst children. Similarly the personal hygiene of the soldier in camp and trench life is often of necessity of a low standard as compared with good civil conditions. These considerations suggest that one of the chief protections of the army as well as of the civilian population will be the explicit instruction given to all soldiers in dysentery-infected areas as to the possible danger that may arise to their fellows if they do not maintain the highest possible standard of personal hygiene, and educational work in this direction should be, and we believe is, one of the chief functions of the R.A.M.C. in its sanitary work.

The treatment of the carrier with a view to the early arrest of his carrier state resolves itself into the thorough treatment of any local lesions of the gut which are accessible. Many of the so-called healthy carriers would doubtless, if examined thoroughly, be found to be suffering from slight diarrhoea, or to show slight local lesions of the rectal mucous membrane. Such cases, therefore, call for careful supervision and treatment in the interest of a sound prophylaxis.

The treatment of dysentery may be specific or non-specific; in the matter of specific agents we are now well equipped. Emetine acts as a specific germicide on the *Entamoeba histolytica*, while bacillary cases have been treated with great success by Ruffer and Willmore, and many others, by means of polyvalent serums derived from horses immunized by the injection of the bacillus of Shiga and various Flexner strains. Antidysenteric serum may, indeed, be considered one of the most successful of all serums used in treatment.

Of novel forms of non-specific treatment which have recently been found of value we may mention the administration of bolus alba¹ and animal charcoal in large quantities, while in acute severely toxic cases the intravenous injection of hypertonic saline solution appears to be of great value. The internal administration of adrenalin appears to have a favourable influence on the tendency to haemorrhage.

Of prophylactic vaccination against bacillary dysentery in man little is yet known. The chief stumbling-block to progress in this work is the intense toxicity of the Shiga strains, both for animals (rabbits) and for man. So far attempts to establish a practicable and efficient method of prophylactic vaccination in man have not been very successful, but the matter is one to which far more experimental research should be devoted than has been the case hitherto. In an early issue of this JOURNAL we hope to return to this side of the dysentery question.

¹ Kaolin, native aluminium silicate powdered and freed from gritty particles by clarification; insoluble in all ordinary solvents and unaffected by most chemical reagents.

PARATYPHOID FEVER AND ITS PREVENTION.

MEDICINE and surgery stand to gain a great deal of practical knowledge from the vast campaigns of the present war, though at a cost of human suffering that is appalling to contemplate. Both the lessons to be learned from the paratyphoid fevers that are endemic in camps and trenches, and the precautions that may properly be taken to lessen the incidence of these fevers among the combatants and the civil population alike, are illustrated by papers in this issue. Captain Torrens and Lieutenant Whittington add considerably to our knowledge of the signs and symptoms of the two varieties of paratyphoid fever distinguished by the bacteriologists as A and B. These two authors have had three or four hundred cases of paratyphoid fever under their charge, all of them, it may be assumed, among the well-trained and unusually well-fed occupants of our trenches, men in the prime of life and on a diet of high caloric value and rich in protein. It would be interesting to know how far such a diet may be held responsible for the initial diarrhoea observed by Torrens and Whittington in more than half their patients. Due emphasis is laid on the facts that paratyphoid B is a much less severe and fatal disease than typhoid fever, speaking generally, and that paratyphoid A is even milder than paratyphoid B. Indeed, the mortality is fortunately low in both these diseases, for only sixteen of the patients died, and only one of the sixteen had paratyphoid A. But by dwelling too much on the low mortality we fail to get paratyphoid fever A or B in true perspective as an incapacitating disease, and may therefore underestimate its importance from the military point of view. The fever lasts two or three weeks or more, and sudden recurrences are common, especially in cases of the A type, while definite relapses occur in both types, but more often in A than in B. We have no data as to the duration of convalescence, but it seems safe to assume that a man who contracts paratyphoid fever can rarely be fit to return to duty in less than three or four months.

Particular attention may be drawn to the interesting remarks made by Torrens and Whittington on the diagnosis of paratyphoid fever, a diagnosis depending in the last resort upon bacterial cultures and the specific agglutinative powers of the patient's serum. There is reason to believe that not a few cases of paratyphoid escape detection under such a diagnosis as influenza or pyrexia of unknown origin. Due prominence is given to the fact that the detection and exclusion of paratyphoid carriers among the combatants is the best way of preventing the spread of these diseases, and one bears on all sides from men who have returned from "somewhere in France" that this duty is being carried out with unrelenting thoroughness by the medical authorities responsible.

The other possible method of prevention is that described in their paper by Castellani and Mendelson, who have been applying it on the large scale in Serbia. It consists in preventive inoculation with cultures of paratyphoid A and B bacilli which have been killed by carbolic acid. In view of the special conditions existing in that country, inoculation against paratyphoid has been combined with inoculation against typhoid fever and cholera as well. Professor Castellani therefore employs what he calls a "tetra-vaccine," or preferably a quadruple vaccine, to protect against these four infections. His paper shows that it has been administered to over 170,000 persons among the military and civil population of Serbia, without the occurrence of any untoward results.

Naturally we have no means as yet of judging the success attained by the use of this quadruple vaccine up to the present time. But if it is at all comparable to the success which has attended the employment of antityphoid inoculation in our own armies, Professor Castellani and his medical colleagues will have effectively conferred a most valuable benefit upon the inhabitants of that much vexed country, and prospectively a comparable benefit upon the armies of the Allies which are going to its assistance.

THE LIFE-HISTORY OF AMOEBÆ IN DYSENTERY.

THERE are two amoebæ commonly found in man, one, the *Entamoeba histolytica*, the cause of amoebic or tropical dysentery, the other *Entamoeba coli*, supposed to be harmless. To distinguish between these two amoebæ in their so-called vegetative state is not by any means easy. Different characteristics have been given from time to time which are supposed to distinguish them, but in many instances these are not altogether clear, and even experts may at times be in a difficulty. When, however, the cystic stage is reached the matter becomes relatively easy. The cysts of *E. histolytica* contain four nuclei, and are smaller than those of *E. coli*, which contain eight nuclei. It is the cystic stage of the parasite that passes from man to man; therefore men who are carrying the pathogenic cysts in their bowel are dangerous to others. The cysts are passed in the faeces, and may fall into water; if water so contaminated is drunk the infection passes back again to man. Patients may go on with few clinical symptoms but yet harbour cysts in their bowel probably for long periods. One case of the kind, therefore, if the conditions are such that he contaminates water used for drinking, may be the source of an outbreak of dysentery. The cyst can survive in water for a period which, so far as we are aware, has not been determined, but it is believed to be killed by drying. When the cyst is swallowed, the four nuclei develop into young amoebæ, which burrow into the mucous and submucous coats of the bowel, and so produce the infection and consequent lesions. After this the amoebæ go on and multiply, but eventually, when the case becomes chronic and the infection tends to become quiescent, cysts are again formed. Indiscretions in diet, the abuse of alcohol, and especially getting wet and chilled, may light up an acute exacerbation with the return of blood and mucus in the stools, and the presence of the parasite in the vegetative state again.

IPECACUANHA AND ITS ALKALOIDS.

EMETINE HYDROCHLORIDE, as now used hypodermically for the treatment of amoebic dysentery, is the crystalline salt of a single alkaloid having the empirical formula $C_{20}H_{17}N_3O_4$. The name "emetine," however, has until recent years been applied to the total mixture of alkaloidal substances obtained from ipecacuanha. It was in the early years of the nineteenth century that basic principles were first isolated from crude drugs; at that time, as is well known, ipecacuanha had long been in use in medicine, and had a deservedly high reputation. Following the preparation of morphine from opium by Sertürner, the French chemist Pelletier (who in collaboration with Caventou first prepared pure quinine) turned his attention to ipecacuanha, and in 1817 separated an alkaloidal substance to which he gave the name emetine; the total alkaloid of the drug continued to be known by this name until about 1894, when the English chemists Paul and Cownley showed that it consisted principally of two alkaloids, to which they gave the names emetine and cephaeline. The latter has

the formula $C_{20}H_{17}N_3O_4$, and emetine is dimethyl-cephaeline $C_{23}H_{17}N_3O_4$. Subsequently the same workers showed the drug to contain also a third alkaloid—psychotrine. Rio ipecacuanha, which is the only kind recognized by the *British Pharmacopœia*, is the dried root of *Psychotria ipecacuanha*, formerly called *Cephaelis ipecacuanha*. This contains about 2 per cent. of total alkaloid, of which about two-thirds is emetine. Cartagena ipecacuanha—from *Psychotria acuminata*, which is also official in the United States—contains about the same total amount of alkaloid, but in this cephaeline preponderates, emetine being about two-fifths of the whole. In both drugs the amount of psychotrine is very small, about 0.04 to 0.06 per cent. of the weight of the drug. The physiological action of emetine and cephaeline appears to be very similar, both having an emetic effect. It is usually stated that emetine is the better expectorant, but less powerfully emetic and less toxic than cephaeline; psychotrine appears to have no emetic properties. Sir Leonard Rogers, in a paper contributed to the discussion on dysentery at the Asiatic Society of Bengal a couple of years ago, related some experiments and clinical observations on the relative value of emetine and cephaeline hydrochloride.¹ He administered the two alkaloids separately and together to a number of cases of amoebic dysentery in whose stools pathogenic amoebæ were found microscopically; his conclusion was that, though pure cephaeline hydrochloride and mixtures of it with emetine hydrochloride both gave results far superior to the old oral administration of ipecacuanha powder, yet the results, as judged by the rapidity of improvement in the number and character of the stools and the disappearance of the amoebæ from them, were distinctly inferior to those obtained by the use of an equal quantity of pure emetine hydrochloride. Moreover, the pure cephaeline was inferior to the mixtures of the two alkaloids. He therefore concluded that pure emetine hydrochloride is the best alkaloid in amoebic dysentery. The drug in these cases was administered hypodermically, and experiments in the laboratory pointed in the same direction. It was at one time supposed that the value of ipecacuanha in dysentery depended on some non-alkaloidal constituent or constituents, and even in so recent a work as Henry's *The Vegetable Alkaloids* (1913) it is suggested that for the cure of dysentery the tannin present may be the chief active agent. Acting on this view, the so-called "de-emetized ipecacuanha" was some years ago prepared for use in this disorder; in this a substantial amount of the alkaloid was removed, while the "extractive matter" was returned to the drug. Some alkaloid, however, and often a considerable proportion, was left behind, and was no doubt the active agent in maintaining the reputation of the drug. Improved methods of preparation led to the more complete removal of the alkaloid, with consequent greater freedom from emetic properties, and the reputation of the drug then declined. Now that further research has shown emetine to be the substance having a specific amoebicidal action, the failures of the de-emetized drug are explained. Emetine is a colourless amorphous powder, but its halogen salts and its nitrate are crystalline; the sulphate, acetate, etc., have only been obtained in the amorphous form. Of the crystalline salts, the hydrochloride is the only one which is sufficiently soluble to be suitable for hypodermic use, and it is therefore always employed. This salt, having the formula $C_{20}H_{17}N_3O_4 \cdot 2HCl \cdot 3H_2O$, is a white crystalline powder, easily soluble in water or alcohol. A solution for hypodermic use is made by simply dissolving it in recently boiled distilled water; it can conveniently be prepared as required from the hypodermic tablets supplied by certain firms of a suitable strength for the purpose. The constitution of the alkaloid is unknown, but it is believed to be a quinoline derivative.

THE HISTORY OF IPECACUANHA IN DYSENTERY.

IPECACUANHA had long been in use in Brazil as a remedy for dysentery, but was unknown in Europe till it was introduced by G. Piso in 1648. He accompanied the Prince of Nassau on exploring expeditions in the West Indies and Brazil, and wrote an account of his observations in a treatise entitled *De Indiæ utriusque re naturali et medica*, which was published at Amsterdam in 1648. Apparently Pison's description of the ipecacuanha treatment failed to attract the attention of the profession, except perhaps in Holland. There is no mention of the drug in C. DeLion's *Traité des Maladies particulières aux Pays Orientaux*, published in Paris in 1665. It was first brought into public notice in 1686 by J. A. Helvetius, grandfather of the famous farmer general and philosopher, who treated dysentery in Paris with a secret remedy containing a large amount of ipecacuanha. He was so successful that he was called in to the Dauphin, son of Louis XIV, and was fortunate enough to cure the royal patient. The remedy was then tried with good results in the Hôtel-Dieu, and Helvetius sold the secret for one thousand *louis d'or* to the French Government, which in 1688 made its composition public. The treatment came into general use, but, as inevitably happens in medical practice where the problems are so obscure and complex, there were many fluctuations in professional opinion as to its value. After its first vogue, its use seems to have been abandoned for a considerable time, for Andrew Davidson says that at the beginning of the nineteenth century Balmain, and afterwards Playfair, "adopted, or rather rediscovered, the method of administering it in large doses."¹ Balmain frequently gave ipecacuanha to the extent of two drachms with sixty drops of tincture of opium, and in many cases he found that a dose or two was sufficient to remove every dangerous symptom. This method of treatment, though it excited some attention at the time, did not gain the confidence of the profession. To E. S. Docker, an army surgeon, belongs the credit of finally impressing the value of large doses of ipecacuanha in dysentery on the mind of the profession.² Stationed in the Mauritius from 1851 to 1857, he had to deal with a large number of cases of that "hitherto intractable and fatal disease." He gave the drug in doses ranging from 10 to 90 grains, rarely less than 20. He says: "The action of these large doses is certain, speedy, and complete; and truly surprising are sometimes their effects. In no single instance has failure attended this medicine, thus employed." Although not sanguine enough to expect that it will be invariably successful, he expresses his "firm belief that henceforward dysentery may be as much under control and as expeditiously cured as simple diarrhoea." Docker no doubt had to do with amoebic dysentery, and the value of the drug in that form of the disease has in recent years been established on a scientific basis, largely by the work of officers of the Indian Medical Service. Annesley, Twining, Parkes, Mackinnon, Morehead, Fayer, Maclean and Chevers laid the foundations of our present knowledge of amoebic diseases, but it is only since 1912 that the more exact way of using ipecacuanha root and its alkaloids has been scientifically determined.

EMETINE AND IPECACUANHA IN DYSENTERY.

Though the mixed alkaloids of ipecacuanha were isolated by Pelletier in 1817, and named emetine, a name now confined to one of them, the use of the alkaloids in medicine seems to be comparatively recent. In 1891 Major Tull Walsh, I.M.S., in a paper on the rational treatment of acute dysentery,³ gave an account of the excellent results he had obtained with an average dose of 1 grain of emetine in twenty-four hours. In 1912

Vedder showed experimentally the high amoebicidal action of the alkaloid upon saprophytic and pathogenic amoebae, and suggested the application of his results to human amoebiasis. Sir Leonard Rogers improved upon Vedder's idea by administering emetine hypodermically in cases of acute amoebic dysentery in Calcutta, and found that it had the effect Vedder hoped. Major R. Markham Carter, I.M.S., Professor of Pathology in the Grant Medical College, Bombay, in the course of a discussion on the subject at the Asiatic Society of Bengal, reported in a special number of the *Indian Medical Gazette*, (Murch, 1914), said that these results had induced him to introduce the method at St. George Hospital, Bombay, in 1912; he had at once been struck with the swift results obtained. From an experience of 168 cases he had come to the conclusion that emetine administered hypodermically in doses of 1 to 2 grains a day acted rapidly in early cases of uncomplicated amoebic dysentery, but was valueless in bacillary dysenteries. It was a specific in presupplicative amoebic hepatitis and of marked value in chronic latent amoebic colitis which gave rise to that condition. He thought the value of emetine in liver abscess doubtful and believed that rational operative treatment gave as good results without as with the exhibition of the drug. He found that both the pathogenic amoebae and the so-called harmless commensal amoebae rapidly vanished from the stools in early cases of amoebic dysentery on administration of a few grains of emetine hypodermically. If amoebic dysentery had lasted for a week or more, emetine injection destroyed the vast majority of the amoebal trophozoites in the first twenty-four hours, but the stools rarely became free from amoebae under seventy-two hours. Even after a week's injection and apparent cure by emetine, there was in some cases a tendency to relapse. The dose of emetine for an adult should be at least 1 grain a day, and in severe cases the drug should be pushed without hesitation. Professor Carter had found that small doses of $\frac{1}{2}$ grain did harm, and accounted for this on the hypothesis that they sensitized the residual source of undestroyed amoebae in the gut wall so as to render them emetine-proof. Such cases passed out from hospital apparently cured, but carried the amoebal cyst and were sources of infection to others. He went on to express the opinion that acute amoebic dysentery required the exhibition of the entire root with all its alkaloids in powdered form, as well as emetine. He gave 90 grains of ipecacuanha powder in 5 grain pills, coated with salol, by the mouth, and 1 grain of emetine hydrochloride hypodermically. Administration of the drug by the mouth insured that the intestinal contents were thoroughly permeated with it, and the amoebicidal effect of the parent drug upon the parasites buried in the wall of the affected intestine was reinforced by emetine carried to them by the blood stream after the hypodermic injections. With regard to the coincident occurrence of amoebic and bacillary dysentery, he made the following observations: "Another point of interest in the dysenteries of Western India is that mixed true amoebic and true bacillary dysentery of one variety or another is not uncommon. As yet we have no means whereby we may gauge the proportional relationship between these two groups of factors as regards virulence, numbers, etc., and it is these conditions of variability that tend to deceive the clinician relying mainly upon the effect of his treatment for his experience in this group of diseases. Further, in cases of true bacillary dysentery it is not uncommon to find that periods of rapid multiplication of the so-called harmless commensal amoebal parasite occur. . . . I believe that where marked alteration in the intestinal flora has taken place as the result of dysenteric infection, with all its conditions of inflammation, toxicity, etc., the normal commensal parasitic amoebae have the power of assuming a pathogenic rôle, and exhibit a degree of multiplication which hitherto has passed unnoticed by observers

in this field of work. Each year adds new varieties to a small list of bacillary dysenteries, and we read of new types of amoebae with scepticism."

THE PREVENTION OF RELAPSE AFTER EMETINE.

DR. NATHAN BARLOW who, we gather, is the medical officer of a plantation at Cuyamel, Spanish Honduras has attempted to determine the percentage of permanent cures of dysentery after various methods of treatment.¹ He recognized that the cases to be used for statistical purposes must have been carefully examined and recorded, that not less than six months must have elapsed since the cessation of all treatment, and that the cases must be free from complications which might confuse the results. In particular he, like others, had found that intestinal infection with flagellates, or ciliates, or metazoa made the removal of the amoebae much more difficult. He was able to study 400 cases in the Charity Hospital in New Orleans, and 300 cases at Cuyamel. He found that only 18 of the cases in New Orleans and 40 of those at Cuyamel fulfilled all the conditions he had laid down. The most important result of his inquiry appears to be that the initial treatment with emetine must be very thorough. The conclusion he draws from the examination of these 58 cases, which seems to have been most carefully carried out, is that about 80 per cent. or more of cases of infection with *Entamoeba histolytica* remain free from relapse for seven months or more, if treated for at least ten days continuously and with not less than one grain daily of emetine. If treated for less than nine days, relapse is, he considers, almost inevitable. This is in accordance with the experience of British authorities, who, we believe, advise that the initial period of treatment should be twelve days. The simultaneous administration of ipecacuanha does not diminish the number who relapse, but its subsequent administration does. He holds that a permanent cure is possible in a shorter time with emetine than with ipecacuanha. Cases of hepatitis and liver abscess usually remain free from either intestinal or hepatic relapse, partly on account of the more thorough treatment they receive. The plan which he considers best can be carried out only with intelligent patients who are within reach of a competent laboratory worker. One grain (or more, for one or two days) is given daily for fifteen days, followed by 60 to 80 grains of ipecacuanha for from five to twenty days, according to whether intestinal irritation is produced or not. The bowels are cleansed by a saline at the beginning of treatment, and about every five days. If there is either diarrhoea or colic, it is checked by opiates, usually paregoric, in small repeated doses, until comfort is obtained. If severe diarrhoea is present, liquid diet and rest in bed are required until the symptoms improve, when a more nourishing diet and gentle exercise are allowed. On discharge the patient is instructed to return once each month for examination of a fresh stool obtained after a saline cathartic. If either amoebae (of any variety) or cysts of *Entamoeba histolytica* are found, the treatment is repeated. The advantages he claims for his plan are—first, that if amoebae are actually found, patients will readily submit to a second treatment, while even intelligent patients might resent this second treatment merely as a prophylactic measure; secondly, he believes that when a patient is clinically well, and with merely a latent infection, the second course of treatment will usually result in a complete cure; and, thirdly, he points out that the repeated examination of cases results in the accumulation of data which will make it possible to determine the dose and duration of treatment necessary for permanent cure, and is therefore of the highest scientific and practical value.

AMOEBIIC CARRIERS.

DR. ALBERT J. CHALMERS (director) and Captain R. G. Archibald, R.A.M.C. (pathologist), of the Wellcome Tropical Research Laboratories, Khartoum, published recently¹ a paper, in the course of which they insisted upon the importance of amoebic carriers not only in the spread of the disease, but in the consideration of a cure. They agree with Rogers that amoebic bowel disease is frequently overlooked, and that it is necessary to examine the motion for amoebae after a purge in all cases of indigestion living in or coming from dysenteric areas. They state that they have frequently observed this form of cryptic or latent dysentery in Khartoum and that mild anaemia may be the only evidence of infection; as Rogers has pointed out, there is a rare form in which the symptoms of appendicitis are simulated, and Chalmers and Archibald state that they have observed cases of lung abscess and cold abscess in a joint. They have evidence that the latency may continue for as long as three or more years with recurrent diarrhoeal attacks. They consider that the only quick and ready means for the diagnosis of latency is a differential leucocytic count, the important feature being the increase of the mononuclear leucocytes without distinct evidence of malarial or other protozoal blood infections; such an observation should lead to most careful and repeated microscopic examinations of the faeces after the administration of a purgative. The same method, they add, affords a means of ascertaining whether a case has been cured, as the amoebae, though they may gradually disappear from the motions under the treatment, may reappear after a longer or shorter interval if treatment be stopped too soon. Usually after a course of emetine treatment, though the amoebae disappear from the faeces, the mononuclear leucocyte count remains high, or may increase; the treatment is stopped for a couple of weeks, and, if the patient's health continues to improve, the mononuclear leucocytic count is made again, and is generally found to be still high. If during the fortnight the patient becomes languid, and particularly if he suffers from discomfort over the caecum and ascending colon, or other portion of the large intestine, the emetine is at once resumed; this plan, lengthening the intervals of non-treatment and shortening the intervals of treatment, is continued until the mononuclear leucocytic count returns to normal or nearly normal in uncomplicated cases, or is reduced in cases complicated with malaria. They have also observed an increase in the number of eosinophilic leucocytes, and believe that this is in some way a sign of bodily reaction against the amoebae, for with a cure of the anaemic conditions and a cessation of the emetine treatment the eosinophilia disappears. They are so persuaded of the value of the blood count that if, when treating in the Anglo-Egyptian Sudan any person with anaemia not due to malaria or kala-azar, or any person who has peculiar intestinal, urinary, pulmonary, or joint affections, a marked mononuclear increase not to be explained by malaria is found, they administer a purgative, and examine the stools for amoebae on more than one occasion. "We draw," they say, "a number of blanks, but in our opinion we also cure a number of cases of amoebiasis and prevent serious illness." Under treatment the mononuclear leucocytes and also the eosinophilic increase, and only regain a normal percentage after some considerable lapse of time. In another paper written by Chalmers in association with Dimitri Papathodorou, a warning is given against giving full doses of emetine to pregnant women: a daily dose of $\frac{1}{2}$ grain may, however, safely be administered. The attempt to obtain complete cure by elimination of all amoebae must be postponed until after delivery.

CAMERAS DE SANGRE: BLOODIE FLUX.

THE Clarendon Press has issued a facsimile of a very scarce pamphlet¹ by G. W., entitled, *The Cures of the Diseased, in Remote Regions. Preventing Mortalitie, incident in Foyraine Attempts, of the English Nation*. It was printed in London in 1598, and Dr. Charles Singer, who has written an introduction and notes, believes it to be the earliest work devoted to tropical or naval medicine published in English, and not improbably the first work of the kind in any language. The author, there seems little doubt, was George Whetstone, who was a playwright, and produced *Promos and Cassandra*, which is considered to be the original of Shakespeare's *Measure for Measure*. This was written four or five years after he had served for a time with distinction against the Spaniards in the Low Countries. Later on he served again with the army in the West Indies, and was for some time a prisoner in Spain. It was, he says, during his imprisonment that he gathered the notes in his pamphlet from the observation of the practice of the special physician of the King of Spain. In his address to the reader G. W. disclaims writing as a medical practitioner, and says: "The cause that induceth mee, publiquelie to expresse the Cures of Diseases of such consequence, as every iudiciall conceite may perceine. to haue been the onely prejudice to our Nation, in the expeditions of our time to the Southerne parts: from whence in this and former ages, the English haue returned with renowned Victorie: yet exceedinglie opprest with extreame and pennisious sickness, that hath much more prevented the proceeding and performing of their pretentions, than the power of Enemies." One of his chapters is on *Las Cameras, or Cameras de Sangre*, which is the *Bloodie Flux*. This disease, he says, is produced by eating too much fruit or by sudden cold or drinking water abundantly when hot. "And also eating of Butter, Oyle, and Fish, is so hurtfull to the parties that haue it, that they must refrain to cate thereof: and whatsoever els, that defiles the entrailles, with any slimie substance." To cure the disease he says, "With the more expedition, that medicine is ministred to the diseased of *Cameras de Sangre, Laxatiues, or Bloodie Flux*, there is the more possibilitie it should preuaile. And detracting it, the Patients often die suddenly, without feeling much griefe. For speedie and assured remedie thereof, the Patients bodie must be cleansed of the slimines, engendered in the passages of the nutriments; before any sustenance can remaine in his bodie. And for that purpose, gine to purge him in the morning, halfe a pint of white Wine coold, wherin $\frac{1}{2}$ ounce of Rubarb hath been sodden, being small cut; putting in some Sugar Candie to sweeten it. And immediatly after he hath so purged, keepe at his nauch Rosemarie sodden in strong Viueger, applied in the morning and evening verie hot, untill it be stayed; giuing him often Quinces brused and rowled in Marmelct like Pils, which he should swallow whole, and none of the Fruits, or meates before recited, nor any more white wine, but red wine of any sort. And if it be on Land, the liuers of Goates (especiallie) Sheepe, or Bullocks roasted: not willingly permitting the Patient to cate any other meate. And if at Sea, Rice only sodden in water, rather than any thing else vsuall there, untill the infirmitie is perfectly asswaged." Many physicians experienced in the treatment of dysentery within recent times will agree with G. W. as to the need of a laxative at the beginning, and at one time sodium sulphate was very popular for this purpose; they will probably also agree with him as to the advantages of hot applications to the abdomen, although probably preferring a very big mustard plaster covering the whole abdomen, the umbilicus being protected with vaseline.

THE GRAND PUMP ROOM AT BATH.

A FRESH page in the story of Bath was turned on November 8th, when the famous Grand Pump Room again became available for the drinking of the waters. For some months past this has been closed for redecoration, for its faded glory was thought to have become too depressing for invalids, and there were hints that even the eighteenth century would be none the worse for the infusion of modern ventilating science. The renovated room is certainly elegant enough to satisfy any early Georgian master of ceremonies. It has been made to appear, even to the most fastidious detail of decoration, as it must have appeared two hundred years ago. The general tone is ivory white and cream; the original gilding of the capitals of the Corinthian pillars has been retained, and whatever gold has been added elsewhere has been toned down to match. The substitution of clear for coloured glass has opened up the view of the King's bath from the pump room. The statue of Beau Nash and the Tompion clock are in their accustomed places, but the furniture is more truly of the period than it used to be, and before long the whole of it will be Chippendale. When to all this are added draught-proof revolving doors, radiators in recesses under the windows, a ventilating fan and large air ducts in the roof, and a tank for the more expeditious washing of glasses, while even the old candle brackets have been wired for electric light, there is a combination of ancient and modern which should make the pump room more than ever the focus of the life of Bath. If there was any pricking of consciences at the spending of money on a gilded saloon at a time like the present, it subsided after the opening speech by the mayor of the city (Mr. F. W. Spear), who said that the day's function would be without excuse if it were not related in some way to the great war. He proceeded to recount what Bath had done since war broke out. It had, he said, been decided that as a city Bath would place freely at the disposal of the army medical authorities every facility which it could afford. No wounded or sick soldier whose trouble would be alleviated by a visit to the healing springs was to be put to any expense in obtaining the treatment. Sufferers from stiffened limbs, the result of wounds, or from acute rheumatism following exposure in the trenches had been submitted to the Bath waters with the anticipated benefit, and the same was true of soldiers recovering from tropical diseases or from nervous breakdown. Convalescent homes for officers completing their cure had been provided in the city by Lady Stavthoua and Lady de Blaquiere, while the men were being treated at the Royal Mineral Water Hospital. In Combe Park, to the south of the city, a new military hospital to accommodate 500 was in course of establishment, and presently Bath would be treating not far short of 1,000 wounded. Following the mayor's remarks came some personal testimonies to the efficacy of the waters from Dr. O'Sullivan, a visitor to the city, and from Colonel Churchward, an officer from the front undergoing treatment. The mayor then formally drank a glass at the fountain, and, like a celebrated character in fiction who did likewise, declared in solemn and emphatic terms that he felt a great deal better.

THE GROUP RECRUITING SCHEME AND THE MEDICAL PROFESSION.

THE first application of the scheme of the Director-General of Recruiting—namely, the appeal to unstarved men—has touched the medical profession in two directions. In the first place, a certain number of medical men in practice have received the appeal. This point was discussed last week in an interview, at which Sir Alfred Keogh was present, between Lord Derby and representatives of the Central Medical War Committee, which meets at the house of the British Medical Association, and of the Scottish Medical Service Emergency

¹ *The Cures of the Diseased in Foyraine Attempts of the English Nation*. By G. W. Reproduced in facsimile with introduction and notes by C. Singer. Oxford: The Clarendon Press. 1915. (Cr. 8vo. pp. 32. 1s. 6d. net.)

Committee, which meets at the House of the Royal College of Physicians in Edinburgh. The official statement issued after the interview sets out that "the representatives explained to the Director-General of Recruiting the system under which the committees have been working and the measure of success which had hitherto resulted from their efforts. Lord Derby informed them that he fully approved of the scheme, and expressed a wish that this work should be continued, and that the War Emergency Committees should undertake the whole of the arrangements for procuring medical men for the army, and he agreed that, on the recommendation of the Director-General Army Medical Service, the Committees should be recognized as the means of organizing the medical profession with regard to military service." This is a satisfactory decision, and proof of the wisdom of the profession in instituting committees to deal with the matter, but it places a great responsibility on these committees. These committees for England and Wales, Scotland, and Ireland respectively now have in relation to the Director-General of Recruiting and the War Office an established status. They become the agents of the Director-General of Recruiting for the purposes of meeting the necessities of the army for medical officers, and thus the tribunal to which medical men of military age may apply in any difficulty they feel in deciding whether in their own interests, and in those of the profession and of the civil population, they should apply for a commission. The other point in the scheme which has affected the medical profession is that the appeal has been received by a number of medical students who are in doubt as to the proper course to pursue. With regard to men in the fourth and fifth years the position is clear. The view of the War Office, as expressed for it by Mr. Tennant in the House of Commons as recently as November 3rd, is that fourth and fifth year students should continue their studies, but that students in the first, second, and third years must consider for themselves what answer they should make to the recruiting appeal addressed to them, and should not regard themselves, so far as the War Office is concerned, as under the duty of continuing their medical studies. The President of the General Medical Council, speaking in the name of that body, stated during its recent session that the Council desired to inform licensing bodies, medical schools, and approved teaching institutions that the Director-General of the Army Medical Service had intimated to the Council his entire agreement with Lord Derby's decision regarding the recruiting of medical students—namely, that it is the duty of medical students other than those in the fourth and fifth years of study to join His Majesty's forces. These pronouncements have given rise to a considerable amount of criticism by authorities engaged in medical education, who, while indicating their desire loyally to co-operate with the War Office, yet deprecate the enlistment of junior students and the interference which will thereby be caused in the continuity of their studies. It is urged by many that there will be a serious dearth of medical men in the future if this policy is pursued, but we think it may be assumed, and indeed we know, that all such arguments were most ably represented and fully discussed at an interview which the President of the General Medical Council and also the Presidents of the Colleges in London had last week with the War Office. The result was that the decision in regard to first, second, and third year students was maintained. The circular addressed by the President of the General Medical Council to all licensing bodies is the result of this decision. Sir Clifford Allbutt, in a letter to the *Times*, raises another point—namely, that it would be a great hardship and a misfortune for the country if students, who are preparing for the examinations in anatomy and physiology in this term should be prevented from sitting, and he very properly draws attention to the serious loss, financial

and otherwise, which would be inflicted upon them. There should, however, be no difficulty in meeting Sir Clifford Allbutt's wishes. Under Lord Derby's scheme men can either join the colours at once or enlist under the group scheme. Under that scheme there are two primary classes—married and unmarried men—and these in each class are grouped according to age; men in the unmarried groups are to be called up first. The group system provides that any man in a group will get one fortnight's notice before his group is called up, and also provides that if any one in a group called up has good reason to be starved, he can put such reason before the local recruiting tribunal, and may by this tribunal be exempted, or the period at which he is required to join the colours deferred. If individual students will follow this latter method they will not be called upon to join the colours until their group is called upon. When this occurs, members of the group receive a fortnight's notice, and on getting such notice individuals affected are entitled to petition the local recruiting tribunal to be "starved," or at least exempted from joining the colours for a period. Students of medicine following this plan, and, in addition, taking advantage of the help and influence which the authorities of their school might bring to bear, could have the period of their taking service deferred until they have had an opportunity of appearing for an examination for which they happened to be working. We think that a good case has been made for special treatment from the point of view of the future supply of the profession, but we also think that a good case can be shown for consideration in the interests of the army itself. We understand that it is the policy of the War Office to allow a man when enlisting to join the branch of the army he prefers, providing there is a vacancy, and we submit that it would be undesirable to enlist medical students who have advanced sufficiently far in their course to have passed the examination in anatomy and physiology in any other branch than the R.A.M.C. or as orderlies in that corps. In normal conditions these men, as soon as they have passed the examination in anatomy and physiology, would begin clinical work as dressers or clerks, and we suggest that it would be possible, and indeed easy, to give them some probationary status now in the army and employ them in military hospitals abroad or at home in corresponding capacities. The Central Medical War Committee, at its meeting on November 10th, determined to ask the Director-General of Army Medical Services whether it be possible to offer commissions as second lieutenants or surgeon-probationers to third year medical students.

The first annual report of the Medical Research Committee, for the year 1914-15, has been presented to Parliament. We hope to refer to this important document at length in our next issue.

OUR BELGIAN COLLEAGUES AT HOME AND ABROAD.

The following additional subscriptions have been received:

	£ s. d.		£ s. d.
Dr. G. D. H. Carpenter...	1 0 0	Mr. R. F. Priestley ...	1 0 0
Dr. H. M. Page ...	1 1 0	Mr. A. Chapman ...	0 7 11
Mr. R. W. Clarke ...	0 10 0	Mr. W. W. Thomas ...	0 5 0

Subscriptions to the Fund should be sent to the Treasurer of the Fund, Dr. H. A. Des Voeux, at 14, Buckingham Gate, London, S.W., and should be made payable to the Belgian Doctors' and Pharmacists' Relief Fund, crossed Lloyds Bank, Limited.

THE APPEAL FOR SURGICAL INSTRUMENTS.

Surgical instruments should be sent to the Master of the Society of Apothecaries, Apothecaries' Hall, Blackfriars, E.C. The Master acknowledges gifts from Miss May Rathbone, London, W., and Dr. A. H. Penistan, Cleveleys, near Blackpool.

Medical Notes in Parliament.

The New Taxation.

THE third Finance Bill of the war is making slow progress through the Commons, and as it will apparently be some weeks before it has passed through all the necessary stages and become operative as an Act of Parliament, it may be useful to indicate the progress that has been made and the scope of some of the amendments which the Chancellor has accepted or promised to introduce.

The bill is at present in its Committee stage, and, as was generally anticipated, its framework has not undergone any substantial change, although several alterations have already been made in matters of detail which must have an appreciable effect on the structure as a whole. The scheme for the increase in taxation falls into three main divisions, dealing respectively with the new import duties, the income tax, and the excess profits tax. The first two divisions have been discussed and may reasonably be regarded as practically settled, although one or two minor matters still remain open. The excess profits tax, on the other hand, being novel in its form and heavy in its incidence, has already provoked much discussion, and few if any of its numerous critics show any signs of becoming "gravelled for lack of matter."

We have previously called attention to the fact that the Chancellor has acceded to the request made by the users of motor vans for commercial purposes that such vehicles should be exempted from the new import duties. The case of the professional user of an imported car was again referred to when the section in question was debated in Committee, but no promise was made on behalf of the Government to give further consideration to what is undeniably a new anomaly in British taxation. We hope that the point may not be lost sight of when the bill is before the Commons at a later stage. The old saying that "hard cases make bad laws" is true enough, but the application of that maxim to the whole class of medical practitioners in a bill which recognizes—in connexion with the petrol duty—their right to an analogous relief, savours rather of political or administrative convenience than of a regard for sound and just legislation. If any relief is introduced in respect of the purpose served by the imported vehicle, the discrimination should be based on the essential distinction between pleasure and utility, and on that foundation professional and commercial users of motor vehicles have an equal right to exemption.

It will be remembered that the income tax sections provided for a drastic cutting down of the allowances by way of "abatement," and a reduction of the exemption limit from £160 to £130. Protests against these proposals were not successful. It was stated that the new allowances had been fixed with reference to the average rates of indirect taxation by the classes affected, and after exhaustive inquiry as to the total taxation they could quiteably be called upon to bear. Comment on the fact that though equitably the exemption limit was £130 the maximum allowance for abatement was only £120, elicited the explanation that the amounts had been fixed in that manner to avoid the necessity of dealing with a large number of small charges which, from an administrative point of view, might not be worth the cost of their collection.

Under Section 27 it was proposed that interest on bank deposits should be subjected to tax at the source—that is, that the banker should deduct the appropriate tax and account for it to the Revenue. This proposal evoked considerable opposition on the part of the banks, as they apparently feared that it might lead customers to transfer small deposits to the Post Office Savings Bank, where the section would not apply. It was announced that the provision had been inserted under a misapprehension, and that a new clause would be introduced at a later stage in place of that withdrawn.

Another of the income tax sections which was opposed purported to give the Board of Inland Revenue large powers of appointing officials to perform various duties under the proposed system of quarterly collection of income tax from employed persons. These appointments are at present made by the District Commissioners of Income Tax, who appear to be jealous of their prerogatives

in this connexion. The Chancellor explained that the section was not intended to grant such extensive powers as might be gathered from its wording, that he was negotiating with the authorities concerned, and hoped that the matter might be settled by mutual agreement.

As we pointed out in our issue of October 23rd, the Excess Profits Tax does not apply to professions except where substantial capital expenditure is required. Several members spoke strongly in favour of its extension to all professions and employments, but this suggestion was negatived. The discussion on this point threw an interesting light on the view which the Government takes as to the scope and justification of the new tax. When it was first discussed the tax was popularly regarded as being a tax on any increase in income due to the war, and its justification the plea that a cause of so much financial and personal loss to some ought not to be the cause of gain to others. As viewed in the light of recent explanations, it seems to be intended as a tax on that increased yield of capital which is received during the war, even though not directly or indirectly attributable to the special conditions arising out of it. The administrative advantage of the view taken by the Government is sufficiently obvious. It removes the necessity of proving the cause of the increase—a proof not easy to establish where the material is in the possession of the person to be assessed, and at the same time made for simplicity of assessment in that there is no necessity for discriminating between pre-war and ante-war profits. Incidentally it carries one step further the differentiation first introduced into our system of taxation by the Finance Act of 1907—the principle of treating the income derived from earnings more leniently than that arising from invested capital. The Government also take the view that there are few cases where liability would in any case attach to professional profits, and there will not be many medical practitioners prepared to contest that statement. Two alterations were made in the original scheme of the bill. The excess tax payable is to be calculated after £200 is allowed to the taxpayer instead of £100, and the liability is to attach to concerns making up their accounts after August 4th, instead of after August 31st, 1914. It will be seen that this latter alteration is in accordance with the taxation of all increases received after the commencement of the war, irrespective of their periods of accrual.

The amendments summarized above do not in most cases affect the medical profession directly, but proposals for increased taxation can never be of merely academic interest. A tax is an individual contribution, but it is for the expenses of the community, and when any section escapes, by faulty administration or lack of political foresight and courage, from a payment which they can fairly be called upon to make, the remainder of the community must sooner or later make good the loss.

Price of Quinine.—In reply to Commander Bellairs, Mr. Prettynan, Parliamentary Secretary to the Board of Trade, said that the advance in the price of quinine had been under the consideration of the Government; it had recently been decided to prohibit its export, and since that decision became known there had been a sharp fall in price.

Exemption of Dentists from Military Service.—In reply to Mr. Raffan, who asked whether, in view of the dental requirements of the community, practitioners in dentistry would be starred as men to be exempted from military service under Lord Derby's recruiting scheme, Mr. Tennant said that the matter had not escaped the attention of the Army Council. Every case of the kind would, if represented to the proper authority, receive due consideration.

Enlistment of Pharmacists.—Mr. Glyn-Jones asked, on November 9th, whether pharmacists were to be enlisted except to perform duties for which their special technical qualification was needed. Mr. Tennant replied that a pharmacist who wished to join the R.A.M.C. would always be accepted for that arm if a vacancy were available, but if he desired to enlist in some other branch of the army he could not well be refused if a vacancy existed in it.

THE WAR.

CASUALTIES IN THE MEDICAL SERVICES.

ARMY.

Killed.

LIEUTENANT FERDINAND HAY YOUNG, R.A.M.C., was lost in the transport *Marynetta*, torpedoed and sunk in the Aegean Sea on October 23rd. He was the son of Mr. John Young, of Fernbank, Kirkintilloch, and was educated at Glasgow University, where he took the M.A. in 1907, the M.B. and B.Ch. in 1911. After qualifying he went to New Zealand, but returned when the war broke out, and joined the R.A.M.C. as a temporary Lieutenant on January 18th, 1915.

Wounded.

Captain R. V. Morrison, I.M.S. (Cameroons).
 Captain J. E. Stacey, R.A.M.C. (temporarily), France.
 Captain T. H. Wilkinson, R.A.M.C. (temporarily), Dardanelles.
 Lieutenant W. R. Stewart, I.M.S., Dardanelles.
 Lieutenant A. L. E. F. Coleman, R.A.M.C. (temporarily), France.
 Lieutenant E. U. MacWilliam, R.A.M.C. (temporarily), Dardanelles.
 Lieutenant G. Richardson, R.A.M.C. (temporarily), France.
 One item of some interest in the above list is that an officer of the I.M.S. has been wounded in the Cameroons. Probably few were aware that any Indian troops were serving in West Africa. The officer in question, Captain R. V. Morrison, is medical officer of the 5th Bengal Light Infantry, the regiment a part of which mutinied at Singapore last February.

DEATHS AMONG SONS OF MEDICAL MEN.

HUME, William Young, Lance-Corporal 7th Battalion Cameron Highlanders, son of the late Dr. Walker Hume, of Jedburgh, reported wounded and missing in France on September 25th. He was in the employment of Messrs. T. and F. Gregory, dentists, Dundas Street, Edinburgh.
 Warnock, H. A. H., Lieutenant 4th, attached 1st, Battalion Royal Fusiliers, eldest son of the late Dr. Hugh Warnock, of Clogher, county Tyrone, reported wounded and missing in France early in September, now stated to have died of wounds. He was educated at St. Columba's College and at Trinity College, Dublin, and got a commission from the Officers' Training Corps on August 15th, 1914.

Webb, Gerald Vernon Tisdall, Lieutenant Second Battalion Hampshire Regiment, son of the late Captain W. W. Webb, J.M.S., killed before Achi Baba, in the Dardanelles, on August 6th, having been first reported as missing. He was educated at Berkhamshead and Exeter Schools, got his commission as Second Lieutenant in September, 1911, and was promoted to Lieutenant on October 1st, 1914. He had served with his battalion in Mauritius and in India, returned to England in December, 1914, went to the Dardanelles and took part in the first landing on April 24th-25th, was wounded on May 4th, but subsequently returned to duty.

HONOURS.

THE *London Gazette* of November 4th publishes a long list of 100 decorations, 36 D.S.O.'s and 64 Military Crosses, bestowed on officers for good service, chiefly in the fighting which began with the British advance at Loos and Hulluch on September 25th. Of these, six D.S.O.'s and nine Military Crosses go to the medical services, as follows:

D.S.O.

Major Geoffrey Wallace Grainger Hughes, 6th Cavalry Field Ambulance, R.A.M.C. For conspicuous ability and good work in arranging for the care and evacuation of the wounded at Loos on September 26th and 27th, 1915. A large number of wounded infantry were tended and evacuated by the two cavalry field ambulances, in addition to wounded cavalrymen. During the greater part of the time Loos was under heavy bombardment.

Captain Whiteford John Edward Bell, M.B., No. 2 Field Ambulance, R.A.M.C. For conspicuous gallantry and devotion to duty on all occasions, notably near Loos between September 28th and October 1st, 1915, when he visited the advanced bearer post day and night under continuous shell fire, and personally supervised the arrangements for collecting and evacuating the wounded in that area. Captain Bell has commanded a bearer division since August, 1914.

Captain temporary Major John Wilfred Bird, 6th London Field Ambulance, R.A.M.C. (T.P.). For conspicuous devotion to duty during operations at Maroc and Loos, between September 25th and 30th, 1915, in dealing with casualties. On one occasion he worked for twenty-three hours without any cessation in dressing and attending the wounded. He set a fine example, which had far-reaching results.

Temporary Captain Charles Stewart Hamilton, R.A.M.C., attached 2nd Battalion the Buffs (East Kent Regiment). For conspicuous gallantry and devotion to duty from September 27th to 30th, 1915, in France. He dressed the wounded in the firing line, being for hours together under heavy shell fire, and went to points of great danger, often to where bombers were actually fighting.

Captain Frank Robson Kerr, M.B., R.A.M.C. (S.R.). For conspicuous gallantry and splendid devotion to duty at Cninchy on September 25th, 1915. After a successful attack on the enemy's trenches this officer crawled over our own parapet and brought in a wounded man from about a dozen yards outside in full view of the enemy at a range of only 70 yards. He then went out again for 30 yards and rescued a man whose thigh had been broken, being fired at the whole time. During the night of September 25th Captain Kerr was out attending to the wounded for two hours under constant machine-gun and rifle fire, and on the night of September 27th-28th he went to within 25 yards of the enemy's position to rescue a man reported wounded, but found that he was dead. Captain Kerr, M.B., B.S. Melbourne, D.S.O., after a brilliant career at the University of Melbourne, where he graduated M.B., B.S., was appointed Rhodes Scholar for Victoria, Australia. He applied to enter University College, Oxford, and was accepted for admission in October, 1915. His name was given for a vacant post on the staff of the Royal Victoria Hospital, Melbourne, on January, 1914, in order that he might complete his resident appointments at the Melbourne Hospital. He had been two terms at University College when the war began. He at once offered his services and was only recently promoted Captain. He was intending to read for honours in the Final Honour School of Natural Science (Physiology, B.Sc.), and also to carry on a research in the Department of Zoology. It is hoped that he will yet be able to carry out these intentions.

Captain Arthur John Alexander Menzies, M.B., R.A.M.C., attached 1st (Royal) Dragoons. For conspicuous gallantry and devotion to duty from September 26th to 29th, 1915, in Loos. Captain Menzies was unremitting in his attention to the wounded of all units. He was twice seen carrying wounded on a stretcher under rifle fire, and for fifty-five hours he was continuing to expose himself to heavy shell fire while carrying out his duties.

Military Cross.

Captain Frank Percy Freeman, R.A.M.C. (S.R.), attached 23rd Field Ambulance. For conspicuous gallantry and devotion to duty during operations near Hulluch from September 25th to 28th, 1915. He brought in and attended to the wounded during four consecutive days and nights, repeatedly going out unaided to collect the wounded. He was a fine example of his men. (Captain Freeman had his medical education at the Royal Colleges of Physicians and Surgeons in Ireland.)

Captain James Ronald McCurdie, M.B., R.A.M.C. (S.R.), attached No. 2 Field Ambulance. For conspicuous gallantry and devotion to duty from September 25th to 27th, 1915, at Le Kuloite farm, where, although continuously exposed to shell fire, he collected and treated the wounded. By his efforts and organizing power a large number of wounded were collected. Captain McCurdie set a fine example to the officers and men under him in most trying circumstances.

Temporary Captain James Murray McLagan, M.B., R.A.M.C., attached 3rd Battalion, the Royal Fusiliers (City of London Regiment). For conspicuous gallantry and devotion to duty during the operations between September 27th and 30th, 1915, when he attended the wounded in the firing line under very heavy shell and rifle fire. His coolness and skill undoubtedly saved many lives. For three days and four nights he worked incessantly with unflagging energy.

Temporary Captain Charles Joseph O'Reilly, M.D., 21st Field Ambulance, R.A.M.C. For conspicuous gallantry and devotion to duty during operations near Hulluch, from September 25th to 28th, 1915, when he brought in and attended to the wounded for four consecutive days and nights under heavy fire, notably on September 27th, when he voluntarily went out to collect wounded under very heavy shell fire. He has consistently set a splendid example to his men.

Captain Thomas Walker, M.B., R.A.M.C. (S.R.), attached No. 2 Field Ambulance. For conspicuous gallantry and devotion to duty from September 25th to 27th, 1915, when he worked continuously collecting the wounded from the area between Lone Tree and Hulluch road, and beyond. This area was under continuous shell fire, and at first under machine-gun fire also.

Temporary Lieutenant David Carnegie Alexander, M.B., R.A.M.C., attached 5th Battalion the Queen's Own Cameron Highlanders. For conspicuous gallantry and devotion to duty between September 25th and 27th, 1915, near "Fosse 8." He attended to the wounded under very heavy shell and rifle fire, lying in the open under enfilade machine gun fire, and on several occasions at the Manager's House at the Fosse carried out his duties under heavy shell fire.

Temporary Lieutenant John Bruce Baird, No. 1 Field Ambulance, R.A.M.C. For conspicuous gallantry and devotion to duty from September 25th to 27th, 1915, when in charge of different bearer sections he brought in and attended to the wounded between Lone Tree and Hulluch road under shell and machine-gun fire.

Temporary Lieutenant George Rankine, M.B., R.A.M.C., attached Headquarters 9th Divisional Royal Engineers. For conspicuous gallantry and devotion to duty from September 26th to 28th, 1915, at Sully and Vermeilles, when attending to and evacuating the wounded from the area between Lone Tree and Hulluch road under shell and machine-gun fire.

in spite of shell fire and bombing, assisted to get back many wounded. On the return journey many of the bearers were killed and wounded by a shell, and Lieutenant Rankine carried in a wounded man on his back.

Temporary Lieutenant Bernard Score Browne, M.B., R.A.M.C., attached 2nd Battalion the Cheshire Regiment. For conspicuous gallantry and devotion to duty near Vermelles. He spent the whole night of the 2nd and 3rd October searching for and carrying back wounded who were lying between our own and the enemy's lines, which were only 200 yards apart. The enemy were firing and the ground was lit up by flares. After daybreak he carried back three more men under a very heavy fire. At one time he tended the wounded within fifteen yards of the enemy's trenches. By his courage and ceaseless work all the wounded in his area were brought in.

SIR IAN HAMILTON'S DISPATCH.

The *London Gazette* of November 5th publishes a dispatch dated September 22nd, from General Sir Ian Hamilton, Commander-in-Chief of the Mediterranean Expeditionary Force, in which a further large number of officers and men are mentioned for good service. Among them are included the following members of the medical services:

Staff.

Lieutenant-Colonel A. E. C. Keeble, R.A.M.C.,
Captain J. Hare, R.A.M.C.

R.A.M.C.

Lieutenant-Colonel L. Humphrey,
Major E. McDonnell,
Major A. Macdonnell,
Sergeant-Majors H. Underwood and A. F. Robinson;
Sergeants W. T. Mathies, F. H. Mattock, B. T. Colls (dead), and G. A. Scales.

R.A.M.C. T.F.S.

Lieutenant-Colonel J. J. O'Hagan,
Corporal R. Paine; Privates W. E. Lloyd, G. A. Walton, H. Price, and J. Morris.

Royal Naval Division.

- 1st Field Ambulance:
Staff Surgeon A. F. Fleming, R.N.,
Temporary Surgeon J. Pratt, R.N.,
Corporal J. A. Liney;
2nd Field Ambulance:
Temporary Surgeon H. L. G. Foxell, R.N.,
Sergeant S. Ibbotson; Privates P. Lowes and S. Sterland (killed).
3rd Field Ambulance:
Fleet Surgeon A. J. Finch, R.N.,
Corporal J. N. Ainards; Lance-Corporal H. Bulman,

Australian and New Zealand Forces.

- Staff:
Colonel N. Manders, Army Medical Service (killed).
Australian Army Medical Corps:
Colonel J. L. Beeson,
Lieutenant-Colonel H. W. Bryant,
Captain B. W. Chambers,
Captain H. J. Fry.
Sergeants R. Bryce, W. Gunn, and O. R. Hookway; Corporal H. W. Faulkner; Lance-Corporals B. S. Goode, G. T. Hill; Privates H. H. Collis, F. A. Macrae, G. L. Peel, H. Sawyer, J. Simpson, A. J. Vines, H. T. Watts.

New Zealand Medical Corps.

Lieutenant-Colonel C. M. Begg,
Captain B. S. Finn.

Indian Medical Service.

Captain H. J. M. Cussajee, 14th Sikhs,
Captain T. J. C. Evans.

Captain B. S. Finn, of the New Zealand Medical Corps, had the D.S.O. conferred upon him in the *London Gazette* of October 29th, as stated in the *BRITISH MEDICAL JOURNAL* of November 6th.

NOTES.

MEDICAL OFFICERS WANTED.

21st South-Western Mounted Brigade Field Ambulance.
A vacancy exists in the above unit. Any gentleman desirous of accepting a commission should apply to Major C. W. Edwards, Maresfield Park Camp, Uckfield, Sussex.

26th London Field Ambulance.

There are vacancies for officers in this unit. They must be fully qualified, able to ride, and prepared to go abroad at short notice. The terms now offered compare favourably with those offered to civil surgeons. Apply Major John C. B. Wells, 26th London Field Ambulance, Baintree.

21st South-Midland Mounted Brigade.

Medical officers wanted for the above. Candidates must be willing to take foreign service obligations, and should apply to Major D. M. Spring, R.A.M.C.(T.), Senior Medical Officer, Hampton Green, Falkenham.

England and Wales.

UNIVERSITY OF LIVERPOOL.

At a recent meeting of the Court, the University resolved that Latin shall no longer be a compulsory subject in the matriculation examination for those aspiring to degrees in medicine. In this step the university states that it has followed the example of the other northern universities. The resolution was not passed without a certain amount of opposition, but the claims put forward by the Medical Faculty prevailed. Although the General Medical Council has long ago decided that Latin must be one of the subjects in which a candidate must pass an examination before he can be registered as a medical student, registration is not necessary for any student taking his degree at the University of Liverpool. The number of medical students enrolled in the faculty this session is 54. This is by far the largest number of entrants that the university has had since it came into existence; of these 17 are women. It is believed that the Insurance Act has had a considerable influence in attracting men to the study of medicine. The increase in the number of women students is noteworthy.

ROYAL MEDICAL BENEVOLENT FUND.

The annual service for medical men usually held in Liverpool on the Sunday nearest to St. Luke's day, October 18th, was omitted this year. The reason given was the absence of so many men on war service. The Committee of Management greatly regretted the loss of opportunity that the service has afforded of contributing to so worthy a charity as the Royal Medical Benevolent Fund. It has, however, circularized the profession to the effect that any sum sent for that purpose will be gratefully acknowledged by Mr. R. J. Hamilton, 82, Rodney Street, and we should like to draw special attention to the claims of the Royal Medical Benevolent Fund, which is likely to be more called upon than ever in the near future.

CIVIL ECONOMY IN LIVERPOOL.

The city authorities are setting the inhabitants a good example in the matter of thrift. No improvements that can be well postponed, are being undertaken, and expenditure is limited to necessary repairs. It is hoped that some £30,000 a year will be saved. In the matter of street lighting it is estimated that at the end of twelve months some £6,000 will be saved. Nevertheless, Liverpool is by no means in civician darkness. Dr. Hoop has also drawn attention to the importance of economy in the household, and emphasized the value of pulse foods. He praised hotpots, stews, and soups, and shows how important efficient cooking is to obtain the maximum amount of sustenance from articles of diet. The dinner of joint is not only expensive, but it is open to question whether it is as nutritious as many wholesome made-up dishes from so-called inferior cuts.

Scotland.

ROYAL FACULTY OF PHYSICIANS AND SURGEONS OF GLASGOW.

At the annual meeting of the Royal Faculty of Physicians and Surgeons of Glasgow on November 1st Dr. Ebenezer Duncan, Langside, was elected President. Mr. J. Walker Downie, Vangoir, and the retiring President, Dr. John Barlow, Councillor. Dr. W. G. Dun was re-elected Treasurer, and Dr. Alexander Napier, Honorary Librarian. Mr. D. N. Knox continues to act as representative to the General Medical Council. Before demitting office, Dr. Barlow handed over to the custody of the Royal Faculty a silver-mounted oak mallet stand, presented by Mr. James D. Hedderwick, I.L.D. The inscription on the stand is: "To the Royal Faculty of Physicians and Surgeons, Glasgow, from Jas. D. Hedderwick, I.L.D., Chairman of Glasgow Royal Infirmary 1901-1914; Grown in the Forest of Luss, from the Roof of Glasgow Cathedral about 1237 to 1911." It happens that the mallet itself presented by Dr. W. G. Dun in 1910 is made of wood from the old Glasgow Royal Infirmary, and it is quite fitting and appropriate that the mallet should rest upon wood

taken from its venerable neighbour, the Glasgow Cathedral. At the same meeting the Treasurer intimated a donation from Dr. Barlow, the retiring President, to the Benevolent Fund of the Royal Faculty.

Ireland.

ELECTION OF MASTER OF THE ROTUNDA HOSPITAL.

At the annual charter meeting of the Board of Governors of the Rotunda Hospital held last week to fill a vacancy at present existing in the Mastership, Dr. Henry Jellett was unanimously elected Master on the proposition of Sir William Smyly, M.D., seconded by the Deau of St. Patrick's, and leave of absence was given to him for three months, without prejudice to any further extension he may require. Conditionally the three ex-Masters—Sir William Smyly, M.D., Dr. Purcof, and Dr. Tweedy—have kindly undertaken to carry out the duties of the Master. Dr. Henry Jellett, who was Master of the Rotunda, last December applied to the board for leave of absence for six months to go to France to drive a motor ambulance. Leave of absence was granted, and was renewed for another six months. That he is doing excellent work at the front is shown by the fact that he was mentioned in dispatches.

DUBLIN CASTLE RED CROSS HOSPITAL.

At a meeting of the Committee of Management last week a resolution was passed, on the recommendation of the Medical Committee, appointing the Presidents of the Royal Colleges of Physicians and Surgeons to act in an advisory capacity in rotation as honorary visitor to the hospital. It was reported that there were at present in the hospital 10 officers and 111 men.

The Committee had under consideration the very much increased cost of maintenance by reason of the general rise in prices, including the very serious increase in cost in connexion with the supply of drugs and medical requisites generally. It was resolved to ask the War Office to place this hospital on the same footing as the ten civil hospitals in Dublin and other hospitals in the United Kingdom as regards the capitation grant for wounded soldiers.

Obituary.

BRIAN O'BRIEN, B.A., M.D.(T.C.D.),

MEDICAL INSPECTOR, LOCAL GOVERNMENT BOARD IN IRELAND.

It was with deep grief that the news of the death of Dr. Brian O'Brien was received among the profession and the public in Ulster, and perhaps more especially in Belfast, where he was so well known for many years. Dr. O'Brien was in good health and discharging his duties as medical inspector of the Local Government Board up to October 21st; he fell ill on the following day, and cerebrospinal fever of a very acute and severe form developed on the 23rd. He was removed from his home in Malone Park, Belfast, to the Purdysburn Fever Hospital, under his friend, Dr. Gardner Robb. From the first the attack was of a malignant type, and he succumbed on October 29th. The profession are glad that he was under the care of Dr. Gardner Robb, who since the epidemic of this disease in Belfast some few years ago has had such exceptional experience, and has visited Flexner in New York with regard to the bacteriology and serum treatment.

Dr. Brian O'Brien belonged to a very old Irish family. He was a grandson of William Smith O'Brien, M.P., the leader of the "Young Ireland" movement of many years ago. He was born in 1872. He received his medical education in Trinity College, Dublin, in 1896, and obtained the M.D. degree in 1898. He was appointed dispensary medical officer in Faghlan, co. Derry, and also at Portsalon. Fourteen years ago he settled in private practice in Belfast, and became medical officer of one of the districts of the Royal Irish Constabulary, and assistant surgeon to the Queen Street Hospital for Sick Children. About eight years later he was appointed medical inspector of the Local Government Board for Ulster. His last report to the Board was on the subject of cerebro-spinal meningitis. In it he

says: "Since the beginning of the year 1915 this disease has made its appearance in my district in epidemic form." He had not been, however, knowingly in personal contact with any case for several weeks. His professional ability, skill, tact, and high sense of honour brought him rapidly to the front, and the promise of rapid advance in the service of the Local Government Board was sure to one with so many high qualifications.

Dr. Brian was an athlete. He was a prominent amateur golfer, and won many club trophies; he also rowed for his college, and took his part in most games. Personally he inspired more than liking in those with whom he came in contact. His private friends were innumerable and closely attached, but all claimed him as a friend. He leaves a widow and three young children, with whom much sympathy is felt.

DEPUTY SURGEON-GENERAL WILLIAM FARQUHAR, Madras Medical Service (retired), died at his residence in London on October 15th. He was educated at Marischal College, Aberdeen, where he took the degree of M.B. in 1853 and that of M.D. in 1857, as well as the L.R.C.S.Ed. in 1853. Entering the Indian Medical Service as assistant surgeon on May 28th, 1858, he became surgeon on May 31st, 1870, surgeon-major on July 1st, 1875, brigade-surgeon on May 16th, 1885, and deputy surgeon-general on July 1st, 1885. He retired on July 1st, 1890. The Army List assigns him no war service, though most of his service was spent in military employ in the Madras Presidency, the Straits Settlements, and Burma. In November, 1882, he was appointed to the medical charge of Utakamand, the summer capital of the Madras Government; and from 1885 to 1890 he was administrative medical officer of Belgium and the Western District.

Universities and Colleges.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.

The annual report of the Council, 1915, contains the report of the annual meeting held on November 14th, 1914, the letter addressed to the Home Secretary by the President of the College on the scarcity of "subjects" for dissection, the Council's reply to the Director of Public Prosecutions respecting the observations of Mr. Justice Avory in his charge to the grand jury at Birmingham on a case in which the question of professional secrecy was raised in respect of clinical abortion, the special regulations during the war, and other minor matters. The President (Sir W. Wilson Cheyne, Bt., C.B.), who holds the rank of Surgeon-General in the Royal Navy, was away from the June meeting, and leave of absence was given to Sir George Makins, K.C.M.G., C.B., Sir Anthony Bowly, K.C.M.G., Sir Berkeley Coynihan, and Mr. F. F. Burghard, C.B., in France, and to Mr. C. J. Symonds, Mr. C. A. Ballance, M.V.O., and Mr. W. Thorburn, at Malta. Mr. R. H. Burne, physiological curator of the museum, is working at Dunkirk, under the French Red Cross, and a large proportion of the servants of the College have enlisted. The obituary of Fellows includes thirty-three names, three of whom lost their lives on active service, and the obituary of Members includes 385 names, thirty-three of whom died on active service, while of the twenty-one Licentiates in Dental Surgery one died on service. The Conservator's annual report is followed by a similar communication from the Librarian, who announces that the great catalogue is now practically completed. The Librarian's request for additions to the library in a previous report has been liberally responded to, and in consequence it is enriched by many works of real value, among which are the late Mr. Edmund Owen's donation of medico-historical works by Asher and Cabanès.

The Services.

EXCHANGES DESIRED.

R.A.M.C.(T.F.) Captain, temporarily invalided, whose unit is now abroad, wishes to effect an exchange into home service unit. Only suitable for surgeon who can perform major operations quickly. Address No. 5490, BRITISH MEDICAL JOURNAL Office, 429, Strand, W.C.

Officer in home service field ambulance (T.F.), wishes exchange to casualty clearing station, hospital, hospital ship, etc., either home or abroad. Address Alpha, BRITISH MEDICAL JOURNAL Office, 429, Strand, W.C.

MR. DOUGLAS CRAWFORD CLERK has been awarded a university entrance scholarship, value £50, at King's College, London, for anatomy and physiology.

Medical News.

A SALE in aid of the funds of the Royal Medical Benevolent Fund Guild will, by kind permission of the Earl and Countess of Crowe, be held at Crew House, Curzon Street, London, W., on the afternoon of November 24th.

The Cuban Parliament has voted an allocation of 400,000 pesos for the construction of six maternity hospitals, one in each of the provinces of the Republic.

THE SWINEY Lectures on Geology will be delivered this year by Dr. J. D. Falconer, the subject being "Ice and the Ice Age." The course will be given at the Victoria and Albert Museum on Mondays, Tuesdays, and Saturdays at 3 p.m., beginning on November 13th.

AMONG the medical men who have assumed or resumed office this week are Dr. R. J. Smith, Lord Mayor of Cardiff, and the following Mayors: Dr. James Pearson (Bristol), Dr. A. Macgregor Sinclair (Burnley), Dr. S. R. Alexander (Faversham), Dr. Miles C. Atkinson (Leamington), Dr. Lewis Hunt (Richmond, Surrey), and Dr. J. Parkinson Atkinson (Saffron Walden).

At Nottingham Assizes, on November 5th, William Henry West, described as a physician, and Ernest Townsend, a boot salesman, were convicted of the manslaughter of a girl, who died as the result of an illegal operation performed by West at the other prisoner's request. West was sentenced to seven years' penal servitude and Townsend to three years.

At a meeting of the Society of Public Analysts on November 3rd, Mr. Edward Hinks, F.I.C., stated that the length of time for which hydrogen peroxide persisted in milk depended upon the age and condition of the milk. In one instance 0.2 per cent. peroxide added to a perfectly fresh milk was still present in estimable proportion after the lapse of eighteen months. It was found that within the range of 15 to 37 C., the higher the temperature the longer did the peroxide persist.

IN the ninth annual report of the Norwood Sanatorium, issued to the medical profession only, Dr. Francis Hare has avoided the temptation, to which editors of such reports often fall, of indulging freely in tables and statistics, to the weariness of the average reader. Though figures are, of course, not wanting, the report on the whole is an interesting essay on the treatment of alcoholism and other drug habits by a writer who combines first-hand knowledge of his subject with a facile pen.

THE staffs of the medical and dental schools of Guy's Hospital, at a meeting on November 9th, recorded the unanimous opinion that all schools should endeavour to facilitate the recently expressed official wish that students in their first, second, and third years should place themselves at the disposal of the military authorities, but that in view of the national necessity of a constant influx of newly qualified medical and dental practitioners for the services of the navy and army, representations should be made to the Government that students after enrolment should be required to pursue their technical studies until otherwise instructed by the Admiralty or the War Office. A committee was appointed to consider how effect could best be given to this resolution.

THE Central Midwives Board held a special meeting on October 28th for hearing penal cases. Sir Francis Champneys was in the chair and Mr. Parkington, Professor Briggs, Dr. West, and Miss Paget were present. Of the seven women about whom final and interim reports had been received, one was struck off. Twelve fresh cases were heard, and eight midwives were removed from the roll, two were censured, and two cases were adjourned for judgment in three and six months. Apart from the usual charges of neglect with regard to taking pulse and temperatures, and of want of cleanliness, both personal and in connexion with their appliances, there were various serious cases of neglected puerperal fever, ophthalmia neonatorum, and rupture of the perineum. Two women were charged with insobriety, and another with employing an uncertified person as her substitute.

DR. R. O. MOOR, in his third Chadwick lecture on typhus fever in Serbia, said that the Mussulman population seemed to suffer less than the rest of the inhabitants, owing, as he thought, to their greater personal cleanliness due to the frequent ablutions enjoined by Mohammedan law. Much evidence pointed to the contagion of typhus being carried by lice, and ordinary measures, such as its use for lighting, was an efficient and economical insecticide. He thought, however, that the opinion, formerly held in this country and still maintained by many Serbian doctors of much experience in the disease, that it might be conveyed by direct inhalation, had not been disproved.

Letters, Notes, and Answers.

ATTORNS desiring reprint of their articles published in the BRITISH MEDICAL JOURNAL are requested to communicate with the Office, 429, Strand, W.C., on receipt of proof.

THE telegraphic address of the BRITISH MEDICAL ASSOCIATION and JOURNAL are: EDITOR of the BRITISH MEDICAL JOURNAL, *Antelope, Westland, London*; telephone, 2531, GERRARD. GUY, 21, St. Giles, W.C.; AND THE SECRETARY, *Antelope, Westland, London*; telephone, 2531, GERRARD. MEDICAL SECRETARY, *Mediævera, Westland, London*; telephone, 2534, GERRARD. THE address of the Irish office of the British Medical Association is 16, South Frederick Street, Dublin.

Queries, answers, and communications relating to subjects which special departments of the BRITISH MEDICAL JOURNAL are devoted will be found under their respective headings.

ANSWERS.

EXAMINATION OF RECRUITS.

J. A. C. The medical examination of recruits for the navy and army does not differ in any respect from the examination of any man for life insurance of the lesser orders, or for entry into any of the many civil forms of service which nowadays demand such examination. There are differences in point of detail according to the standards set up for the men in the several grades of the services. For example, a seaman for the navy must have perfect eyesight; for the army a soldier need not have such a high standard of vision. The difference of detail and the general scope of the examination can be found in *Recruiting Regulations*, to be obtained at any military bookshop; some parts of the examination are dealt with in the *Regulations of the Army Medical Service*, to be obtained at the same source.

LETTERS, NOTES, ETC.

THE GRIEVANCES OF SHIP'S SURGEONS.

G. M. H. In the course of a contribution to the correspondence on this head, says that the attitude assumed by "Nauticus" must tend to prevent the much-needed reform in the status of ship surgeons. So long as the companies can get men "to take a voyage" they are, he says, not greatly concerned in establishing a regular medical branch in their services, with increased pay and the best ships for the longest-service men. Why, he asks, should they not be a well-organized medical service in the British mercantile marine of equal importance and with equal prospects to the British navy? Both are equally important to the nation. Again, a ship's surgeon has a good deal of authority if only he knows how to use it. With regard to placing a man on the sick list or returning him to work, he has practically absolute power, for nobody dare oppose his orders for fear of trouble under the Compensation Acts. Let "Nauticus" be in charge of a ship, will say, an outbreak of small-pox, and he will soon see how much authority is given to the surgeon. Naturally, no surgeon himself gives orders to the crew, except his own hospital attendants. Such orders go through the executive department. If "Nauticus" maintains that by so doing he loses all "authority," then, of course, the senior medical officer of a flagship has no "authority" which, as Euclid says, "is absurd." Perhaps the cost of an outfit for only one voyage is a little expensive, but it is just the one-trip man who is preventing any improvement in the service. Let me add that I have had over two years' experience as a ship's surgeon, and as such the war is over. I have no objection to being "a member of the crew." In the meanwhile I am serving in the navy.

THE GIANT CRICKETER.

DR. CLIPPINGDALE writes: Those who follow family history and hereditary proclivity may be interested to know that the patronymic "Grace" is a transformation of the French "Gros," a sobriquet bestowed originally upon a man of large stature, the first to bear the name being Raymond Fitz-Waller, surnamed "Le Gros," one of the companions in arms of Strongbow. The fine physique of the late Dr. Grace has therefore apparently lasted in his family during eight centuries and approximately through twenty-four generations.

SCALE OF CHARGES FOR ADVERTISEMENTS IN THE BRITISH MEDICAL JOURNAL.

	£	s.	d.
Seven lines and under	0	0	0
Eight to ten lines	0	6	0
A whole column	3	10	0
A page	10	0	0

An average line contains 10 words.

All remittances by Post Office Orders must be made payable to the British Medical Association, 429, Strand, London, W.C. No responsibility will be accepted for any such remittance not so safeguarded.

Advertisements should be delivered, addressed to the Manager, 429, Strand, London, not later than the first post on Wednesday morning preceding publication, and, if not paid for at the time, should be accompanied by a reference.

NOTES.—It is against the rules of the Post Office to receive *post restante* letters addressed either in initials or numbers.

CLINICAL ASPECTS OF TYPHUS FEVER:

OBSERVATIONS ON SOME 2,000 CASES IN
A PRISON CAMP IN GERMANY.

BY

MAJOR P. C. T. DAVY, M.B.LOND., R.A.M.C.,

AND

CAPTAIN A. J. BROWN, R.A.M.C.(S.R.).

We were captured on August 26th and 27th, 1914, and were kept in various prisons with other British officers, without being employed in our medical capacity, until February 11th. On this date we were sent to Gardelegen, and made our first acquaintance with a *Kriegsgefangenen Lager* for non-commissioned officers and men.

THE CAMP AT GARDELEGEN.

The camp at Gardelegen is situated in an opening amongst pine forests, on a gentle slope facing north-west. The soil is excessively sandy, and is in winter a sea of most appalling mud, and in summer a perfect horror of dust.

When we arrived there was about a foot of snow on the ground, and this continued with scarcely any intermission until the middle of April.

The camp occupies an area of about 350 by 550 yards. It is surrounded by a triple fence of barbed wire about 8 ft. in height. Within, the camp is divided in two equal parts, known as the first and second battalions. Each battalion is again subdivided into four companies. Each company is 230 metres (252 yards) long and 52 metres (57 yards) broad. In each company there are two rows of three barrack rooms, built facing each other. Each room is intended for 300 men. Each company is quite self-contained, with its own administrative staff of officers and under officers. The prisoners of one company can see and even talk to those of another, but they are separated from each other by barbed wire fences, and in normal times do not leave their company. Each of the two battalions has its own cookhouse, where the preparation of the food is done by the prisoners, assisted by some German women.

The total number of prisoners is between 11,000 and 12,000, made up chiefly of Russians and French, the latter slightly predominating; and include about 800 or 1,000 Belgians and 230 British prisoners.

At the upper end of the camp is a hospital which contains 200 beds. It is grossly overcrowded even in ordinary times; and allowing even the minimum cubic space per patient, it should not have contained more than 90 beds. The dimensions of a ward containing 62 beds are: Length, 25 metres (=27½ yards); breadth, 10.5 metres (=11½ yards); height, 2.80 metres (=3 yards).

Conservancy.

Each company has its own latrine and urinal under one roof. These are permanent latrines, built over trenches about 7 ft. deep with boarded sides. They are emptied at irregular intervals by hot air suction pumps into tank carts. The hand system of emptying into carts is also employed as a supplementary measure. The entire supervision and management of these latrines is erratic in the extreme. It is a frequent occurrence for a latrine to overflow and its contents to foul a large area of ground around.

Water Supply.

This is drawn from the main supply of the town. It is pumped to a water tower and distributed by pipes. Wells have also been dug, but are generally out of action for various reasons. We were informed that a bacteriological analysis of the water was made weekly. The water supply is very insufficient even in winter. The supply is cut off most days from 10 a.m. until 3 or 4 p.m. in the hospital, and the supply in the rest of the camp is even more precarious.

Abution.

In each company are one or two stand-pipes leading to troughs used for personal abution, washing of clothes, and washing of eating utensils. There is also one bath-house

for the entire camp, in which are twenty-four shower jets. The number of men who could pass through this place in an ordinary working day is never large, and there are many days on which for some reason or other the apparatus is not working. The men could occasionally get a small handful of soft soap on entering the baths. Inquiries showed that no man could go to the bath unless he was detailed to go, and many men waited for more than one month—some nearly three months—till their turn came round. It is only fair to say that, recognizing the gross inadequacy of the bathing facilities, the Germans hastily erected, towards the end of the epidemic, a second bath-house, with a dry heat disinfecter attached.

Barrack Rooms.

The dimensions of these buildings are: Length, 65 metres (= 71 yards); breadth, 10 metres (= 11 yards); height, 2.80 metres (= 3 yards); giving a cubic space of 1,820 metres. Each barrack accommodates 300 men, giving approximately 6 cubic metres a man (= 21.87 cubic feet a head). The barracks and camp generally were lit by electric light. Ventilation is carried out mainly by doors and windows, and is very defective. The prisoners live in an atmosphere of fetid warmth. Each barrack room is divided up into two parts, and each half is heated by a closed stove. The men sleep on palliasses on the ground in four rows—the palliasses nearly touching. No tables or chairs are provided. Each man gets a small enamelled bowl and a spoon, and a larger bowl for washing purposes, and a towel.

There is a plentiful supply of blankets, and the men do not appear to have suffered from cold in their rooms last winter.

The four nationalities are distributed as far as possible in equal proportion in every room. Very stringent orders were issued to ensure that English and Russian prisoners should always occupy the same rooms together.

Meals are usually as follows:

From 6 to 7 a.m.: A black liquid which claims to be coffee, accompanied by the slice of bread which forms each man's daily allowance.

From 11 to 12 noon: Soup made with meal, barley, potatoes, or preserved vegetables, and a suggestion of meat or fish. Each man gets about two pints of this.

From 4 to 6 p.m.: A soup of watery consistency in similar amounts.

In June the amount of bread was reduced to 250 grams a head a day.

The foregoing brief description of the camp is necessary for a proper understanding and appreciation of the conditions which obtained when the epidemic started.

THE EPIDEMIC.

The earliest cases of typhus which occurred were mild and atypical, and had undoubtedly been unrecognized. There was at this time a large number of cases of scarlet fever and of acute tonsillitis with anomalous rashes. When typical cases occurred, a few days after our arrival in the camp, a commission of German doctors came, to whom our French colleagues and we showed the cases which had aroused our suspicions. These cases were at once pronounced to be typhus. Immediately the camp was declared to be in quarantine, and every German officer, under officer, and man was withdrawn. The locked gates between the various companies were opened, allowing the prisoners to circulate freely anywhere within the camp limits. It will thus be seen that any hope of limiting the outbreak to the companies from which the first cases came was instantly destroyed.

In the hospital the German doctor remained in charge till he contracted typhus a few days later. He quickly succumbed to the disease. All the German hospital orderlies were withdrawn from the onset, and thereafter the sick were nursed by their fellow prisoners.

CLINICAL ASPECTS.

Etiology.

The case against the body louse as the carrier of the disease appears quite clearly established as far as clinical observation can make it. The lice swarmed everywhere in the camp; it is not too much to say that every prisoner in the camp was infested with them. On the other hand, there was a singular immunity from other parasites. We never once saw fleas or bugs. The transference of lice

was facilitated by the gross overcrowding and the lack of facilities for personal cleanliness. The mixing of the nationalities in the rooms of course led to a nearly equal race incidence. The general power of resistance was considerably lowered by malnutrition, confinement, and mental depression. There is some vague but interesting evidence for the influence of mass dose infection, in the heavier incidence and case mortality amongst those most exposed to infection. These were seen in the following order: First, sick attendants; secondly, doctors; thirdly, prison population generally.

Age.

The average age of the population was probably 29. It must be remembered that the prisoners were nearly all reservists in their armies. Apart from a few Belgian civilians there were no persons of the extremes of life. We found, however, that the prognosis was distinctly graver in persons over 40, of whom there were considerable numbers in the camps. Most of the material for statistical purposes was taken by our captors, so we are unable to substantiate this, and many other statements, by figures. They must therefore remain largely the impressions we formed from a study of some 2,000 cases.

There is no evidence that the infective agent is carried by any of the dejecta. The twelve doctors in the camp who contracted typhus were all nursed by the same six orderlies. The period of attendance of these orderlies lasted in all over three months; their personal precautions in the handling the dejecta were of the scantiest, yet none of these attendants contracted the disease. The explanation that occurs to us is that they nursed their patients in separate huts, and they and their patients remained for the whole period lice-free.

The case incidence amongst the orderlies employed in the hospital where lice swarmed was excessively high, as will be seen below. There is further evidence against the infectivity of dejecta in the fact that several patients remained in hospital for long periods, suffering from other diseases, but nursed by the same orderlies as attended the typhus cases, yet these in all cases escaped the disease, as long as they were protected from lice. We found evidence that the infective agent resides in the body for at least three weeks after defervescence. Fresh outbreaks occurred when patients were returned to their companies after the three weeks' period, though they and their clothes were disinfected and were presumably lice-free. When this period of isolation was extended to one month, recrudescence of the epidemic in the companies of these returned patients did not occur.

Incubation Period.

Our observations on this point show it to be extremely variable. From the two fresh outbreaks mentioned above it would seem to be from seven to twelve days. One doctor contracted the disease fourteen days after entering the camp, another sixteen days after, a third twenty-one days after, and this was the longest period which could be accurately fixed.

SYMPTOMS.

The onset is sudden and fairly well defined, but the severity of the initial symptoms is variable. The most constant are general malaise, cold shivers, headache generally confined to the frontal region, and tenderness of the eyeballs. A definite rigor is extremely rare in our experience. Coupled with the above is a sense of lassitude and faintness; our French patients invariably described themselves as "complètement courbaturé." In many cases the patient is suddenly seized with general convulsions which subside into a fairly active delirium; these cases were not by any means always of bad prognosis.

Epistaxis at some time in the course of the disease is extremely characteristic. We were accustomed during the epidemic to regard this as pathognomonic. In more than half the number of cases in which it occurs it is seen in the first three days of the disease and is often very profuse and persistent. In the remainder it occurs between the middle and end of the pyrexial period.

Early Symptoms.

In speaking of the early symptoms, an important practical point is the correlation of the pulse-rate and tempera-

ture. One of us (A. J. B.) kept a careful record of pulse-rates and temperatures of those men who reported sick in their barrack rooms. It was found that at the hour that these men were seen (from 9 to 10 a.m.), many presented for one, two, or even three days the symptoms of headache with rapid and increasing pulse, whilst the temperature was normal, the evening rise of temperature not being observed. It was possible to make a provisional diagnosis and isolate these cases, which, with very few exceptions, proved to be typhus.

Table I gives some cases illustrating this point.

TABLE I.—To illustrate the Correlation of the Pulse-rates and Temperature in the Early Days of the Disease.

	Day of Illness.	Temp. C.	Pulse.	Symptoms.
Patient No. 232	2nd	36.8°	98	"Courbaturé," headache.
	3rd	37.0°	120	As above.
	4th	36.6°	116	"Courbaturé," headache better.
	5th	38.0°	130	Very ill; rash on abdomen.
Patient No. 390	12 hrs.	37.2°	72	General malaise.
	2nd day	36.8°	100	Headache, etc.
	3rd "	37.0°	92	No headache; still "courbaturé."
	4th "	37.2°	110	As above.
	5th "	36.4°	116	Headache, "courbaturé."
	6th "	37.4°	128	Rash, epistaxis, headache.
Patient No. 228	2nd day	36.4	120	"Courbaturé."
	3rd "	37.0°	132	As above.
	4th "	36.8	128	As above.
	5th "	37.2°	140	Rash, "courbaturé," headache.
Patient No. 265	3rd day	37.0°	116	Headache.
	4th "	36.8°	98	Feeling better.
	6th "	37.5	126	Headache, epistaxis, rash.

In the first three or four days of the disease congestion of the conjunctivae and occasionally swelling and redness over the malar eminences are seen. Later, slight nasal discharge with obstruction in the nasal passages is very commonly noticed. Subjectively, a sensation of congestion of all the air sinuses is common.

Temperature.

In most typical cases there is an initial rise with morning remissions and a characteristic saddle-back fall on the third or fourth day; thereafter there is a rise with the onset of the rash to 103° or 104° with very slight remissions till the thirteenth or fourteenth day, when the temperature falls by a not very abrupt crisis (see Fig. 1). Fall by lysis during the eleventh, twelfth, thirteenth, and fourteenth days is also seen (see Fig. 2). In both cases there is often a slight reactionary rise at the beginning of the convalescent period.

Hyperpyrexia was never seen. Cases with a low irregular temperature throughout and marked asthenia were generally of very bad prognosis.

Prodromal Rash.

We saw occasionally what we regarded as a prodromal rash (P.C.T.D.). It appears on the backs of the wrists and exterior surface of the forearms as a vague but definite mottling resembling much the mottled skin of the young infant. It is seen twenty-four hours before the typical rash appears, is very transient, and is often quite gone before the main eruption is seen. It is generally an indication that the subsequent rash will be profuse.

The Eruption.

The typhus eruption appears usually on the fifth day. We saw it rarely as early as the third and as late as the seventh day.

It first appears on the upper abdomen and thence spreads upwards and downwards. Its usual limits are the level of the nipples above and the intertrochanteric line

below. The rash is indeed often well developed in the region of the hip-joints. Very rarely indeed does it appear as high as the neck and down to the calves of the legs. The face always escapes.

The rash is somewhat polymorphic. Degrees of intensity of eruption varying from seven or eight ill-defined macules, and so transitory as almost to pass unnoticed, up to a profuse morbilliform grouping are seen. In every case the macule becomes hæmorrhagic within twenty-four hours of its appearance. Macules vary in size from that of a pin's point to 3 mm. in diameter. We looked in vain for anything in size or colour justifying its ancient appellation, "mulberry." The macules when matured are reddish-coppery colour, and leave a copper stain for from three to five days. A fairly profuse, very fine desquamation is the rule during convalescence.

As the disease progresses a slight cough is present in nearly every case, accompanied by thin mucopurulent expectoration, which is often of fetid odour.

In the multiplicity of smells which pervaded the hospital we were unable to detect any characteristic odour of the disease. The tongue, coated with white fur in the first twenty-four hours, quickly develops a central brown band; later it is wholly brown and dry, and accompanied by

exceeds perception to watch contact. It is apparently of the conductive order. It seldom appears before the eighth or ninth day. It is in no way dependent on the mental state; indeed it is seen in its most marked form in those whose minds remain clear throughout.

It often persists well into the third week of convalescence. It is not dependent on suppurative otitis media (of which we speak later). As far as we could see, the hearing always completely returns.

Delirium occurs at some time in the course of the disease in about 75 per cent. of the cases. It is usually active and often extremely violent. Persistence and violence of delirium is generally of grave prognosis. It may persist after the temperature reaches normal. Real mania is occasionally seen, accompanied by hallucinations of sight and sound. It is of interest to note that hallucinations were often connected with the "fighting line."

Types of the Disease.

It is a disease difficult to classify into types. All degrees were seen, from the very slight larval form to those with initial symptoms of extreme gravity and a fatal termination on the eighth or ninth day.

Cerebral Type.—This is perhaps not happily named, as

Fig. 1.—n, Itash.

Fig. 2.—n, Rash; D, delirium.

sordes and general oral sepsis in an extreme degree. One of the earliest signs of a favourable turn in the disease is a moistening and cleaning of the tongue.

In a typical case of moderate severity the initial headache grows more intense and persists till the eighth or ninth day, when delirium usually supervenes and the patient does not complain of headache in his lucid intervals. The patient becomes weaker, the tongue is with difficulty protruded, the hands tremulous. With the full development of the rash he is usually in what may be called the "typhus state." The following table contains an attempt to contrast this with the "typhoid state":

Typhus State.

Typhoid State.

- | | |
|---|--|
| 1. Is not commensurate with physical weakness. | 1. Is commensurate with the physical weakness. |
| 2. A condition of mental inebriety and slow cerebration from which the patient can be roused. | 2. Cannot be roused when fully developed. |
| 3. A vacant stare, tendency to divergent squint, and a condition which is best described by the expressive French word "abrutissement." | 3. A more profound stupor. |
| 4. A delirium more active and often violent. | 4. Low muttering delirium. |
| 5. Appears early in the course of the disease and develops quickly. | 5. Appears later and develops more gradually. |
| 6. Often accompanied by evidence of cortical irritation, itching, and hyperaesthesia. | 6. Not so. |

Deafness is another symptom which we observed in certainly more than 50 per cent. of cases. This very often

the nervous system is affected to a greater or less degree in every case. The cases were of two kinds:

- One with very early delirium and slight convulsions, well marked cutaneous hyperaesthesia, incontinence of urine and faeces, resentment of examination or disturbance. Prognosis most grave of all.
- With early onset of mild delirium, early prostration, but with absence of other symptoms of (a). Prognosis quite favourable.

High-tension Type.—We have ventured to so name a certain type of case from its clinical appearance. It was not uncommon. It is characterized by absence of grave cerebral symptoms. The temperature is moderate. The headache is generally extreme, violent, and persists throughout the entire pyrexial period. There is a sensation of intense discomfort in the maxillary and frontal sinuses, great tenderness of the eyeballs, and marked photophobia. There is no delirium, but the patient is mentally very irritable. The pulse-rate is relatively very slow throughout, but is very full and bounding. A chart characteristic of this type is shown in Fig. 3.

Abdominal Organs.—Taking the disease as a whole, neither diarrhoea nor constipation are the rule; perhaps the latter was most often seen. The spleen was rarely enlarged to palpation point, and then only in severer cases and in the later stages—that is, the twelfth to the fourteenth day. The liver is occasionally enlarged. A mild degree of jaundice was seen in some three cases—all fatal.

Urine.—Albumin is usually present, but disappears early in convalescence. Retention of urine to a degree needing catheterization is very rarely seen.

COMPLICATIONS AND SEQUELAE.

Respiratory System.—Hypostatic congestion was seen in a considerable number of cases, some of which terminated fatally; yet on the whole the lungs escape in a remarkable manner. As has been mentioned, the majority of patients have some slight cough and expectoration. In some cases there is a profuse secretion of viscid and extremely tenacious mucus. We recall two cases in which such grave obstruction was thus caused that the question of tracheotomy was seriously discussed.

Pyaemia.—One case terminated fatally with pus in the larger joints and multiple superficial abscesses.

Otitis media (suppurative) was extremely common. The intense oral sepsis which most patients exhibited (the result, no doubt, of our limited nursing facilities) is sufficient to account for this.

Suppuration of the parotid was very common for the same reason.

Cardiac System.—There is an extensive degeneration of all muscle tissue, and the heart muscle naturally does not escape. We found evidence of this to a greater or less degree in every case. During convalescence a pulse, intermittent and of persistent rapidity, was extremely common. Dilatation bruits were commonly heard. Syncopeal attacks frequently occurred, and we saw many sudden deaths in the early days of convalescence.

Fig. 3.—R. Rash.

Gangrene of the feet occurred in a few cases, and was invariably a fatal complication.

Bedsore unfortunately were frequent. The lowered vitality of all the tissues renders the patient specially liable to this complication.

Peripheral Neuritis.—A sequela distressing to the patient and difficult to deal with is a condition of peripheral neuritis which manifests itself as extreme painfulness and tenderness of the extremities. It is seen in the first or second week of convalescence. We met this condition very often, but never observed any accompanying trophic or circulatory change. It adds considerably to the discomfort of a patient already helpless from prostration. More rarely sciatica and neuralgia of the fifth nerve is seen as a late sequela.

Scarlet Fever coincident with Typhus.

We saw a few cases, all of which terminated fatally. Several cases of typhus supervening upon scarlet fever were seen, and several of these recovered.

PROGNOSIS.

From this somewhat formidable list the impression may be gained that typhus is a disease of many and grave complications. In our opinion this is not so. The vast majority of cases run an uncomplicated course. Given proper facilities for nursing and supervision, many of these troubles would be avoided or successfully dealt with.

The symptoms of grave prognosis we found to be early violent and persistent delirium, signs of cortical irritation, incontinence of urine and faeces, and well-marked jaundice. The intensity of the eruption was of

no prognostic value. The convalescence in the majority of cases was extraordinarily rapid and complete.

The mortality in our 2,000 cases was 15 per cent. The mortality-rate amongst the French and Belgian prisoners was the highest. Next came the British; there occurred 129 cases amongst the 230 British present in the camp, with a mortality-rate of 6 per cent.

The Russian mortality was the lowest. There is no doubt we were fortunate in having a milder type of the disease in our camp. Since our return we have learnt that in other camps—notably Cassel and Wittenburg—the mortality percentage was far higher.

There were 10 French abbés in the camp, all of whom volunteered their services as nursing orderlies, and displayed devotion and zeal beyond all praise. Of these, 8 (80 per cent.) contracted typhus, and 5 (62 per cent.) died.

There were 16 doctors of different nationalities in the camp. Of these, 12 (75 per cent.) contracted typhus, and 2 (16 per cent.) died.

The British soldiers employed as nursing orderlies numbered 22. Of these, 20 (91 per cent.) contracted typhus, and 2 (10 per cent.) died.

The figures for the French and Russian nursing orderlies we have not got; but they were practically the same as for the English.

TREATMENT.

The secret of the successful treatment of typhus lies (as with enteric fever) in the nursing of the patient. Force of circumstances condemned our patients to starvation diet, and they did well on it. Absolute rest in a recumbent position is essential from the onset; as is also the care of the mouth. Plenty of liquid should be given throughout the disease. Solid diet of the most easily assimilated character should be given as soon as the tongue begins to clean, at which moment a vigorous appetite usually asserts itself. The patient should be kept in bed until the pulse has been normal at least one week. In those cases in which special attention could be paid to the condition of the mouth, the ear and parotid, complications did not occur.

Our energies in the matter of medication were curbed by a scarcity and even lack of all but some four drugs—namely, calomel, aspirin, quinine, and Epsom salts. Generally speaking, two lines of treatment were attempted.

1. *Early and continuous stimulation*, mainly by hypodermic and intramuscular injection of camphorated oil, and to a lesser extent of strychnine and ether.

2. *Purely expectant and symptomatic*, combined with free use of morphine in every case in which it was not obviously contraindicated. Our preference was, and still is, for the second method. We are inclined to regard morphine as a sheet anchor in most cases, and we never had cause to regret its use. At any rate, it satisfies some of the Hippocratic injunctions.

In regard to the first line of treatment the immense crop of abscesses which resulted (in many of which the unabsorbed camphorated oil was evacuated) condemns it at once, in our opinion, in the absence of any perceptible beneficial result. A large number of cases were tried, on the recommendation of the Germans, with a 10 per cent. tincture of iodine t.a.s., increased gradually. No benefit was observed.

Prophylaxis.

As regards personal prophylaxis, a rigorous search of the clothing for parasites was made twice daily by all the hospital staff. As parasitocides, powders containing iodoform, camphorated oil, and various proprietary lotions, were tried, but with disappointing results. An outfit consisting of overalls with trousers tucked into gum boots, and rubber gannet gloves, would, we consider, make for practical immunity.

TRIBUTE TO FELLOW WORKERS.

In conclusion, we feel we must take this opportunity of placing on record our appreciation of the whole-hearted and harmonious co-operation of our Russian and French medical confrères. The work, both of organization and treatment, was divided up amongst us without distinction of nationality, though naturally the confusion of tongues (as far as our Russian fellow prisoners went) sadly hampered our efforts.

Further, the services rendered us by those British soldiers in the camp who volunteered to act as nursing orderlies,

will not soon be forgotten by us, nor by the patients they tended so devotedly. Knowing the risks they ran they were indefatigable in their efforts for their comrades—British, French, and Belgians alike. The toll they paid for their devotion is shown in the figures we give above.

ON THE RECRUDESCENCE OF LOCAL SEPSIS IN COMPLETELY HEALED WOUNDS

AS THE RESULT OF SOME SURGICAL INTERFERENCE
OR PASSIVE MOVEMENT.

BY

R. H. JOCELYN SWAN, M.S. LOND., F.R.C.S.,

SENIOR SURGEON, ROYAL HERBERT HOSPITAL, WOOLWICH; SURGEON
TO THE CANCER HOSPITAL, S.W.;

AND

KENNETH GOADBY, M.R.C.S., L.R.C.P., D.P.H. CANTAB.,

BACTERIOLOGICAL SPECIALIST, ROYAL HERBERT HOSPITAL,
WOOLWICH.

(A Report to the Medical Research Committee.)

IN an article published in the BRITISH MEDICAL JOURNAL of September 25th under this heading by Colonel C. J. Bond, R.A.M.C., various questions are raised involving the power of organisms to remain dormant in the tissues, and to become suddenly active after some slight surgical interference. This problem has also impressed us, and in a long series of cases routine bacteriological examination has been undertaken of the tissues surrounding fragments of shell, shrapnel bullets, etc., which have remained imbedded in the body for varying times, but in which the wound of entrance has healed. In such cases it has become necessary to remove the fragment owing to pain or other cause. Two conditions are found:

1. The fragment is enclosed in a cavity lined by a smooth wall, and containing a glairy, mucoid fluid.
2. The fragment is tightly surrounded and adherent to the tissues, with no surrounding fluid.

Bacteriological examination was made from the fluid or from the fragment itself, including pieces of cloth carried in with the fragment. In a case under our care organisms have been obtained in pure cultivation from a piece of cloth carried into the wound, without any signs of surface suppuration.

The routine method of examination in all cases was as follows: Swabs were made from the incision before the foreign body was exposed, and from the cavity after exposure. Any fragment of cloth was removed intact to a sterile tube. Films were made from the material and stained by Gram's method and counterstained, and by Giemsa. Cultivations were made on (1) glucose formate broth; (2) egg broth recently boiled, with a layer of paraffin (anaerobic); (3) stab cultures on gelatin. The cultures obtained were plated out under aerobic and anaerobic conditions, and the organisms subsequently tested.

The aerobic and anaerobic organisms were thus determined, and in some instances anaerobes only were isolated.

The following cases illustrate the fact that organisms may remain for a considerable time in the vicinity of the foreign body without giving rise to constitutional symptoms.

CASE I.

Private W. M. M. was wounded by shell fragments on November 2nd, 1914, one entering just below level of right knee-joint on the outer side of the tubercle of the tibia. The wound healed at once and had never discharged. Several months later the patient began to be conscious of pain on kneeling or upon pressure on the outer side of the knee-joint. Radiographic examination demonstrated a fragment of shell casing embedded in the outer condyle of the tibia, $\frac{1}{2}$ in. from the articular surface. On August 9th, 1915, the fragment was removed by rephrasing the outer condyle of the tibia. There was no pus or fluid around the fragment, but attached to it was a small piece of cloth. This was removed and immediately dropped into a sterile tube. The wound was flushed with saline, and closed by suture; healing occurred by primary union.

Films failed to reveal the presence of any organisms. No growth appeared on any media for forty-eight hours, when gas formation took place in the glucose formate broth, and an organism identified as *B. proteus* was isolated in pure culture. This organism alone was present in the

anaerobic and gelatin cultures. The organism, moreover, agglutinated with the patient's serum in a dilution of 1 in 600. Normal man's serum gave no agglutination in 1 in 50. Culture from the incision was negative.

In cases in which mucoid fluid surrounded the fragment, *B. perfringens* (*B. welchii*), streptococci, and a large Gram-positive diplococcus, etc., have been found.

CASE II.

Lieutenant W. Shrapnel bullet wound of right shoulder, probably ricochet. External wound healed over. Six days after injury deformed bullet removed by incision. Bullet, not in contact with bony surface, was surrounded with mucoid fluid. Films showed numerous cells, mostly mononuclear, but no organisms. The aerobic cultures gave no growth. Anaerobic cultures, on the other hand, gave a growth of Gram-positive, non-motile bacilli conforming to the type of *B. perfringens*. The wound healed without complication.

CASE III.

Lieutenant R. Multiple small shrapnel case fragments in right shoulder. External wound healed. Fragments in closed cavity, surrounded by thick cartilaginous granulation tissue. No pus or fluid. Films showed a few cells of mononuclear type and a few Gram-positive cocci. Aerobic cultures gave no growth after seven days. Anaerobic cultures gave a growth of large Gram-positive cocci only.

These cases serve to show that organisms may remain dormant without causing clinical symptoms, and at the same time explain the lighting up of local inflammation long after the external wound is healed.

The recrudescence of local sepsis in healed wounds is by no means infrequent, and we have observed many instances, of which the following are examples:

CASE IV.

Lieutenant D. Motor accident on June 28th, 1915, when he sustained comminuted fracture of the lower end of the left femur. One sharp spicule pierced the upper pouch of the knee-joint and the skin immediately above the patella. There was also an oblique fracture of the left tibia and a simple fracture of the left radius. The area in front of the knee-joint was well scrubbed with iodine under an anaesthetic. On July 8th all the effusion into the knee-joint had disappeared. On August 12th the fractures were well united, but the patella was fixed to the articular surface of the femur and lateral movement of the patella was begun. On August 14th there was tense effusion of the knee-joint. On August 15th fluid was drawn off into a sterile tube. The fluid separated into three layers—an upper clear yellow fatty, a middle red clear, and a lower purer. Smears from the lowest layer showed numerous streptococci and diplococci, very few of them within the pus cells. The organisms stained well, and showed no signs of plasmolysis. A pure culture of a long-chained streptococcus, growing best under anaerobic conditions, was obtained.

These streptococci had evidently gained entrance to the knee-joint at the time of the fracture, but had remained dormant until lit up to an acute process by the simple expedient of breaking down the adhesions between the patella and the femur.

CASE V.

Private G. A. Severe gunshot wound of lower right arm on May 5th, 1915, with compound fracture of the humerus 12 in. above the lower articular surface. On May 9th the wound was opened under an anaesthetic. It was very septic and foul-smelling; several pieces of bone and cloth were removed. The fracture was comminuted, extension was applied, and the wounds thoroughly drained. Bacteriological examination made at the operation showed the presence of a large number of organisms in the pus: Gram-positive bacilli, a few with spores of clostridial form; Gram-negative bacilli, fine and slender, with oval terminal spores; Gram-negative diplobacilli; and Gram-positive cocci. The aerobic cultures gave *B. proteus*, streptococci, and staphylococci. The anaerobic cultures gave a large number of motile bacilli, Gram-positive, with oval central spores staining irregularly by Gram's method. Many free spores were also present. Gram-positive bacilli, non-motile and capsulated, were also found. In addition, many long-chained streptococci were observed. The bacillus of malignant oedema—*B. perfringens*, and an organism similar to *B. rodentia 3*—were isolated anaerobically. The wounds were merely covered with layers of sterile gauze soaked in peroxide, and oxygen passed in with it. On May 31st, as the fragments could not be retained in alignment, a vertical incision was made through the triceps, the ends freshened and wired together. On August 15th, the wounds being entirely healed, there being little movement of the elbow-joint, the elbow was moved under an anaesthetic, which was followed next day by diffuse inflammation about the joint, requiring surgical incision. Again, on August 30th, passive movement in the joint produced intense inflammatory reaction.

CASE VI.

Private K. Wounded November 6th, 1914, in the anterior aspect of the right thigh. Femur fractured. December 5th, on admission, there was a small depressed sinus in middle of thigh discharging foul pus. On December 9th the sinus was opened through wound in front of thigh, and a counter opening made. In thirty-six hours the thigh was much swollen and there was a discharge of thick serous fluid, which contained a large number of sporing bacilli and bubbles of gas. The wound was freely opened, and the muscles in the centre of the sinus were found blackened and semi-digested. A portion of this tissue was examined microscopically. The individual muscle bundles were burst, semi-digested, and large numbers of spore-forming organisms were seen tightly packed between the muscle bundles, and actually passing into and invading the muscle fibres themselves. Surrounding the larger collections of bacteria, the tissue was transparent and hardly took up the stain at all. Practically no pus cells were seen. The sporing organisms were isolated in pure organism of the bacillus of malignant oedema. An culture and identified as the bacillus of malignant oedema. An organism of the *proteus* type was the only other organism isolated, although a few capsulated Gram-positive organisms were observed in the original films. Within three days of the operation the patient's haemoglobin had fallen to 40 per cent., and he was acutely ill, but finally made an excellent recovery. The wounds were treated throughout with hydrogen peroxide, covered by a thin layer of gauze soaked with peroxide, and oxygen constantly passed into the wounds. The limb was ultimately useful, though somewhat shortened.

In this case the bacillus of malignant oedema had apparently lain dormant for nearly five weeks, but was activated by the incision to provide adequate drainage. Bacteriologically this case suggests symbiotic activity between the bacillus of malignant oedema and the *B. proteus* or *B. perfringens*.

Another type of case, such, for instance, as Case IV and possibly Case V, owes its peculiar features to a process analogous to anaphylaxis; the tissues, having originally been subjected to constant doses of bacterial poison, are, after an interval, subjected to an anaphylactic dose of the original poison.

OBSERVATIONS ON
THE TREATMENT OF WOUNDS IN WAR.

By Dr. J. TISSOT,

SURGEON TO THE HÔTEL-DIEU, CHAMBERY, FRANCE.

[Translated for the "British Medical Journal" by
Dr. A. S. GUBB, Aix-les-Bains.]

FROM the first I instituted the following treatment: The only dressing employed was the aseptic. The material for dressings—gauze and absorbent cotton—is autoclaved in special tin boxes of limited capacity, which are only opened when required. The ordinary cotton and carded peat for padding splints and the cloths for covering the field of operation are sterilized in the same way. The gauze compresses and cotton bandages are taken out of the boxes with sterilized forceps.

Instruments to be used at operations are sterilized in a Popinac sterilizer, as are those for use in dressing wounds; the drainage tubes are boiled in a solution of borax. All antiseptic solutions are made with boiled water.

Before being dressed every wound is cleansed by washing with an antiseptic solution: dilute hydrogen peroxide, 1 in 1,000 solution of potassium permanganate, 50 per 1,000 solution of carbolic acid, or a 7 per 1,000 solution of salt. The neighbouring skin is freely painted with tincture of iodine (1 in 20).

It is now many years since I gave up using antiseptic dressings—carbolic or boricated cotton, or iodoform, salolized or mercury perchloride gauze—on account of the drawbacks attending their use: painful erythema round the wounds, excoriations consequent upon outbreaks of medicinal eczema, iodoform poisoning, etc. Injurious to the animal cell, hindering the natural processes of healing and organic defence, antiseptics should only be employed within very narrow limits.

Rapid complete disinfection of the wounds, after free opening up, with antiseptic solutions and a dry aseptic dressing, has been my rule of conduct throughout.

Early and free laying open of all war wounds, more particularly those inflicted by fragments of shell, drainage with simple or perforated tubes, according to their length. In the neighbourhood of vessels as few dressings as possible—these also are rules that have been rigidly adhered to.

As soon as supuration begins to diminish the drains are removed, and directly the sloughing tissues have been eliminated and the wound takes on a healthy aspect, washing with saline solution is substituted for antiseptic solutions.

Tetanus.

During the first few months of the war we had several cases of tetanus, but such cases have become excessively rare since injections of antitetanic serum have been systematically given at the front. I give a second injection eight days after the first.

Gaseous Gangrene.

I have pretty frequently met with cases of gaseous phlegmons which all had a favourable termination after free opening up, and the extraction of projectiles and débris of clothing.

The three following cases, which came from the front in the same train, are of interest in that they exemplify what may be termed the fulminating form of this infection, in contradistinction to the cases in which the decomposition of pus in partially closed cavities or pockets determines a variable amount of subcutaneous emphysema. To put it plainly, all cases of infection, or even gangrene associated with gas formation, are not cases of gaseous gangrene. The latter term should be reserved for instances of deep, rapidly spreading, rapidly fatal infection. Unfortunately the stress of war is such that it is hardly practicable to devote much attention to the bacteriological aspect of the question, but clinically there is every difference between the real cases of gaseous gangrene and the comparatively mild infections in which there may be some gas formation. My experience is that in the grave form no treatment is of any avail, since death follows in from six to twelve hours after the supervention of the earliest characteristic symptoms of the affection.

These three cases all came from the same corner in Champagne (Souain), and, as might be expected, the infection is particularly apt to occur in subjects who from force of circumstances have been left for many hours, or possibly days, on the ground without medical aid. It is not, however, confined to such cases, for there are instances of its occurrence in men whose wounds were attended to promptly.

CASE I.

A. G., a volunteer, received his wound in the grand offensive of September 29th, and was dressed two hours later at the *poste de secours*. He presented an enormous contused wound involving the left calf and popliteal space, in addition to a seton wound of the left shoulder by a fragment of shell. He received an injection of antitetanic serum on September 29th. He came under my care on October 2nd. On the evening of October 3rd the wound showed signs of gangrene. The tissues were swollen, of a dark colour, and on pressure they crackled with subcutaneous emphysema was felt. The limb was at once amputated through healthy tissue, but the disease rapidly spread, and he died on the following afternoon.

CASE II.

This man was a German soldier, wounded in the same fray on September 27th. He was admitted under my care on October 1st. He had a very extensive lacerated wound on the outer aspect of the right arm, with fracture of the humerus; also a contused wound of the left hand, entailing the loss of the index and middle fingers. A gutter had been ploughed in the region of the right olecranon. Resection of the elbow-joint was forthwith performed; within a few hours symptoms of gaseous gangrene set in, and, in spite of extensive incisions and the application of antiseptics, he died thirteen hours later.

CASE III.

C. C., wounded on September 28th, was admitted on October 2nd. As he had fallen in a spot which was constantly swept by the enemy's fire, it was not found possible to bring him in for forty-eight hours. He presented a seton wound by bullet of the left thigh, fracturing the femur, also a deep excoriation of the left hand, there was already some gaseous formation round about the wound, and amputation was performed high up the thigh, through apparently healthy tissue. The gangrene, however, spread upwards, distending the scrotum and penis, and proved fatal within a few hours.

It was noted that these patients, far from feeling depressed or ill, experience a curious impression of comfort and well-being which persists to the moment of death.

In two other cases amputation of the thigh in the first, extensive incisions and injections of hydrogen peroxide, etc., in the second, proved ineffectual. Both patients died in six or eight hours with abdominal distension, intestinal haemorrhage, and the euphoria peculiar to this affection.

Sepsis and Septicæmia.

Although now and then we do meet with bullet wounds that remain aseptic, the fact remains that almost every wound is infected and that wounds by fragments of shell or bomb contaminated by debris of clothes or soil are the most septic. The practically constant infection of war wounds necessitates as prompt disinfection as possible of such wounds. The fact that nowadays we get vastly fewer cases of major sepsis than at the beginning is no doubt to be explained by the better organization and more rapid access to the surgical services.

Wounds of Joints.

Early arthrotomy, lavage with 50 per 1,000 carbolic water, followed by irrigation with saline solution and drainage, has been my rule, and its application has yielded me numerous successes, especially in penetrating wounds of the knee. The most rapid recoveries have been those in which the synovial sac was found to contain a rather turbid blood-stained fluid. In such cases we are justified in anticipating complete restoration of articular functions.

In presence of suppuration of the joint, especially of the elbow, resection of the articular surfaces is indispensable. The same remark applies to the shoulder and wrist. A properly performed resection under these conditions yields a better and more rapid result, with less risk for the patient, than the freest arthrotomy. Amputation is a last resource when the infective complications do not yield. I have been constrained to have recourse thereto several times for suppurating arthritis of the knee, and once in arthritis of the elbow.

Amputations and Disarticulations.

I have only performed a small number of amputations, in every instance on account of grave septic mischief or extensive lacerations. After ligation of the vessels I always employ copious lavage of the raw surfaces with a very hot solution of carbolic acid (50 per 1,000); then I drain and suture the stump.

I have had to deal with numerous cases of open stumps set back from the front. It is difficult to express an opinion on this method, which was brought into practice by Verneuil some forty years ago. Verneuil used to keep the stump under carbolic spray. Rapidity of execution, the opening up of all suppurating pockets, and the rapid escape of fluid are the advantages of this method. The drawbacks, on the other hand, are: secondary resection of the stump is often rendered necessary by the projection of bone affected by proliferating osteitis, huge osteophytes, prolonged suppuration, painful cicatrices adherent to the bone, frequent ulceration, and so on. Here I should like to mention, apart from the secondary operations, the excellent results I have obtained by the aid of heliotherapy in hastening the healing of these extensive raw surfaces. It seems to me, moreover, that the scars following heliotherapy are softer and less painful.

As for "sausage amputation," judging from the few cases of the kind that have come under my notice, I hold that it is an unsurgical method, which ought to be abandoned.

Wounds of the Integuments of the Skull.

Every wound of the scalp in war surgery, whether complicated or not, should be incised down to the bone, and the latter must be carefully examined. When exploratory incision of the scalp proves negative the intervention is but trifling, one which, done under aseptic precautions, cannot possibly injure the patient. On the other hand, if we wait for cerebral symptoms to supervene before intervening, it is often too late. Here are a few instances in support of my contention:

CASE I.

L., wounded on July 16th at Eparges, admitted to the hospital on July 30th, after a sojourn in the Verdun Hospital. Apart from left facial paralysis, no cerebral symptom could be detected. His mind was quite clear. On examining the scalp I noticed a small scab in the left occipital region over an almost healed excoriation. An immediate exploratory incision was made. In the lower part of the left occipital bone I slighted upon a small cerebral hernia the size of a pea. There was no radiating fracture. I trephined and evacuated an abscess of the cerebellum, into which I was led by a small track opposite the orifice of entry, containing a teaspoonful of pus. We could not discover the bit of shell.

CASE II.

D., wounded on July 12th, at Eparges, in the left temporal region. When admitted to the hospital on July 16th he presented some incoherence of speech and mental confusion. I operated on July 17th. I came down on a fracture of the left temporal bone. After clearing with the gonge forceps and removing splinters, and following up an intra-cerebral track running obliquely upwards and forwards, I removed three splinters embedded in the cerebral substance and evacuated a small abscess of the left temporal lobe. Radioscopic examination was negative.

CASE III.

S., wounded on July 13th at Eparges. Admitted to the hospital on July 16th, coming from the Verdun Hospital. Independently of other grave sounds, I noticed a small contused wound in the left frontal region unaccompanied by any cerebral symptom. I operated immediately. Underneath the temporal muscle I found a small cerebral hernia the size of a pea. The frontal bone in the upper part of the temporal fossa was perforated, the hole being about the size of a lentil, clean cut. Having removed a piece of bone with the trephine, I followed a small track into an abscess of the frontal lobe, from which escaped a teaspoonful of pus. Drainage to the depth of over an inch was necessary. Radioscopic examination revealed the presence of a small piece of shell situated in the right side of the frontal lobe near the longitudinal sinus.

CASE IV.

This man was wounded on June 28th in the trenches of Calonne, and admitted to hospital on July 7th. There was a contused wound of the left frontal region. After ablation with the gonge forceps of a circle the size of a halfpenny-piece, we found underneath it a tuft of hair squeezed under the inner table, and numerous splinters. An abscess the size of a walnut was opened in the middle of the frontal lobe, and a small fragment of shell found in the centre of the abscess cavity was extracted.

All these patients are in a fair way to recovery. Such instances might easily be multiplied, confirming the formal indication for deliberate exploration of every contused firearm wound of the cranium, whether or not there be cerebral symptoms.

Disruption of Muscles.

Not infrequently a simple seton wound masks extensive muscular disruption, entailing grave functional impotence. Among others, the following instance may serve to illustrate the type: In February a wounded soldier was brought to me presenting a seton wound in the right pectoral region. The aperture of entry was situated below the clavicle, and the aperture of exit at the margin of the pectoralis major. As there was a blood-stained, fairly copious oozing, I joined up the two orifices under anaesthesia, and, on everting the margins, found the pectoralis major cut right through. It was the cut muscle that gave rise to the bleeding *en nappe*. I sutured the muscles, aponeuroses, and skin separately. Recovery rapidly took place, with perfect restoration of the shoulder movements. If suture of the divided muscles be not done, healing takes place with scar tissue and consequent functional impairment.

Secondary Union of Wounds.

More frequently than at the beginning we get wounded men presenting big gutters scored by bullets or by fragments of shell. When only the soft parts are involved, I consider it useful to unite these wounds by secondary union as soon as the sloughs have come away and the wound is looking clean and healthy. After freely reviving the edges I separate the aponeurosis from the skin; then I suture separately muscle, aponeurosis, and skin, leaving a small drain at each corner of the wound. More rapid recovery, a linear cicatrix, and less functional disturbance are the advantages of the method.

Damage of Nerves.

Damage of nerve trunks is of frequent occurrence during the present war. I have had quite a large number of such cases to deal with. Nerve trunks buried in scar tissue, embedded in the callus of a fracture, hypertrophies, often keloids of large size, notches or complete division, central haematoma, are some of the lesions I have met with. On two occasions I found the median nerve strongly adherent to the axillary artery in the armpit. In the first case the attempt to separate the two brought about a wound of the artery, which I was obliged to ligature, fortunately without causing any damage to the limb. In the second case I let the adhesion alone.

The nerve trunk most frequently involved was the radial, a fact which is explained by the frequency, especially during the first few months of the war, of fractures of the humerus.

Neurolysis is a protracted, delicate, tedious operation, lasting from an hour to an hour and a half. In order to discover the nerve it is better to tackle it in healthy tissue, following it up to the seat of damage. The anatomical relations have disappeared, the parts have changed aspect, and the search is often very difficult. I have invariably done my best to spare the smallest nerve fibre, and when the nerve is incompletely divided I join it up partially with every regard for the remaining fibres.

I only did complete suture in two cases of divided sciatic. The first was completely divided and the two ends, swollen and clublike, were 3 cm. apart. The second was three-quarters cut through, only a frail band remaining.

The results are usually long delayed, though they may be more rapid where the nerve is gripped by fibrous tissue; they are very long in becoming manifest when the nerve is completely divided.

Vascular Lesions.

Under the term "diffuse secondary aneurysmal haematoma" I described in the *Presse médicale* for February 11th of this year a special form of haematoma which only makes its appearance from three days to three months after the infliction of the wound. I have been called upon to operate in a fairly large number of these cases of haematoma, the clinical characters of which are: (1) delayed appearance; (2) sharp pain radiating throughout the limb, due to stretching of the nerve trunks; (3) anaemia varying according to the size of the haematoma; (4) apyrexia. The rule I follow is to open the pouch and tie the two ends of the damaged vessel after rapid removal of the clots. But in certain cases of large haematoma the anatomical relations are destroyed, while in others the ends of the vessels are shrivelled and undiscoverable, or, after removal of the clots, the cavity turns out to be very deep, so that it is impossible to apply the ligature. Under these conditions ligature of the artery above the lesion yields the best results.

Extraction of Foreign Bodies.

Among the numerous projectiles that I have been called upon to remove fragments of shell were the commonest, then rifle bullets and the round shrapnel balls. In one instance I removed from the calf a bit of wood 8 cm. long; in another, after opening up a very septic track in the buttock, I lighted upon a square-headed hobnail.

Shrapnel balls, and particularly fragments of shell, invariably cause septic wounds, because they always carry in bits of clothing. It is a common experience, when we are called upon to remove a splinter of shell a long time after the infliction of the wound—by which time the track of the missile has quite healed—to find it encysted in a pouch full of pus of very attenuated virulence. We must therefore proceed very cautiously when called upon to remove bits of shell or shrapnel balls lodged in or near a joint. The breaking down of the protecting adhesions in this case may determine suppuration of the part as a whole.

Bullets sometimes break up, especially when they strike a bone, or ricochet before entering the body. In such case we sometimes find the envelope of the bullet more or less torn open and fragments of lead disseminated in the tissues.

Among the interesting cases of projectiles which I have had to extract I may mention (1) a rifle bullet lodged behind the sternum opposite the third rib; one inside the hip-joint; two in the knee-joint; one in the elbow-joint; another in juxtaposition to the left axillary artery, under the pectoral muscle; (2) a bit of shell in the left pleura; a fragment of shell weighing 350 grams under the fractured left scapula, where it had lain twenty days; another between the two condyles of the femur in front; (3) a shrapnel ball implanted in the small trochanter, one in the knee, etc. I should like to call attention to the method of extracting projectiles under the radioscopic screen devised by Dr. Vullyamoz, which has been of the greatest service to me.

AUSCULTATION OF THE HEART OF THE RECRUIT.

By SIR JAMES KINGSTON FOWLER, K.C.V.O., M.D.,
CONSULTING PHYSICIAN TO THE MIDDLESEX HOSPITAL, ETC.;
LIEUTENANT-COLONEL R.A.M.C.(T) IN CHARGE OF THE
MEDICAL DIVISION, 3RD LONDON GENERAL
HOSPITAL, WANDSWORTH.

THE issue by the War Office of a memorandum on the significance of abnormal signs in the heart of the recruit, and the papers on that subject in the BRITISH MEDICAL JOURNAL of October 30th, 1915, suggest that possibly it may be of use to reproduce what I wrote thereon in an article on auscultation of the heart in *A Dictionary of Practical Medicine* in 1899.

I have made no alterations, but have omitted certain sections dealing with conditions unlikely to be met with in the recruit. The italics are in the original.

All murmurs should be timed by the carotid pulse, *not by their relation to the apex beat.*

Cardiac murmurs may be present without structural change in the valves or orifices, especially in anaemia and chlorosis, and when the action of the heart is excited.

Sounds closely resembling those resulting from organic disease of the valves, but really produced outside the heart, are of frequent occurrence, and are termed *false* or *cardio-pulmonary* murmurs.

The various conditions which may give rise to these murmurs may be classified thus:

1. Displacement of, or pressure upon, the heart, the result of disease of the (a) lung, (b) pleura, (c) thorax, or (d) abdomen.
2. Effusion into the pleural cavity.
3. Changes in the pleura of the praecordial area.
4. Changes in the lung overlying the heart.
5. Changes in the pericardium.

4. *Changes in the Lung overlying the Heart.*—... a systolic murmur about the apex of the heart which closely resembles the murmur of mitral regurgitation. The sound is caused by the impact of the heart upon the lung... producing an audible sound by displacement of the air in the bronchi... It is almost always most distinct during expiration, is superficial, high pitched, and disappears when the breath is held after a deep inspiration, and often becomes inaudible when the patient lies down. This murmur may sometimes be heard in the axilla and at the angle of the left scapula.

5. *Changes in the Pericardium.*—False murmurs, when due to chronic changes in that membrane, are frequently heard at one particular spot—namely, the sixth left interspace and over the seventh rib close to the base of the costal cartilage. Here the right ventricle is in contact with the chest wall, and it is on its anterior surface that the "white patch" is most commonly found. The sound produced by the movement upon each other of the pericardial surfaces at this spot is systolic in time, usually short, sharp, localized, and superficial; it seldom acquires a blowing character. In fact, it often resembles more nearly a rough reduplication of the first sound than a murmur. It is, perhaps, doubtful whether the altered sound, which is so commonly heard at this spot, is in all cases due to the presence of a "white patch" on the pericardium. It is especially common in emphysema with downward displacement of the heart. The effect of change of position upon this murmur is variable. It may disappear entirely when the patient is in the recumbent position, as often happens with friction sounds audible elsewhere over the heart, whilst at times it is hardly at all affected by such a change. When the heart is not displaced, a murmur presenting similar characters may often be heard in the fifth left interspace close to the sternum. Thickening of the pericardium of the left auricular appendix occasionally produces a rough systolic murmur in the second left interspace.

The following precautions should be observed in the examination of all cases presenting murmurs. Assuming that the presence or absence of these consecutive changes in the heart, which are almost invariably associated with disease of any given valve, has been noted, if there is still room for doubt, the following points must be observed carefully:

1. The exact period in the cardiac cycle occupied by the murmur. False murmurs are often not exactly synchronous with the commencement of systole or diastole; they may precede or follow the one or the other.

2. The site of maximum intensity and the line of conduction of the murmur. These do not usually coincide with what is found with similar murmurs of organic origin.

3. The condition of the lungs. With doubtful apex murmurs evidence of pulmonary engorgement is strongly in favour of organic valve disease, as that condition is almost invariably absent in the reflux of anæmia.

4. The effect of change of position upon the sound. *It is essential to examine every case of suspected valve disease both in the standing and recumbent position.*

It may be stated with confidence that an opinion given in a doubtful case without observing this precaution is of no value. Functional and false murmurs often disappear when the patient lies down, whilst an organic murmur, especially that of mitral stenosis, may be only audible in that position. A murmur which suddenly and completely disappears when the patient lies down, provided there is not at the same time any marked alteration in the pulse-rate, is almost certainly not due to organic disease of a valve.

5. It is important in all cases to auscultate the trachea. A murmur audible in the trachea may be due either (1) to the conduction of the murmur of aortic stenosis; or (2) to the impulse of an aneurysm; or (3) to the impulse of the heart causing an air wave in the bronchi and trachea, this latter being by far the most common cause of tracheal murmurs. Mitral murmurs are not audible in the trachea.

6. False murmurs often disappear completely when the breath is held.

7. The state of the pulse may at once negative a suspicion of organic disease founded on the presence of a murmur.

I am disposed to add that *it is essential to examine the heart of every recruit both in the standing and recumbent position.*

Experience gained in civil practice is not always applicable to military practice. The civilian, as a rule, stops when he feels that his work is overtaxing his strength; the soldier may be obliged to continue until he is ordered to halt or drops from exhaustion. Compensation which might have lasted for fifty years or more in civil life, may, in a soldier, be quickly destroyed by prolonged over-exertion.

I published many years ago in the *Clinical Society's Transactions* the case of a man with aortic stenosis and regurgitation and mitral regurgitation, changes due to an attack of acute rheumatism with endocarditis, which occurred when he was a boy aged 14, who had worked for fifty-five years as a turner in wood at a treadle lathe, without a day of illness, and in whom compensation was still well maintained. It does not, however, follow that it would have stood the stress of active service, at or about the age of 20, and still have lasted for such a long period.

A personal physical defect of which the soldier is unaware may be of little importance, but it may become of great importance when he has got to know of its existence.

Examiners of recruits who pass defects as of no importance, when all symptoms are absent, must be prepared to support their opinion when, at a later date, the defects are found to be unchanged but accompanied by many subjective symptoms.

TARTAR EMETIC IN KALA-AZAR.

BY

PERCIVAL MACKIE, M.D., M.R.C.P., F.R.C.S.,

MAJOR, I.M.S.; PATHOLOGIST AND SANITARY OFFICER, NO. 12 MEEBAT INDIAN GENERAL HOSPITAL, FRANCE.

My attention has been drawn to a letter on this subject from Lieutenant-Colonel Sir Leonard Rogers, I.M.S., in this *Journal* for July 31st, 1915. I have had a little experience of the antimony treatment of leishmaniasis which I will now briefly refer to.

CASE I.

The first case was that of an officer in the XIIIth Pioneers, who was stationed in Queita. He first noticed the disease when he was in camp at Christmas time, and it began in a deep fissure in the mucous membrane of the lip which had been caused by the cold dry wind then prevailing. It increased rapidly, and when I saw it was the size of a pigeon egg, and was painful, ulcerating, and very unsightly. He had had various kinds of treatment, including the application of CO₂ snow, but

the condition was worse rather than better. He also had a cyst-like swelling deep in the cheek, which had no visible communication with either the mucous or skin surfaces. This was punctured, and yielded *Leishmania* in pure culture, and the exudate from the ulcerating lip also showed these parasites, together with *Staphylococcus albus*. Treatment with intravenous injection of tartar emetic was begun on February 11th, 1915, and six injections were given at intervals of two days or three days, in doses of 4 to 6 c.cm. of a 1 per cent. solution in normal saline. The treatment was very successful so far as the cutaneous and subcutaneous part of the disease was concerned, but the mucous ulceration of the lip also showed some improvement only after several applications of carbon dioxide snow.

The officer was cured and shortly afterwards proceeded on active service.

There are three noteworthy points in this case:

1. The disease began in a fissure in the lip and apart from any exposure to insect infection.
2. The presence of a subcutaneous nodule due to *Leishmania* which had no discernible connexion with the outside surface. (Cases of this sort have been described, I think, in the Sudan.)
3. The good effect of antimony in rapidly sterilizing the cutaneous and subcutaneous lesion and its slower action on the mucous ulceration. (This has been noted by Terra.)

CASE II.

The second case of leishmaniasis which I treated with antimony injections was that of a native officer in the Gurkha Rifles. He seems to have contracted the disease in passing through an infected village in the Nepal Terai where he spent four days in returning from leave at the outbreak of war. It was an acute case of kala-azar with persistent high temperature, irritable heart, darkening of the skin and rapid emaciation. The spleen enlarged very rapidly, doubling its size in three weeks, and posture revealed *Leishmania* in that particular state which indicates rapid division and a high state of vitality.

He was going downhill rapidly, so I commenced intravenous injection of antimony tartrate, and gave him doses increasing from 4 c.cm. to 7.5 c.cm. of a 1 per cent. solution on alternate days. The treatment was begun on May 23rd, 1915, and continued till I left Queita on service about June 10th. The temperature shot up after the first two injections and fell rapidly to normal after the second injection. He had no more fever and the spleen began to recede and the general symptoms to abate. Without going into details as to his condition, I can say that in two and a half years' experience of kala-azar, I have seen no such promising result from any drug or any line of treatment. When I left for Europe he was improving, but I have heard nothing of him since. His blood state, according to Arneft's system of differential counting, was as follows:

	May 22, 1915.	May 25, 1915.	May 29, 1915.	June 2, 1915.	June 8, 1915.
White cells, in thousands ...	0.9	1.0	1.0	1.7	2.7
Basophiles	—	—	—	—	—
Eosinophiles	—	0.5	1.0	—	1.0
Neutrophiles— Myelocytes	—	—	—	—	1.0
Juvenile	2.0	4.5	5.0	2.5	2.5
Rod-nucleate	21.0	17.5	12.0	8.0	12.0
Segmented nucleate	29.0	39.5	36.0	14.0	19.0
Lymphocytes	30.0	29.0	34.0	12.0	38.0
Large mononuclears	18.0	9.0	12.0	113.0	26.0

* Before the first antimony injection.
† Fifty per cent. of decapsulated mononuclears.

The study of the blood bears out the general tendency to improvement which was so marked from the clinical side.

During the last two years tartar emetic has been used successfully in the treatment of leishmaniasis by Machado and G. Vianna (1913), Terra (1913), Cardina (1914), Da Silva (1914), Lapa (1914), Di Cristina and Caronia (1915).

In my opinion the credit for first using antimony tartate in leishmanial infection belongs to the Brazilian workers, Machado and Vianna, who used it in 1913 for cutaneous lesions, and to Di Cristina and Caronia, who, previous to February, 1915, used it in the treatment of Mediterranean kala-azar.

The Director of the Bombay Bacteriological Laboratory kindly arranged to provide me with capsules of 1 per cent. solution of antimony tartate sterilized by filtration, and he would, no doubt, supply it to others on application.

BILHARZIOSIS IN NATAL.

BY

F. G. CAWSTON, M.B., B.C.CANTAB.

ESTIMATES of the extent to which bilharziosis prevails in Natal vary considerably. It occurs both amongst natives and Europeans, and is more common amongst boys than girls. Those boys who learn to swim in the baths and avoid loitering in shallow streams seem to be less liable to be attacked, and since the attention of schoolboys has been directed to the dangers of the shallow rivers the disease has become less prevalent. Decomposing reeds abound in the shallow parts of these rivers, and in many cases these reeds are covered with snails. Acting on my advice the municipality of Pietermaritzburg, Natal, has removed these reeds from its popular bathing pool.

In a typical case the patient complains of a varying amount of blood in the urine, a certain degree of scalding on passing water, general depression, and anaemia. In a chronic case there may be the attendant symptoms of cystitis or calculus of the bladder. Symptoms of calculus are often present when none is to be found.

The miracidia can only live in fresh water. They soon die in water which has urine in it. This seems to disprove the theory of urethral infection by miracidia. The practice of washing out the bladder of uncomplicated cases followed by some practitioners seems to be due to the mistaken idea that the eggs hatched in the bladder, or even that it was the worm and not the miracidium that hatched out of the egg.

I had a patient under treatment for bilharziosis on May 10th, when my attention was drawn to the account of the life-history of *Haematobia japonica* in the BRITISH MEDICAL JOURNAL of January 30th, 1915. I therefore visited a favourite swimming pool and collected a number of snails (*Limnaea natalensis*) which abounded on the decomposing reeds at the shallow part of the pool. Microscopic examination of the snails revealed nothing abnormal in the liver or kidney, though several were infected in the foot with the ova of parasitic mites. Diluted urine was then added to the water in which some of the snails were kept. The water was changed on the following day and as frequently as necessary for the next few weeks. The results of experiments with snails from this bathing pool proved negative; but early in June Dr. Warren, the director of the Natal Government Museum, discovered undoubted cercariae with bifid tails in the liver of a snail (*Physopsis africana*) which is common in South African rivers, and which had been exposed to infection from urine supplied by another patient of mine four weeks previously. The appearance of these cercariae and the sporocyst in which they were contained corresponded to those illustrated in the BRITISH MEDICAL JOURNAL on January 30th, 1915.

Experiments are being conducted to demonstrate the possibility of infection by these cercariae. The evidence against infection by drinking infected water whilst bathing in infected streams is not conclusive. It is common for the small boys who loiter in these bathing places to complain of ulcerated skins, and it is quite possible that their opinion that infection can take place through these sores is well founded.

It is difficult to see what influence such drugs as male fern can have on the course of the disease. Complications may arise and need appropriate treatment; but to wash out the bladder of an uncomplicated case of bilharziosis would seem to be as unnecessary as to wash out the gall bladder; for the worms themselves abound in the vicinity of both. Diuretics are of undoubted service, for they prevent the accumulation of blood, bacteria, and eggs in the bladder and lessen the risks of cystitis or of the formation of stones from phosphatic concretions round the shells of the eggs. Urinary antiseptics are needed, for bacteria are usually present in varying numbers, and the possibility of a monomicrobial infection being converted into a mixed infection during the acute and more susceptible stage contraindicates resort to instrumental measures. Hexamine, being a slight diuretic and a powerful urinary antiseptic, is of particular service in this disease. Then, as the parasites are present in greatest numbers in the blood of the portal vein and in the vesical veins, it would seem that efficient treatment must aim at

destroying them in these places. By experiments carried out at the pharmacological laboratory of the Johns Hopkins Hospital in 1908, S. J. Crowe showed that hexamethylenetetramine was excreted in practically all the body fluids; he showed that in cases of post operative biliary fistulae it appeared in the bile and in the urine almost simultaneously, and that large doses—at least 75 grains daily—inhibited the growth of bacteria in the bile. These observations lead one to suppose that the drug would be of especial service in bilharziosis in averting the dangers of bacterial infection in the regions where the parasites are especially numerous, whilst it might destroy the parasites themselves in the blood stream.

The eggs present in the urine of these cases were all characterized by the presence of a terminal spine. As the presence of bilharziosis in cattle has not been demonstrated in Natal, it is reasonable to suppose that the cercariae found in the snail which had been exposed to infection were associated with the human form of the disease.

Memoranda:

MEDICAL, SURGICAL, OBSTETRICAL.

THE "IRRITABLE HEART" OF SOLDIERS.

NO ONE acquainted with the clinical study of heart disease would doubt the group of cases to which Drs. Cotton, Lewis, and Thiele allude in the BRITISH MEDICAL JOURNAL of November 13th, p. 722. They are generally recognized, are puzzling, and require, no doubt, a broad survey of the possible factors. Identical symptoms, as I have pointed out on several occasions, may occur in children and young adults following a rheumatic infection, which damages the myocardium but spares the valves or pericardium. At first there is dilatation, but long after that has passed away the symptoms described by the writers may remain, and show the characteristic tendency to relapse on imprudent exertion. Looking, as I do, upon rheumatism as a streptococcal disease, this evidence affords some indirect support to their investigations. The difficulty for me is this: May not nerve shock and overstrain, physical and nervous, produce poisons akin to some bacterial poisons? This is a speculation which has arisen before, naturally enough, over the problem of rheumatism, chorea, and nerve shock. When now we look at the clinical side of this "irritable heart of soldiers," we are faced at once by the same possibility. The strongest man after five months in Gallipoli—always under nerve strain, often much exposed to extremes of cold and heat, driven to intense exertion, menaced by numerous infections, and irregularly fed—may break down in this fashion. The pale, not fully grown, high-strung young soldier may collapse far more rapidly; nevertheless, infection may possibly explain both cases. How, on the other hand, can we explain "shell shock"—a nerve insult of the grossest and most abrupt kind? Yet, in my experience, it will produce precisely the same symptoms; and so, too, will burial by a "Jack Johnson." Infection here is again possible, but we must incline to other factors as more probable, yet to me the symptoms are identical. Again, I have had an opportunity of studying the cardiac state of some twenty people victims of a severe railway accident, and at the time noted the symptoms of six who developed cardiac symptoms such as are described by the writers. A young naval cadet came to me in 1913 with all these symptoms, the result, so far as I could judge, of physical over-exertion. After a period of quiet he became and remained well. Two years later he is a midshipman in the Dardanelles engaged in strenuous and exciting work, and he sees, while still a growing boy, stern and terrible sights. His nerves in the general sense do not feel it, but gradually there creep on palpitation, giddiness, and weakness, and at last he drops out. I see him again, and find his heart as before with symptoms of the well-known type.

Another point to be mentioned is illustrated in the treatment. A young soldier who thinks his heart is damaged is much handicapped by that thought. A determined assurance that there is no real injury and a cautious

use of rest, coupled with a judicious admixture of friends to take his mind off himself, have again and again in my experience produced encouraging improvement. Thus, it seems to me, we are faced with the same problem as in rheumatic chorea and fright chorea. May not shock, fright, and strain produce some disturbance akin to that produced by bacterial poisons?

Dr. Paine and I have shown that streptococci of the rheumatic group, and those found in malignant endocarditis which many believe have no connexion with rheumatism, can produce tachycardia and heart failure in rabbits without pericarditis or endocarditis, and it seems very possible that Drs. Cotton, Lewis, and Thiele may produce a similar result with the streptococci they have isolated. Thus I feel they may reach the same dilemmas that I am faced with. Do such results explain the irritable hearts that we are meeting with in this war? If they explain some of them, how can we separate, on the clinical side, this infective group? How can we prove that the essential factor is the infection, in the face of the mass of evidence favouring physical and nervous overstrain, coupled often with immaturity, as the prime causes? If we argue that the latter factors are so frequent, and yet this group of cases so few in comparison, others will argue that insidious infection is ever with us, but this group of cases always appears in numbers under conditions of special strain and nerve shock. I must express my appreciation of the memorandum which is the cause of this note.

London, W.

F. JOHN POYNTON.

HAVING SEEN a large number of cases of hyper- and hypothyroidism in soldiers back from the front I am somewhat interested and rather amused at the apparently serious note under the above heading in the BRITISH MEDICAL JOURNAL of November 13th by Drs. Cotton, Lewis, and Thiele. Having fairly accurately described the symptoms of hyperthyroidism they branch off in the opposite direction, though evidently of opinion that they are dealing with a variety of the same class. "In many subjects there are other evidences of vasomotor instability—coldness and blueness of hands and feet or a prominent *tache*." About 5 grains of thyroid gland thrice daily quickly alter the complexion of the latter cases, while the former are also very amenable to ordinary lines of treatment. Excess and deficiency of function of the thyroid gland are easily recognized without waiting for the development of Graves's disease or myxoedema. There is no doubt that streptococci and staphylococci can be found in some excretion or other, even when not introduced from without, of most individuals, but there is no advantage in unnecessarily calling up their assistance to explain all the ills to which flesh is heir.

Liverpool.

JAMES BARR.

Reports of Societies.

DISCUSSION ON GUNSHOT WOUNDS OF THE HEAD.

A MEETING of the Medical Society of London was held on November 15th, the President, Dr. W. PASTEUR, being in the chair.

Indications and Contraindications for Operation.

Mr. PERCY SARGENT (Temporary Lieutenant-Colonel R.A.M.C.), in opening the discussion, said that in the case of head injuries the need for early operation was not so pressing as in abdominal injuries. Head cases travelled well and did not appear to be adversely affected by the journey. They did not, however, bear transport well immediately after operation, and those operated upon ought to be kept where they were for at least a week. In times of stress this was obviously impracticable near the fighting line. He did not suggest that early and efficient cleansing of head wounds was not important, but procedure directed to this end alone was on quite a different footing from an operation undertaken for the relief of cerebral symptoms, or for the removal of bone fragments and missiles without the aid of x-ray examination. Gunshot wounds were to be regarded from two points of view—first, the neurological, and secondly, that of a compound fracture.

Compound fracture was an almost constant factor; the cerebral injury might be so slight that no evidence of its existence could be detected, or the clinical signs might point to widespread disturbance of function of every sort and degree. In point of severity there was no constant relation between the cranial and the cerebral injury, and cerebral symptoms were not wholly dependent upon the existence of a cranial lesion; the two were coexistent, but not interdependent; once the blow had been struck the relation between the cranial and cerebral injury ceased, and nothing that was done to the wound could influence the cerebral symptoms. So long as the dura was uninjured this rule remained true. When, however, the dura was lacerated so as to open up an avenue for infection, then what was done to the wound, whilst not influencing the initial cerebral lesion, might, by diminishing the chance of intradural infection, prevent or minimize the further destruction of brain tissue. Subdural haemorrhage of such a degree as to cause, of itself, symptoms of any severity, or to require operation, was very rare. In some six cases which had been observed it had manifested itself slowly and had given rise to unmistakable symptoms. Exploratory operations for possible haemorrhage had no place in the treatment of gunshot wounds, especially as such wounds were invariably septic, and as opening the dura in their presence carried with it very great danger of meningeal infection.

If operation were undertaken it should be done to assist the healing of the wound and to minimize the danger of intracranial suppuration, which was the cause of death or of further disablement in nearly all those cases which survived the initial cerebral injury. At the field ambulance and clearing stations many patients arrived with extensive defects in scalp, bone, and dura, from which large masses of brain protruded and from which brain matter, blood, and cerebro-spinal fluid issued. Most of these were either deeply unconscious or very noisy and restless, and the injury was such that they died in a few hours. Clearly such cases were excluded from the scope of operation. In some similar cases, however, careful examination revealed that although the amount of brain matter lost was large, yet the injury was less than seemed at first sight. After a few hours improvement began, the cerebral shock passed off, and recovery was not impossible. In those cases the wound should be cleaned under an anaesthetic, and perhaps its edges excised, but no intracerebral manipulation involving a search for bone fragments or missiles should be undertaken, especially if a radiographic examination could not be made.

Secondly, there was the common case of a tangential wound with cerebral laceration, where the scalp defect took the form either of two wounds separated by a bridge of skin, or an open gutter. These cases generally needed operation.

Thirdly, the single penetrating wounds through which a missile might or might not have entered, determinable only by x-rays, usually required operation.

Fourthly came cases in which a bullet had traversed the cranial cavity from side to side. They showed that at certain ranges, at which the velocity was still sufficiently high to allow the bullet to traverse the cranial cavity and to emerge therefrom, as well as in cases in which the velocity was so low that the bullet was retained within the skull after traversing the brain, no explosive effect could be demonstrated, for patients in both classes often exhibited no symptoms or neurological signs whatever. They rarely required operation, and many recovered by dressing merely.

Fifthly, there was a large group with injuries of the superior longitudinal sinus. Operation upon them had given very bad results, and they should be left alone, unless some other condition was added.

Sixthly were the minor injuries in which a fracture existed without laceration of the dura. Traumatic epilepsy in such cases resulted from the subcranial damage sustained at the time, rather than from the mere presence of the injured bone; consequently, if all such were operated upon, many of the operations would be unnecessary. He operated upon depressed fractures, as a rule, only when they were of considerable extent, and when the broken bone, exposed at the bottom of a septic scalp wound, threatened to become necrosed, and thus indefinitely delay healing.

In discussing the question whether operation should be

performed immediately or after an interval, Mr. Sargent^t said that immediate operation could only be required in the very rare cases in which progressive haemorrhage threatened life from cerebral compression. At a later date progressive neurological symptoms, when due to haemorrhage or suppuration, might call for operative relief, and therefore the question arose whether these later complications could be avoided by earlier operation. Early experience in the war showed that a large proportion so treated died later from meningitis, because of the ease with which the subarachnoid space could be infected, and the tendency to the formation of hernia. Subsequent experience had shown that delay lessened both these dangers. There was some risk in allowing bone fragments to remain buried in the brain, because an infective encephalitis might spread from such a focus and might reach the ventricles. The two dangers, those of meningitis and hernia, attendant upon the earlier operation and that of ventricular infection which beset delay, had to be balanced against one another, but his experience from a large number of cases had shown that the former predominated. The best time for operation was after from two to four days from the date of the wound; during that time the patient could be transferred to the base, an x-ray examination made, the head shaved, and the wound and scalp thoroughly cleansed.

Such evidence as he had obtained seemed to show that bullets and fragments of shell were best left alone unless they were so situated as to be easily removed with the bone fragments, or unless they subsequently caused symptoms directly referable to their presence. The symptoms which existed at first were not due to the mere presence of a foreign body—they depended upon the damage done during its introduction, and its removal would not only fail to effect an improvement, but by causing additional damage, would be more likely to aggravate those symptoms. Such foreign bodies were not always septic. If septic complications occurred later they were more likely to arise in some part of the track of the missile, where hairs and other septic material had been implanted, than to take the form of abscess or diffuse cerebral softening. The question of removal was further influenced by the nature, position, and number of the metallic foreign bodies. Many lay in positions inaccessible to legitimate surgery. More than one patient had died as the direct result of operating for removal of such foreign bodies, and many patients, in whom removal had not been attempted, had been sent to England with good prospects of recovery and had since been progressing favourably, their wounds having completely healed.

In all wounds in which the dura had been torn and the brain lacerated the primary object of any operation was to remove infective material and provide efficient drainage. When the dura was not lacerated, it was an exceedingly dangerous proceeding to incise it, and one which was uncall for, except in a very small number of cases. It was unjustifiable unless there were an extensive subdural haemorrhage. When the missile or bone fragments had caused a laceration of the dura, it was similarly dangerous, and almost as unnecessary, to enlarge the dural opening. If these cases exhibited signs of a dangerous degree of intracranial pressure, lumbar puncture or a contralateral decompression operation afforded a much safer and an efficacious mode of relief.

Glancing wounds with laceration of the dura and brain, being commonly produced by rifle bullets, were comparatively clean, and the bony fragments were not driven in to any great depth. On the other hand, when the splintered bone had been removed the dural tear and lacerated brain were often seen to be considerable in extent, and if such an area of damaged brain were left exposed, suppuration was prolonged, and hernia cerebri were likely to follow. He then described the means which had been devised for covering in this damaged brain, whilst providing for free drainage. Briefly, the gap which resulted from excision of the original wound was closed by flaps of muscle or of pericranial or aponeurotic tissue. The operation was modified to suit the case of a penetrating wound in which the dural opening was small but where the cerebral laceration extended relatively deeply and bony fragments had been driven in for a distance of from one to two inches.

Dr. GORDON HOLMES (Temporary Lieutenant-Colonel R.A.M.C.), who had collaborated with Mr. Sargent in his

work in France, said that the main aim had been to establish efficient drainage. Infection was always present by the time the patients could be dealt with. Such remarks as they could make were only of relative value for those working at home, as the conditions and objects were different. It was their object to place the patients in such a condition that they could be safely evacuated to England. They had found it advisable either to leave head cases alone or only to operate in the presence of clear and emphatic indications. Foreign bodies were well left alone. Many head injuries could be dealt with more successfully at home, after the scalp had healed. It was more dangerous to operate with the idea of preventing problematical secondary effects than to refrain from operating.

Nature and Treatment of Microbic Infection.

Professor WILSON and Colonel Sir VICTOR HORSLEY, A.M.S., sent a contribution to the discussion. In their view the principles which should guide the treatment of head injuries in the field practically resolved themselves into those underlying the means, general or special, of preventing the spread of microbial invasion of the brain from the track of the projectile and surfaces of the wound. Such means must depend upon our determination of two points:

(a) What species of microbe were found in such wounds.

(b) What was the nature of the lesion they respectively produced.

They had made, with the assistance of Lieutenant G. B. Bartlett, Pathologist to the 21st General Hospital, Alexandria, many observations and determinations of the infections in a number of gunshot injuries of the head in the hospitals at Alexandria. From the cultures obtained from these cases they had carried out a series of experimental subdural inoculations in rabbits. Their conclusions tabularized were briefly as follows:

TABLE I.—Species of Microbe found.

Microbe.	Average Course of Case Clinically.
1. <i>Staphylococcus albus</i> .	Favourable.
2. <i>Staph. aureus</i> , occasionally <i>citreus</i> .	Favourable (in uncomplicated infections).
3. <i>Streptococcus</i> .	Unfavourable.
4. <i>B. cholerae gallinarum</i> .	Variable; 2 cases observed - 1 recovered, 1 died.

In each case the pathogenic activity of the microbe (obtained by aspiration with all precautions from the softened brain beneath the hernia cerebri, etc.) was established experimentally.

The kind of cerebral lesions and the pathological changes observed clinically were reproduced with complete fidelity in the experimental inoculations with the pure cultures and could be tabularized thus:

TABLE II.

Microbe.	Cerebral Lesion.
1. <i>Staphylococcus albus</i> .	Slow localized cerebritis and small hernia cerebri.
2. <i>Staph. aureus</i> , occasionally <i>citreus</i> .	Abscess formation with pyogenic membrane; small or no hernia cerebri.
3. <i>Streptococcus</i> .	Acute cerebritis; progressive oedema of brain, large hernia cerebri; final stage, internal hydrocephalus and epiduralitis.
4. <i>B. cholerae gallinarum</i> .	Acute cerebritis with some abscess formation; small hernia cerebri.

From the facts thus collectively stated it would follow that:

(a) In all cases of gunshot injuries of the head a bacteriological diagnosis should be made.

(b) That all cases of gunshot injury of the head should be disinfected actively and completely from the earliest possible moment—that is, by excision of the primary wound, no closure of the wound, and by frequently repeated dressings soaked with antiseptic lotions—and that in any case in which streptococcal infection was found the free use of antistreptococcal serum was essential.

Experience at Home Hospitals.

Mr. L. B. RAWLING (Temporary Major R.A.M.C.) agreed that, as his work was in England, he was speaking from a totally different experience. He deplored the lack of co-operation between the surgeons

abroad and those at home, the absence of notes of the cases which were sent home, and the impossibility of knowing what surgeon had operated previously, and thus of communicating with him. He considered that a certain proportion of those he had seen should have been operated upon earlier. The majority of the scalp incisions and the stitches were suppurating when the patients arrived. The cases with the lesser incisions were apparently more favourable than those in which larger ones had been made, and those in which the wound had been extended in various directions better than those with a large flap. The infectivity of the wound was such that primary excision was unsuitable. Those with smaller osseous defects were better than those with larger. He had found that if the hernia of the brain were shaved off the condition recurred, and that the second protrusion was often worse than the first. The second protrusion generally included a distended horn of the lateral ventricle. He had consequently given up the method and regarded the expectant attitude as the correct one. He had encountered foreign bodies in the hernia, and could not but think that they should have been removed. This often had to be done afterwards, as they kept up the suppuration. He dissented from the opinion of those surgeons who approved of the finger as a means of detecting what lay at the bottom of the wound, and disapproved of the probe. The latter was preferable to the finger. Deeply-seated bodies obviously must be left. He had contented himself with removal of the more superficial, and the results had been favourable. His experience of paralysis following these injuries was that it only improved up to a certain stage. The outlook after cerebral injuries was somewhat gloomy, but excellent results had followed those in the frontal and temporo-sphenoidal regions. Every fracture of the external table was associated with a greater fracture of the internal, injury of the frontal sinus excepted. A common occurrence was for the patient to appear very well, but a small superficial septic wound existed, and a probe showed that a fracture was present. The pulse-rate was slow in proportion to the temperature, the blood pressure raised, headache was present, and the mental condition was not quite sound. It was not possible to tell without exploration how serious the injury was. He was in favour of early operation before the patients arrived in this country.

Mr. WILFRED TROTTER (Temporary Captain R.A.M.C.) said that the point which had struck him most in the opening paper was that it was possible to leave so much of the nature of foreign bodies in the brain. It might be the best practical procedure for a short time, but not for an indefinite period. He had been impressed by the frequency with which serious lesions developed and remained latent in the central nervous system. In view of this it was a mere assumption that patients who appeared well soon after the injury, or who improved some months later, could be regarded as cured. If the slightest evidence of a lesion persisted, it should be dealt with. It was often assumed that hemiplegia was due to loss of brain substance, but probably any extensive hemiplegia denoted some haemorrhage or skull injury.

After Captain SIDNEY SMITH and Major W. PEARSON had spoken, Mr. SARGENT and Dr. GORDON HOLMES briefly replied.

THE WORK OF HUGHLINGS-JACKSON.

At the opening meeting of the Section of Neurology of the Royal Society of Medicine Dr. JAMES TAYLOR delivered his presidential address, taking as his subject "The ophthalmological observations of Hughlings-Jackson, and their bearing on nervous and other diseases."

Dr. TAYLOR said he did not think it could be easy for any one who was not brought intimately into contact with him to understand the reverent affection always entertained, by those who enjoyed that good fortune, for the great personality of Hughlings-Jackson. One of his earliest and most lasting interests was in ophthalmological and ocular conditions, and most of his early writings dealt with these, especially in reference to the symptomatology of intracranial tumours. He was never tired of insisting on the necessity of routine ophthalmological examination in nervous diseases. In his paper, contributed in 1863, dealing with defects of sight in brain disease, he pointed out the occurrence of two kinds of atrophy: One

in which the nerve gradually whitened, the other in which whitening followed certain acute changes, the latter being known as "amaurosis." Emphasis was also laid on ophthalmoscopic examination in hemiplegia, and especially in seeking for evidence of Bright's disease, and in cases brought in comatose; and all the time he insisted on the need for preserving a philosophical balance of mind, so as to ensure that everything was seen in its true perspective. To the ophthalmologist amaurosis was a disease of such great importance, calling for particular action on his part, that he might underrate its significance as a symptom in general conditions of the system. It was when it occurred with other phenomena that the discovery of what it meant was most likely to be made. He held that disease of the cerebellum *per se* did not produce blindness, and that neither did disease of the cerebrum, of itself, but that tumour in either region did so by setting up optic neuritis the result of local encephalitis. Lecturing on optic neuritis in 1871, Hughlings-Jackson said that the intracranial disease most often associated with double optic neuritis was coarse, a lump of something, an adventitious product; and, further, that double optic neuritis did not point to any particular kind of coarse disease, only to some coarse disease. The condition scarcely ever occurred in chronic and general convulsive attacks, a condition of hemiplegia from local softening, etc.; and he pointed out that optic neuritis was not a localizing sign. He insisted on the three following points: (1) That optic neuritis frequently exists when the patient can read the smallest type; (2) that in cases of adventitious products in the cranium the ophthalmoscopic appearances vary greatly, also at different stages in the same case; (3) that the use of the ophthalmoscope should never be omitted when a patient has severe and continued headache. Hughlings-Jackson's *Physician's Notes on Ophthalmology* were a storehouse of interesting record; in them he insisted that intracranial tumour might be present without optic neuritis, that optic neuritis might be observed and yet no tumour be found, and that optic neuritis did not necessarily result in blindness though there was usually great danger of it leading to impairment of sight.

In his annual oration before the Medical Society of London in 1877 he dealt with the importance of the effects which refraction errors might produce. Thus, hypermetropia might cause symptoms simulating those of brain disease, such as headache and squinting; and observation of hypermetropic discs was of the utmost importance, because of the close resemblance they bore to the inflamed disc associated with tumour. He went on to show the inseparable connexion of motor activity with sensory activity in ideation. Whilst the colour—the secondary or dynamical quality of an object—was a sensory affair, its size and shape—its primary or statical quality—was a motor affair. In the light of this, ophthalmological facts became of inestimable value, showing that the estimation of the extension of objects was due to motor activity, and that activity of motor centres would suffice. Optic atrophy often occurred in tabes dorsalis and in general paralysis of the insane, and might occur with or without pupil changes, with or without pain, with or without ataxy. Retinal embolism, revealed by the ophthalmoscope, might be associated with cerebral embolism. The ophthalmoscope might also render visible other tissue change in the fundus, such as that resulting from tubercle, syphilis, or Bright's disease, though the ophthalmoscopic appearances of Bright's disease were often closely simulated by those occurring in intracranial tumour.

At a very interesting discussion in which Hughlings-Jackson participated, reported in the first volume of the *Ophthalmological Society's Transactions*, he stated his belief that there was but one kind of optic neuritis from intracranial disease; also that uniocular optic neuritis rarely occurred in intracranial tumour. He considered it important to distinguish between the development of neuritis and consequent loss of vision from a foreign body, and loss of sight from a destructive lesion. Thus, hemiplegia was usually the result of a destructive lesion, and in itself implied no change in the fundus. In the ordinary hemiplegia from haemorrhage or clot fundal changes did not occur.

With regard to the question of the mode of production of optic neuritis, against von Graefe's view that it was caused by raised intracranial pressure inducing venous congestion in the central vessels of the optic nerve, was the fact that a small tumour might cause intense optic neuritis, whereas a large haemorrhage might not be

accompanied by any optic neuritis. He regarded as "the most plausible" Benedict's view of reflex vasomotor action inducing instability in the grey matter and influencing vessels in the optic nerves. A further plea for the early and systematic use of the ophthalmoscope arose from the fact that the best time for treatment of optic atrophy was early in its appearance.

Hughlings-Jackson's Bowman Lecture before the Ophthalmological Society in 1885 was a philosophical treatise on Spencerian lines, but with a practical side. In it he showed the benefit of co-operation of specialized fields of research and knowledge; he also dealt with the complexity of nervous diseases, such as epileptic paroxysms.

It was not easy, Dr. Taylor said, to sum up briefly the outcome of Hughlings-Jackson's teaching, but in addition to the points mentioned, he was much impressed by the educative effect of work carefully and energetically pursued at an ophthalmic hospital. Such work need not lead to a more barren specialism or differentiation; nor had it done so, for in addition to definite increase of knowledge of eye conditions, it had led to discoveries which had been a means of investigation of several important diseases, and had produced co-operation between neurologists and ophthalmic surgeons in the study and treatment of different morbid conditions.

Reviews.

PATHOLOGY AND EPIDEMIOLOGY OF SWINE FEVER.

A PAMPHLET containing the results of a research into the pathology and epidemiology of swine fever, by Dr. J. P. MCGOWAN, Assistant Superintendent of the Royal College of Physicians' Laboratory, Edinburgh, has been issued by the Edinburgh and East of Scotland College of Agriculture.¹ It is in every respect worthy to be placed alongside of the research on *Leaping-ill*, by the same author, to which attention was directed in these pages lately (*JOURNAL*, August 7th, p. 221); indeed, it may be said to surpass it in practical importance, for, according to the latest official reports, 4,356 outbreaks of swine fever occurred in Great Britain alone in the twelve months ending December, 1914, and, as a consequence, 39,277 swine were slaughtered as diseased, or as having been exposed to infection. One of the questions which Dr. McGowan makes an effort to settle is whether this wholesale slaughter of pigs exposed to infection was necessary or justifiable.

The question is of no small economic importance, for the occurrence of a single case—if the present theory of intense infectivity be accepted—will lead to the destruction of perhaps thirty or forty pigs valued at £40 each, and their sale for the price of bacon. Dr. McGowan, however, is doubtful of the validity of the present etiological theory which postulates a filter-passer or ultramicroscopic organism, which prepares the way, by lowering the vitality, for a secondary invasion of the *Bacillus suisepidicus* or the *Bacillus suispestifer*, or of both. This view was strongly upheld in the recent article (published in 1913) by Uhlenhuth and Haendel in *Kollo und Wassermann's Handbuch der pathogenischen Mikroorganismen*; but Dr. McGowan insists on the great difficulty which exists in diagnosing swine fever owing to differences not only in clinical symptoms but also in pathological findings, and he also criticises the experimental methods of the German investigators, pointing out the apparent impossibility of proving by experimental injection that a multiplying virus filtrate is the cause of swine fever, and drawing attention to the fact that this was practically the only method employed. He further emphasizes the weakness of the conclusions of Uhlenhuth and Haendel due to their neglect of the *Bacillus suisepidicus* and of the variants of the *Bacillus suispestifer* in their experiments; he thus undermines the deduction (by exclusion) that the cause must be a filter-passer.

His own observations were made on material obtained from three epidemics of swine fever; the main one occurred in March, 1915, at a farm near Edinburgh. It is unnecessary to enter into the technical details on which

Dr. McGowan builds up his conclusion—they are fully stated in the pamphlet—but he enunciates the view that the *Bacillus suispestifer* may vary considerably in its biological reactions, and may even be considered to be a variant of *Bacillus suisepidicus*; he thinks that it may even turn out that there are both variants of a micro-organism with which may be identified also Gläser's *Bacillus typhi suis* and Gläser's *Bacillus suispestifer* (Voldagsen), which are said to cause in pigs contagious diseases resembling swine fever. From the facts observed in connexion with the three outbreaks which came under his notice, Dr. McGowan believes, first, that swine fever may arise in a piggy without any connexion being traceable between the outbreak and a previously existing case of the disease outside; secondly, that in some outbreaks, as in the one in question, the evidence is not sufficient to establish the view that in all cases the disease, once having arisen in a piggy, spreads by contagion to the other animals in the piggy—it may do so, but it is possible in some cases that contagion may be stimulated by some common injurious factor (for example, gross chilling) acting on all the pigs simultaneously, and producing the disease in them at or about the same time. It is not, however, denied that the disease, once having arisen in a piggy, may spread thereafter through the piggy by contagion. The conclusion seems to follow that swine fever is by no means so contagious as it is usually supposed to be; indeed, if it were as intensely contagious as it is necessary to postulate in order to uphold the current theory of spreading, it is hard to see how any pig could have escaped.

Two main conclusions seem to follow upon the researches made by McGowan: the first is that the case for the filter-passer as the cause of swine fever has not been established in an impregnable position, and the second that considerable doubt must be felt as to the intensity of the contagion of the disease. It is obvious that such a conclusion may be of immense economic importance if it leads to a marked reduction of the wholesale slaughtering of suspected animals. In place of the present widespread destruction of animals Dr. McGowan would put, first, attention to diarrhoea in sucklings; secondly, the immediate killing, on the first evidence of the condition being present, of all "wasters" and "piners" of any degree whatever; and, thirdly, the paying of closer attention to the general health of pigs, especially to their protection from sudden exposure to great cold. They ought to be kept in pens in large, airy houses entirely under cover during the winter season. It is interesting to note that in these modern researches into the diseases of animals the old idea of chilling is coming to the front again, not, indeed, as the primary cause of the malady, but as a means of lowering the vitality of the animal, and so permitting micro-organisms not otherwise active to become detrimentally so.

A POPULAR ACCOUNT OF TUBERCULOSIS.

The publication of a general and detailed description of a widespread disease, for the enlightenment of all and sundry, has not usually been regarded with professional favour. But in the case of tuberculosis any such objections would be irrational. The whole success of preventive, as well as of curative, measures must rest largely with the common sense and goodwill of the community, and already the public have been partially instructed by numerous lectures, leaflets, and limelight demonstrations in schoolrooms, concert halls, and travelling caravans throughout the country.

The time would certainly seem to be ripe for the publication of a comprehensive account of the subject, set forth in simple language by an acknowledged expert. In undertaking to present such an account, Dr. JEX BLAKE has set himself a difficult task. The use of descriptive terms, so familiar to the professional reader, but so confusing to the layman, has had to be avoided, and even the simplest anatomical details have of necessity been presented in popular guise.

His book is entitled *Tuberculosis: A General Account of the Disease; its Forms, Treatment, and Prevention*,² and, although arranged in the order usually followed in textbooks, he has managed to instil into many of his chapters

¹ *Some Points in Connection with the Pathology and Epidemiology of Swine Fever.* By J. P. McGowan, M.A., M.D., B.Sc., M.R.C.P. From the Laboratory of the Royal College of Physicians, Edinburgh. William Blackwood and Sons, Edinburgh, July, 1915. (Pp. 40.)

² *Tuberculosis: A General Account of the Disease; its Forms, Treatment, and Prevention.* By A. J. Jex-Blake, M.D., F.R.C.P. London: G. Bell and Sons, Limited, 1915. (Cr. 8vo, pp. 231. 2s. 6d. net.)

a strong flavouring of the clinical experience of everyday happenings which so often tend to influence the success or failure of treatment. To the non-medical reader the conclusions of the expert are of more interest than are the details of evidence upon which they are founded. Statistics may point to heredity as a helpful influence, but in the opinion of many experienced clinicians that influence may tend to benefit the present sufferer rather than the reverse. The possibility of infection by way of tubercularized milk, although by no means to be disregarded, may in like manner be viewed without undue anxiety as tending to protect the infected child from a more serious attack of the disease in later life. Recognition of the possible paths of infection is in itself the first and most important step in the direction of prevention, and in an early chapter these paths will be found to be very closely examined. The lay reader will doubtless be duly impressed with the vast amount of important information that has been obtained by way of direct experiment on animals. Popular notions with regard to consumption are mostly derived from novels. Familiarity with modern works of fiction has enabled Dr. Jex-Blake to point to many of the gentle errors and misleading fancies of certain contemporary writers as texts for his own lay sermons. In describing the oft-quoted familiar symptoms and their significance, he has managed to steer clear of any trespass upon the province of the physician, while giving the non-professional student a clear idea of the usual course of the disease.

Surgical tuberculosis is firmly associated in the lay mind with disease of the hip joint. This idea will be considerably expanded after perusal of the chapter dealing with the clinical features of the disease as it affects other parts than the lungs.

The latter part of the book is mainly devoted to treatment, both curative and preventive. The rational application of the rules, which are now so well established, will be greatly aided by the explanation in plain terms of the facts that have led to their adoption. Tubercular treatment is described and its use is commended as not being likely to do any harm if used in doses which are not strong enough to produce a reaction. The more important element for success—namely, the intelligent use of fresh air—is very carefully and fully discussed. The recognized methods of prevention are in like manner rendered intelligible and interesting to the non-medical mind.

The book as a whole will be found to be instructive and useful to all who may desire to make, or improve, acquaintance with a subject of absorbing interest, as introduced to them by a writer who has combined literary ability of no mean order with ripe professional experience of the disease and those who suffer from it.

SAMUEL GEE.

THE fourth edition of the late Dr. GEE'S *Medical Lectures and Aphorisms*² contains fourteen of the brief lectures or addresses of that most excellent physician, and the 272 aphorisms in which he condensed a vast amount of practical medicine. Two further papers are given in an appendix, and at the end of the volume Dr. Wickham Legg gives a most interesting though sadly incomplete sketch of Dr. Gee's life and habits of thought. Dr. Gee was a man of encyclopaedic knowledge in all matters of medicine, and as his biographer shows, his great knowledge and academic turn of mind were apt to make him intolerant of ignorance or pretension, to paralyse the springs of action, and to give him a pessimistic outlook on the crude and practical world in which, like all of us, he had to live. This is certainly the most complete edition of Dr. Gee's medical writings we have seen, and now that it has been enriched by Dr. Wickham Legg's "Recollections" it may perhaps be regarded as a final edition. It is needless to say that Dr. Gee's *Lectures and Aphorisms* should have been read by every practitioner of medicine for they are among our modern medical classics. The present edition gains greatly in interest by the inclusion of a biography of their talented but retiring author.

² *Medical Lectures and Aphorisms*. By S. Gee, M.D.; with Recollections by J. Wickham Legg. Fourth edition. Oxford Medical Publications, London: H. Frowde, and Hodder and Stoughton, 1915. (Cr. 8vo, pp. 414. 6s. net.)

NOTES ON BOOKS.

The First Medical Report of the Lord Mayor Treloar Crisples' Hospital and College, Alton, Hampshire (London: Horace Marshall and Son, 1915, pp. 60, 1s. net), has been prepared by Mr. H. J. Gauvain, the medical superintendent, whose monograph on the use of celluloid for the treatment of tuberculous disease of the spine was read before the Medical Society, and published, with illustrations, in the *JOURNAL*, vol. 4, 1913, p. 1200. The work of the hospital is in every sense national, admissions having been made from nearly every county in England and a large number from Wales. The compiler has adorned the report with many instructive photogravures, especially a series representing whole batches of youthful patients parading in the open air for sun treatment, and nature study lessons. The preparation and application of plastic splints are also represented pictorially, as well as many children with acute and chronic tuberculous disorders before and after treatment. Another illustration demonstrates the apparatus for artificial heliotherapy which produces ultra-violet rays that cause pigmentation. Thus Mr. Gauvain's pamphlet is a publication of a character, not of a governor's official annual, but rather of a hospital "report" such as is issued by many medical schools in London and the metropolis.

MEDICINE, MAGIC, AND RELIGION.

DR. W. H. RIVERS, in his first FitzPatrick Lecture before the Royal College of Physicians of London, said that medicine, magic, and religion were abstract terms, each of which connoted a large group of social processes by means of which mankind had come to regulate his behaviour towards the world around him. Among ourselves these three groups of processes were more or less sharply marked off from one another, but there were many peoples among whom they were so closely interrelated that the disentanglement of each from the rest was difficult or impossible, while there were yet other peoples among whom the social processes to which we give the name of "medicine" could hardly be said to exist.

In any attempt to study a social institution there were three chief lines of approach and methods of inquiry—the historical, the psychological, and the sociological. A necessary preliminary to any knowledge of the history of medicine must be the study of its relations to those other social processes with which it was associated. This preliminary task would be the object of these lectures, which would deal with certain prolegomena to the early history of medicine rather than with the history of medicine itself. Dr. Rivers said he would limit himself as far as possible to one part of the world, namely, Melanesia and New Guinea, with occasional references to the allied culture of Australia.

He began by defining the three kinds of social process under consideration. Among many peoples it was far from easy to draw any definite line between magic and religion, and a term was needed to include both. He would employ the word "magico-religious," which implied, from our own point of view, an attitude in which phenomena were dealt with by supernatural means. The use of the word "supernatural" implied the existence of the concept of the natural, but this concept, as we had it, was lacking among the people dealt with in these lectures. The essence of medicine, as we now understood it, was that it regarded disease as a phenomenon subject to natural laws. One chief object of the lectures would be to discover what was the nature of the concept of disease among those who failed to distinguish medicine from magic and religion.

Provisionally, for descriptive purposes, by "magic" he would mean a group of processes in which man used rites which depended for their efficacy on his own power or on powers believed to be inherent in, or the attributes of, certain objects and processes which were used in these rites. Religion, on the other hand, dealt with the same condition, but by means of processes the efficacy of which depended upon the will of some higher power, whose intervention was sought by rites of supplication and propitiation. Religion differed from magic in that it involved the belief in some power in the universe greater than that of man himself. "Medicine" was a term for a set of social practices by which man sought to direct and control a

specific group of natural phenomena known as "disease." One of the chief tasks of the lecture would be to ascertain how far this notion of disease existed among the peoples included in the field of study, and this would be done mainly by means of an inquiry into the processes by which man reacts to those phenomena we call "morbid."

One way of approaching the problem would be to inquire how far different groups of mankind had set apart certain members of the community to deal with the morbid. He would use the old English term "leech" to designate such a member. The chief line of inquiry, however, would be an examination of the processes by which man at different stages of culture dealt with disease. Even when there was no clear differentiation of the leech from other members of society, mankind had theories of the causation of disease, carried out proceedings corresponding with those we called diagnosis and prognosis, and, finally, had modes of treatment which might be regarded as making up a definite system of therapeutics.

One element of the concept of disease which also appertained to savage peoples was that it included within its scope the factor of causation. There were usually clear-cut ideas concerning the immediate conditions which led to the appearance of disease. By starting from etiology we should find ourselves led on as naturally to diagnosis and treatment as in the case of our own system of medicine.

According to the belief of mankind in general, the causes of disease might be grouped in three chief classes: (1) Human agency, in which it was believed that disease was directly due to action on the part of some human being; (2) the action of some spiritual or supernatural being, or, more exactly, the action of some agent not human but yet more or less definitely personified; (3) what we ordinarily called natural causes. Among savage or barbarous peoples the beliefs concerning the causation of disease fell in the main into one or other or both of the first two categories. In that lecture he would confine his attention to those cases in which native ideas concerning causation must either be definitely classed with magic or belong more nearly to this category than to that of religion.

The magic of many peoples of rude culture differed from that of the Middle Ages in that disease or injury was, in many cases, ascribed to purely human agency. This mode of causation was not merely brought into play to explain cases of illness which had no obvious antecedent, but also those in which what we should call the natural cause was obvious. Such ideas were not empty beliefs devoid of practical consequences, but acted as the motives for processes of treatment in cases of injury, or for acts of revenge if the magical process should lead to the death of the victim. There were many other cases in which the cause of the disease was ascribed to the action of some non-human being, either under the control of human agency from the beginning or capable of being brought under such control when it was desired to influence the results produced by its action. In such cases the methods of diagnosis and treatment were often indistinguishable from those employed when the condition was ascribed to human agency, supplication and propitiation playing no part.

Three main classes of cases could be distinguished: (1) Those in which some morbid object or substance was projected into the body of the victim; (2) those in which something was abstracted from the body; (3) those in which the sorcerer acted on some part of the body of a person or on some object which had been connected with the body of a person in the belief that thereby he could act on the person as a whole. These classes were then considered in detail. The first could be divided into two groups according as the morbid objects had found their way into the body of the victim by direct human agency or by the action of some non-human agent. Both kinds were of frequent occurrence in Australia, where material objects were believed to be projected into the body either by sorcerers or spiritual beings. In Melanesia, when disease was believed to be due to such projection, it was usually held that some invisible influence—a morbid essence or effluvium—was so projected. The lecturer described the *tamatetkwa*, or ghost-shooter, the instrument by which such an influence

was supposed to be projected, and the procedure called *talumalai*, by which a parcel consisting of a dead man's bone, or part of an arrow which had killed a man, was placed in leaves in the path of the man it was desired to injure. The treatment followed directly from its etiology, its aim being to extract the object or essence from the body. Men and women were believed to have the power of removing objects, usually by sucking some part of the body. In some cases it might be necessary to discover the agent, for which purpose some method of divination was used.

Concerning the second group, the substance which was thought to be abstracted in Australia was the kidney fat or that of the omentum. In New Guinea and Melanesia the people believed in the causation of disease by the abstraction of the soul, or of some part of it, by spiritual agency. The treatment consisted in the recovery of the soul by one called *Gismana*, whose soul left his body in sleep and sought out the soul of the patient. In the *Gazelle Peninsula* of New Britain and *Duke of York Island* it was believed that disease was produced by a *kai*, a being having the tail of a snake and the head of a man, and if any one fell ill in these places a process of divination was employed to determine whether the disease was so caused. The lecturer described the rites carried out.

The third kind of magic, known as "sympathetic" magic, was exemplified by the *Kai*, an inland people of New Guinea. They believed in a soul substance which permeated not only every part of the body, but also extended to anything which had been in contact with the body. When a sorcerer secured part of the body of his proposed victim, or an object which had been in contact with his body, he was believed to be really securing part of the soul of the person; and it was thought that it was by the action of his magical processes upon this isolated portion of the soul that the rites of the sorcerer produced their effect. He described the rites in detail, and those by which they were counteracted, the soul substance being again freed. They were full of acts which showed a belief in the efficacy of imitation—a belief summed up in the phrase, "Like produces like," which found its counterpart in modern medicine.

In his second lecture Dr. W. H. R. Rivers said that definite rites performed for the purpose of diagnosis often had a religious character, even when the treatment appeared to be entirely of a magical order. Thus, in Murray Island it was believed that certain men, through their possession of objects called *zogo* and their knowledge of the appropriate rites, had the power of inflicting disease. One *zogo* was believed to make people lean and hungry, and at the same time to produce dysentery, another to produce constipation, and a third insanity. When any one fell ill he might know at once whom he had offended, but often either lie or his friends had recourse to certain men who owned a shrine called *Tomog zogo*, where diagnosis by a process of divination was carried out; it was also consulted for prognosis. In one form of divination the behaviour of lizards provided the data for diagnosis or prognosis; in another, employed also in other islands of the Torres Straits, the skulls of relatives were used for this purpose, the ghost to whom the skull belonged in life giving the desired information in a dream. The latter formed part of a religious cult of ancestors, still more definite in Melanesia, where it provided an example of religion of a relatively high order, in which the elements of supplication and propitiation were clearly present.

Methods of prognosis were even more apt to have a purely religious character. It was a matter of interest that the aid of superhuman or divine powers should show itself so definitely in this connexion, and that this difficult and uncertain art should, in such a people as the Melanesians, bring out more clearly than any other aspect of their leechcraft the close dependence of medicine and religion.

The close relation between the practice of medicine and the cult of dead ancestors existed all through Melanesia, but probably the combined rites nowhere reached a greater pitch of elaboration than in the western islands of the British Solomons, where the subject had been carefully studied by Mr. A. M. Hocart and himself. In the little island of Mandegusa a connexion so intimate was found between the treatment of disease and certain religious

practices, especially that of taboo, that the account of medical practice was at the same time an account of taboo. Nearly every disease was ascribed to the infraction of a taboo on the fruit of certain trees, especially of the coca-nut and betel-vine. A number of rites were learnt which were intended to cure or ameliorate the disease which fell on one who used the fruit from tabooed trees without the performance of the rites which should accompany its removal. The rite used for therapeutic purposes was known as *Sulanga*. With certain exceptions all the rites belonged to the same man, or group of men. Thus, it was only the man who was able to impose or remove the taboo who could treat the disease produced by its infraction, and there was a close resemblance between the rites connected with the process of taboo and those of the more strictly medical kind. Mr. Hocart and he had found about one hundred examples of such conjoined processes of taboo and medicine, and had obtained a complete record of more than sixty. As an example of one of the shorter of these processes, the lecturer described that connected with the taboo called *kirengge*, the infraction of which produced epilepsy and other convulsive seizures. The religious element in these rites was obvious. A note of supplication ran through all the formulas, which could definitely be regarded as prayers to beings who had the power to withhold that for which they were asked. A burnt offering at the end of the proceedings had clearly a propitiatory character and might also be regarded as a thank-offering to the ghostly being or beings through whose intervention the successful treatment had been brought about. The special interest, however, in these proceedings was the intimate blending of the therapeutic process with the institution of taboo, which both in this and other parts of Melanesia had a definite religious character.

The natives of Mandegusu also believed in a number of beings to whom the power of producing disease was ascribed. These beings were personifications of such natural phenomena as thunderbolts, shooting stars, and the rainbow, and most of them had special haunts often associated with shrines. Intrusion into these haunts was one of the causes held accountable for disease, but they were believed to inflict disease apart from any offence on the part of the victim. The most frequent mechanism, however, by which they were believed to produce sickness was through the breaking of a taboo. There was thus a fusion between two different beliefs—one in the production of disease by a personification of a natural phenomenon, and another according to which disease was ascribed to a transgression of the institution of taboo. There were examples, too, in which a similar process of fusion had given a religious character to processes for the production of disease which would otherwise fall into the category of magic. Thus the breaking of one kind of taboo exposed the transgressor to the action of one of a number of men called *njiana*, whose powers closely resembled those ascribed to the evil eye. The infraction of another caused a disease ascribed to the action of a sorcerer called *mba*, who was believed to produce disease by acting on a fragment of food or an object which had been used by the person on whom it was intended to inflict illness. The alliance between medicine and religion was so strong that processes which belonged most clearly to the realm of magic were brought into relation with religion by the assumption that men would not fall victims to the sorcery of their fellows if they had not exposed themselves to this danger by the sin of breaking a taboo. The close connexion between medicine, magic, and religion was also brought out by the procedures employed in the diagnosis and treatment of diseases ascribed to a *mba*.

This close relation between religion and the production and cure of disease was met with throughout Melanesia. Thus, in those islands which possessed the institution of totemism, disease was said to follow any infraction of totemic ordinances, such as killing or eating the totems. Side by side with the religious character of leechcraft, magical practices of the most definite kind were found in many parts of Melanesia. In some these took the most important place in the lives and thoughts of the people; in others, the religious aspect of leechcraft was predominant.

"Minor ailments" were often considered to arise in-

dependently of any action on the part of human beings or of higher powers. They were largely treated without the aid of any specialized practitioners, and by measures which corresponded to our own domestic remedies, a sorcerer being only consulted when ordinary treatment had proved of no avail. The belief in the occurrence of disease independently of human or spiritual agency introduced an element of variety into the leechcraft of savage peoples. Such peoples as the Melaneseans put their faith in many doctors, and were not content with one physician or one remedy.

In Mandegusu (Eldystone Island) a distinct step had been taken towards the differentiation of the leech from the priest. Although the man who bought the knowledge which enabled him to impose a taboo necessarily bought at the same time the knowledge of the process by which to treat the illness which followed its infraction, it did not follow that he used the latter. Certain men of the island had acquired a special reputation for success in the application of remedies—such men, called *tinoni salanga*, clearly presenting the beginning of the differentiation of the leech from the priest. There was another indication that medicine in the strict sense was becoming dissociated in Eldystone Island from the religious attitude. There seemed to be a tendency to diagnose and treat *tayosoro*, a combination of fever, pain, and weakness, as a morbid entity, independently of any belief in the anger of the being who was supposed to cause it or of the transgression of a taboo. This modification might be due to recent European influence, which might also be responsible for the movement towards specialization of the leech.

Specialization of the medical function itself was marked. Such people as the Papuan or Melanesian had carried the differentiation of medical function in some respects to a far higher pitch than even we had reached. In Eldystone Island one man would treat rheumatism, another fever, a third epilepsy, and a fourth insanity, although in each case the cure was intimately associated with religious functions. Epidemics were ascribed to the action of sorcerers, but it was supposed that they were produced by the sorcery of members of some other village or island. They were also ascribed to the agency of higher powers, examples of which were beings called *Ave* in the Eldystone Island. When an epidemic attributed to *Ave* visited the island, the people appealed to one who knew the appropriate rites, which the lecturer described.

The intimate relation of medicine, magic, and religion among these peoples carried with it other relations of an economical and juridical kind. The process called *kenje*, for example, was also a means by which certain kinds of property—namely, the fruit of certain trees—was kept for the special use of individuals. The institutions were not inventions in the interests of private property, but the belief in the production of disease as a punishment for theft provided a motive which tended to perpetuate the ideas and practices which brought medicine and religion into such close relation.

The part played by suggestion in the production and cure of disease among such people as the Papuans and Melanesians was evident. There was no doubt about the efficacy of the procedures employed. Doubtless with this real factor of suggestion there was mixed much deception on the part of those to whose special knowledge the production and cure of disease was ascribed. These practitioners were, however, sincere and earnest, and not merely impostors. From the psychological standpoint the difference between the rude arts he had described and much of our own medicine was not one of kind, but only of degree.

The chief lesson to be learnt from the facts brought forward in the lectures was the rationality of the leechcraft of such peoples. Their practices in relation to disease were inspired by definite ideas concerning its causation, and their mode of treatment followed directly from their ideas concerning etiology and pathology. They practised an art of medicine which, in some respects, was more rational than our own, for diagnosis and treatment followed more directly their ideas of causation. There were examples of leechcraft which did not follow so strictly logical and consistent a system. Such were the use of bleeding and massage in New Guinea. This led to another set of problems—namely, the study of the transformations suffered by medical beliefs and practices as the result of the contact and blending of peoples.

THE FIRST YEAR'S WORK OF THE MEDICAL RESEARCH COMMITTEE.

The first annual report of the Medical Research Committee, presented recently to Parliament, necessarily recapitulates much of the information already published in this JOURNAL, and especially in the article which appeared on December 5th, 1914 (p. 972), and that published on May 22nd, 1915 (p. 697).

In presenting a year ago its first list of research schemes, the Committee explained that the beginning of the war had already interfered with the plans previously prepared, and it was stated that the carrying out of many of the recommendations must be contingent upon the requirements of military duties. As the war proceeded the need for medical and scientific assistance increased with the growth of the forces engaged, and consequently the research work done on behalf of the Committee in directions not specially connected with the war has progressively diminished, but it has not been altogether suspended, and researches with regard to tuberculosis, dust and pulmonary disease, anaphylaxis, the hygienic relations of milk, and chronic rheumatoid arthritis, have been continued.

Department of Bacteriology.

It will be remembered that Sir Almroth Wright was placed at the head of the Bacteriological Department of the Committee's work. The whole services of the department have from the beginning of the war been made available for inquiries into matters of military importance.

Since his appointment in September, 1914, to be consulting physician to the forces overseas, Sir Almroth Wright has prosecuted important researches at Boulogne, bearing especially upon the pathology and treatment of infected wounds. In this work he has been assisted by Captain S. R. Douglas, Captain W. Parry Morgan, R.A.M.C., and Lieutenant H. H. Tanner, R.A.M.C. One of the results of these researches was the circulation of a memorandum addressed to medical officers with the forces at home or abroad with regard to their application in practice, and another was the publication of Sir Almroth Wright's address upon the use of hypertonic salt solution and physiological methods of treatment of wounds, before the Royal Society of Medicine last March.¹ In June last the staff of the laboratories was increased by the appointment of Captain W. d'Este Emery, Dr. A. C. Inman, and Captain S. W. Patterson, R.A.M.C. Captain Emery has studied in particular the infections associated with gas production in wounds. The Committee has also maintained three members of Sir Almroth Wright's staff to work under his direction in the inoculation department at St. Mary's Hospital, where 25 beds have been maintained by the Committee for clinical research work.

Department of Applied Physiology.

In the Department of Applied Physiology, temporary accommodation was at first found for the director, Professor Leonard Hill, M.B., F.R.S., and Dr. Martin Flack, in the physiological laboratory of the London Hospital Medical School, and Professor Benjamin Moore, the other member of the staff, was at first allowed by the University of Liverpool to work in the laboratory of bio-chemistry of the university. The Committee was subsequently enabled to rent three suitable rooms from the London Hospital Medical School, where the work of the department has been carried on since January 1st, 1915. In connexion with the investigation of the incidence of phthisis in particular occupations and industries, Dr. Hill and Dr. Moore were appointed members of a Special Investigation Committee, consisting of Dr. Addison (Chairman), Dr. Hill, Dr. Moore, and Dr. Brownlee, of the Committee's scientific staff, and Dr. E. L. Collis, medical inspector of the Factory Department, Home Office. They paid a large number of visits to boot and shoe factories, leather and hide works, and printing shops, and in connexion with these visits experimental work has been done in the laboratory upon questions of ventilation and other physiological conditions of work. The Investigation Committee has at the same time prosecuted statistical

inquiries, and a report upon the boot and shoe industry has already been presented, in which the advantages of a factory sanatorium are pointed out where the patients could continue to carry on their trade with due regard to their condition. A report upon the printing trade is in course of preparation.

Dr. Hill and Drs. Flack and McQueen have published measurements of arterial pressure in man, and an investigation has been carried out, in collaboration with Dr. Fildes, as to the conditions of union between inorganic antiseptics and the serum of a wounded surface. The resources of the department have been made available for certain special inquiries in connexion with the war, including the characters and effects of poison gases. Dr. Hill has visited France to demonstrate the treatment by oxygen inhalation, and apparatus has been devised for giving for long periods of time inhalations of oxygen at higher concentration than those usually obtainable. In addition, Dr. Hill has become a member of the Health of Munition Workers' Committee, and the resources of the department have been placed at the disposal of that committee for such specific experimental inquiries as may be necessary.

Department of Biochemistry and Pharmacology.

In the Department of Biochemistry and Pharmacology, under the direction of Dr. H. H. Dale, F.R.S., a general survey has been made of the alkaloids not generally in use, but giving promise of therapeutic importance, and much time has been given to a systematic examination of the rates of absorption and distribution in the animal tissues of particular synthetic drugs in order to put the standardization of such drugs by biological tests upon a scientific basis. Work done on the nature of the toxic principle found in one of the organisms held responsible for gas gangrene has shown that the effects described previously by others were due to the presence of a large quantity of ammonium salts. The subject of anaphylaxis has also been taken up as a part of a co-ordinated scheme of work; and Dr. G. S. Walpole was last May attached for two years to the department to co-operate in the work, and in particular to deal with the problems in colloidal physics which are fundamental to the general inquiry. The department has also done special work arising out of the war, particularly in connexion with the synthesis of certain drugs.

Statistical Department.

In the Statistical Department, under Dr. John Brownlee, normal research work has been continued, especially in connexion with tuberculosis and measles, and some of it has been published in this JOURNAL in Dr. Brownlee's papers on the curve of the epidemic and on Farr's theory of the epidemic.

The offer of the Medical Research Committee to place its resources at the disposal of the War Office for medical statistical purposes having been accepted, the Statistical Department is now conducting the compilation of the statistics of the sick and wounded from the home and expeditionary forces. For this purpose a house has been hired in Guilford Street, Russell Square, and equipped with the necessary furniture, apparatus, and clerical staff. Card indices are being compiled from the returns provided from official sources, and the sorting and classification of the medical and surgical case-sheets from the military hospitals has also been undertaken. It has been found that this work greatly facilitates the supply of information with regard to the later history of patients in this country sought by medical officers abroad for guidance in the treatment of similar cases at early stages.

Pathological Work at Military Hospitals.

In addition to placing its building at Mount Vernon, Hampstead, at the disposal of the War Office for use as a hospital, the Committee has given assistance in conducting the pathological work of many of the military general hospitals. In some instances special inquiries have been undertaken. Thus special work has been done in the 1st Eastern Hospital at Cambridge in connexion with cerebro-spinal fever; with coliform organisms in wounds, by Dr. Matthew Stewart, at Leeds; with anaerobic wound infections, by Professor H. R. Dean, at Sheffield; and with typhoid infections and cerebro-spinal fever at Manchester, under Professor Dolépine. A number of special inquiries

¹ BRITISH MEDICAL JOURNAL, April 10th, p. 625; April 17th, p. 655; April 24th, p. 720; May 1st, p. 762.

relating to the war have been undertaken in consultation with Colonel Sir William Leishman, Adviser in Pathology to the British Expeditionary Force; among these have been the researches of Sir Ahuroth Wright, already referred to, and those into the value of hypochlorite solution by Professor Lorrain Smith and his colleagues in Edinburgh, and by Dr. Dakin of Compiègne, the results of which have been published in this JOURNAL.

In Professor Delpeine's laboratory in Manchester Dr. Dawson has conducted researches into the diagnosis of typhoid fever in inoculated persons, which was the subject of a paper in the BRITISH MEDICAL JOURNAL of July 24th, 1915, and the same subject has been studied at Oxford by Professor Dreyer and Captains Ainley Walker and Gibson. One result of Professor Dreyer's work was noted in the BRITISH MEDICAL JOURNAL of October 9th (p. 548) in a memorandum on the subject, stating that materials and apparatus for the necessary standardization would be supplied to bacteriologists at military hospitals.

Cholera.

In the autumn of 1914 the Committee sent Dr. John Freeman to Galicia, where, with the co-operation of the Russian authorities, he investigated the various strains of cholera infection. It was considered important that these strains should be available for the preparation of vaccines, and cultures have been placed at the disposal of the inoculation department at St. Mary's Hospital, which has been able already to supply large quantities of anti-cholera vaccines to the Serbian Government and the British forces in the Mediterranean.

Bilharziosis.

In co-operation with the War Office and the London School of Tropical Medicine an expedition, consisting of Dr. Leiper, with two assistants—Dr. Cockin and Dr. J. G. Thomson—was sent to Egypt to apply the results of recent discoveries with regard to the life-history of bilharzia and to ascertain the best prophylactic measures for the protection of the military forces in that country. A full account of the work is appearing in the *Journal of the R.A.M.C.*, showing that Dr. Leiper has succeeded in demonstrating that Egyptian bilharziosis can only be communicated to man through a fresh-water snail, in which its alternate form is parasitic. The expedition was enabled to establish an important fact—that transient collections of water are quite safe after recent contamination, but that all permanent collections of water, such as the Nile, the canals, and the marshes, are always dangerous from the possible presence of the snail as the essential intermediary host. It has also been established that an area may remain infected—at least for many months—through the persistence of intermediate hosts. It appears, therefore, that infected troops cannot reinfect themselves and convey the disease to other parts of the world, except where a local snail can act efficiently as a carrier. The expedition determined the special precautionary measures in regard to the treatment of water which are sufficient to safeguard the military forces for immediate purposes. Colonel Leiper, in collaboration with Dr. Dale, is making experiments in the Committee's biological department with a view to finding therapeutic agents for the treatment of the acquired disease.

Cerebro-spinal Fever.

Dr. Mervyn Gordon was appointed by the Committee to organize and direct bacteriological work with regard to cerebro-spinal fever, and has been supplied with the whole-time assistance of Dr. Macaulay Hino and Dr. E. G. Murray. The Committee has also made grants for work done on behalf of the War Office in this connexion by a number of other workers. The research beds in St. Mary's Hospital have been placed at the disposal of the War Office for a special investigation by Dr. Colebrook and Dr. Tanner into the sterilization of positive contacts. Regarding an outbreak of the disease in the early months of next year as probable, an Advisory Committee has been appointed, consisting of Dr. F. W. Andrewes, F.R.S., Professor R. T. Hewlett, Professor W. Bulloch, F.R.S., and work on chemical factors of bacterial growth in connexion with the infective agent in cerebro-spinal

fever has been begun and is thought likely to develop into a general scheme for chemical research bearing upon manifold problems of bacterial disease.

Neurology.

In the compilation of the medical statistics of the war it has been thought advisable to give special attention to neurological inquiries, and in connexion with workers abroad nearly fifty neurologists in London and various provincial centres are now working upon a common plan; in this connexion the Committee has made grants for part-time work.

"Epidemic Dropsy."

Arrangements have been made for the reception of cases of acute nephritis (epidemic dropsy) in two of the military wards of St. Bartholomew's Hospital, under the care of Captain W. Langdon Brown, the clinical work being correlated with the bacteriological work by Captain F. W. Andrewes. Captain Langdon Brown has recently published a preliminary account of his observations in the *Journal of the R.A.M.C.* Special bacteriological work in connexion with the types of dysentery coming from the Mediterranean Expeditionary Force is being carried out at the London Hospital, St. Mary's Hospital, and in Edinburgh.

Wounds of the Chest.

Professor T. G. Brodie and Professor J. J. Mackenzie, have been detailed by Surgeon-General Carleton-Jones, Canadian Army Medical Corps, for special work upon the structural changes of the lungs and of the breathing capacity supervening upon gunshot wounds of the chest. Captain A. H. Caulfield, C.A.M.C., has also been detailed by Surgeon-General Carleton-Jones for investigating at St. Bartholomew's Hospital particular infections of the pleural cavities. For the laboratory expenses of these inquiries the Medical Research Committee has made grants.

Disorders of Soldier's Heart.

The Committee has arranged, under the direction of Sir James Mackenzie, a scheme of study of cardiac disorders of military importance. Special beds reserved by the War Office at University College Hospital have been placed in charge of Dr. Thomas Lewis, Captain R.A.M.C.(T), and Captain Cotton, C.A.M.C. The apparatus of the cardiographic department of the medical school are at their disposal, and for the investigation of cases in which the cardiac disorders depend upon infective conditions part-time bacteriological assistance by Mrs. Briscoe, M.B., has been provided for work under Dr. Teale's direction. The Committee has also provided Sir James Mackenzie with the assistance of Dr. R. M. Wilson for the examination of military cases elsewhere, and of recruits, and for the organization of work by particular medical officers at provincial centres.

In concluding the report it is pointed out that the existence of the Medical Research Fund has made it possible to bring auxiliary agencies rapidly to the service of Government departments during the war, and especially to that of the Army Medical Department in its varied and vitally important activities. The report is signed by Lord Moulton, Chairman of the Medical Research Committee, and by Dr. W. M. Fletcher, F.R.S., its Secretary.

Excelsior, the quarterly magazine of James Murray's Royal Asylum, Perth, issued its hundredth number in October. Our contemporary protests that it is tired of centenaries because "they are commonly far too expensive for the celebrants, and usually leave nothing behind but a bad headache," but it comforts itself with the reflection that it is a centenarian only in respect of the numbers that have appeared; in years it can only reckon twenty-five. That is still a goodly record, on which we offer our congratulations, coupled with the hope that it may continue to flourish without any nipping of its liveliness by the frost of advancing years. If the local flavour of its jokes necessarily makes them to some extent caviare to the general, one can easily see that they must add to the gaiety of the little nation to which they are addressed. That is the true function of such a periodical, and it is excellently fulfilled by *Excelsior*.

British Medical Journal.

SATURDAY, NOVEMBER 20th, 1915.

NEED FOR RESEARCH IN TIME OF WAR.

Two propositions with regard to the growing importance of pathology in practical affairs have been maintained in this JOURNAL during the last ten years or so. The first is that a laboratory for clinical pathology is an essential part of a modern hospital, and the second that the hospital laboratory must do research work. The battle for the first was easily won. The demand from the clinical staffs of hospitals rapidly grew too insistent for the governing bodies to resist even had they wished to do so; to do them justice, however, they showed no disposition to obstruct, for the more enlightened members were quick to perceive that to complete the armament of a hospital by adding a department which made diagnosis speedier and more certain, which prevented complications in the individual and checked the spread of disease to others, was a scheme worthy of encouragement, since it would diminish alike the sum of suffering and the expenditure of money. The new position was appreciated as quickly by many doctors engaged in private practice, and not a few general practitioners fitted up small laboratories for themselves. The modern student witnessing during his hospital training the constant assistance given by the clinical laboratory, will not willingly be deprived of it afterwards, and asks for it in a military hospital.

But the other proposition was not so readily established. To the layman, to some persons engaged in public health work, and even to some members of the clinical staffs of hospitals, it seemed that the pathologist's sphere should be strictly limited, that he should occupy a very subordinate position, and be content to go on from month to month and from year to year doing routine work on the lines laid down in the textbooks. This is one of those curious mistakes which even able men can make when they forget human nature and the food on which the mind of man thrives. Under such conditions even routine work cannot continue to be well done. If a man is content to sink to it, the very drudgery of it makes him lose interest, so that his daily task is done in a perfunctory way. No man worth his salt could sink to it, because in pathology as in every department of biology, and particularly when a new science is in an early stage, as bacteriology is to-day, the living things dealt with so frequently escape from the textbook, which, as every man who practises medicine or surgery knows, can serve only as a general guide by giving a conspectus of the knowledge of yesterday. The coming of the Medical Research Committee was a turning of the ways. The research penny provided by the Insurance Act might easily have done more harm than good had not the point we are trying to make here been understood. Fortunately the direction of the enterprise was committed to good hands. The Executive Committee consisted for the most part of men of science; it was perhaps too much to expect that in the present stage of political education its

Chairman should be one of them, but in Lord Moulton was found a Chairman who, though not himself a man of science, had during his distinguished career at the bar been brought more closely into contact with the actualities of science than is common among members of his profession, or among politicians. The Committee was fortunate also in obtaining the services of Dr. W. M. Fletcher, F.R.S., as its Secretary. He is a man of science; he was at one time Demonstrator in Physiology in the University of Cambridge, and has made important contributions to knowledge himself. In his new post he has shown himself able not only to understand the good that the judicious expenditure of an annual income for medical research might accomplish, but also the risks of failure were it injudiciously administered on a "cash on delivery" system.

The Committee had barely been got into working order when the war broke out; hence the research scheme it put out about a year ago has necessarily undergone great modifications, because not only were the staffs of the pathological laboratories depleted by the call upon them for military medical service, but the Committee rightly felt that its most urgent duty was to co-operate with the War Office for the benefit directly of the very large proportion of the active male population in the prime of life who enlisted, and directly and indirectly for that of the civilian population to which, sooner or later, they would return. It was certain that the existence of a national medical research fund, if wisely administered, would mark an epoch in British medicine, but it was not altogether a misfortune that it should only just have come into existence at the outset of a world-war, because the immediate practical value of its work quickly became manifest. The executive of the Medical Research Fund has, in fact, formed an intelligence department for the military medical services, and has been able to provide direct and rapid service in organizing inquiries, in obtaining expert advice, and in supplying personal service. That we have "to beat the Germans" is the dominating fact of our national life to-day, but only a fool would use the fact as an argument against the earnest intensive prosecution of research while the war continues. If we are to beat the Germans it must be, as the military authorities and military critics din daily into our ears, by providing big battalions, and it is no use enlisting men, or worse than no use, unless we take every means which science can provide for keeping them in health. Routine work will not do; that has been abundantly proved already. All medical work, from the study of a single case to the investigation of an epidemic, partakes of the nature of research work; within the first few months of war many details of former practice were changed for the better, and many opinions on epidemic disorders were reviewed in the new light thrown on them by study and experience won in the field. The conditions of warfare are such that the study must be intensive and experience quickly pooled, if knowledge essential to success is to be gained quickly and diffused quickly. Neglect to organize inquiry means that action has to be taken in the dark. The results of the inquiries into the causes and treatment of sepsis, of gas gangrene, of the treatment of head injuries and fractures of the lower limbs, of typhoid and paratyphoid and dysentery, are examples at once to hand.

When the general territorial hospitals were being organized the offer made to the War Office by the Committee to help it by making additional provision for pathological work was accepted. It was found

that the needs of various hospitals varied widely in different places, both in character and amount; at some complete arrangements had been made for pathological and bacteriological work, at others none. Owing, perhaps, to the fact that the territorial hospital scheme was worked out some years ago, before it had been fully recognized that clinical pathological laboratories had become a necessary part of every general hospital, the instructions on this head were not precise and much depended upon local circumstances. The lesson that good opportunities and facilities for pathological work of the best and highest kind is a vital necessity has now been learnt probably in every centre, but there seems still to be hesitation in giving proper recognition to the men who are doing it. The head of the pathological department of a big hospital ought to be placed in respect of status and rank on an equality with the heads of the surgical and medical departments. Indeed, if we were logical, which heaven forbid, we should put the general's badge on his shoulder, for is he not the medical strategist concerned with the institutes of medicine and the principles upon which effective treatment must be based?

An article published in another column indicates some of the directions in which the Committee has been able to assist the work of the clinical pathological laboratories of military general hospitals. Its efforts in instituting or encouraging combined researches into particular questions have already yielded results of the greatest value not only to the individual for the alleviation of suffering, but to the country by safeguarding lives and economizing resources both in men and money. Some of the results have been published in detail in original articles in our pages, such as, for instance, the researches of Sir Almoth Wright into the physiological principles underlying the effective treatment of wounds, the experimental inquiries as to the value of hypochlorites as antiseptics, and the researches illustrating the value of systematic bacterioscopic examinations in infectious disorders. War makes experiments on man on a huge scale, horrible to contemplate, but the horror is mitigated when the opportunity is taken to institute inquiries into means of prevention or alleviation; such inquiries serve not only the immediate practical needs of the army by saving the life and health of the troops now engaged, but also the civil population of to-morrow, while hastening the progress of medicine throughout the world.

The schemes of work undertaken under the direction or at the instigation of the Committee for the War Office and other Government departments in connexion with the war are many, and will probably become even more numerous and more important, but the results of what has been done are already so striking that, as has happened before, people who call themselves "practical men" are becoming impressed with the fact that there is nothing so cheap as knowledge, if only you go the right way about gaining it. A research which costs a few hundred pounds may yield results which in their application at once save the country as many millions in money. From the financial side research is truly economical, the saving of life and the saving in long illness and chronic disablement have a value which can be expressed in pounds, shillings, and pence; but we will not with the anti-thises and the anti-thats pretend to put out of mind the saving in suffering to the brave men who of their own free will have come out to fight for their country in its dire need. We wish Mr. Tennant, who seems too ready to suffer fools gladly, or some other

minister who is heckled by these folk in the House of Commons, would some day speak out, dealing boldly with well ascertained facts and principles, and tell the country what experimental medicine and bacteriological research have already done for it in this great crisis.

HUGHLINGS-JACKSON.

It was a happy thought of the editors of *Brain* to bring out a double number¹ devoted to an exposition of the views on aphasia of that very great genius Hughlings-Jackson. A considerable number of his scattered papers on aphasia are here collected and reprinted; and are prefaced by an admirable summary of his views from the pen of Dr. Head. Hughlings-Jackson's methods of publication were curious. He fully recognized that his doctrines were caviare to the general, and he did not seek for them a wide publicity. As soon as he had thought out a section of any subject, he was anxious to publish it, or rather to get it into print. He had great difficulty in expressing himself clearly, not because his ideas were lacking in clearness, but because of their abstruseness and complexity, and he would liken his literary efforts to those of a coachman driving six horses abreast and having to keep all the traces tight. He was punctiliously accurate, and this led him, as Dr. Head reminds us, to pepper every page with explanatory phrases or footnotes, so that the generalization can scarcely be distinguished from its qualifications. So difficult did he find the task of literary composition that he wrote his papers over and over again, and could never get them into a form satisfactory to himself. It was probably his despair of reaching his ideal that led him to publish them as he did. He sent them to be printed in order to get them into permanent form, and to put a stop to the otherwise endless task of revision and rewriting. As long as they were got into print he did not much care where they appeared, and many of his most valuable articles are stored away in the columns of journals that never had any considerable circulation, and that have long been extinct. The task of unearthing them and collecting them must therefore be one of considerable difficulty, and the present generation owes a debt of gratitude to Dr. Head for this collection of those papers that refer to the difficult subject of aphasia.

Hughlings-Jackson's work has of late years been much neglected. It is now known to comparatively few, except in as far as it has permeated and modified methods of thinking about the constitution of the nervous system and the effects of nervous lesions. But a revival of interest in it is inevitable; this must come sooner or later, for he laid down for all time certain fundamental principles which govern the constitution of the nervous system and the working of its processes. His fundamental principle was that the nervous system is the product of evolution; that it has gradually grown up to be what it is through a process of budding, and branching, and growth, and elaboration, in this direction and in that, to meet the requirements of the living acting organism; that it is therefore divisible, more or less arbitrarily, into "evolutionary levels," of which the lowest are the oldest, and most completely and compactly organized; they represent functions that are crude, simple, gross, general, fundamentally necessary to life, and implicate massive movements of visceral and trunk muscles,

¹ London: Macmillan and Co.; New York: The Macmillan Co. Price 8s. or 2 dots. It contains a chronological list of Hughlings-Jackson's papers bearing on affections of speech.

such as the functions of circulation and respiration. On the other hand, however, the newest and most loosely and incompletely organized represent functions that are elaborate, complex, fine, precise, accessory, and implicate delicate movements of peripheral muscles, such as those that move the eyes, the tongue and lips, and the fingers. Disease is, according to Hughlings-Jackson, a process of dissolution, a pulling down of that which evolution has built up, and proceeds in the reverse direction, attacking first and most severely the highest evolutionary level, which is also the last to recover when recovery takes place, and proceeding downwards from level to level until the lowest level of all is the last to be damaged, the least affected, and the first to resume its functions.

A corollary of this doctrine is that quoted by Dr. Head, that destructive lesions never cause positive effects. They can only destroy and abolish. Any positive manifestation, such as convulsion, or mania, or mistakes in words, is not produced, but permitted by the lesion. It is due to the uncontrolled and disorderly action of those lower levels that are permitted to overact by the removal of the control formerly exercised by the higher level that has been destroyed. This is now become a commonplace, but it was a very startling heresy when Hughlings-Jackson first formulated it, and it was long before it made its way and was received and accepted. It has now the appearance of a truism: and his other doctrines, when once the tangled phraseology in which they are expressed is penetrated and their meaning is grasped, captivate the judgement, and appear as much as this in the light of truisms.

Hughlings-Jackson's rank as a pioneer and discoverer in medicine is not inferior to that of Harvey and Lister, and in due time he will take his place among the very brightest of medical luminaries.

THE NOBEL PRIZES.

The awards of the Nobel Prizes for Chemistry and Physics 1914 and 1915 are now made known. The 1914 award for Medicine, as we have already stated, has been made to Bárány, of Vienna, who has observed and formulated certain seemingly constant relations between vestibular vertigo and ataxia and vestibular nystagmus. In 1910 Dr. Bárány was a guest of the British Medical Association when the annual meeting was held in London. In the Section of Otolaryngology he opened a discussion on the "Diagnosis and treatment of infective labyrinthitis," and in the Section of Psychology and Neurology he read a paper on the "Vestibular apparatus and the cerebellum."¹ His work on the peripheral nervous system has also been of great value. He was on duty in a field hospital in Przemyśl during the siege by the Russians. From there he sent his last work, dealing with the treatment of skull lesions, by aërial post. He is now a prisoner of the Russians. The award in Medicine for 1915 is reserved. The awards for Chemistry go respectively to Professor Theodore William Richards, of Harvard, and Professor A. B. Willstätter, of Berlin. The former has devoted himself to experiments on atomic weights, the compressibilities of elements, and electrothermal dynamics. A great deal of his work has been published by the Carnegie Institution. Professor Willstätter holds a chair of chemistry in the University of Berlin and has specialized on alkaloids. The awards for Physics are of special interest, in the first place because one of them comes to this country (for the third time), and in the second, because the work honoured by the one award is in direct sequence with the work honoured by the other.

The prize for 1914 goes to Professor M. von Laue, until recently of Zurich, and now, apparently, of the new university of Frankfurt-on-Main. The prize for 1915 is divided between Professor W. H. Bragg, of London University, and his son, Mr. W. L. Bragg, of Cambridge, who is now serving in France as an officer of the Leicestershire Royal Horse Artillery (Territorials). The investigations both of Laue and of the Braggs relate to the analysis of x rays by means of crystals; taken together their results mark the greatest advance on this side of physics since Roentgen's discovery. Three years ago it occurred to Laue, who believed x rays to be rays of light having wave lengths of an atomic order of magnitude, that the regular groupings of atoms in a crystal should be capable of producing interference effects when a beam of x rays was passed through the crystal structure. His theory was that the repetition of the atoms at certain definite intervals in the crystal might act as a kind of diffraction grating for these rays of short wave length. The theory was put to the test, a parallel beam of x rays being made to traverse a crystal, and some beautifully symmetrical interference patterns were recorded on a photographic plate. This investigation, which demonstrated conclusively that x rays underwent diffraction, was the starting point for fresh researches. In this country the Braggs, father and son, were able to show a little later that x rays were regularly reflected by the cleavage planes of crystals. Laue on the one hand and the Braggs on the other differed, however, in their ideas as to the constitution of the x -ray beam, the former thinking it to be made up of a limited number of independent homogeneous constituents, representing only certain wave lengths, while W. L. Bragg supposed it to be like light, containing every possible wave length over a wide range and capable of forming a continuous spectrum. Experimental investigation has gone to prove the truth of the latter theory, and the Braggs have obtained x -ray spectra with different anticathodes, and by means of a special spectrometer they have been able to measure wave lengths with an accuracy comparable with the spectroscopic analysis of ordinary light. The result has been to demonstrate the nature of x rays. Until recently there was some doubt as to whether the rays might not be the flight of material particles, but with the discovery that they can be diffracted and reflected by crystals, it becomes clear that they are electro-magnetic disturbances of the same nature as light, heat, and electricity, and that their novel properties are due to the shortness of their wave length. The *Proceedings* of the Royal Society for 1913 and 1914 contain full accounts of the investigation. Before occupying the Quain Chair of Physics at London University, Professor Bragg was professor at Leeds for seven years, and previously at Adelaide for twenty-two years. Practically all his scientific writings have been concerned with the problems of radioactivity. His *Studies in Radioactivity*, published three years ago, recites the theoretical reasoning which led him to predict the nature of the absorption of alpha rays by matter—another piece of research with which his name will always be coupled.

MILITARY SERVICE AND LIFE ASSURANCE.

The question of life assurance must still be a matter of anxious thought to those who may temporarily leave civil practice to undertake military service. We have previously mentioned that the majority of life offices are either declining to entertain proposals with such a contingency or are charging, as a war extra, to those who may be ordered for service outside the United Kingdom rates which can only be called prohibitive. Realizing the necessity of assisting medical men who may join His Majesty's forces the Medical Insurance Agency has entered into an agreement with a substantial office whereby life policies are issued at ordinary tabular rates so long as the military service is confined to the United

¹ BRITISH MEDICAL JOURNAL, 1910, vol. II, p. 1215.

Kingdom. Should the assured be ordered abroad, the full value of the policy is maintained, but an additional premium of nine guineas per cent. per annum is required to cover the increased risk. If the assured finds his work abroad does not take him within the actual firing zone, or to within a radius of ten miles of the firing zone, and on his return to civil life is able to show a clean bill of health, the office in question undertakes to refund a sum amounting to at least one-half of the war extra premium. So far as we know, no such favourable conditions are offered generally, and the contract appears to offer equitable terms to the assured. Another point worthy of consideration is that in which, as has often happened one partner has undertaken military service, leaving a partner at home; in such cases the life of the latter is of great financial importance to the other on military duty. As an act of prudence the life of the partner at home should be assured, and for him the ordinary rates prevail. A man on active service unfortunate enough to lose his partner by death would run the risk of serious financial loss. In such a case the protection would be provided by taking a short-period policy on the life of the partner remaining at home, or by a whole-life policy with a surrender value after the second year, or a guaranteed return at the end of five years, in the event of it being no longer necessary to continue the policy. As an example, we may take the case of a man with a partner aged 55 years. A five years policy for £1,000 on his life would cost £24 2s. 6d. per annum, or £120 12s. 6d. for the five years. If, however, an ordinary whole-life policy was preferred, the annual cost would be £45 0s. 10d. In five years a sum of £225 4s. 2d. would have been paid in premiums, but at the end of this period the expediency of maintaining the policy might no longer exist, when the office guarantees the return of a sum of approximately £93, or would issue a fully paid up policy of £166. This contract affords the greater elasticity, and on the whole appears to offer the best protection for the absent partner unfortunate enough to lose by death his colleague at home. Full particulars can be obtained by those interested if they will apply, stating age next birthday of the life it is proposed to insure, to the Medical Insurance Agency, c.o. British Medical Association, 429, Strand, London.

THE NEW HOUSE OF THE GENERAL MEDICAL COUNCIL.

For the last time the General Medical Council has met in the place so long its home, and before Christmas the office and the work of registration will be transferred to Hallam Street. Very soon, too, the familiar front, built originally for the Royal College of Chemistry, will have disappeared, and will be replaced by a more imposing building. But the memory of the Royal College of Chemistry will be preserved by a foundation stone, upon which it is recorded that it was laid by Prince Albert. This Mr. Delissa Joseph, the architect who is going to erect the new buildings on the site, has most kindly presented to the General Medical Council, who will doubtless find a fitting place for its preservation. The completion of the new premises of the Council in Hallam Street has been somewhat delayed by the difficulty of obtaining certain materials for the sanitary and hot water work, but this has been surmounted, and it is now possible to judge of the general effect of the front. It is of stone and has been treated by Mr. Frere, the architect, with a dignified simplicity, the spirit of Greek architecture being kept so far as this is compatible with the amount of window required for the darker London climate. It is to be hoped that whatever is to be erected upon the vacant site next to it may harmonize with it, or at least be no detriment to its appearance. On a plinth over the door are three sculptured panels executed by Mr. Lessore; the one represents Aesculapius as a healer, with Telesphorus bringing a cock for sacrifice; the

middle one has Aesculapius as a judge, and the third is an attempt to represent symbolically the work of registration, one of the figures bearing a scroll. The work of these panels is of high artistic merit, and in the selection of the motives the intimate knowledge of Greek art possessed by Dr. Eaton has been freely drawn upon. The bay windows of the new Council room run through two stories, and the monotony of the long upright mullions has been relieved by forming their upper parts into symbolic figures. It is a difficult matter to treat a figure which is of necessity narrow and elongated, and which has to carry weight, but this difficulty has been very satisfactorily overcome and these figures look very well. The other ornament, sparsely used but sufficient, is excellent both in design and execution. In the interior an office, much larger than the present office, which has proved too small for convenience, is provided. Very much better accommodation is being given for witnesses, solicitors, and counsel who have to attend during the transaction of penal business. A staircase separate from that used by the members of the Council, has been provided for them, as well as lavatory and waiting rooms, in all of which respects the old premises were very inconvenient, many people having had to wait about in the hall. The Council chamber itself is a fine room, but its decoration—to be mainly in the form of oak panelling—has been postponed in order to allow the walls to dry. The domestic offices are, as is now not uncommon, placed at the top of the building instead of in the basement. Hallam Street in the past has not been well known, and at first those who have business with the Council may not know where to find it. It may not be amiss, therefore, to mention that it is parallel to Portland Place and to Great Portland Street, lying between them. As the leases are all falling in almost at once, the rather shabby houses of which it partly consists will be wholly replaced within two or three years by others of quite a different grade, and the character of the street will be entirely changed.

THE HISTORY OF IPECACUANHA IN DYSENTERY. With reference to a note on the history of ipecacuanha which appeared in the BRITISH MEDICAL JOURNAL of November 13th, Sir Dyce Duckworth has called our attention to articles in vols. v and vii (1869 and 1871) of the *Saint Bartholomew's Hospital Reports*, in which he recorded the results of a series of experiments made by him "on the action of ipecacuanha and its alkaloid emetia." In it he gives some information as to the history of the introduction of ipecacuanha into Europe which may usefully supplement our own brief note. He quotes a private letter from Sir Robert Christison in which it is stated that both Maregraf and Piso, who first made the virtues of the drug known in Europe, recommended 1 or 2 drachm doses in dysentery. Christison further says: "How European physicians came to substitute 1, 2, or 3 grains for Maregraf's 1 or 2 drachms I do not know, but the inquiry would be curious could we follow it out well." Sir Dyce Duckworth cites Baglivi, who, in the seventh edition of his treatise on medical practice, published at Lyons in 1714, wrote: "Radix ipecacuanhae est specificum ac ferme infallibile remedium in fluxibus dysentericis." Baglivi adds that he learnt its virtues from a Dr. William Sherard at Rome. Sir Dyce Duckworth conjectures that Sherard was the famous botanist, Fellow of St. John's College, Oxford, who was English Consul at Smyrna, bequeathed his herbarium to his university and founded the chair of botany there in 1731. In his treatise *De Dysenteria Commentarius*, published in 1761, Mark Aken-side, the poet, who was physician to St. Thomas's Hospital, wrote warmly in praise of the drug. In 1831 the Madras Medical Board published a number of reports by different medical officers, showing the efficacy of 5 grain doses given every hour in acute dysentery till frequently hundreds of grains were given in a short period. Sir Dyce Duckworth

adds the testimony of Mr. Alexander Hunter, colonial surgeon at Belize, British Honduras, who informed him that in cases of acute dysentery he began the use of ipecacuanha by giving 1 scruple of the powder. A second dose of 25 grains given after the first had the effect of allaying all the symptoms and altering the character of the discharges: it was seldom necessary to administer more than two or three doses. Sir Dyce Duckworth also quotes Mr. Hulke and others who saw the effects of ipecacuanha in dysentery in the Crimea as bearing witness to its great value. We think it right to state here that an account of the introduction of the drug into France, which differs in certain particulars from that given in our note, is to be found in Flückiger and Hanbury's *Pharmacographia* (second edition, London, 1879). They say that a traveller named Jegras brought a quantity of the root from South America to Paris in 1672; some of this was obtained by Jean Adrien Helvetius, then living in the French capital. The first trials of it were unsuccessful because too large doses were used. In 1680 a merchant of Paris named Garnier became possessed of 150 lb. of ipecacuanha, the valuable properties of which in dysentery he vaunted to his medical attendant Afforty, and to Helvetius. Garnier, on his convalescence, made a present of some of the new drug to Afforty, who attached little importance to it. Helvetius, on the other hand, again used the root, this time with great success. He was so elated by this that he is said to have caused placards to be affixed to the corners of the streets (about the year 1636) announcing his triumphs with the new drug, supplies of which he obtained through Garnier from Spain, and sold as a secret medicine. The fame of the cures effected by Helvetius reached the French Court, and caused some trials of ipecacuanha to be made at the Hôtel-Dieu. These having been successful, Louis XIV. accorded to Helvetius the sole right of vending his remedy. Subsequently several great personages, including the Dauphin of France, having experienced its benefit, the King consulted his physician, Antoine d'Acquin, and the well-known Jesuit, Père François de Lachaise, who had become the King's confessor in 1675. Through them was chiefly negotiated the purchase from Helvetius of his secret for 1,000 louis d'or: it was made public in 1688. The right of Helvetius to this payment was disputed in law by Garnier, but maintained by a decision of the Châtelet of Paris. Flückiger and Hanbury give references in support of these statements which will help any one interested in the history of ipecacuanha to pursue the investigation. There is evidently a sufficient amount of discrepancy among authorities to tempt the critical student. And even when the exact part played by Helvetius is cleared up there will remain the following out of Sir Robert Christison's "curious inquiry" as to the abandonment of the larger doses of Marcgraf and Piso.

ROYAL MEDICAL BENEVOLENT FUND GUILD.

A DRAWING-ROOM sale in aid of the funds of the Royal Medical Benevolent Fund Guild will, by kind permission of the Marquis and Marchioness of Crewe, be held at Crewe House, Curzon Street, W., on Wednesday, November 24th, from 12 to 7 p.m. We take this opportunity of once more calling attention to the excellent work done by the Guild in helping the families of doctors who, owing to the ill-health or the untimely death of the breadwinner, have been left without adequate means of livelihood. The profession has answered the country's call with a self-sacrificing devotion of which it may justly be proud. To the heavy tribute which death and disablement by sickness or wounds have already levied must be added the loss of income caused by absence on active service. It is too likely that in a large number of cases this loss will never be made up, as with the most loyal assistance from those who take the place of the men

who go, it must become increasingly difficult to keep practices that have been laboriously built up from falling to pieces. On no members of the community do the burdens of the war fall more heavily than on the wives and mothers of medical men who have given their husbands and sons to the service of our defenders, and by none are they more uncomplainingly borne. The dependants of the men who are doing so much for the relief of suffering on the battlefield, in the trenches, and in hospitals, have a special claim on the gratitude of the whole people of this country. To the medical profession they will not look in vain, but doctors as a class are not rich. Calls on the resources of the Royal Medical Benevolent Fund Guild are constantly increasing, and must, it is to be feared, continue to increase. We hope, therefore, that the sale now being arranged for the benefit of the Guild will bring a substantial addition to its funds. Among the stall-holders are Lady Barlow, Lady Pearce Gould, Lady Ferrier, Lady Fripp, Mrs. Fred Smith, and Mrs. Donald Armour.

CHOLERA IN AUSTRIA HUNGARY.

CHOLERA has prevailed in Austria and Hungary for the last year or more, but seems to have attained serious epidemic proportions in Galicia only. From December 27th, 1914, to September 18th, 1915, the official statistics in the monthly *Bulletin* of the International Office show 27,591 cases and 15,270 deaths. Of these, 699 cases with 180 deaths occurred among prisoners of war, and only 172 cases with 34 deaths among soldiers. Judging from the statistics for Austria for the period from August 15th to September 18th it would appear that the epidemic has been severe among the civil population, as there were no fewer than 15,175 reported cases and 9,113 deaths, of which only 327 cases with 32 deaths occurred among the troops, and 39 cases with 12 deaths among prisoners of war. The comparative immunity of the army may be due to the use of anticholera vaccine, for it is reported that the Austrian cavalry general v. Ziegler, who died on August 1st of Asiatic cholera, the diagnosis being confirmed by a bacteriological examination, was the only case of cholera either among his staff or among the civil population of the place where he was stationed. The general, it is stated, was the only officer on the staff who, in spite of repeated medical advice, had refused to be vaccinated against cholera.

Medical Notes in Parliament.

The Medical Service of the Army.—On November 11th Mr. Joynson-Hicks asked the Under Secretary of State for War to give the number of doctors in the Royal Army Medical Corps on the active and Special Reserve lists at the present time, and the number in the Territorial Medical Corps; and to indicate the increase in the figures since May 18th last, when Mr. Joynson-Hicks, if he may be remembered, asked a similar question. Mr. Tennant said that the total number of medical officers (regulars, retired officers re-employed, temporary commissioned, Special Reserve, and Territorial Force) was now 9,626. There had been an increase of 2,599 over the figures he gave on May 19th last. The present number of Territorial Force medical officers was 2,474. In the answer given on May 19th (*BRITISH MEDICAL JOURNAL*, May 29th, p. 941) the number of medical officers R.A.M.C. Territorial was given as 2,122.

Red Cross Medical Officers and the R.A.M.C.—On November 9th Sir Philip Magnus asked whether, having regard to the fresh call for doctors for the army, the services with the Red Cross Society of those who had returned home after spending some months in the discharge of medical duties at the seat of war could be recognized; and whether, as an inducement to offering a further term of service, the War Office would take into consideration the time already served toward the reduction of the six

months now required before a lieutenant could be promoted to the rank of a captain. Mr. Tennant said that, as the question pointed out, these gentlemen undertook only a short spell of service and then returned to their civil practices. Without criticizing the course they took, he hardly thought that they could now claim to be treated exactly on the same lines as those who, when they joined the R.A.M.C. of the Special Reserve or the Territorial Force, put themselves at the disposal of the country for the period of the war. He hoped that those medical men who had served with the Red Cross Society would respond to the appeal for more medical officers without asking as a condition for the full recognition of their previous services on the same footing as if the Government had been from the first put in a position to count upon benefiting by it continuously for the whole period of the war.

Hospital Administration Work.—In reply to questions by Mr. James Mason, who asked whether men of military age having experience of hospital administration work could be utilized in similar work for the War Office instead of joining the combatant ranks, and whether many doctors holding commissions in the R.A.M.C. were employed in purely administrative work, Mr. Tennant said that he could not accept the principle which underlay the question. There were no purely administrative appointments in connexion with military hospitals. The work of the administrative officers R.A.M.C. was technical and required special education and experience. The officers in charge of hospitals must be qualified medical men, as their duties necessitated their acting in that capacity. To ascertain the number of R.A.M.C. officers doing administrative work in addition to professional work would entail much labour, and he hoped the point would not be pressed. It might be assumed that the proportion was large and included every commanding officer.

Enlistment of Pharmacists.—On November 11th Mr. Tennant informed Mr. Glyn-Jones that the list of occupations prepared by Lord Lansdowne's Committee did not include pharmacists. Pharmacists indispensable in their civil employment should enlist under the Royal Warrant of October 20th, 1915. They would then be placed in the group appropriate to their age and martial condition, and could return at once to their civil occupation until their group was called up. If a pharmacist or his employer claimed that more time was still necessary, the matter would be one for the local tribunal, which could still further postpone the date of calling up for actual military service.

Income Tax (Free Board and Lodging).—Mr. Rendall asked the Chancellor of the Exchequer, on November 11th, whether persons such as medical and other officers of institutions receiving residential, boarding, and laundry allowances as part of their pay are taxed for income tax purposes on the actual salary paid to them, and that these allowances are not treated as part of their income, whilst non-resident officials of the same institutions are taxed on their full salary. Mr. McKenna said: The officers referred to would be liable to income tax in respect of all pecuniary emoluments of their office, but not in respect of allowances in kind not convertible into money. In reply to Sir Charles Henry, on November 15th, the Financial Secretary to the Treasury (Mr. Montagu) said that, in making returns for income tax purposes under the provisions of the Finance (No. 3) Bill, persons who, in addition to the receipt of salary, were lodged and boarded free, should not add the estimated value of either or both these considerations to the amount of the salary.

Highlands and Islands Medical Service Board.—In reply to Mr. Leicester Harmsworth, the Secretary for Scotland said that the Highlands and Islands Medical Service Board would take steps to make public the arrangements made with practitioners in particular areas as soon as the arrangements in each area were sufficiently advanced to enable this to be usefully done. A considerable proportion of the doctors in the Board's area had already entered into formal agreements with it, and the Board was endeavouring to complete arrangements with all the practitioners before the end of the current year.

THE WAR.

TREATMENT OF HEAD INJURIES.

(From a Correspondent in France.)

I HAVE paid a good deal of attention to head injuries out here, but can speak of them solely from the point of view of a listener and onlooker. Subject to these qualifications I should say it was quite true that considerable progress has been made in their treatment since this time last year. There is, for instance, greater uniformity in the technique employed. As a whole this is better suited to the actual needs of the situation; in other words, it is of a kind more likely to keep operative interference within the limits of indubitable desirability and to avoid the risk of extending any existing sepsis more deeply than before.

In respect of general principles and their application to particular cases, there must always be plenty of occasion for differences of opinion, since the injuries of the head seen in this war differ so greatly in their extent and specific importance. Yet there is progress.

Twenty-five years ago the peritoneum was regarded as a resentful god, forming a mysterious cavity which could only be approached on bended knee, and the same kind of feeling prevailed in regard to the brain at the beginning of this war. It was considered that if there were the slightest reason to suppose that it had been in any wise injured atonement must be made by the immediate performance of an operation.

This view is now pretty generally discarded, and more especially by those who have not only been out here a long time, but have had opportunities of going into the matter thoroughly. They hold, as far as I can make out, that whatever may be the consideration to which the brain is entitled so long as it is inside an intact head, quite different considerations arise when a gunshot wound has been inflicted. In that case the brain is to be regarded less as a vital organ than as the seat of possible sepsis. Not all of its parts are equally vital, and if a missile strikes one of the parts that are in fact vital, the patient is either killed on the spot, or is picked up in a practically moribund condition. It is held that, apart from these cases, it is sepsis that accounts for the majority of all deaths from gunshot wounds of the head, and it is to its elimination and avoidance that all efforts should primarily be directed. They must not be diverted from this aim by considerations based upon a belief that the local injury is one which, if unremedied, will interfere with the patient's intellect, or indirectly set up some form of paralysis.

The immediate outcome of this conclusion is a tendency to agree that there is rarely any need for haste in the performance of a formal head operation, and that, in considering the condition of any patient after receiving a gunshot wound in the head, it is to be remembered that many of the initial phenomena are due not to local injury but to general concussion of the brain.

This latter fact has a direct bearing on the question of early operation. Brain concussion always results in temporary cerebral oedema, and if during its continuance any operation which involves increasing the size of an existing opening in the cranium be performed, the prospect of a satisfactory immediate and eventual result is decidedly diminished. The tension created by the oedema causes the brain to bulge out through the opening, and thus increases the surface exposed to the risk of infection, and simultaneously damages the deeper parts of the brain by placing on them a dragging strain such as its finer structures are unable to withstand.

This concussion oedema is perhaps the best proved reason for not being in a hurry to undertake any complete head operation, but it is not the only one. It has been found that healthy brain substance itself possesses considerable power of limiting microbic invasion, and that its soft coverings tend likewise to protect both themselves and it. Observations made at *post-mortem* examinations on cases of penetrating gunshot wounds of the head in which no trepanning operation has been performed show that the opened-up portion of the subdural space is sealed off from the rest with considerable rapidity by exudates from the pia mater and arachnoid membranes.

These two facts, and especially the latter, are considered by some to be a further reason for confining the primary

operation in most cases to a surgical cleansing of the scalp and of any already exposed portion of the skull cap and brain. These natural defences, it is contended, may be destroyed by an early trepanning operation, and are quite certain to be destroyed if the operation approaches a decompression procedure; it is further held that if anything of this kind seems in itself to be indicated by the symptoms, it is much wiser to meet the situation by lumbar puncture.

A further conclusion is that cases that have been trephined travel very badly; they should not be moved for at least a fortnight. Those, on the other hand, still in the concussion stage and on whom no trepanning operation has been performed travel well. They can be sent long distances without any apparent detriment to their condition. Consequently it is held by many that advantage should be taken of this circumstance to send them to hospitals at which their treatment can be considered in the light of x ray and other sources of information, and be undertaken at leisure in an environment wholly favourable to success.

In regard to considerations other than those involved by the question of immediate or deferred operation there is far less agreement.

The question, for instance, of the treatment of depressed portions of the inner table or of free fragments of bone, or of buried bits of shrapnel or shell casing, is one of those on which there is no consensus of view. Hitherto the commoner practice seems to have been to remove such fragments and portions of bone forthwith as a matter of general principle. But this procedure is losing favour, some whose experience in the matter is long having come to the conclusion that it is safer to leave such bodies untouched unless there are symptoms definitely attributable to their presence, or their removal is necessary to secure free drainage.

There may be said, in fact, to be almost two schools of thought on this subject. The one is disposed to engage in a more or less extensive operation in any case in which the cranium is known to have been injured, and inclines to undertake exploratory procedures even when the appearances seem to point to the conclusion that the lesion is nothing more than a scalp wound.

The other school—which is formed, it should be noted, of ex-members, so to speak, of the foregoing—takes a very different view. It is disposed to restrict all interference to absolutely proved needs, and the only need it habitually recognizes as such is the provision of free drainage if the wound is septic.

The reasoning seems to be as follows: Attempts to remove fragments are accompanied by grave risks of extending any existing sepsis, and, however successful, cannot undo the damage already caused to the brain. At the best the latter must result in the formation of scar tissue, and the extent of this is certain to be increased by the procedure adopted in removing the fragments. The evil effects of retained fragments of bone or missiles are, they consider, more or less problematic, and the time to deal with them is when the fears to which they give rise are actually realized. With a scalp wound healed the necessary measures can be undertaken with comparative safety. The case, in fact, will have left the province of military surgery and will be envisaged precisely as is a brain case in civil life, its treatment being the combined expression of both medical and surgical views.

The foregoing is as faithful a description as I can supply of the present position of matters. Which of the two schools is destined to prevail is a matter of pure speculation. Between the operative skill of the protagonists of either there is absolutely nothing to choose. Personally I am more attracted by the second and at present smaller school, for the simple reason that, extremely conservative as are its practices, it represents what seems to me really the more progressive line of thought.

CASUALTIES IN THE MEDICAL SERVICES.

ARMY.

Prisoner and Wounded.

TEMPORARY LIEUTENANT JAMES RICHARDSON SPENSLEY, R.A.M.C., whose death in action was officially reported on October 13th, and of whom an obituary notice was given in the BRITISH MEDICAL JOURNAL of October 16th, has

since been reported as living as late as October 20th, but a prisoner, seriously wounded, in the hospital for officers at Mainz, Germany.

Died on Service.

Assistant Surgeon Archibald Wilfred Cummins, Indian Subordinate Medical Department, is reported as having died in France. He was born on October 4th, 1886, became a fourth class Assistant Surgeon on March 4th, 1907, and was promoted to the third class on March 4th, 1912. His last station in India was Firuzpur.

Captain James Fairburn Fairey, R.A.M.C., is reported in the casualty list published on November 15th to have died in France. He was an Australian, and was educated at the University of Melbourne, where he took the degree of M.B. in 1909, that of B.S. in 1910, and the M.D. in 1912. He took the diploma of F.R.C.S. Eng. in 1914. He joined the R.A.M.C. as a temporary Lieutenant on August 16th, 1914, and was promoted to Captain on completion of a year's service.

Assistant Surgeon Archibald Albert Frenck Hart, of the Indian Subordinate Medical Department, is reported to have died on service at Aden. He was born on December 3rd, 1879, entered the department as a fourth class assistant surgeon on March 3rd, 1899, and reached the second class on April 17th, 1911. Previous to the war he was in civil employment in Burma. He was at first erroneously reported as wounded.

Wounded.

Major C. H. Turner, R.A.M.C., France.
 Captain F. B. Bevan-Brown, R.A.M.C. (temporary), France.
 Captain G. R. Rickman, R.A.M.C. (temporary), France.
 Captain B. Hughes, R.A.M.C. (T.F.).
 Captain Henry James Burke, R.A.M.C. (temporary), France.
 Lieutenant J. B. Woodrow, R.A.M.C. (temporary), France.
 Lieutenant C. J. H. Sharp, R.A.M.C. (temporary), France.
 Lieutenant J. M. McLachlan, R.A.M.C. (temporary), France.
 Assistant Surgeon P. J. Doran, I.S.M.D., Indian Frontier.
 This is the second time Captain Burke's name has appeared in the casualty lists. He was reported as wounded once before, in the list published on August 7th.

Suffering from Gas Poisoning.

Lieutenant G. Redpath, R.A.M.C. (temporary), France.

NURSES IN THE CASUALTY LIST.

The death of Staff Nurse A. G. Hawken, of the New Zealand Nursing Service, in the Mediterranean area of war, was reported in the casualty list published on November 14th. On the same day it was also announced that ten staff nurses of the same service had been lost in the transport *Marquette*, torpedoed in the Aegean Sea on October 23rd. Lieutenant F. H. Young, R.A.M.C., was lost in the same vessel, as stated in the JOURNAL last week. There were in all thirty-six nurses on board, of whom twenty-six were saved. Of the other ten the first nurse M. Rogers, is reported as drowned; the other nine as "missing, believed drowned." The names are: M. Rogers, M. S. Brown, J. Clark, C. A. Fox, M. Gorman, N. M. Hilyard, H. K. Isdell, M. E. Jamieson, M. K. Rae, L. A. Ratray.

DEATHS AMONG SONS OF MEDICAL MEN.

Hall, Bruce, Lieutenant 2nd Battalion South Staffordshire Regiment, twin son of Dr. Hall, of Hodnet, Shropshire, killed in France on September 25th. He was educated at Denstone College, where he was a prefect and was in the O.T.C., and was on the point of going up to Cambridge when the war broke out; he took a commission from August 15th, 1914.

Hammond, G. O. Sergeant 2nd Battalion Border Regiment, son of the late Dr. Hammond, of Penarth, killed in France on September 25th, aged 33.

McGachen, Francis Stewart, Lieutenant-Commander R.N., son of the late William Dobson McGachen, M.D., of Bedford Square, London, W.C., died at Southsea on October 29th, aged 32. He was educated at Rugby and in the training ship *Britannia*, joined H.M.S. *Endymion* as a midshipman, and served in the third China war of 1900, for which he received the medal. He had recently been serving in the Persian Gulf expedition.

Taylor, Charles E., Second Lieutenant 1st Battalion West Yorkshire Regiment, son of Dr. Michael H. Taylor, coroner for the Richmond and Kingston districts of Surrey, killed in France on November 1st, aged 23. He joined the 6th Battalion East Surrey Regiment in 1913, and got a commission in the West Yorks on October 1st, 1914.

Wright, Walter Herbert, Lieutenant-Colonel, reserve, King's Own Yorkshire Light Infantry, last surviving son of the late Dr. T. G. Wright, of Wakefield, died in the Second Northern General Hospital, Beckett's Park, Leeds, on November 8th, aged 67. He retired from the Volunteers some years ago with the honorary rank of Lieutenant-Colonel, and was appointed a Major in the Territorial Force Reserve of the K.O.Y.L.I. on August 12th, 1914.

HONOURS.

THE *Gazette* of November 8th publishes a list of honours conferred for services in the Dardanelles expedition on officers mentioned in Sir Ian Hamilton's last despatch. Among them are the names of three medical officers.

Distinguished Service Cross.

Surgeon J. Pratt, R.N.

C.M.G.

Colonel the Hon. J. L. Beeston, Australian Army Medical Corps.

Lieutenant-Colonel C. M. Begg, New Zealand Medical Corps.

Second Lieutenant C. S. Peddie Black, of the 6th Battalion Highland Light Infantry, who was decorated with the Military Cross on October 29th for gallantry in the Dardanelles, took the M.B. and B.Ch. at Glasgow in 1910. After qualifying he acted as assistant medical officer at Stobhill Hospital, Glasgow, after which he served as surgeon in the British Red Cross Hospital in the Balkan war of 1912-13, and received from King Peter the Serbian order of St. Sava. On his return he became assistant physician to the Glasgow Royal Asylum at Gartnavel, leaving that post to take a combatant commission from September 10th, 1914. He is a native of Dufftown, and the son of Captain Black, superintendent of the Monarch Steamship Company, Glasgow.

Temporary Captain J. M. McLaggan, on whom, as was announced last week, the Military Cross has been conferred, graduated at Aberdeen in the summer of 1913, and shortly afterwards became house-physician at the Aberdeen Royal Infirmary. His term of office had not quite expired when he obtained permission to join the R.A.M.C.

Captain J. R. McCurdie, who, as was announced last week, received the Military Cross for conspicuous gallantry on September 25-27th, graduated at Glasgow in 1912. At Glasgow he was a member of the University O.F.C. After graduation he held the posts of junior and senior house-surgeon to the North Riding Infirmary, Middlesbrough, and at the outbreak of war was house-surgeon to the North Ormesby Hospital in that town.

NOTES.

MEDICAL OFFICERS WANTED.

21st Highland Mounted Brigade's Field Ambulance.

Two medical officers are urgently required to complete the establishment of this field ambulance, now sending drafts overseas. Full particulars regarding pay, duties, etc., will be given on application to the Officer Commanding, 21st Highland Mounted Brigade Field Ambulance, R.A.M.C., 2, Mount Street, Duss, Norfolk.

5th Provisional Field Ambulance.

There is a vacancy for an officer, who need not be physically fit for foreign service, in this unit. Further particulars will be found in our advertising columns.

ambulances have still to be tested and their relative efficiency compared with horse ambulances." In the official publications of the British Red Cross Society it is claimed that the first year of the war evoked the motor ambulance, and that its possibilities had previously passed unnoticed. We understand that Mr. A. F. P. Roger, who has laboured so successfully in organizing the service of the British Red Cross Society, has admitted the inaccuracy of that claim. The history of the motor ambulance is recorded in the Home Office Committee's report in 1909 on the London service, and statutory recognition of "ambulances and other vehicles to be drawn by electric and other mechanical power" was embodied in Sir William Collins's Metropolitan Ambulances Act of the same year. We congratulate the London County Council on their tardy but successful completion of the limited service thus far approved; and we are sure that under Commander Sladen, R.N., of the Fire Brigade, the maintenance and full development of this necessary communal service will be assured.

THE RETRENCHMENTS OF THE LONDON COUNTY COUNCIL.

The financial retrenchment policy of the London County Council includes a reduction of over £2,000 a year in the amount to be expended on the medical inspection of school children. The proposal was that, instead of the present arrangement whereby the whole of the entrants into the schools are subjected to a thorough medical examination, only children specially selected by the teachers and nurses, or judged from their general appearance by the inspecting doctor to require it, should be subjected to detailed examination. It was thought, moreover, that school doctors might be asked to extend the time given to medical inspection with a view to the examination each session of thirty cases instead of twenty-five, except in the case of entrants selected for further examination. The principle of employing both full-time and part-time doctors was maintained. The Chairman of the Education Committee said, in reply to criticisms, that the restriction of medical inspection was not wholly put forward on the ground of economy, but also in order to free a number of doctors to meet the demands of the War Office; the effect of the arrangements would be to enable the Council to release the equivalent of four and a half full-time doctors and four full-time nurses for war service. Dental treatment had been increased to an extraordinary degree during the last four or five years; 57,000 cases were dealt with in thirty-three dental centres, and there was no intention of reducing this number. The saving would be effected in connexion with four new centres. The proposals were carried, as were also proposals negating during the war the provision of additional schools for children suffering from high myopia, and rearranging in the direction of greater economy the schools for the physically and mentally defective. The special committee on war estimates also recommended a saving of £1,450 on the public health services by reducing from 3,000 to 1,200 the number of samples of milk examined.

England and Wales.

THE LONDON MOTOR AMBULANCE SERVICE.

THE London County Council has received a report from its General Purposes Committee, which announced that the tentative scheme for a motor ambulance service, approved by the Council on March 10th, 1914, is at length in full operation. The reference to the Special Committee which had this matter in hand was accordingly discharged, and the duty of maintaining and managing the ambulance service in the future was formally handed over to the Fire Brigade Committee. Thus, after thirteen years, the Council has reverted to the proposal put forward in 1902 by a subcommittee, which, under Sir William Collins's chairmanship, advised the establishment of such service in connexion with the Fire Brigade. At that time the motor ambulance was criticized as a "fad," and its suitability for the London service was hotly contested in official quarters for several years. We have uniformly supported the scheme as originally propounded to the Council, and rejoice to see that it has at last been carried out. The enormous development and high appreciation of the motor ambulance during the war make us apt to forget that even so recently as August 29th, 1914, as was stated in the *JOURNAL*, "in military work the motor

Scotland.

MAIMED SOLDIERS.

A SCHEME has been worked out at the suggestion of the Scottish Veterans' Garden City Association for the establishment in the various areas of Scotland of villages wherein a soldier, whose economic value in the labour market has been reduced on account of loss of a limb or other disability, may find a home for his family, and may be trained in some useful work by which he can supplement his pension. It is proposed to establish committees in each locality, and in Edinburgh, Glasgow, Aberdeen, Perth, Inverness, and Dumfries, such committees have been established or are in process of formation. There is a central council which has had plans prepared showing villages containing thirty-nine houses, three shops, and three workshops, on three acres of ground. The estimated cost of building such a village is £11,000. The intention is to let the houses to suitable men, who will be trained in such work as carving, metal work, basket work, and poultry farming.

OBSTETRICS IN GLASGOW AND THE WEST OF SCOTLAND.

The *Glasgow Herald* published on November 10th a strong appeal for education in mothercraft, in the course of which statistics brought before a conference, recently held in Glasgow, by Dr. Jardine, one of the physicians to the Glasgow Maternity Hospital, and Professor of Midwifery in St. Mungo's College, were quoted. He stated that in one month in this year 127 obstetric cases were dealt with, and that of these 41 were normal and 86 abnormal; he doubted whether there was an institution in the world which could show a similar proportion of abnormal cases that they could. Caesarean section had had to be done thrice in one day within two hours, and on a certain day in the past year it had been performed four times. Maternity hospitals were more than local charities, they were national institutions. The antenatal department in connexion with the Glasgow hospital had been reorganized, and it was hoped soon to have a post-natal one to complete the work. The article concludes with references to the pressing importance of a Midwives Act for Scotland, and to the value of maternity hospitals as training institutions for doctors and nurses. Two days before this article appeared Dr. Samuel Cameron read a paper at the opening meeting of the session of the Queen Margaret College, Glasgow, on "Two famous Lanarkshire obstetricians." These were William Smellie and William Hunter. The life of the former was divided between Lanark, his birthplace, and London, the scene of his work as a lecturer on midwifery. It was almost impossible to estimate the great value of Smellie's services to obstetrics. "By careful observation he placed before the profession valuable clinical facts, which entirely changed the methods of teaching and brought great benefit to humanity." The name of William Hunter was perpetuated in Glasgow by his gift of the Hunterian Museum, which was received by the university in 1807. He was born in 1718—twenty-one years later than Smellie—at Long Calderwood, near East Kilbride, the seventh child of a family of ten. He entered Glasgow University at the age of 13, intending to study divinity, but changed to medicine, with great profit to that science, and especially to the obstetrical part of it. In London, whither Hunter also betook himself, he came into touch with Smellie, and he was joined there by his younger brother John.

Ireland.

IRISH MEDICAL WAR COMMITTEE.

A MEETING of the Irish Medical War Committee was held at the Royal College of Physicians, Dublin, on November 8th, when Dr. MacDowall Cosgrave, President of the Royal College of Physicians, occupied the chair. The other members present were: The Right Hon. M. F. Cox, F.R.C.P., P.C., Dr. J. F. O'Carroll, Vice-President, R.C.P.I., Colonel Heron, R.A.M.C., Dr. T. Hennessy, and Dr. M. R. J. Hayes, Honorary Secretary. A large amount of correspondence was dealt with. The following resolution was unanimously passed and directed to be forwarded to the Local Government Board:

That, in view of the urgent need which exists for doctors to serve in the R.A.M.C., the Irish Medical War Committee strongly urges Boards of Guardians and other corporations to facilitate their medical officers to the fullest extent in volunteering their services. In furtherance of this object, the Committee are of opinion that public bodies should accept the substitutes nominated by their medical officers, provided that the interests of the sick poor are safeguarded to the satisfaction of the Local Government Board.

Dr. T. Hennessy was selected to represent the Irish Medical War Committee on the Central Medical War Committee.

UNIVERSITY COLLEGE, CORK.

The number of students attending the University College, Cork, during the session 1914-15 was 420, as against 407 during the session 1913-14. Of the 420 students 396 were matriculated, 14 were non-matriculated, and 10 were post-graduate. The number of new students was 123. The steady and gratifying rise in the number of matriculated students, as well as the great increase in the number of engineering students, are noteworthy points in the report. The difficulty of carrying on the work of the

college had been increased by the war, no fewer than five members having been withdrawn from the staff; and over 200 former students of the college had taken service in the war. The deaths of Professor Molohan, Professor of Latin as well as Registrar, of Professor Keene (Greek), and of Dr. Cotter, who was a member of the governing body and a prominent surgeon in the city of Cork, and in previous years a teacher in the medical school, had been keenly felt. Consequent on the deaths of the two classical professors, the governing body, after prolonged discussion, and acting on the advice of the Academic Council, decided to abolish the chairs of Latin and Greek, and to constitute in place thereof a professorship and lectureship in Ancient Classics. The reason for this change was that the number of students in Latin was very large, and in Greek comparatively small. Several improvements have been made in the buildings, including the enlargement of both men's and women's clubs, the heating of the observatory, and the construction of a new stand at the athletic grounds.

ULSTER MEDICAL SOCIETY.

At the opening meeting of the session Dr. J. S. Morrow, the outgoing president, took the chair, and, after the reading of the minutes, introduced his successor, Dr. A. Gardner Robb, who before giving his address recalled the deaths of three Fellows during the past year—Dr. John Melroy of Belfast, Dr. J. W. O'Phiers of Downpatrick, and Dr. Brian O'Brien, Local Government Board Inspector—and paid a suitable tribute to each. A resolution expressing the deep regret and sorrow of the society at the recent death of Dr. O'Brien was passed. Dr. Robb in his address dealt with recent experiences of acute poliomyelitis. He said that only in recent years had acute poliomyelitis appeared in epidemic form. The first epidemic was recorded in 1881; since then outbreaks amounting at times to epidemics had appeared in Norway, Sweden, the Continent of Europe generally, and America. Various names had been assigned and varieties had been distinguished; the incubation period was probably five to ten days but might be shorter; its onset was often mistaken for cerebro-spinal meningitis or influenza. Experiment had shown that the virus was transmissible to monkeys, was capable of passing through a porcelain filter and was ultra-microscopic, and that antibodies were produced, but no practical use had yet been made of this knowledge. The disease was probably transmitted by acute and chronic cases and by healthy carriers. The stable fly was not an agent. A hearty vote of thanks to Dr. Morrow for his conduct in the chair during the past year and to Dr. Robb for his address was passed with acclamation, on the motion of Professor Lindsay, seconded by Dr. McCaw.

IRISH WAR HOSPITALS SUPPLY DÉPÔT.

It is proposed to start a central dépôt in Dublin with the object of drawing together the various dépôts and work guilds which are already working throughout Ireland, in making dressings for the war hospitals both at home and at the front. A central committee has been formed, with Lady Waterford as chairman, under the auspices of the city and county branches of the British Red Cross Society and the St. John Ambulance Association, and has received the approval of the joint committee in London. These three organizations are represented on the Central Irish War Hospital Supply Committee by two members each; the Presidents of the Royal College of Physicians and Royal College of Surgeons, as well as several ladies, who are already engaged in war hospital supply work, have also consented to act. It is a necessary part of the scheme that all dressings should be standardized, as far as making and packing are concerned, and that extreme cleanliness should be exercised in their handling. Dépôts are advised not to undertake this work until instruction has first been obtained. Home work is not permitted, as the risk of possible infection must be reduced to a minimum. Several experienced ladies will act as teachers, and arrangements can be made for one of these to instruct classes in the country, wherever a new dépôt is being started. One feature of this scheme will be the utilization of fresh sphagnum moss, the preparation of which and its use as a dressing were described by Mr. Cathcart in the *JOURNAL* of July 24th, p. 137. This moss is to be found in all bogs in

Ireland, and can be easily collected, and there is now a big and growing demand for it from the front, where its utility has been proved. Bandages, swabs, sponges, slings, many-tailed bandages, splints, etc., are also included in the list of supplies to be made, and the intention is that boxes and bales will be sent to hospitals for our own troops, or for those of our allies. Steps are being taken to procure a house in Dublin in a central position, and when the organizers, officers, and managers of departments have been appointed, invitations will be issued to the members of Voluntary Aid Detachments and other ladies to give their services daily. It is also proposed to form a men's committee to assist as packers and to make boxes, splints, etc. Money will be wanted as well as labour to make the Dublin depot worthy of Ireland, and it is hoped that this practical and useful scheme will receive the support that it deserves.

Correspondence.

THE TREATMENT OF GUNSHOT FRACTURES OF THE LEG WITH POSTERIOR WOUNDS.

SIR,—I was glad to see Professor Morton's paper under the above heading in your issue of August 28th, and I welcome his criticisms.

Unfortunately Professor Morton does not appear to have given the splint I described a trial, so that the criticisms lose their value to a great extent. He fears the extension I described would be sufficient for a bad case of comminuted fracture of, say, both bones, and that is so; the remedy is, of course, more slings, for which the upper bar is provided; in most cases extension *plus* one sling is sufficient, I find, but there is no objection to the use of any number of slings if they are found to be necessary.

Possibly the "extension" might be better described as "fixation," but extension, however carried out, is necessary in the first instance to get the bones into proper position; when this has been accomplished fixation is rather an advantage than otherwise. Whatever it be called, the pull on the straps overcomes the tendency of the muscles to cause overriding of the fragments, and if that "pull" be not fixed in some way, overriding will recur, as has happened in a case now under treatment, in which the upper extension straps slipped, and the patient's leg also slipped downwards, with the result that there was overriding and sagging of the fracture area.

As regards the extension on the ankle, I usually bind the foot evenly on to a foot-piece as well, so that the pressure is distributed evenly, and the foot-piece I make to project below the heel, so that the latter rarely touches the supporting shelf. The extension itself, of course, tends to keep the heel from dropping; so far no case has complained of any pain from the extension apparatus on the ankle. In view of the tendency of the suppurating in bad cases to track up the calf, I think much raising of the foot of the bed for the purpose of extension by the weight of the body inadvisable. Professor Morton's splint would seem to be excellent for simple cases: it is slings without extension, and looks as if it would be comfortable and efficient.—I am, etc.,

C. H. BARBER,
Capt. I.M.S.

Busra, Oct. 6th.

BROMIDES IN EPILEPSY.

SIR.—Considerable interest attaches to the letter of Dr. Humphrey Davy in your issue of November 6th. Dr. Davy states that calcium bromide is effective in diminishing the frequency and intensity of the fits in half the doses of the potassium salt, and not only so, but that under its use (and more especially if the patient has been taking the potassium salt previously) mental activity increases and the general health improves. Now, as regards the dosage, it is to be remembered that a molecule of calcium bromide contains twice the quantity of bromine in a molecule of potassium bromide, and as the molecular weight of KBr is 119.11, and that of CaBr₂ is 200.2, it follows that a half-dose by weight of CaBr₂ is practically equivalent in bromine content to a corresponding whole dose by weight of KBr. As each of these salts may be

assumed to be dissociated freely in the usual quantities of water added, it follows that the benefit observed by Dr. Davy is not associated with any reduction in the bromine ions. It must therefore be due to the calcium. It is interesting to recall, in this connexion, the observation of Loeb that sodium salts, which precipitate calcium, cause irritability of muscle and nerve, and he suggests the administration of calcium as a cure for neuroses and forms of nervous irritability or instability. The same observer pointed out that a bivalent cation (such as Ca or Sr) has what may be termed an "antitoxic" action on a monovalent anion (Br) not possessed by a monovalent cation (K, Na); in other words, it is the magnitude rather than the sign of the charge which is effective.

Some interesting experiments by H. von Wyss showed that large doses of sodium bromide were followed by unfavourable symptoms (paræsis), which were due, not to the bromine, but to a very great reduction in the chlorides of the blood. Such symptoms were very quickly relieved by giving sodium chloride. This suggests the addition of a liberal dose of chloride to bromine mixtures for epileptics. It is at any rate evident from the foregoing considerations that there is some room for investigation.

Dr. Mercier's very low estimate of the percentage of epileptics which are benefited by bromides—"unlikely more than one out of seventeen"—is certainly very different from one's experience of hospital cases. I have had many epileptics from the homes or "colonies" where they received no bromide, get rapidly and permanently well under full doses of the drug.—I am, etc.,

London, W., Nov. 8th.

A. G. AULD.

Universities and Colleges.

UNIVERSITY OF LONDON.

DR. E. P. PORTLON has been recognized as a teacher of medicine at Guy's Hospital Medical School.

It is reported that owing to circumstances connected with the war Mr. J. Sherren has been appointed examiner in surgery, in place of Mr. Warren Low, and Dr. C. H. J. Lockyer in obstetric medicine, in place of Dr. G. F. Blacker.

The Senate has forwarded to the Government a report giving details of the large amount of research work in connexion with the war now being carried out by the staffs of the incorporated colleges of the University.

UNIVERSITY OF GLASGOW.

Professor Ferguson.

At a meeting, on November 11th, of the Glasgow University Court; presided over by Principal Sir Donald MacAlister, an appreciation was submitted of Professor John Ferguson's services on the occasion of his retirement from the Chair of Chemistry (see the JOURNAL for November 6th, p. 694), to which he had been appointed by the Crown in 1874. The appreciation referred to Professor Ferguson's unbroken association with the University as student, assistant, and professor, extending over sixty years, and specially alluded to the goodwill and unselfish devotion to the best interests of the University which had always characterized his counsel and co-operation in connexion with the organization and expansion of the chemistry department both for the purposes of study and of research. Other business before the Court was the consideration of the institution of a degree in the theory, practice, and history of education.

GRADUATION CEREMONY.

A number of degrees in the various Faculties at Glasgow were conferred at a graduation ceremony on Saturday, November 13th. Principal Sir Donald MacAlister presided. The following is a list of the graduates in Medicine (M.D.):

M. Young, E. M. Milne, E. G. Glover, R. M. Macfarlane, F. J. Barber, E. Barr, Jane Reid, Fionula Gilhoun (Mrs. Strussell), Elizabeth Maud M'Vail, R. M. Walker.

With honours. † With high commendation.
With commendation.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.

AN ordinary council was held on November 11th, when Sir William Watson Cheyne, President, was in the chair.

Issue of Diplomas.

Diplomas of Membership were granted to 103 candidates found qualified at the recent examinations. Diplomas of the Licence in Dental Surgery were granted to five candidates recently found qualified.

Addition to Dental Schools.

The Dental Department of the University of Illinois, Chicago, was added to the list of dental schools recognized by the

College, and graduates in medical sciences of the University were exempted from the Preliminary Science Examination for the Licence in Dental Surgery under the conditions of par. 7, Sec. ii of the Regulations.

Graduate Lectures.

The Bradshaw Lecture will be given by Sir Anthony Bowley on Monday, December 20th, at 5 p.m., the subject being "Wounds in war."

Library of the University of Louvain.

The President and Mr. D'Arcy Power were appointed delegates to serve on the British Committee which is being formed to co-operate with the Institute of France with the aim of reconstituting the library of this university.

Medical Students and the O.T.C.

A letter was received from the War Office on the subject of medical students and military training, urging that all senior students who have not already done so should become cadets in the medical units of their University Officers' Training Corps. The Council expressed its concurrence with the course suggested.

CONJOINT BOARD IN ENGLAND.

THE diplomas of L.R.C.P. and M.R.C.S. have been conferred upon the following candidates, who were successful at the final examination in Medicine, Surgery, and Midwifery:

F. W. I. Andrew, G. A. Baek, B. F. Bailey, R. T. Bailey, O. Barkan, E. G. Barker, Mahmud Basani, G. C. Beng, C. F. Bevers, Sohan Lal Bhatia, Batros Bishara, Satish Chandra Biswas, A. Le Bodilly, Margaret S. G. Bott, G. K. Bowen, Alice D. Brooks, E. F. Buckler, C. H. C. Byrne, E. L. Caldwell Smith, M. Carrasco, M. Chadwick, V. M. Costes, R. C. Cooke, Euclytanthy Comarassavy, S. A. Cornelius, T. R. Davies, E. V. de Souza, D. McEl. Dielson, E. G. Dingley, Ganayudam Mangalathani, Dominick, T. H. Edes, Nassir Gohari El-Gary, Ahmed Fahmi El-Hakim, H. Elliott, H. H. Ellis, H. J. Ellis, G. C. J. Emmerson, Monair Farag, V. Feldman, J. Y. Ferguson, E. Ferret-Paton, Luis H. Garcia, C. Gardner-Hill, P. C. Gilson, G. T. Gillester, B. Graves, E. A. T. Green, A. F. G. Guinness, Honoria J. Haughey, Constance Hart, R. Heaton, G. O. Henpison, F. E. Higgins, P. Hudson, G. W. Hughes, S. C. W. Ireland, Luis G. C. Iturrigo, E. L. Ivons, F. N. Jaywardene, D. S. Jones, J. P. Jones, C. S. J. Karlov, C. H. Keay, T. H. V. King, Yambel Krupenia, A. A. Lee, E. C. Lees, J. K. Leslie, E. M. Littlejohn, M. D. Lovelock, W. B. Lovelock, H. G. Lush, F. K. Marriott, H. N. Morgan, Hannal G. Morland, J. K. Muir, W. G. S. Neely, W. D. Newland, Violet Scrimshere, Kathleen E. Parkinson, J. F. M. Payne, F. Porter-Smith, A. E. A. Poulter, S. H. Prall, E. A. Pritchard-Evans, H. E. R. Robinson, L. C. S. Roche, W. W. S. Savage, E. G. Sherrinford, S. Simons, G. E. Spicer, E. C. Tampion, T. J. Tampion, B. E. Hoon Oo Tha, J. W. T. Thomas, W. Thomas, W. L. Thomas, H. C. C. Vetch, A. D. Vernon-Taylor, G. M. Veyers, H. Vickler, A. R. S. Warden, J. W. Wayne, P. H. Wells, H. Whyte, W. R. Wilson.

* Under the Medical Act, 1876.

APOTHECARIES' HALL OF IRELAND.

THE next examinations for the Licence will begin on the following dates: Primary, December 6th; Intermediate, Part I, December 13th—Part II, December 20th; Final, January 3rd, 1916.

Obituary.

ROBERT BOXALL, M.D., M.B. AND B.C. (ANTAB).

AFTER spending several years in retirement in the country, this distinguished scientific obstetrician suddenly died on November 7th at his residence, Abinger, Surrey. Dr. Boxall was the son of Mr. Henry Boxall, F.R.C.S., and a nephew of the late Mr. Albert Napper, the founder of the cottage hospitals. He was born in 1858, at Wisborough Green, a village near Horsham, in Sussex, and was educated at Epsom College.

Dr. Boxall studied medicine at University College and its hospital. He was known from the first as a very hard-working student, and recognized by his teachers as a first-rate note taker. He took the diplomas of M.R.C.S. in 1882 and L.R.C.P. in the succeeding year, and afterwards was appointed obstetric assistant, first at University College Hospital, and then at the General Lying-in Hospital, where he ultimately became obstetric physician. In 1889 Dr. Boxall was appointed assistant obstetric physician to the Middlesex Hospital. He was made lecturer on practical midwifery in July, 1889, and full lecturer in midwifery in February, 1902, holding the latter chair until his retirement in March, 1903, owing to ill health. From first till last he worked incessantly. When occupied with his duties at the lying-in hospital he took the Brussels degree of M.D. and afterwards the Cambridge M.B., so that his

clinical and scientific labours were complicated by much travelling.

Dr. Boxall, when attached to the General Lying-in Hospital, drew up an important clinical and scientific monograph on scarlatina during pregnancy and in the puerperal state, based on the investigation of 16 cases of undoubted scarlatina amongst 423 patients under his care about the time of the epidemic of that disease in the south of London in 1884. His main conclusions were that the agency of scarlet fever as a cause of puerperal fever had been, at that time, greatly over-rated, and that scarlet fever breeds true in the pregnant and puerperal woman, and produces not puerperal fever but typical scarlet fever, which runs the ordinary course of the disease. Sir John Williams, President of the Obstetrical Society, when the monograph (to be found in the thirtieth volume of the Society's *Transactions*) was read and discussed, remarked, in commending it, that no inferences of any value with regard to the relation of puerperal to scarlet fever could be arrived at save under conditions in which puerperal fever arising from other causes than scarlet fever could be excluded. The main reason why so high a value must be attached to Dr. Boxall's work was that those essential conditions were present when he carried on his work. Dr. Boxall's researches also testified to the priceless value of antiseptics in midwifery, and he contributed a paper on the chemical incompatibility of anti-septic agents to this *JOURNAL* (vol. i, 1888, p. 896). He wrote also a valuable clinical paper on fever in childbed, which is preserved in the thirty-second and thirty-fifth volumes of the Obstetrical Society's *Transactions*. The first part (1890) dealt with general hygiene and antiseptics; the second (1893) treated of the relation of external meteorological conditions to the incidence of febrile illness in childbed. The late Dr. Herman, President of the society when the second part of this second monograph was read, spoke of Boxall's splendid contributions to the knowledge of puerperal diseases. The evidence consisted of statistical tables, the compilation of which must have involved the examination of enormous masses of detail. There was no more painstaking, practical, and scientific obstetrician at that time than Dr. Boxall. He also contributed to the forty-seventh volume of the Obstetrical *Transactions* a third monograph, on mortality in childbed, both in hospital and general practice, read before the society in April, 1905. His general conclusions were: (1) That the total death-rate from childbed had not diminished either in England and Wales, in Scotland, or in Ireland, where it was abnormally high as compared with the other divisions of the kingdom, but had declined considerably in London. (2) That the death-rate from accidents of childbed had declined slightly in each division of the kingdom, but was abnormally high in Ireland, and in London had markedly diminished. (3) That the death-rate from puerperal septic diseases had, if anything, shown a tendency to increase in each division of the kingdom, but in London had been declining for at least a decade.

Dr. Boxall likewise made many minor communications to the *Transactions* of the Obstetrical Society, and wrote an independent work on antiseptics in midwifery. To Allbutt and Playfair's *System of Gynaecology* he contributed an article on diagnosis in gynaecology.

Dr. Boxall practised for several years in Portland Place. A relative having bequeathed to him a considerable sum of money, he retired from the profession and spent a great deal of time in gardening, especially in the rearing of Dutch bulbs. He was likewise a keen fisherman, and for many years used to go to France, where he knew of a good trout stream.

We have received the following appreciation of Dr. Boxall from Sir FRANCIS CHAMBERS: "The Robert Boxall of whom I propose to give a few lines from memoirs was the house-physician of the General Lying-in Hospital, York Road, Lambeth, while I was visiting physician there. He did his medical work there admirably; he was the best taker of notes I ever knew—they were always to the point, accurate, terse, and complete. He was an admirable cross-examiner, and succeeded in gaining information from a reluctant witness in a most unusual manner. In pursuing an investigation for others he was unsparing of his time and trouble, his only object being to

elucidate the problem and to arrive at the truth. It was at this period that he wrote his paper on scariatina and the puerperium—a paper which has let light and common sense into a subject which was till then confused and obscure. I think that this was the best period of his work; and, looking back, I seem to see the shadow of the ill health which affected him in after-life rather early. This was one of the chief causes why the promise of his youth was not fulfilled. In the latter part of his life he transferred the interest which he had formerly devoted to his profession to gardening, on which he was very keen, and which the inheritance of a competence enabled him to pursue."

ALEXANDER MACGREGOR BUCHANAN, A.M.,

M.D. GLASG. AND F.R.F.P.S. GLASG.,

PROFESSOR OF ANATOMY, ANDERSON COLLEGE MEDICAL SCHOOL,
GLASGOW.

PROFESSOR BUCHANAN died at his home in Glasgow on November 9th, at the age of 71. He was born at Leith, where his father was a supervisor of Excise. He was educated at the High School and the University of Glasgow, where, after taking the degree of M.A., he graduated M.B. and C.M. in 1868, and obtained the degree of M.D. in 1871. He held for a time the appointment of resident house-physician at the Royal Infirmary, Glasgow. In 1868 he was appointed demonstrator under the late Dr. Allen Thomson, and in 1873 professor of anatomy in the Andersonian University; when the medical faculty of the old institution was separated as Anderson's College Medical School, Dr. Buchanan's services as professor of anatomy were retained. He held the examinership in anatomy both in the Royal Faculty of Physicians and Surgeons of Glasgow and in the University of Glasgow. He contributed several anatomical papers to the *Journal of Anatomy and Physiology*. He also published in 1906 *A Manual of Anatomy, Systematical and Practical, including Embryology*. He chiefly distinguished himself as an able teacher of his science, and was personally very popular with his pupils; his manual gained a high reputation in Glasgow as a students' textbook.

GEORGE COATS, F.R.C.S., M.D. GLAS., M.B., CH.B.

MR. GEORGE COATS died on November 2nd at a nursing home in Edinburgh, at the early age of 39. Born at Paisley, he was the son of the late Mr. Alan Coats, and nephew of Professor Joseph Coats. He entered Glasgow University in 1892, and graduated M.B., CH.B. in 1897 and M.D. in 1901. He held resident appointments in the Glasgow Royal Infirmary, the Western Infirmary, and the Eye Infirmary, and afterwards went abroad to work at eye surgery in Vienna, Munich, Freiburg, and Zürich. He settled in London in 1902, and was appointed pathologist and curator at the Royal London Ophthalmic Hospital; subsequently in 1909 he became assistant surgeon to that hospital, full surgeon in 1914, and also assistant ophthalmic surgeon to St. Mary's Hospital in 1911. He was for a time attached in the same capacity to the Great Ormond Street and Great Northern Central Hospitals. He made many contributions to the literature of eye surgery, beginning with an excellent pathological thesis for the degree of M.D., prepared when he was house-surgeon to the Glasgow Eye Infirmary. In 1910 he filled the appointment of Hunterian Professor at the Royal College of Surgeons, choosing for his subject congenital abnormalities of the eye, including cystic dilatation of the posterior chamber, an abnormality hitherto undescribed.

In 1912 the Nettleship prize and medal of the Ophthalmological Society were awarded to him. He read many papers before the Ophthalmological Society of the United Kingdom, and worked at the comparative anatomy and pathology of the eye. In particular, he studied the structure of the membrane of Bruch and its relation to the formation of colloid excrescences, and published a monograph on the subject in the Royal London Ophthalmic Hospital Reports. An abstract note of another memoir on the membrane of Bruch, read at a meeting of the Ophthalmological Society, was published in the *JOURNAL*, vol. ii, 1910, p. 1345. An article on retinitis hæmorrhagica interna, written in German, appeared in the *Archiv für Ophthalmologie* in 1912, when he had already made public his researches throwing light on diseases of the vessels of

the retina. Mr. Coats translated, in association with Mr. J. H. Parsons, Von Hanke's *Therapie der Augenkrankheiten*. He was also a skilful operator, and careful in clinical work.

DR. DAVIS SANDLER, medical missionary of the Church of Scotland Mission, died suddenly on October 20th at Constantinople. He took the degrees of M.B. and CH.B. at Edinburgh in 1902. He contributed to the *Lancet* in 1906 a paper on the "Causes of Leprosy," and was the author of "The Bride of the Bosphorus" and "Abel."

Public Health AND POOR LAW MEDICAL SERVICES.

RANCID BUTTER FOR COOKING.

ACCORDING to the report of the clerk to the metropolitan borough of Bromptley, 82 casks of butter were found on June 21st, 1915, by Mr. Ashdown, Wharves and Food Inspector, to be rancid and unfit for human consumption. This opinion was confirmed by the Medical Officer of Health and by Mr. Bolmer, the Public Analyst. A prosecution was instituted, and the case was heard in the Tower Bridge Police Court on August 25th. The defence was that, although the butter might be unsuitable for sale in the ordinary way over the counter, it was quite sound and fit for cooking purposes—that is, for confectionery, etc., and the magistrate, after examining the butter, decided that it was fit for human consumption. No order was therefore made under the regulations, and the butter was released.

According to the report of the Public Analyst the butter contained 3.16 per cent. of free fatty acids, although the amount of these acids in fresh butter is well under 0.5 per cent. This fact, coupled with the butter's rancidity—rendered it, in the opinion of the M.O.H., unsound and unfit for food. It was proved that the rancid taste and smell could not be distinguished in cakes by the ordinary customer, yet when the butter was extracted from the finished article the percentage of fatty acids had increased and the rancidity had not disappeared. It appears from this judgement that, though a vendor or importer can be summoned for having 1 per cent. of water in his butter above the prescribed standard, he may have over 3 per cent. of free fatty acids in his butter with impunity.

Medical News.

THE War Office Memorandum on the Treatment of Injuries in War Based on Experience of the Present Campaign, a full notice of which appeared in the *JOURNAL* of August 21st, p. 305, has now been placed on sale; it can be obtained through any bookseller, price 4d.

THE Prime Minister stated in the House of Commons on November 16th that applications from disabled and partially disabled sailors and soldiers for employment in Government departments would be duly considered; at present the demand for the services of such men exceeded the supply.

THE Naval and Military War Pensions, etc., Act has been printed, and can be purchased through any bookseller, price 1s.

A DISCUSSION on the national and social aspect of the lower birth-rate will be opened by Dr. Louis Parkes at a meeting of the Royal Sanitary Institute, at 90, Buckingham Palace Road, on Tuesday next, at 4.15 p.m. Dr. J. H. Lidgett, Campden, Director of Quarantine, Melbourne, Australia; Dr. J. S. Purdy, Officer of Health, New South Wales; Dr. J. E. Purvis, Cambridge, and Dr. Thomas Orr, Ealing, have been elected Fellows of the Institute.

AT a meeting of the Medico-Psychological Association of Great Britain and Ireland to be held at 11, Chandos Street, London, W., on Tuesday next, at 3 p.m., the President, Lieutenant-Colonel David G. Thomson, M.D., will describe the conversion of a county asylum into a war hospital for 1,050 sick and wounded soldiers.

THE Municipal Council of Bordeaux has voted a sum of £1,600 towards the creation of a "practical and normal" school for the industrial re-education of soldiers mutilated in the war. The General Council and the Chamber of Commerce have also contributed.

WE are glad to learn that the *Journal de Médecine de Bordeaux*, which has been in a state of suspended animation since August, 1914, has come to life again. For the present it will be a monthly publication, but the hope is expressed that it may be possible to arrange for more frequent issues.

THE regulations issued by the Minister of the Interior of France in regard to the sale of alcoholic beverages to the

civilian population are practically identical with those issued by the Minister of War with regard to soldiers and munition workers, but the sale of spirits is altogether prohibited before 11 a.m., or to women and minors at any time.

THE autumn meeting of the Irish Medical Schools' and Graduates' Association will be held at Pagnu's Restaurant, Great Portland Street, on Wednesday, November 24th, at 7 p.m. Afterwards, at 7.30, members and friends will dine together. In the unavoidable absence of the president (Sir Charles Cameron), Dr. W. Douglas will take the chair. Tickets (5s. 6d. each) may be obtained from the honorary secretary, Dr. W. J. Corbett, 18, Weymouth Street, Portland Place, W.

AT the anniversary meeting of the Royal Society on St. Andrew's Day, November 30th, Sir Joseph J. Thomson, Cavendish professor of experimental physics at Cambridge, will be proposed for election as president, and Professor Arthur Schuster, and Mr. William Bate Hardy as secretaries. Among the Fellows to be elected to the Council on the same occasion are Professor J. G. Adams of Montreal, Sir T. Clifford Allbutt, Dr. Henry Head, and Professor E. H. Starling.

THE Council of Epsom College will shortly award a John and Bridget Greycock Pension of £50 a year. Candidates must be legally qualified medical men who have retired from professional work, and who in the opinion of the Council are in need of this pension. There is no limitation as to age, but the Council will give special consideration to the claims of candidates having association with Worcestershire, Lincolnshire, or Carmarthenshire. Forms of application can be obtained from Mr. J. B. Lamb, the secretary of the college, 37, Soho Square, W.

DR. ADDISON, Parliamentary Secretary to the Ministry of Munitions, gave the following particulars in the House of Commons on November 15th with reference to the number of convictions for drunkenness in the London area in the four weeks preceding and following the Order of the Board of Liquor Control. In the four weeks prior to the Order the average number of convictions was 923 (685 men and 237 women); in the four weeks following the Order the number of convictions was 710 (484 men and 226 women).

Letters, Notes, and Answers.

Readers desiring reprints of their articles published in the BRITISH MEDICAL JOURNAL are requested to communicate with the Office, 52, Strand, W.C., on receipt of proof.

THE clearest addresses of the BRITISH MEDICAL ASSOCIATION and JOURNAL are: (1) EDITOR OF THE BRITISH MEDICAL JOURNAL, *Anatomy, Westminster, London*: telephone, 251, Gerrard. (2) FINANCIAL SECRETARY AND BUSINESS MANAGER (Correspondence, etc.), *Artists, Strand, London*: telephone, 263, Gerrard. (3) MEDICAL SECRETARY, *Medico-legal, Westminster, London*: telephone, 264, Gerrard. The address of the Irish office of the British Medical Association is 16, South Frederick Street, Dublin.

For queries, answers, and communications relating to subjects of which special departments of the BRITISH MEDICAL JOURNAL are devoted will be found under their respective headings.

QUERIES.

C. D. asks for advice in the treatment of corns on the soles of both feet not relieved by salicylic acid preparations.

INFANT FEEDING.

DR. W. B. DUNNISON (2, Braidburn Terrace, Edinburgh) desires to see specimens of leaflets on infant feeding used for distribution to mothers.

INCOME TAX.

DIMINISHED asks for information as to agencies for the repayment of income tax and refers to a system of calculating the liability of medical practitioners on a basis of one-half the gross receipts.

There are several agencies of the kind referred to by our correspondent; we do not feel able to recommend any particular agency in these columns, but are sending to him the address of one which we believe to be conscientiously and efficiently conducted. We have no information as to the extent to which assessments were in the past based on one-half on the gross receipts, but it is extremely unlikely that that method of calculation would be accepted at the present day. If our correspondent is in a position to state his gross receipts for three years accurately he may be able to prepare his own income tax statement with the assistance he may obtain from the article which appeared in our issue of April 18th, 1914, p. 877.

MAJOR R.A.M.C. (TEMP.) inquires whether he is liable to income tax on a payment of £50—presumably £50 per annum—in lieu of board and lodging in the hospital.

* The payment is a pecuniary emolument, and as such is liable to taxation. The matter was dealt with in an answer by the Home Secretary noted in our parliamentary column this week. His answer was no doubt based on a leading income tax case decided over twenty years ago—*Tennant v. Smith*. The difficulty arising from the absence of any satisfactory criteria for estimating the value of non-pecuniary emoluments is inherent in all systems of income tax, and explains the fact that in this country all income received "in kind" is exempt from tax unless it is capable of being converted into money. An illustration is afforded by the case of a resident assistant; the cost of his board and residence is an admissible deduction in calculating the income of the practitioner, but is not assessable on the assistant inasmuch as the value thereof is not capable of conversion into money.

S. A. F. asks whether he is entitled to deduct, for income tax assessment, the commission paid to a medical agent for securing an appointment.

* To be deductible the expense must be incurred solely, exclusively, and necessarily in the performance of the duties of the appointment. Whether necessary or not, the expense was incurred prior to the performance of the duties, and appears to be outside the scope of the words quoted above.

ANSWERS.

BULGARIA. The author of "The Bulgarian bacillus in the treatment of exanthema and pyelitis with alkaline urine," noted in the EDITORIAL OF THE JOURNAL, No. 97, September 25th, is Dr. Francis R. Hunter, Professor of Genito-urinary Surgery in the George Washington University, Washington, D.C., U.S.A. He does not give any reference to the writings of North, Calkin, and Young in his article. Our correspondent would like to hear some opinions as to the value of the Bulgarian bacillus in a case of chronic catarrhal colitis due to *Bacillus coli*, and as to any special dietary precautions required.

C. E.—In the article by Dr. Risien Russell in Allbutt and Rolleston's *System of Medicine* it is said with regard to convulsive fits, of which salivatory spasm is one, that therapeutic measures are to be resorted to in nearly all cases, but that massage, passive movements, gymnastics, hydrotherapeutic measures, and the like, may be useful adjuncts to general treatment by iron and moral and physical discipline, and that static electricity, when combined with hydrotherapeutic measures and isolation, appears to do good when employed for a long time.

LETTERS, NOTES, ETC.

RESIDENT PATIENTS AND BOOKING FEES.

IT has come to our notice that some of our readers who are willing to accept resident patients are being appealed to by business firms to supply information generally as to what terms they are prepared to accept and at the same time invited to pay a booking fee, varying in amount, for the privilege of being included on the register of those taking resident patients. We venture to warn our readers against falling in with such a proposal. We have no quarrel with the regular agents who keep a register of those willing to accept resident patients, and, when an introduction has resulted in business, expecting a certain commission. This is a method of business to which no exception can be taken, but it should be quite unnecessary to pay a booking fee on the mere chance that business may follow. We hope our readers will make a firm stand to prevent such methods becoming general.

SCALE OF CHARGES FOR ADVERTISEMENTS IN THE BRITISH MEDICAL JOURNAL.

	£	s.	d.
Seven lines and under	0 5 0
Each additional line	0 8 0
A whole column	3 10 0
A page	10 0 0

An average line contains six words.

All remittances by Post Office Order must be made payable to the British Medical Association at the General Post Office, London. No responsibility will be accepted for any such remittance not so safeguarded.

Advertisements should be delivered, addressed to the Manager, 429, Strand, London, not later than the first post on Wednesday morning preceding publication, and, if not paid for at the time, should be accompanied by a remittance.

NOTE.—It is against the rules of the Post Office to receive *poste restante* letters addressed either in initials or numbers.

The Goulstonian Lectures

ON
SPINAL INJURIES OF WARFARE.

DELIVERED BEFORE THE ROYAL COLLEGE OF PHYSICIANS
OF LONDON.

BY GORDON HOLMES, M.D., F.R.C.P.

ASSISTANT PHYSICIAN TO CHARING CROSS HOSPITAL, AND NATIONAL
HOSPITAL FOR PARALYSED AND EPILEPTIC, QUEEN SQUARE;
LIEUTENANT-COLONEL (TEMPORARY) R.A.M.C.

[WITH SPECIAL PLATE.]

I. THE PATHOLOGY OF ACUTE SPINAL INJURIES.

I MUST first express my appreciation of the honour the College has done me by inviting me to give the Goulstonian Lectures for the year 1915.

It is with much diffidence that I approach the task, more particularly on recalling the list of lecturers who have preceded me, and the valuable contributions they have made to medicine, and especially to that branch of it in which my chief interests lie. The conditions under which I have had to work during the past fourteen months have made me realize that the ambition to attain their high level is scarcely practicable; I can only hope that the number of clinical observations I have the opportunity of presenting to you will in some measure atone for the absence of completeness and detailed analysis you will find in my lectures.

And even what I can offer has been possible only through the co-operation and help I received from the medical officers of the numerous hospitals in France, in which the material was collected. I am more especially indebted to my colleague, Lieutenant-Colonel Sargent, in association with whom the work has been done. In addition to operating on many of the cases he took a coequal part in the necessary clinical investigations, and his name must be consequently associated with mine in any observations of value I can place before you.

The chief interest of our observations lies in the symptoms produced by different types of spinal injury and when different portions of the cord are affected, but in order to interpret and estimate their significance correctly it is first necessary to study the nature of the medullary lesions to which they are due. We have been hitherto able to obtain *post-mortem* examinations in about fifty cases, and the histological changes have been studied in a certain number of these.

The spinal cord may be injured directly by the projectile and either completely or incompletely divided, but more commonly it escapes direct damage by the missile and is injured only by displaced fragments of bone, which either compress or lacerate it; frequently, however, it is not injured directly either by the projectile or by indriven fragments of bone, and the structural changes in such cases can be attributed only to the concussion or commotion effects produced in the cord by a missile which has struck some portion of a vertebra. Spinal concussion is most commonly seen when the projectile has touched either a spinous or transverse process, which it may have fractured or not, but it may be also produced by a bullet which penetrates or perforates the body of a vertebra.

It is obvious that this classification into *direct injury*, *contusion*, and *concussion* cannot be exact, as contusing or compressing fragments of bone frequently lacerate the cord as a missile may, while concussion effects are liable to occur whenever the missile strikes the vertebral column, and whether or not it injures the cord directly or drives fragments of bone on to it.

DIRECT INJURIES.

On examining a case in which the spinal cord has been completely divided, we find as a rule a considerable amount of clot and often pieces of bone between its two ends. A few days after the infliction of the wound these are swollen, irregular, and very soft to touch for at least 1 cm. from the point of division; indeed they may be more or less diffused, and on handling semifluid disintegrated material, frequently stained with blood, which S.

George Makins, from his experiences in the South African war, very accurately described as custard-like, may extrude. After hardening these portions still seem swollen, softened, and oedematous; the outlines and details of their cross section are obscured, and there are often minute or larger hæmorrhages within them, chiefly in the grey matter.

Not infrequently the spinal wound is infected, but these appearances are then modified only by the existence of a septic meningitis which may spread rapidly upwards and downwards from the lesion. It occasionally happens, however, that hæmorrhages and early adhesions between the arachnoid and dura, and in the subarachnoid space limit the infection to the wound. Subdural hæmorrhages of considerable size also occur, but they are rarely sufficiently large to compress the spinal cord. Inæmorrhages, which are, however, generally small and insignificant, are more common in the soft meninges.

Microscopical examination always shows that there are severe and relatively extensive changes in the spinal cord immediately above and below the lesion; for the distance of half a segment at least and often further the tissue is completely softened and none of its normal elements are recognizable. Under the microscope only ruptured disintegrating axis cylinders and globules and irregular masses of myelin can be seen; the latter rapidly become smaller and smaller and are absorbed by the numerous scavenger cells which quickly pervade the tissue. Hæmorrhages, generally small but occasionally of considerable size, are usually found in these softened areas, but they are more common and, as a rule, larger in the grey than in the white matter. In many cases, however, hæmorrhages have been rare or very small, and they are evidently not an essential feature of the condition. The blood vessels are always engorged, but they are, as a rule, thrombosed only in the immediate neighbourhood of the primary wound.

The most striking feature in these sections, however, is the presence of large spherical or irregular cells, which are frequently, apart from the blood vessels, the only recognizable tissue elements (Plate, Fig. A).

They have, as a rule, a single round or oval nucleus, larger than that of a lymphocyte but smaller than those of endothelial cells, which is granular and stains darkly, and is usually situated to one side of the cell; two or three nuclei in a cell are not uncommon. The cytoplasm is finely granular and stains deeply in the early stage, but when the cells are fully developed they are usually filled with coarse fatty granules which are derived from the disintegrated myelin. Later they become larger, and more irregular in shape and their cytoplasm frequently contains large vacuoles. The nuclei are now shrunken or deformed, stain more deeply and usually lie immediately on the periphery of the cell. Eventually these cells seem to extrude their nuclei and break up and pour their softened and digested contents into the tissue in which they lie. They are usually smaller and more tightly packed in the grey than in the white matter; when the tissue is severely necrotic they may be found only in the neighbourhood of vessels.

These are obviously compound granule cells, the origin of which has been much discussed; by some they are attributed to connective tissue, endothelial or leucocytic origin, but others believe they are wholly, or in greater part at least, derived from the neuroglia. The study of our specimens certainly supports the latter view, as the rarity of cell infiltrations or proliferations in the neighbourhood of the vessels has been a striking feature in most of our sections, and there has been no evidence that they develop in those regions only in which either connective tissue or endothelial cells are to be found, that is in the vessel walls. On the other hand, one can frequently see in less damaged portions of the tissue that a neuroglial nucleus accumulates cytoplasm around it, which at first takes an irregular or angular shape, but rapidly swells into a spherical element that is identical with an immature granule cell. Further, gradual transitions between neuroglial nuclei and those typical of the granule cells can be frequently seen.

A proliferation of connective tissue elements around the smaller blood vessels also occurs. They take the form of elongated spindle-shaped cells which appear to be engaged in the formation of new capillaries.

These secondary changes, which occur in the neighbourhood of a laceration or division of the cord, evidently produce further destruction of it. They are obviously degenerative rather than inflammatory, and are due to the oedema and circulatory disturbances that occur in the bruised and necrotic tissue on the borders of the injury, spreading into and involving parts which were not directly damaged by the missile. Oedema is the most important factor; it seems to affect the vitality of the neuroglial matrix as well as of the nerve cells and fibres, and combined with circulatory disturbances leads to their disintegration.

Even infection of the wound does not as a rule materially affect these histological changes; leucocytic infiltration is rarely extensive, and when pus cells are found they appear only as an accidental complication in the section. Evidences of infection are always most prominent in the meninges, and it is a striking fact that invasion of even the softened tissues by pus cells which extend along the vascular sheaths is rare.

In addition to these pathological changes in the immediate vicinity of the wound more distant and more irregularly distributed lesions are found in the majority of cases, and often extend over four or five segments in either direction.

Distant Lesions.

Oedema of both grey and white matter with some swelling and softening of the cord is the most constant of these changes. It gradually diminishes away from the wound, and often seems to bear no definite relation to its severity.

Hæmorrhages of various sizes are often associated with it, but these are less constant; they are generally small punctiform extravasations of blood, which give a mottled appearance to the cross section of the cord, but they are frequently larger (Plate, Fig. B); a large central hæmorrhage with a tendency to spread longitudinally in the cord, such as is generally understood by the term "hæmatomyelia," was not present in any of the fifteen cases in which the microscopical examination has been completed. These hæmorrhages are found particularly in the grey matter and about the central canal; one of the most common sites is the dorsal horn, where they can obviously interrupt the reception of afferent impulses. In the grey matter they are liable to break up and destroy the tissue, but when small they produce surprisingly little change in the white columns, the extravasated cells merely tracking along the vessels or between the fibres; occasionally, however, there is some local softening, and later neuroglial proliferation, around larger extravasations.

The extent of these small disseminated intraspinal hæmorrhages is occasionally surprising; in one case they spread over two and a half segments on each side of the wound. They are found with lesions of all regions of the cord, but they are usually most prominent when the cervical region is wounded and probably least so with injuries of the lower dorsal and lumbar segments. Owing to the relatively slight destruction they produce in the tissues their importance in the production of clinical symptoms may be easily over-estimated.

Interesting changes which cannot be directly connected with the trauma or with the occurrence of these small disseminated hæmorrhages are frequently found in the nerve cells and fibres at a considerable distance from the wound. The most striking of these is swelling of the axis cylinders. Frequently all those in a considerable area of the white matter are found slightly swollen in the neighbourhood of the wound where the tissue is oedematous, but a more unexpected condition is the relatively enormous increase in size of either isolated axones or of groups of axones, unassociated with any other obvious changes in the tissue, and often at a considerable

distance from the injury (Plate, Fig. C); in fact, this is usually the most far-spreading lesion recognizable, and may be often seen throughout the four or five segments adjacent to the lesion. The swollen axis cylinders may be in either ascending or descending tracts, and there is no evidence to suggest that the change is related to a secondary degeneration of the fibres. They are most commonly seen in the white columns, but also occur in the grey matter and in the dorsal roots, generally, however, in proximity to the wound. When the increase in size is moderate the swollen fibres appear circular in cross section and either granular or homogeneous, but as soon as they become larger their cross section is often oval or irregular, and not infrequently they contain more darkly staining central cores.

In longitudinal sections the swollen fibres may appear of almost uniform calibre for a certain distance, but they are more commonly moniliform or bead-like; in such fibres Bielschowsky preparations frequently show that the component fibrils of the axis cylinders are separated in the swollen parts by a great increase of the interfibrillar substance (Plate, Fig. D). The most swollen fibres may be frequently seen degenerating and undergoing disintegration; some apparently break up into a granular debris, others become vacuolated and are occasionally invaded by small phagocytic cells (Plate, Fig. E).

In sections stained by hæmatoxylin a thin irregular ring may be generally seen around them, which, when

stained by Weigert's method, is obviously the myeline sheath. This is occasionally ruptured, so that an incomplete ring surrounds the axone, and in longitudinal sections it is often found broken and discontinuous. In other parts, especially when oedematous, the sheaths are swollen and irregular in outline and calibre, and they are frequently disintegrated into globules of myeline, especially in the neighbourhood of the lesion. In more distant regions, however, apart from any other

pathological alteration, the myeline sheaths of isolated or small groups of fibres are found in parenchymatous degeneration.

Two types of change are seen in the nerve cells of the grey matter: in the region of the wound they are often shrunken, stain darkly, and present none of the normal details, or if the tissue is oedematous they may be swollen. Some of them at least break up rapidly, often owing to invasion by neurophages, but when less severe these changes are evidently recoverable. A more common type of change is chromatolysis, with some swelling of the cell body, eccentricity of the nucleus and disappearance of the Nissl bodies, especially from its centre. Bielschowsky preparations often show irregular swelling of the dendrites of these cells.

In addition to these changes in the cells and fibres, irregular focal lesions in which all elements of the tissue may be involved often occur for a considerable distance from the wound, sometimes as far as four or five segments.

Occasionally there are small circumscribed patches of necrosis in which both the fibres and the neuroglial matrix are involved, or in which only the larger strands or neuroglia persist, without any evidence of hæmorrhage of inflammatory reaction around them (Plate, Figs. F, G); there is, in fact, simple uncomplicated necrosis of the tissue, generally accompanied by considerable oedema. The vessels may be slightly engorged, but as they are rarely thrombosed the necrosis cannot be attributed to vascular lesions; further, they are generally in the periphery of the white matter in the region in which its blood supply by the pial vessels is most complete, and neither in distribution or shape are they such as might be expected from vascular lesions.

These focal necroses are generally smaller in the grey matter, and when not complete produce only a rarefaction

DESCRIPTION OF SPECIAL PLATE.

Fig. A.—Granule cells in an area of complete softening. No normal tissue is recognizable in the section.

Fig. B.—Multiple hæmorrhages in both grey and white matter, two segments above a complete division of the cord.

Fig. C.—A cross section of swollen axis cylinders in one lateral column two and a half segments above the level of the maximal damage produced by concussion. There was no other abnormality in the white matter here.

Fig. D.—Swollen axis cylinders in longitudinal section stained by Bielschowsky's method.

Fig. E.—Swollen axis cylinders, lying in round or oval spaces, which are undergoing vacuolation and disintegration.

Fig. F.—Irregular foci of softening and necrosis in the white matter two segments above a complete division of the cord.

of the matrix with severe degenerative changes in the nerve cells. In two cases, however, there was extensive necrosis of the ventral horns and the adjacent parts of the ventral columns, with disappearance of or degenerative changes in the nerve cells and fibres, and invasion of the affected area by granule cells.

Less complete and more irregular lesions of the white matter, in which all fibres are not completely destroyed, are more common, and were, in fact, present in all the cases in which a histological examination has been made.

The periphery of the cord is most frequently involved, and the foci have often an irregular wedge shape, with the base on the periphery and the apex directed centralwards. They are found most frequently in the dorsal and lateral columns, more rarely on the ventral surface, except perhaps in the angle between the ventral periphery and the ventral mesial fissure.

In these affected areas only the coarser neuroglial trabeculae and the dense subpial layer persist, and in section the tissue has consequently a sieve-like or reticular appearance (Plate, Fig. H); in early cases the neuroglia in the process of disintegration may be recognized by its characteristic colour in van tresson preparations. There is usually very little evidence of oedema in or around the foci, and a coagulated transudate can rarely be seen within the meshes. There is never any cellular infiltration, or at the most only an insignificant increase in the number of free cells in the sheaths of the vessels. A considerable neuroglial proliferation is often visible around the foci, and spider cells can be frequently seen here and in the persisting trabeculae.

The majority of the meshes are often empty, but they frequently contain distended or disintegrated myeline sheaths and axis cylinders, which are often enormously swollen. It is, however, a striking fact that relatively normal axis cylinders often persist within them; indeed, these seem to escape more frequently than any other part of the tissue. Other meshes contain large granule cells, which are often loaded with fat and debris.

This change is sometimes more general and diffuse, and may affect the greater part of the periphery of the cord, producing either the appearance of confluent foci or a general sieve-like rarefaction of the tissue. It varies also in degree; in places only the larger glial strands persist with disintegrated detritus between them. Occasionally there are traces of haemorrhage into these areas, but they are rare.

Frequently, however, the only abnormality in a part of the cross section of the cord is the presence of more or less circular vacuoles, either isolated or groups, which may be either empty or contain granule cells or a swollen axis cylinder (Plate, Fig. J). The tissues around generally appear compressed eccentrically from the vacuole, so as to suggest that the latter was produced by some distensive force. Owing to the loose and porous structure of the neuroglia this cannot have been due to an accumulation of fluid within it, and in sections they rarely contain a coagulum. On the other hand, a careful examination of the development of these vacuoles shows that they occupy the site of a single myelinated fibre, and the frequency with which swollen fibres are found within them suggests that they are generally due to the swelling of an axis cylinder or of its sheath. In other instances they are obviously filled by granule cells, but this may be due to secondary invasion.

In a surprisingly large proportion of the cases, in fact in more than half those which have been examined in microscopical sections, and apparently in an equal proportion of those in which only a naked eye examination has yet been made, there were curious cavities, roughly cylindrical or oval in cross section, in the segments of the spinal cord

adjoining the lesion, either in those above or below it, or in both (Plate, Figs. K and L). These often extended a considerable distance, in some cases over four or five segments, and at their ends furthest from the wound they were occasionally the only indication of any abnormality. In three cases they were found on each side of the primary injury, and in four cases only below it. In one cord the cavity lay in and occupied the greater part of one dorsal horn (Plate, Fig. M), but with this exception they were always found in the dorsal columns, generally to one side of the middle line; they did not involve the grey matter or approach the central canal. Their size was always considerable, the greatest diameter usually varying between a quarter and half the dorso-ventral breadth of the dorsal columns. They were consequently distinctly visible to the naked eye when cut across, and generally contained greyish or brownish gelatinous matter, sometimes tinted with blood.

Their contents on microscopical examination are seen to consist of broken up and degenerating fibres and disintegrated neuroglia, which are not, except in cases of long duration, quite necrotic, though shrunken, darkly staining, pyknotic nuclei and degenerating granule cells were generally the only recognizable elements. The latter were usually laden with fat. A certain number of red cells could be seen in many cavities, but excepting that in the dorsal horn none contained much blood.

In some cases this disintegrated matter filled the cavity,

but in most instances, after fixation and the preparations of sections at least, the cavities were partly empty. There can be no doubt that in every case the contents during life existed under pressure, as the unaffected parts around them were compressed, and the dorsal mesial septum was generally displaced towards the opposite side when the cavity lay in one dorsal column only (Plate, Fig. K).

The cavities were, as a rule, very sharply delimited from the tissues around them, which were often quite intact, but in places there was occasionally an irregular softening

on their margins. In certain cavities the degenerating material in them came into direct contact with, or had simply sloughed off from, the normal tissue, but the walls were frequently formed by one or more layers of granule cells, the outer of which remained well developed, while the inner degenerated and added to the disorganized contents.

When a cavity is examined in serial sections it is usually found that it becomes larger away from the lesion and terminates in a rounded or obtuse apex; its other end rarely extends down to the primary lesion, though it is generally connected with this by a haemorrhage or a small track of softening, or in a few instances by an apparently artificial slit, which might be attributed to retraction and shrinkage of the oedematous tissues. There was as a rule very little vascular disturbance around the cavities, apart from the oedema which spreads from the neighbourhood of the injury; haemorrhages were not as a rule found in or around them, and apparently bore no causal relation to their development. In one case a vessel which passed horizontally through a cavity was thrombosed, but this seemed to be a secondary effect, and due to pressure or tension upon it.

Although the cavities contained disintegrated myeline and swollen and disrupted axis cylinders, an examination shows that in relation to their size they involve but little functional tissue; their chief effect must be consequently due to the pressure they exert upon, and the distortion they produce of, the unaffected fibres in the neighbourhood.

Either the dorsal or ventral roots or both are frequently injured by the missile or by displaced fragments of bone, but apart from this considerable changes are often found

DESCRIPTION OF SPECIAL PLATE.

Fig. H.—Sieve-like rarefaction and vacuolation of the periphery of one lateral column two segments above the level of the maximal injury produced by concussion.

Fig. J.—A central softening in the cord with small foci of softening in the periphery of the white matter, and extensive vacuolation.

Fig. K.—A cavity filled with necrotic material in the left dorsal column three segments below the level of maximum injury produced by concussion.

Fig. L.—A cavity in the left dorsal column three segments above a direct injury to the cord. It contains only necrotic detritus. There are also a patch of complete necrosis in the left lateral column and areas of partial softening in the rest of the white matter.

Fig. M.—A descending cavity in the left dorsal horn two and a half segments below a complete division of the cord.

in them, and especially in the dorsal roots near their entry into the cord. Their neuroglial portions are usually swollen and oedematous, and their myelino sheaths are distended or partially disintegrated. The proportion of fibres actually broken across is usually insignificant, and the change does not usually extend beyond the line of the glial and connective tissue junction. These changes in the dorsal roots may have some significance in relation to certain clinical phenomena we will describe later.

These spinal changes, associated with a direct injury of the cord, may be illustrated by one typical case:

CASE I.

FIG. C, 198, was wounded by a rifle bullet on November 27th, 1914. He lost power in his legs at once and developed retention of urine. He had haemoptysis at first, but spat up blood-stained sputum only when he was admitted to the base hospital ten days later. He also complained of a stinging girdle pain just above the level of his umbilicus.

The bullet entered 6 cm. to the left of the tenth dorsal spine and made its exit in the fifth right intercostal space in the mid-axillary line. He had a right-sided hemothorax, cystitis, an early bed sore, and trophic blisters on the front of his ankles and on the inner sides of his knees. His legs were flaccid and paralysed, and no reflex movement could be obtained on stimulating his soles. The abdominal muscles were paralysed to midway between the umbilicus and the xiphoid, and the lower four intercostals did not contract on either side. The knee and ankle jerks, as well as the plantar and the lower abdominal reflexes, were absent, and all forms of sensation were completely lost to 8 cm. above the umbilicus.

He died eighteen days after the infliction of the wound. The wound.—A small right-sided haemothorax was found in addition to the spinal injury. The bullet had passed through the arch of the tenth dorsal vertebra, lacerating both the dura mater and the cord; the latter, after hardening in formalin, was found to be completely destroyed between the upper part of the twelfth dorsal and the middle of the third lumbar segment. There was some meningitis both above and below the injury.

Below the Lesion.—In the fourth lumbar segment the dorsal columns were almost completely destroyed, as well as the inner margin of the left dorsal horn, and the tissue around was softened and infiltrated by granule cells (Fig. 1). The grey matter was oedematous, and its nerve cells were in advanced chromatolysis. The greater part of the right lateral column was necrotic and pervaded by haemorrhages, while the rest of the white matter presented a sieve-like appearance, and contained swollen axis cylinders, granule cells, and proliferating spider cells. From the fifth lumbar segment a large cavity, which contained organized fibres and neuroglia as well as granule cells, extended through the dorsal columns downwards into the conus. The remaining portions of the dorsal columns were oedematous and vacuolated or sieve-like in the fifth lumbar, but normal in the sacral segments. The white matter of the ventro-lateral columns was also vacuolated, but showed only a slight loss of fibres below the first sacral segment; while the grey matter was oedematous and all its cells were swollen and in advanced chromatolysis.

Above the Lesion.—As high as the upper part of the eighth dorsal segment there were irregular patches of necrosis and sieve-like rarefaction of the tissue, in which only the coarser neuroglial strands and a certain number of axis cylinders, normal or swollen, persisted (Fig. 1); there was also some infiltration by granule cells and minute haemorrhages. It was chiefly the

peripheral portions of the lateral and dorsal columns that were involved. A small softening, in which there was an apparently artificial slit, extended upwards in the left dorsal column through the eleventh, tenth, and the lower part of the ninth dorsal segments, and in the upper portion of the latter became continuous with a large cavity which reached the upper margin of the eighth segment; it was sharply defined from the surrounding normal tissue and contained disintegrated debris and degenerating granule cells.

It may be noted that, although the clinical symptoms—the reflex changes as well as the motor and sensory paralysis—indicated a lesion of the ninth dorsal segment, the twelfth was the highest segment in which the spinal cord was actually damaged by the wound; the histological examination, however, explains the discrepancy.

As the immediate and more distant effects of a spinal wound have been described, the anatomical changes produced by compression or contusion, and those due to concussion, will require less time, as in both these classes we

again meet the histological lesions which we have already found associated with injuries produced directly by the missile.

CONTUSION OR COMPRESSION OF THE SPINAL CORD.

When a portion of a vertebra or a detached spicule of bone is driven into the spinal canal, it frequently lacerates both the cord and the theca, and causes lesions which may differ only in degree from those produced directly by a projectile. Frequently, however, there is no obvious external injury to the cord and the dura mater is not torn, even though the clinical symptoms indicated a complete transverse lesion. Small haemorrhages into the meninges are, however, common, and on palpation the cord at the level of the contusion is soft, and if the pia mater is incised or pricked semifluid custard-like material may escape.

When the injury is less severe the normal appearance of the cross section is only obscured, and there are frequently minute haemorrhages throughout it. The damaged area and the segments on either side of it are usually swollen by oedema, and the cord may be indented by the indurated bone. When the lesion is examined under the microscope changes are found very similar to those in the parts adjoining a direct injury, but their intensity naturally varies much. The most important is softening and disintegration of the tissues, always greatest in the region which was directly contused. If the injury is severe the whole cross section may be softened, but more commonly there are discontinuous foci in the ventro-lateral and dorsal columns. The grey matter may be also completely destroyed in whole or parts, but it is more usually extremely oedematous and only partly disintegrated, with its nerve cells necrotic or in advanced chromatolysis. Occasionally only a diffuse or focal necrosis is found in which no stainable elements persist. The affected areas are gradually invaded by granule cells, and a considerable proliferation of neuroglial cells is visible around them, but, apart from a pronounced congestion of the vessels and an occasional increase of the

FIG. 1.

cells in their walls, there is no evidence of any inflammatory process. The amount of haemorrhage into the injured region also varies very much.

The distant lesions differ in no respect from those which are so commonly associated with direct spinal injuries. Diffuse foci of necrosis and softening, vacuolation due to falling out of fibres and the sieve-like rarefaction produced by the disappearance of fibres and of the finer glial matrix, as well as minute scattered haemorrhages, are found in the white matter of the adjoining segments, while the grey matter is also oedematous, and contains similar haemorrhages and perhaps foci of softening. The central cylindrical cavities, which have been already described, also occurred in the dorsal columns relatively as frequently as with direct injuries.

CONCUSSION OF THE SPINAL CORD.

In cases of concussion, when the cord is not damaged by the fracture or dislocation of a vertebra, there may be no external signs of injury or only a more or less uniform swelling opposite the site of impact, and even to touch no definite abnormality may be recognizable.

On microscopical examination the vessels are found engorged, and there are generally punctiform haemorrhages, especially in the grey matter. The most striking change, however, is the oedematous swelling of the most affected segments with either diffuse or focal necrosis and softening, which, at least in the cases that have been examined microscopically, has been most pronounced in that part of the cross-section nearest the point of impact. In these areas there may be complete destruction of the functional elements, but more usually only a proportion of the fibres have disappeared, while the myelene sheaths and axis cylinders of others are swollen. Focal softenings also occur in the grey matter, but are usually unrelated to the haemorrhages which this frequently contains. There is, often, however, some softening and disintegration of the tissue, as well as degeneration of the nerve cells, around these haemorrhages.

The distant lesions in cases of concussion are similar to those found associated with direct and contusion injuries, but they are often very marked in relation to the changes found at the site of maximum damage. Scattered haemorrhages, irregular foci of necrosis, and softening and cavity formation occur, but the most pronounced feature is the extensive parenchymatous changes that often extend over four or five segments in either direction. These consist in the swelling of fibres, either isolated or in groups, in the midst of tissue which is otherwise normal or only slightly oedematous; as a rule the axis cylinder is more swollen and the myelene sheath surrounds it as a distended and attenuated ring, but in places the sheaths are more affected, and are often broken up. The disappearance of these swollen fibres and the partial disintegration of the neuroglia leave vacuoles and round or oval cavities in the white matter and give it a reticular or sieve-like appearance. There are also often considerable histological alterations, either degenerative or chromatolytic, of the nerve cells at some distance from the level of the injury, but these are found most commonly where the tissue is oedematous.

If these distant and diffuse lesions are compared with those found at the point of impact it will be seen that they differ from them only in degree, and as they occur whether the cord has been directly injured or not by the projectile or by indirect bone, it is probable that in each case they are due to the same cause, which we must seek in the effects of concussion of the spinal cord produced by a sudden violent impact on the vertebral column.

We must now consider shortly the nature of these changes which have been described, the causes to which they are due, and their significance in the production of the clinical symptoms that characterize these cases. The conclusions and views expressed must not be regarded as final, as there is still much material to be investigated, and the amount of time which could be allotted to the histological preparations which are already available has been necessarily very limited.

Spinal Concussion.

The most important and obscure factor is that which we understand by *concussion*—that is, functional or

anatomical disturbances produced indirectly in the spinal cord by a sudden and violent impact on the vertebral column. The nature of spinal concussion has been much discussed, and it has been, in fact, questioned if spinal lesions, such as those described above, do occur apart from temporary dislocation or fracture of a vertebra, compression by fragments of bone, or an extra or subdural haemorrhage causing direct trauma to the cord.

But many cases in which none of these possible causes existed have been recorded, and we have had the opportunity of observing cases in which they could not be demonstrated. Further, certain of the distant lesions that we have already described, which often extend over several segments on either side of the primary injury, or beyond the level of the impact on the vertebral column, cannot be due solely to a direct trauma, and they are identical in nature to those attributed to concussion. The changes are irregular focal softenings or patches of necrosis, sieve-like vacuolation of the white matter, disseminated haemorrhages and local lesions of the myelinated fibres.

It is in the first place necessary to insist that these changes are not, as oedema may be, continuous with those in the neighbourhood of the spinal wound; the haemorrhages, for instance, are usually discrete and are often only minute extravasations of blood in the Virchow-Robin or perivascular spaces, while the focal necroses and softenings do not, as a rule, spread longitudinally in the cord from the region of the trauma. Further, when a group of fibres is affected, the lesion is usually focal, and it is not necessarily those of one tract only that are involved; it cannot consequently be either a manifestation of a secondary degeneration, or of a pathological change which has spread from the point at which the fibres were directly injured.

The special character of these lesions is, therefore, their diffuse and irregular distribution and their tendency to diminish gradually from the point of maximal disturbance. They are not due to haemorrhages, as these bear no constant relation to them, and as vascular occlusions are also rare these obviously cannot be the main causal factor. On the other hand, as the chief lesions are foci of primary necrosis and parenchymatous change in the cells and nerve fibres, the essential changes may be described as primary disturbances in the vitality of certain portions of the tissue, associated with oedema and frequently with small scattered haemorrhages.

It is difficult to offer a complete and satisfactory explanation of how a blow on the vertebral column can produce these lesions in the cord, protected as it is within the canal. Certain structural alterations found in cerebral concussion are attributed to the violent oscillations produced in the cerebro-spinal fluid, especially in that of the ventricles, but the spinal cord is only surrounded by fluid, and is able to swing to some extent within the dural sac with its oscillations. The waves of pressure thus set up may, however, produce physical effects within the cord, and possibly disturbance of its lymph circulation, but the most probable explanation is that put forward by Fickler, according to which the cord is made to oscillate within the canal by the impact on the vertebral column, and as its movements will obviously not be synchronous with those of the column it may be directly bruised against the walls of the canal, while at the same time the sudden jarring of the cord produces a physical disturbance in its tissues, and especially in the fluid axoplasm of its fibres. There is much in favour of this explanation, and the factors it hypothecates cannot be neglected. The histological changes in the spinal roots may be, in fact, partly due to the strain thrown upon them by the displacement of the cord. But if it is the whole explanation, the structural lesions should be greatest at the position of *centre coup*; we have, however, so far always found them most pronounced immediately under the site of impact. Further, it must be remembered that the spinal roots and the ligamentum denticulatum limit the movement of the cord within the canal, and in many levels at least must make *centre coup* bruising impossible.

Whatever may be the exact mechanism of spinal concussion, it must be admitted that a sudden violent impact on the vertebral column can produce diffuse, irregular, and severe structural changes within the spinal cord. The factors which determine the severity of these lesions must

be the momentum of the projectile, the part and surface area of the vertebra which it strikes, and the region of the spine which is wounded.

Secondary Changes.

Finally, we must consider the secondary changes which may occur in the neighbourhood of the primary injury and in those portions of the cord which have suffered from concussion.

It has occasionally happened that when the wound is not severe the patient was at first able to perform some movements in his legs, but lost the power to do so within the following two or three days. Further, we have seen new symptoms develop or their level alter under observation. This may be due to a secondary hæmorrhage into the affected tissues or to progressive softening, of both of which we found possible evidence in our sections.

But the most striking secondary change was the development of the cylindrical cavities we have described. Their exact pathogenesis is obscure, but certain features they present must be emphasized in attempting an explanation. In the first place, they seem to involve the destruction of very little tissue, but rather separate and compress the fibres around them; their contents must be consequently under much pressure. In the second place they evidently develop away from the lesion, as the material they contain is always less necrotic at their upper or lower end if they are respectively ascending or descending cavities; and finally they do not as a rule extend to the maximal lesion, but are generally connected with this by a track of oedematous or softened tissue, or by a narrow channel of softening or by a fissure (Fig. 1). It seems, therefore, probable that they originate from the accumulation under pressure of transuded fluid and degeneration products in a small projection of the primary lesion, which tracks upwards or downwards along the lines of least resistance through either normal or oedematous parts, destroying only a relatively small amount of tissue but increasing in size probably under the same principles as a retention cyst. The granule cells which frequently line their walls, or are contained within them, must be due to a reactionary proliferation of the neuroglia in the tissue through which they track.

Finally, it must be emphasized that they are not due to infection, as in several cases in which they occurred the theca had not been lacerated, and there was no sign of infection in either the cord or the meninges.

They are obviously not produced by hæmorrhages, though a certain number of red blood cells may be found within them, nor by vascular lesions, as there has been no evidence of these, and the position of the cavities does not correspond with the distribution of any spinal vessel. The frequency with which they occupy the ventral portion of one or both dorsal columns is striking, but its significance is not clear. This region is, however, a watershed area between the distribution of the anterior spinal arteries and of the small arteries that supply the dorsal columns, and as such may have a relatively poorer blood supply than other parts of the cord. In many cases, too, the dorsal columns seem to suffer more severely with oedema and softening than the ventro-lateral columns.

It is obvious that these irregular and diffuse changes which are found in various types of spinal injury must be taken into account in interpreting and estimating the significance of the clinical symptoms that are observed in these cases. The following conclusions at least can be drawn:

1. The structural lesions in the spinal injuries of warfare are rarely sharply limited or circumscribed, and cannot be compared to those produced experimentally in a physiological laboratory. The level of the lesion, as indicated by the clinical symptoms, for instance, often does not correspond with the level of maximal damage.

2. The lesions are so irregular in distribution and severity when the spinal injury is not complete that much care is necessary in drawing conclusions from the clinical symptoms alone on the functions of parts which it may be assumed have been involved.

3. Secondary changes may occur later in the cord which can alter or modify the clinical symptoms.

MALIGNANT TUMOUR OF THE KIDNEY.

AN ANALYSIS OF SOME SYMPTOMS AND SIGNS OF A SERIES OF CASES.

By R. J. WILLAN, M.S., F.R.C.S.,

HONORARY ASSISTANT SURGEON ROYAL VICTORIA INFIRMARY,
NEWCASTLE-ON-TYNE; STAFF SURGEON R.N.V.R., ATTACHED
TO THE ROYAL NAVAL HOSPITAL SHIP "DINA."

THIS article, written from rough notes made some time ago, is divided into four portions. Part A contains an analysis of age, sex, side, and the onset symptom. Part B deals with the association of pain, hæmaturia, and a palpable renal tumour to each other during the illness. Part C mentions some complications, and Part D includes illustrative clinical cases. The material is extracted from my own case notes; I am also indebted to my colleagues on the staff of the Royal Victoria Infirmary, Newcastle-on-Tyne, for the use of their records.

A.—AN ANALYSIS OF AGE, SEX, SIDE, AND THE ONSET SYMPTOM.

1. Age.

Ten out of the series occurred in children under the age of 10; in each case the condition was sarcoma. No case occurred between the ages of 10 and 29 inclusive—that is, the second and third decades of life; 31 out of the 59 cases occurred between the ages of 45 and 65; or, if children are excluded, and only the 49 adults reckoned, 31 out of the 49 occurred between these ages—that is, 63.2 per cent.

A curious fact, which may only be a coincidence, is that in the fourth, fifth, sixth, and seventh decades the preponderance of cases occurred in the first half of the decade, for 5 cases were between 30 and 35 years old, 7 of the cases were between 40 and 45, 10 of the 17 cases were between 50 and 55, while 9 of the 12 cases were between 60 and 65.

Of the 49 adult cases, 14 occurred between the ages of 45 and 55, a percentage of 28.5.

TABLE I.

Under 9.	10-19	20-29	30-39	40-49	50-59	60-69	70-79	Not Stated.
10	—	—	5	11	17	12	1	3

Total, 59.

2. Sex.

63.8 per cent. of the series were males, there being 36 against 23 females. Of the 10 children, 6 were boys.

3. Side.

In 31 instances the malignant growth affected the left side and in 26 the right side. In 2 cases the side affected was not stated.

4. Onset Symptom.

In 7 cases of the series the actual onset symptom is not stated; these will therefore not be taken into account in calculating percentages. Of the remaining 52 cases, the commonest initial evidence was painless hæmaturia. This was observed in 14 cases.

In 10 cases the illness was ushered in by acute renal colic, while in 10 other cases a painless swelling found in the flank was the first evidence of anything wrong; 9 cases began with chronic pain in the flank, while 5 patients suffered from cachexia before any sign of malignant growth of the kidney became manifest. In 2 cases there was increased frequency of micturition at onset, another went to his doctor for a varicocele, while the remaining one had "swelling of the bowels."

Therefore the separate symptoms of (1) painless hæmaturia, (2) symptomless flank swelling, (3) acute renal colic, and (4) chronic renal pain, account for the onset symptoms in 43 cases, a percentage of 82 per cent.

Of the 7 children included in the above, in 3 cases a painless tumour was found in the flank, in 2 cases there was painless hæmaturia, in 1 case a chronic aching pain, in 1 case cachexia; while in the 3 further cases there was no statement.

1. Pain.

In 11 instances there had never been any pain before the case came under the observation of a doctor. Either painless haematuria or the accidental discovery of a flank swelling, separately or in combination, led the patient to think there was something amiss. This absence of pain bears out the well-known fact that "cancer" anywhere is by no means necessarily associated with pain, especially in the early stages of the condition. Fortunate is the patient with any malignant growth who has pain in the early stages; such pain may be regarded as protective, and is a warning to go to a doctor for investigation, when the chances of a cure after operation would be still greater than they are. Renal pain may be acute or chronic; although both may be present, the causes are different.

Acute renal pain shows itself in the form of colic, which is only present when there is bleeding, but furthermore when the blood becomes clotted in the higher urinary passages. Rarely, it may follow the detachment of a piece of the malignant growth. The colicky pains are due to the muscular contractions of the renal pelvis trying to empty this blood-distended organ, together with similar contractions in the ureter during the downward passage of the blood clot on its way to the bladder. Therefore, although bleeding is the real initial symptom, it may be preceded by acute pain before the haematuria is apparent.

Chronic renal pain is usually present as a localized dull ache referred either to the front or to the back of the affected kidney. Its causes include the stretching of the renal capsule by the increasing size of the tumour, by the dragging weight of the tumour, by involvement of the renal nerves, and by infiltration of the surrounding parts.

Absence of all pain is due to the escaped blood remaining fluid, to lack of tension of the growth owing to a perforation of the renal capsule, through the anchoring of the kidney by local inflammatory adhesions, and to the temperament of the patient.

2. Haematuria.

Apart from the renal sarcomata of children, there are probably few cases which do not present this symptom at some stage.

Haematuria may be painful or painless; this is very often determined by the circumstance whether the blood undergoes clotting or not, especially in the higher urinary passages. It is difficult to say exactly the factor which determines such clotting; it is certainly influenced by the degree of urine concentration.

The bleeding is due to erosion of a blood passage—a normal vessel or one recently formed—by the advancing growth. In one case (mentioned later) the onset of haematuria followed the vigorous massage of a huge malignant kidney. The blood may be either intimately mixed with the urine or in the form of long worm-like casts, due to its coagulation in the lumen of the ureter.

Haematuria is an important link in the chain when making a diagnosis of malignant disease of the kidney; this symptom was definitely present in 24 cases out of 52—that is, in 46 per cent.

3. Tumour.

A renal swelling was present in 49 cases of the series; in 4 cases it was definitely stated that no tumour could be palpated, while in 6 cases the records are incomplete.

The presence of an enlarged kidney greatly facilitates diagnosis of suspected malignancy, but it is the surgeon's aim to make a diagnosis before the organ has attained a palpable size. I have operated upon two cases in which obesity quite prevented a malignant kidney from being palpated even under an anaesthetic; in each case the patient weighed over 18 st. Fortunately special aid is now available for helping the surgeon to arrive at a correct diagnosis in these diagnostic puzzles—that is, pyelography.

4. Cachexia.

The fact that this was an onset symptom in 5 cases emphasizes the urgent need for a thorough general overhaul by the doctor when an adult patient complains to him of the effects of this symptom.

C.—SOME COMPLICATIONS.

1. Varicocele.

In 3 cases of the series it is noted that there was a left-sided varicocele, in addition to a malignant renal tumour on the same side.

The presence of a varicocele, especially on the left side, may of course be only a coincidence. The wise surgeon, however, always satisfies himself that it is a coincidence before he decides to remove a malignant kidney. If the two signs of varicocele and renal tumour are associated, it indicates the spread of the malignant growth along the renal vein towards the inferior vena cava, thereby blocking the exit of the spermatic vein, the resulting back pressure forming the varicocele. Owing to its position the termination of the left spermatic vein is much more readily blocked by growth than the right.

It is almost superfluous to add that it is not justifiable to operate upon either the varicocele or the kidney in such a case. Many of these secondary varicoceles have been operated upon without the malignant kidney condition, the primary cause of that varicocele, having been detected. It is a golden rule to submit no case of varicocele, and especially in a middle-aged man, to operation until the absence of a renal tumour and of haematuria have been established.

2. Clot Retention.

Two of the patients had retention of urine due to clotting following painless haematuria, and in each case the doctor was only called in when the patient had complete retention.

3. Diabetes Mellitus.

One case of sarcoma was complicated by persistent glycosuria; he did well after nephrectomy, but I cannot say what happened to him after he left hospital.

4. Chronic Nephritis.

Several of the cases had this.

D.—REMARKS AND ILLUSTRATIVE CLINICAL CASES.

A routine investigation of the case should include the physical examination, analysis of the urine, cystoscopy, an estimation of the renal function, and pyelography.

Both flanks must be examined for the presence of a renal tumour, and, if there be one, the surgeon must note its consistency; the condition of its surface; if its margins are well defined or not; and its relation to the surrounding structures—that is, if it is fixed or not. A pelvic examination will show any thickening of the palpable lower portion of the ureters, and the existence or not of a varicocele must be verified by examining the spermatic cords.

All urine voided should be carefully collected for three consecutive periods of twenty-four hours. The specific gravity, the estimation of urea output, and a microscopic examination are the most important items of each analysis of the urine.

If the patient has haematuria when the surgeon first sees the case (or on the first sign of such bleeding after it comes under his care), the opportunity must be seized to make a cystoscopic examination immediately. This more especially applies in the case of patients with symptomless haematuria; it may be an isolated bleeding, and the surgeon may not get another opportunity of ascertaining the source of the haemorrhage. Bleeding from a ureteric

urine may be in the form of bright red blood, of smoky urine, or in the form of worm-like clots. I have on many occasions watched one of these bloody urteric casts in process of extrusion from the ureter. So important is this piece of clinical evidence that I always mark the thigh of the same side as the bleeding ureter while the cystoscope is still in the bladder; unless some such routine is carried out, mistakes as to which ureter the blood is coming from can easily be, and have been, made.

An estimation of the renal function is a necessary part of the investigation of the case. To know the amount of work each kidney is capable of performing is to be able to compare the two organs, when it will be usually found that the malignant kidney is capable of doing less work than the sound organ.

The most certain method of collecting a specimen of urine from each kidney is to pass a ureter catheter into each renal pelvis. After the necessary amount of urine has been obtained pyelography can be done, so that the passage of the ureter catheter performs a double purpose. In the routine examination of this urine I place most reliance upon the amount of urea present, the specific gravity—if sufficient urine can be obtained—and the presence or absence of pus cells; the presence of red blood cells I disregard, as it is so easy to get a trace of blood from the mere passage of the ureter catheter.

Theoretically there are many other better tests for the estimation of the renal function, but for practical purposes I consider that a comparison of the percentage of urea excreted from each kidney is a good working guide, especially if the nitrogenous food intake is checked.

The advent of pyelography was a distinct advance as an aid in the diagnosis of a kidney tumour. When the renal pelvis takes part in a general enlargement of the organ, the point can be definitely ascertained by examination of the increased size of the "shadow" of the renal pelvis on the radiogram after the injection of the collargol solution.

Again, other tumours occupy one or other pole of a kidney, and in these cases a study of the radiogram (after collargol injection) will show changes in the normal angle formed by the junction of (a) the line of the lower margin of the renal pelvis, and (b) the line of the ureter. The growth makes that pole heavier than normal, and it tends to rotate upon its central axis. For example, if the growth is in the upper pole, the kidney will tend to rotate downwards and inwards; therefore the angle between (a) and (b) will become more obtuse—that is, it is widened. If, on the other hand, the growth is in the lower pole of the kidney, this rotates upwards and inwards, and the angle between (a) and (b) becomes more acute—that is, it is narrowed. To make an accurate observation collargol must be injected into both sides, so that the sound side can be used as a control; again, the "shadow" of each side should appear on the same negative.

CASE I.—Pain and Haematuria with a Palpable Tumour.

J. M., aged 63, was admitted to the Royal Victoria Infirmary, Newcastle-on-Tyne, two years ago, complaining of (1) attacks of acute left-sided renal pain, which radiated downwards to the left testicle, and which made him vomit; (2) profuse haematuria.

He was very anæmic. He had a large tumour in the left flank, which was rather tender and of hard consistence, irregular surface, well-defined rounded lower margin, and it freely moved upwards and downwards on respiration. On percussion it was dull (except anteriorly, where it was semi-resonant), and the dullness was continuous with the erector spinae dullness. Pressure of the tip of the index finger at the junction of the lower border of the last rib with the outer border of the erector spinae caused a mild edition of the acute pain he had been experiencing. Cystoscopy showed a long worm-like blood clot in process of extrusion from the left urteric orifice; catheterization of the ureters showed that the right kidney was a normal one. A carcinomatous left kidney was removed, but his doctor informed me that he died some months later, probably from a recurrence.

The acute renal colic was due to the blood clotting in the ureter, which resulted in increased tension inside the kidney. After the blood clot had passed the urine became clear; his acute pain then disappeared.

CASE II.—Haematuria with a Palpable Tumour.

J. E. B., aged 60, was referred to me with a history of severe haematuria. For some weeks, his doctor informed me, the patient had not felt quite in his usual health, so he went to a noted London masseur for a course of massage. On the first two days the rubbing was confined to the limbs; on the third day his abdomen was vigorously massaged, and that night he

had a furious haematuria. Twenty-four hours later he had a rigor, followed by a second one at the end of a further twelve hours. He had had some difficulty in urination for a great many years owing to a spinal injury due to a hunting accident.

When I saw him the bladder was distended to the level of the umbilicus. Although he had made constant efforts, he had not micturated for the greater part of the previous six hours. In the left flank was a tumour the size of a child's head; it was hard, nodular, had a well-defined lower margin, and moved upon respiration. The cystoscopy showed a quantity of decomposing blood clot lying on the base of the bladder, also a ball valve intravesical enlargement of the prostate gland. The septum being the dangerous factor of the case, I advised that the blood clot be removed at once. This was done by means of the apparatus used during the operation of litholapaxy—that is, a metal cannula and an indiarubber aspirator bag. The ureters were catheterized and the results showed that the right kidney was normal—moreover, that it was doing the great part of the patient's renal excretion. Three days later I excised a carcinomatous left kidney. He made an uneventful recovery, and three and a half years later he is in excellent health.

CASE III.—Renal Pain with Haematuria.

In August, 1912, I saw H.S., aged 55, in consultation with his doctor. The patient was very stout, and weighed over 18st. He complained of periodical attacks of passing brownish-coloured urine, and on close questioning admitted that he had had some discomfort in the right flank; there had never been any acute pain. No flank tenderness or tumour could be found, but this was not surprising owing to his size. The cystoscopy demonstrated smoky urine flowing through the right urteric orifice. Catheterization of the ureters with collection of the urines showed that the left kidney was a normal one, and that it was doing twice the amount of work that the right one was doing. I excised the right kidney, and there was a large hypernephroma in its lower pole. He is now in excellent health.

The chronic flank discomfort was due to increased tension in the kidney, for the growth was of the variety which has a capsule, and this, to the naked eye at any rate, had not been pierced. There had never been any clotting of the blood, hence the absence of acute colic.

The success of the case, of course, is largely due to the practitioner who was so determined to get to the bottom of the small degree of haematuria, for the patient failed to regard the flank discomfort as anything worth mentioning until I questioned him.

The right renal discomfort, the cystoscopic demonstration of the bleeding from the right ureter, and the information gained by the ureter catheter, gave the diagnosis and the line of treatment to be pursued.

CASE IV.—Haematuria Only.

Miss L., aged 56, was seen in consultation with Professor Rutherford Morrison in 1907. She was an enormously stout woman who complained of periodical attacks of painless haematuria when she passed thick, bright red blood. At first her doctor thought this came from the vagina. No pain or discomfort had ever been experienced, and owing to the huge rolls of abdominal wall fat it was quite impossible to exclude any renal tumour.

Cystoscopy showed a normal bladder and the effluxes of urine through the urteric orifices were clear. As there was no clue whatever to the origin of the bleeding she was instructed to proceed to a private hospital for immediate cystoscopy directly the next attack came on, no matter what the hour was, night or day. The desired opportunity came sometime later, and I was summoned to cystoscope her in the small hours of one morning. Bright red blood was seen to be pouring furiously from the right urteric orifice, but the medium quickly became so turbid I was unable to catheterize the ureters. This was done a few days later when it was found that while the left kidney was functioning normally the right kidney failed to do its full share of the work. Professor Morrison subsequently excised a right hypernephromatous kidney.

This case was entirely dependent upon the cystoscope for a diagnosis. No blood clots were seen and their absence accounted for the lack of any acute pain.

CONCLUSION.

Excluding children, 63.2 per cent. of the cases occurred between the ages of 45 and 65.

The commonest onset symptom was painless haematuria.

In 32 cases out of 52, pain, haematuria and a palpable renal tumour were associated at some stage during the illness.

In 3 cases a varicocele was a complication, that is, the condition was inoperable when first seen.

Two patients had clot retention of urine.

CAPTAIN ANGUS McNAB, London Scottish, M.B., ophthalmic surgeon to King Edward VII Hospital, Windsor, who was killed in France on November 1st, 1914, left estate valued at £9,242.

AN EASY METHOD OF DETECTING *S. PALLIDA* AND OTHER SPIROCHAETES.

By ALFRED C. COLES, M.D., D.Sc., F.R.S. EDIN.,
M.R.C.P. LOND.,

FRENCHMAN TO THE ROYAL NATIONAL SANATORIUM, BOURNEMOUTH.

At the present time three methods are in general use for the detection of *S. pallida*: (1) The examination of fresh cover-glass preparations by means of dark-ground illumination obtained by means of a special oil immersion dark-ground condenser; (2) the examination of dry films stained with Giemsa or other stains; (3) the examination of films made by Burri's Indian ink method.

I have been in the habit of using each of these methods on every case in which I have had to make a diagnosis, but in some cases in which the spirochaetes are present in very small numbers, especially those in which the primary sore has been previously treated with antiseptics, in which healing is taking place, the hunt for a single spirochaete is very trying and requires a considerable expenditure of time.

The following method which I have devised renders the detection of *S. pallida* or any other spirochaete as easy as that of the tubercle bacillus in sputum. It depends on the following principles:

1. That structures which are coloured with a fluorescent dye—for example, eosin, fuchsin, fluorescein, etc.—when examined on a dark ground, stand out very prominently, whilst blue-stained structures are very inconspicuous.

2. That if the medium in which the red stained organisms lie be of very low refractive index, they are exceedingly conspicuous by dark-ground illumination, and can be detected with a comparatively low power, but if mounted in balsam, cedar oil, paroline, or water, they are only seen with the very greatest difficulty. The method briefly consists in examining a film containing spirochaetes, stained in the usual way with Giemsa or Leishman's stain, dry, not mounted in any medium with dark-ground illumination, using a dry lens of medium power. There are, however, some details which considerably simplify this problem.

Method.

It is not necessary to stain with Giemsa, ordinary carbol-fuchsin would answer the purpose, but if the film is subsequently to be examined with the oil immersion $\frac{2}{3}$ objective it is very advisable to stain with Giemsa or its equivalent. Previous fixation of the film with absolute alcohol for ten to fifteen minutes, and subsequent staining with dilute Giemsa as is usually done, requires too much time, and never gives the same intensity of staining as the following:

The stock solution of Giemsa is diluted with an equal part of pure methylic alcohol or acetone.

Films are made from the serum which exudes after cleaning and rubbing or scraping the margins of the primary sore in the usual way. When dry, a few drops of the diluted Giemsa stain are dropped on to the surface of the film, and immediately (the quicker the deeper the staining) ten times as much distilled water is added. This will probably be more than the slide will hold; it is, therefore, advisable to add as much water as will lie on the film, and then flood this off with more water on to the surface of a piece of curved glass plate, and place the slide film downwards in this diluted stain.

Stain for not less than ten to fifteen minutes, then wash off the stain with distilled water; dry, but do not mount.

Dark-ground illumination.—The special dark-ground condensers in use—for example, those of Leitz, Zeiss, Baker, etc.—have two disadvantages for this examination, as, first, they all require to be in oil contact with the under surface of the slide, with the result that one cannot examine a large area of the film without the oil running on to the surface of the stage or its being used up; and, secondly, they do not allow the change from dark-ground to ordinary illumination being made. To overcome these disadvantages, and to do away with the necessity of using oil I use an ordinary achromatic condenser, used dry, without oil, provided with a Travie's expanding stop below it. A simple round stop, as long as it be of the right size, could be used; but the expanding stop is much more convenient. Any of the microscopic agents would fit either

of these, and, if necessary, explain how a dark ground is obtained. An ordinary paraffin microscopic lamp, used with or without a bull's-eye condenser, is ample illumination.

The objective I use is an 8 mm., or $\frac{1}{2}$ in. of Zeiss and Leitz, and a compensating ocular of 8, 12, or 18, or an ordinary No. 4 or 5 eyepiece. I can see *S. pallida* with a $\frac{2}{3}$ in. objective with 18 ocular, but I could not pick them out with this low power. I find I cannot use a $\frac{1}{2}$ in. objective on an uncovered objective, and its NA is too large to obtain a good dark ground with this method.

The stained film must not be mounted in balsam, oil, water, or any other medium; it must be examined dry in air. The easiest and best result is obtained by examining it without a cover-glass, but if such an uncovered film be examined with a dry lens at the correct tube length of that lens for a covered object, the image will be very imperfect and practically useless, but if the tube of the microscope be lengthened to the right height—this can only be found by trial, but when found will be practically constant for that objective—the definition is perfect.

My Zeiss 8 mm. normally working at a tube length of 160 mm. requires to be lengthened to about 195 mm., and the Leitz 8 mm. objective from 170 mm. to 240 mm. The latter length cannot be obtained on an ordinary short-tube microscope without the addition of a cardboard tube. Of course, the inconvenience of lengthening the tube may be overcome by laying a cover-glass on the film, when the objective will be used at about the normal tube length and the definition will be excellent. This, however, has the disadvantage that if a spirochaete be found by dark-ground illumination, and one wishes to examine it with ordinary illumination by removing the stop under the condenser and turning on the $\frac{2}{3}$ oil immersion lens, the spirochaete will not be seen. On the other hand, if there is no cover-glass, the $\frac{2}{3}$ lens still will enable it to be seen at once.

In a stained film examined on a dark ground without any mounting medium *S. pallida* can be easily detected with such a moderate power as a $\frac{1}{2}$ -in. objective. It stands out as a beautiful golden spiral, which cannot be missed by the merest tyro.

The large field of vision, the ease with which a slide can be thoroughly examined, the absence of any eye strain, and above all the remarkable way in which the spirochaete strikes the eye, have only to be seen to be appreciated.

I have now used this method for some years, and am convinced that I should find no difficulty in finding a spirochaete even if only two or three were present in a film the size of a postage stamp. Can the same be said of any other method now in vogue for the detection of these illusive organisms?

It seems to me that it would be invaluable to those who are searching for *S. pallida* in films from the brain in cases of general paralysis of the insane, etc.

It is, of course, equally serviceable in examining the blood for any of the spirochaetes, provided these are coloured a reddish tint with Giemsa, or if stained with eosin or fuchsin. Blue-stained objects are very inconspicuous.

Some few years ago whilst examining a Giemsa-stained film with the $\frac{2}{3}$ oil immersion lens, I found a spirochaete in the blood of a bat, which I provisionally named *S. vesperuginis*. This spirochaete, very slightly larger than the *S. pallida*, was only present in extremely small numbers. It would have been well-nigh impossible to have found another with the $\frac{2}{3}$ objective, but in the remaining 15 films which were not mounted, I had no difficulty in detecting and marking these spirochaetes by examining the films dry on a dark ground, although in many films there was only a single spirochaete present.

I shall be very pleased to demonstrate the extreme ease with which the method is carried out, or to answer any question thereon.

THE next award of the Alvarenga Prize of the Philadelphia College of Physicians, amounting to about £50, will be made on July 14th, 1916. Essays, which may deal with any subject in medicine, must be received on or before May 1st, 1916, by the Secretary of the College, Dr. Francis R. Packard, 19, South 22nd Street, Philadelphia, Pa., U.S.A., to whom intending competitors should write for full particulars. The Alvarenga Prize for 1915 has been awarded to Dr. J. E. Sweet, Philadelphia, for his essay entitled "The Surgery of the Pancreas."

A SIMPLE METHOD FOR THE CULTIVATION OF ANAEROBIC ORGANISMS.

BY

LYN DIMOND, M.B., LIEUTENANT R.A.M.C.,
BACTERIOLOGIST; BRITISH EXPEDITIONARY FORCE, FRANCE.

THE large number of wounds in the present campaign contaminated with anaerobic organisms has brought into prominence the different methods for the isolation and culture of these organisms.

A simple method for obtaining anaerobic conditions is the following, and I have found that by its employment large numbers of these organisms can be investigated with regard to their cultural characteristics, their carbohydrate reactions, etc., with comparative ease, and the laborious technique involved in carrying out many of the methods in common use avoided.

The sole apparatus required are test tubes of two different sizes for cultures on solid media and three different sizes for liquid media.

The diameters of the test tubes which I have found most convenient have been 1.5 and 2.5 cm. for the first method and 1, 1.5, and 2.5 cm. for the second method.

1. For Solid Media.

The test tubes, 1.5 cm. in diameter, are prepared, plugged, and sterilized with the sloped medium, such as glucose agar, in the usual manner. After inoculation of these media, a corresponding number of the 2.5 cm. test tubes are half filled with a solution of pyrogallate acid;

when liq. potassae has been added the plugs of the culture tubes are removed, and they are inserted, with their upper ends downwards, into the alkaline pyrogallate solution contained in the 2.5 cm. tube. The contained air in the tube containing the culture medium prevents the pyrogallate solution from passing up into the tube for more than a few millimetres, and the inverted tube, by virtue of its contained air, floats upon the pyrogallate solution. A few cubic centimetres of liquid paraffin are then poured upon the surface of the pyrogallate solution, thus

preventing it from becoming inert through absorbing the oxygen of the external air.

This method, which I have now used some hundreds of times, has invariably given excellent results. After incubation is completed the culture tube is lifted out of the pyrogallate solution, wiped with sterile wool, and plugged, after which the culture can be investigated in the usual manner.

2. For Liquid Media.

The smaller 1 cm. diameter test tube is prepared with its liquid medium in the usual way. After inoculation it is inserted into the large 2.5 cm. test tube containing alkaline pyrogallate solution, and after removal of its wool plug the 1.5 cm. test tube is inverted over it until its margin dips into the alkaline pyrogallate solution. A few cubic centimetres of sterile liquid are then poured upon the surface of the pyrogallate solution, between the wall of the medium-sized tube and that of the larger tube.

For the investigation of the carbohydrate reactions, gas formation, etc., of anaerobic organisms, I have found this an extremely simple and reliable method.

The diagrams give a general idea of the arrangement of the test tubes in the two methods.

THE TREATMENT OF WOUND INFECTIONS BY ANTISEPTICS.

BY CHARLES A. MORTON, F.R.C.S.,
PROFESSOR OF SURGERY IN THE UNIVERSITY OF BRISTOL.

I SHOULD like to be allowed to say something in support of the view that antiseptics are of value in the treatment of infected wounds. Sir Almroth Wright tells us that they are not necessary because the resistance of the tissues is sufficient to deal with the infection, if the wound is kept by the surgeon in a favourable condition, by adequate drainage and other means; and that, although antiseptics have the power to kill micro-organisms in the laboratory, they cannot act efficiently in contact with the tissues of the body. He tells us that, in judging of the value of antiseptics, we must be guided by laboratory methods, and not by clinical experience, because its results are not "brilliantly successful" or the reverse. He considers that because clinical results do not almost invariably prove the utility of antiseptics we are not to be guided by them, but by laboratory experiments. But is this reasonable? If we have evidence from the use of a drug in a sufficiently large number of cases to enable us to really judge of its action, are we to refuse to believe in its efficacy because it is not "brilliantly successful"? Are we not to judge of the value of vaccine treatment by its clinical results? They can hardly be said to have been "brilliantly successful" for all the various morbid conditions for which they have been used. Why should we not refuse to judge of the value of vaccine treatment because it is not always "brilliantly successful," if we are to refuse to judge of the value of antiseptics on such grounds? There is, indeed, no reason why we should replace antiseptics by vaccines in the treatment of infected wounds, as Sir Almroth Wright says we should do.

And are his laboratory experiments really convincing that antiseptics can do no good in infected wounds? He says they cannot do good at the time of infection because they cannot penetrate "the solid barriers of albuminous substance, provided in the early stages of the wound by exposed muscles and connective tissue." But may they not reach the organisms lying outside these barriers, if applied early enough? Cannot millions of microbes be destroyed by the antiseptic before they have begun to penetrate into the tissues? Even if contact with the albuminous material in the wound reduces the power of the antiseptic by the chemical change which it produces, if sufficient antiseptic is used, and if it is frequently changed and used for a prolonged period, it is not likely to be efficient. If the "barrier of albuminous substance" is formed by the exudation on the surface of the wound, bathing the organisms lying there, and then coagulated into an impenetrable layer by the antiseptic, then it would certainly seem impossible for the antiseptic to destroy the organisms. But it seems to me that we ought to require very strong proof that this was what happened before we abandoned the antiseptic treatment of wounds.

Judging by the results of Dr. Alexis Carrel's work at the hospital at Compiègne, it seems to me that the clinical results of the treatment of infected wounds with an antiseptic have been most encouraging, and should certainly lead to a wide adoption of his thorough methods. With the result of Carrel's work before us, I venture to think Sir Almroth Wright is not in the least justified in stating that the antiseptic treatment of wounds has completely broken down. In the instances it has done so this has happened probably because the surgeon had no chance of dealing with the wound for many hours after it was inflicted, or used an antiseptic in an imperfect way—perhaps just douched the wound with it, and then washed it away at once with saline for fear of its supposed injurious action on the tissues. In cases in which the wound has been well cleaned, and the antiseptic of sufficient strength, and freely and for a sufficient time applied, within a few hours of the injury, experience both in civil and military

* See abstract of his paper in BRITISH MEDICAL JOURNAL, October 23rd, 1915, p. 609. The investigations which resulted in the use of sodium hypochlorite as an antiseptic were carried out by Professor Lorrain Smith and others at Edinburgh (BRITISH MEDICAL JOURNAL, July 24th, 1915, p. 129) and by Dr. Dakin in France (BRITISH MEDICAL JOURNAL, August 28th, 1915, p. 338), and were subsidized by the Medical Research Committee of this country.

practice has shown that it has been efficient in preventing sepsis.

I very much doubt if we can rid an infected wound of organisms by douching it out with saline. If we take a mixture of chalk and water and throw it into a wound, and allow it to remain there a short time, we cannot expect to get even such gross particles as the chalk away from the wound by such means, much less millions of microbes. Just as we could only get rid of the deposited chalk by applying to the wound an acid solution, so as to act chemically on the chalk, so we can only get rid of the microbes by killing them with an antiseptic. Carrel truly says we cannot clean a wound of microbes even by a swab, for as well might we expect to clean a greasy bottle by such means. But, if we cannot mechanically remove the organisms, surely the right thing to do is to apply an antiseptic to kill them.

I admit that it does not seem so reasonable to apply antiseptics to an already suppurating wound as to one just infected, because of the difficulty, if not impossibility, of the antiseptic penetrating the living tissues, into which the organisms have already penetrated; and, as Sir Almoth Wright points out, if you by irrigation wash out the pus, why trouble to try and kill the microbes in that pus? But here again the question seems to me to arise, Can we irrigate out all the microbes in the wound (as distinct from those which have penetrated into its walls), and may we not be wise in employing an antiseptic to kill those we cannot? Is it not possible that some antiseptics may have some power of penetrating into the living wall of the wound? Here, again, Carrel's experience in treating suppurating wounds seems to me quite good clinical evidence of the advantage of using hypochlorous acid or hypochlorite of soda in the treatment of suppurating wounds.

Now, Sir Almoth Wright tells us that the question as to the value of antiseptics cannot be answered by clinical observation, yet, all the same, he does seem to attach importance to such evidence when it is the result of the observation of "experienced and very competent observers." But though he now admits that we may judge of the value of therapeutic measures used in connexion with the healing of wounds by clinical evidence, he tries to show that even these "experienced and competent observers" have been deceived, for he says their good results may have been due to using the antiseptic with a "hypertonic menstruum," the washing out of the wound by peroxide of hydrogen, or the use of antiseptics in the form of fomentation. But the use of such things without the antiseptic has probably not been found by those "experienced and very competent observers" to have the same beneficial action on the wound as the particular antiseptic they consider has been of value.

Let me give one striking example of the value of clinical evidence. It does not refer to the beneficial action of antiseptics but to their harmlessness. It has generally been maintained that antiseptics damage the living tissues, possibly because of experimental evidence, but I do not know of it; but perhaps simply because certain antiseptics have caused irritation of the skin. Mr. Bond of Leicester has recently shown¹ that even quite strong antiseptics can be applied to wounds without interfering with their healing. But we have even some laboratory evidence on this matter, which may appeal to those who think clinical evidence unreliable. The late Mr. Lockwood, writing some years ago of the unreasonable dread of the entrance of antiseptics into wounds, said he had made sections of the tissues from wounds to which antiseptics had been applied, and could find no evidence of damage to them.

The sterilization of the infected wounds of war is a matter of such vast importance to us at the present time that I would plead that further attempts on the lines practised and advocated by Carrel should be made, and that we should not rest content to depend on the resistance of the tissues—a resistance which very often completely fails, the failure leading to the most serious condition of sepsis in the wound, and often costing the wounded soldier his life. Nor, I would urge, should we depend on irrigation with saline to rid a recently infected wound of organisms, but should freely apply, for a considerable period, either hypochlorous acid in 0.5 per cent. or hypochlorite of soda solution; and these antiseptics in

a strength potent to kill micro-organisms will do no harm to the tissues.

I think Sir Almoth Wright's suggestion that physicians should now take charge of wounds will be read with some astonishment. Does he think that a surgeon's only business is with the knife? Can it be possible that he thinks they will be too free in making counter openings for drainage? Or does he think that the surgeon will have a greater tendency to do harm by inflicting on the wound a douching with some antiseptic, because he will be less readily converted to his views on the sufficiency of tissue resistance and the value of only using saline? Is it necessary to remind Sir Almoth Wright that even physicians use drugs which they believe to be internal antiseptics, and that the faith some of them have in the good results of vaccine treatment is very feeble, and that he must not trust them too far? But, after all, it is clear from Sir Almoth Wright's last lecture that he does really use antiseptics himself, for if a 5 per cent. salt solution can prevent the growth of pyogenic organisms what is it but a feeble antiseptic? I fear the knowledge that saline solution is an antiseptic will come as a rude shock to "aseptic" surgeons. They will discover that they have really been using a deadly antiseptic in the wounds all the time, even though, in the strength they have used it, too weak to have any antiseptic power. But it may, by accident, have been used as strong as 2 per cent., and then it would undoubtedly be antiseptic.

Memoranda:

MEDICAL, SURGICAL, OBSTETRICAL.

TREATMENT OF "FLAGELLATE DIARRHOEA" AND OF KALA-AZAR.

SEVERAL authors have recently called attention in the BRITISH MEDICAL JOURNAL to the presence of flagellates in cases of diarrhoea, and discussed their etiological rôle. When present in a small number such flagellates are probably harmless. In the tropics they are found in the stools of more than 25 per cent. of apparently healthy persons after a saline purge. When present, however, in enormous numbers, as in the two cases which I published in the BRITISH MEDICAL JOURNAL of November 11th, 1905, the probabilities are that they play a part in the causation of the intestinal symptoms.

I can confirm Low, Wenyon, Ledingham, and Penfold's experience that ipecacuanha and emetine have no effect on such parasites. I recommend instead the use of methylene blue. This drug has a powerful effect on flagellates. I may quote a paragraph from my paper on the resistance of the intestinal flagellates to various chemical substances¹:

The action of different chemicals on the parasites was tried repeatedly. Without referring in particular to all the experiments made, I may say that methylene blue solutions are without doubt the most active—much more so for instance than quinine solutions. Mixing one loopful of the stools with one loopful of 1 in 1,000 solution of methylene blue and observing the preparation microscopically, the flagellates (*Trichomonads* and *Cercomonads*) are seen to take up the colour, and stop almost instantly their movements, losing their ordinary shape and becoming globular without exhibiting any flagella or undulating membrane.

I give methylene blue by the mouth, in cachets containing 2 or 3 grains of the drug, three times a day, and also by intestinal irrigation (1 in 5,000 or 1 in 3,000). The patient must be informed that his stools and urine will become blue. The treatment has induced in most of my cases a rapid decrease or complete disappearance of the flagellates within a very few days. In a few obstinate cases the administration of the drug may have to be persisted in for a long period of time. In such a contingency the methylene blue should be discontinued from time to time to prevent the formation of methylene blue concretions in the intestine.

In connexion with Major Mackie's interesting paper on the treatment of kala-azar with tartar emetic, published

¹ BRITISH MEDICAL JOURNAL, November 11th, 1905.

in the last issue of the BRITISH MEDICAL JOURNAL, I would call attention to a case—an imported case from India—I treated in Cochin in 1914, and published in the report to the Advisory Committee for the Tropical Research Fund (second half-year 1914) and also in the *Rivista di Pediatria*, 1915 (fas. 4). The treatment consisted in administering to the patient my tartar emetic-potassium iodide "yaws mixture" as well as tartar emetic given intravenously, and Fowler's solution. The improvement was striking, and I concluded in my papers that the drug to which this was due was tartar emetic, as my previous experience and that of others with arsenic and potassium iodide given alone had not been successful.

The case is of some interest, showing that independently and at the same time tartar emetic was found to be useful by me in a case of kala-azar contracted in the tropics, and by Cristina and Carona in cases of Italian origin.

ALDO CASTELLANI.

Society of Tropical Medicine, London, W.

MAGNESIUM SULPHATE IN NON-AMOEBIIC DYSENTERY.

In February, 1898, when our forces engaged against the Waziris on the North-West Frontier of India were being exhausted by dysentery, you were good enough to publish my experience in South America in the treatment of non-amoebic dysentery by drachm doses of magnesium sulphate every two hours. I found it to be a specific; and the observation was confirmed by correspondents at the front, by the medical officer in charge of the gaoi at Mauritius, and, later, in the South African war, by friends engaged in it. The observation is not new, for a correspondent in Belfast pointed out that it was published at least three hundred years ago. But that need not prevent the younger surgeons at the Dardanelles from giving the treatment a trial, when, I think, if it is the non-amoebic form of dysentery with which they have to deal, they will be astonished at the results.

F. WYATT-SMITH, M.B., B.C. Cantab.

THE "IRRITABLE HEART" OF SOLDIERS.

We are grateful to Dr. Poynton for his reply to our memorandum, recognizing in it the earnest thought of a worker upon closely allied problems. His observations upon acute rheumatism and endocarditis are well known; his views as to their causation claim many fresh adherents; and we are conscious that streptococcal infection may yet come to be regarded as the chief cause of the less serious and the most grave forms of cardiac disability.

The purpose of our memorandum was to record the presence of streptococci in the urine in patients of the class we describe; to express the view that these organisms are derived from an infected blood; and to stimulate further search in this direction. During the past two weeks we have been confirmed in our view, having recovered organisms of the same or closely allied morphological type from the blood in 13 patients. But at present we go no further than to suggest our self-evident working hypothesis that this infection is the cause of the ailment. To an actual conclusion we do not as yet commit ourselves, but believe its discussion neither untimely nor without promise.

The argument which Dr. Poynton advances is very pertinent and one which often forces itself to our consideration. "How can we prove that the essential factor is the infection, in the face of a mass of evidence favouring physical and nervous overstrain . . . as the prime causes?" Now physical overstrain and nervous overstrain are terms which are themselves in measure hypothetical; it has not been proved that a healthy heart may damage itself, or a healthy nervous system suffer injury, by over-exercise; infection is determinate and we believe in this instance demonstrable. Moreover, physical strain and nervous strain are distinct, and we look not for two causes but for a single cause of a well-defined symptom group; it may be we have found it in infection of the blood stream. Again, we consider physical strain and nervous strain separately, and in our group of studied cases we find instances in which we have every reason to believe neither one nor the other was ever present, soldiers who have never been abroad, and men who have been

submitted to no very strenuous work and to no unwanted excitement.

But we do find, as we may now assert, infection in each examined member of the group. That is our chief reason for working still and suggesting work along the lines of this hypothesis of infection, and for discarding the hypothesis of strain as a prime factor.

Many of our patients, it is true, give a distinct history of strain to which they attribute their present symptoms; in some of these, where the strain was unaccustomed, we can nevertheless, by persistent inquiry, trace the symptoms in less aggressive form to a date preceding the unaccustomed effort or shock; in others may be we cannot, but infection is demonstrated in these also, and neither effort nor shock will explain infection.

Dr. Poynton and we may perhaps reach agreement in a tentative view that infection, latent may be for months or years, is the prime factor, but betrays itself in the soldier only when the body, poisoned in mild degree, is called upon to yield up its reserves of energy; or betrays itself in the civilian (for we do not doubt that he may be similarly affected) when a change in his resistance or in the virulence of the organism permits the latter to settle down now in the joints, now in the cardiac tissues. Such a speculation, we confess, appeals to us.

Reports of Societies.

DISCUSSIONS ON PARATYPHOID FEVER.

ROYAL SOCIETY OF MEDICINE.

At a meeting of the Section of Medicine of the Royal Society of Medicine, held on November 23rd, Sir WILLIAM OSLER, Past President, being in the chair, the discussion on paratyphoid fever was continued.

The Army.

Colonel Sir WILLIAM LEISHMAN, R.A.M.C., who reopened the discussion, said that his experience related to paratyphoid fever as it was met with in France. The cases had not been many—only 1,200 during the first fifteen and a half months of war. He agreed with Sir Bertrand Dawson that they were not grave as regards danger to life. Eighteen had died, the case mortality being 1.5 per cent. The total number of cases of typhoid and paratyphoid fever combined was less at present than at any previous stage, and numbered only 32. The relative proportions of paratyphoid A and paratyphoid B had not been accurately determined, but the latter composed approximately two-thirds to three-quarters of the paratyphoid infections. Although paratyphoid A was the prevailing type in India, its occurrence in France was not limited to the Indian troops. There had been no such explosive epidemic as could be ascribed to a water-borne infection; carriers were probably the source of the cases. Stringent measures had been taken to limit the spread of the disease. At the clearing stations a blood test was performed on all likely cases. They were then transferred to a general hospital at the base, and afterwards to an isolation hospital, where laboratory accommodation and a competent bacteriologist were available. When a positive diagnosis was made, the medical officer of the unit from which the man had been sent was informed by telegram, and a watch was kept by him for further cases. If any occurred a bacteriologist carried out a thorough investigation. A spot map was kept at head quarters, where such cases as occurred were charted unit by unit. A large proportion of the infection was derived from the native population, especially from the Belgian refugees. House-to-house visiting was carried out; the little farmhouses in which the refugees were living were visited; infected people thus detected were afterwards isolated and treated in hospital. The chance of picking up infection from such sources was very great. For good services rendered in this respect he mentioned with warm approbation the Red Cross unit of the Society of Friends.

He did not agree with Professor Dreyer that many mild cases of the condition were unrecognized in France. This

opinion was founded on Professor Dreyer's method of agglutination, which Sir William Leishman thought contained some fallacies. "Controls" were needed before it could be accepted in its entirety. Diagnosis by agglutination with the low degree of dilution thought by Professor Dreyer to be sufficient was not free from contention. There were many cases of mild fever at the front due to many conditions. It was going too far to say that such belonged to the paratyphoid group. Trench fever, for example, was a definite disease, and gave no agglutination for typhoid or paratyphoid. He thought it was probably mosquito-borne.

He was not satisfied that Professor Castellani's evidence as to the value of mixed vaccines was conclusive. The dosage, he thought, was too small. It was, above all things, undesirable to tamper with the typhoid element of the vaccine, in the preparation of which little things readily made great differences. The incidence of paratyphoid was roughly 1 per 1,000, hence the need for protective vaccination against it was not very urgent.

The Navy.

Fleet-Surgeon P. W. BASSETT-SMITH, R.N., spoke from his experience of the naval cases admitted to the Dead-nought Hospital, Greenwich, and from cases from the Royal Naval Hospital, Haslar, and elsewhere. The greater number had come from the Dardanelles area, the diagnosis having been roughly made, laboratory examinations having been few, and little differentiation having been attempted. About September, 1914, antityphoid vaccination began to be carried out among such men as were likely to be landed with the Expeditionary Force. About the middle of this year paratyphoid cases began to be recognized, and a paratyphoid vaccine was prepared from strains obtained in Gallipoli. In every case of pyrexia a blood culture was made, the excreta were examined for the bacilli of typhoid and paratyphoid and for dysentery organisms, and agglutination was performed, Professor Dreyer's method being used if a sufficient amount of blood was procured. He had come to the conclusion that all cases from the Near East labelled as dysentery should be regarded as probably examples of paratyphoid fever. On bacteriological examination of 70 cases at Plymouth 11 per cent. proved to be typhoid, 40 per cent. paratyphoid A, 20 per cent. paratyphoid B, and 29 per cent. were indefinite. His own results at Greenwich had revealed 12 per cent. typhoid, 14 per cent. paratyphoid A, 36 per cent. paratyphoid B, and 38 per cent. indefinite. Some of the indefinite cases were, no doubt due to infections by *Bacillus coli*. Of 208 cases ascribed to typhoid, 10 had died; of these, 6 had not been inoculated, 1 had probably not been, and 3 had been inoculated. No case of paratyphoid had died. In the navy the view that had been taken was that it was worth while to provide immunity against paratyphoid if it were possible, so that a vaccine had been used with increasing frequency. The typhoid vaccine had been administered first in two doses, and afterwards the paratyphoid in one or two doses. The latter vaccine was polyvalent. More recently a mixed or a triple vaccine had been used in two doses, the first containing 500 million typhoid, 250 million paratyphoid A and 250 million paratyphoid B; the second, 1,000 million typhoid, 500 million paratyphoid A, and 500 million paratyphoid B. No more complaint of disturbance had followed than after the simple antityphoid vaccination and the agglutination values obtained had been good. The amount of true typhoid agglutination had not diminished. He hoped that a full protection had been afforded against typhoid and a moderate protection against the other diseases.

Tropics and Serbia.

Professor A. CASTELLANI spoke of his experience of paratyphoid in the tropics and in Serbia; in Ceylon paratyphoid A was the usual infection; in Serbia, paratyphoid B. In general he agreed that paratyphoid was milder and of shorter duration than true typhoid, but there were many exceptions. He had seen many cases of paratyphoid A ending fatally or lasting for several months. In the tropics the two could not be distinguished clinically, and therefore must be separated bacteriologically. The treatment was on the lines of true typhoid, a liquid diet being given for the whole course of the fever and for some days afterwards. He had known serious results follow the giving of

solid food early in the disease, as was becoming customary in Europe and America. In Ceylon malignant cases were frequently met with and it was better to be on the safe side. He could endorse the view that the fewer the drugs given the better for the patient, but thought that uterotonic had a place in preventing infection of the gall bladder. Vaccines were sometimes beneficial in certain protracted cases. Prophylaxis consisted chiefly in the employment of antityphoid inoculation. In Ceylon he had for some years used mixed vaccines with satisfactory results. He referred to his experiments, by which it had been shown that the immunity conferred by mixed vaccines was equal to that obtained if the vaccines were given independently. The degree of immunity bore no proportionate relation to the amount of vaccine used, provided that the minimum necessary to secure immunity was employed. Those inoculated showed no severe reaction, and could resume their duties within from twenty-four to forty-eight hours. The inoculated individuals produced agglutinating bodies for the three germs in amounts not less than if they had been injected with a monovaccine. There accrued advantages from mixed vaccines. Much time was saved. Paratyphoid A and B were provided against, and they were not rare; nor were mixed infections, and even triple infection occurred. The fear had been expressed that mixed vaccines gave a smaller degree of immunity against true typhoid fever, but that was not so. He could only come to the conclusion that a mixed vaccine should be used as a routine measure, instead of the ordinary monovaccine.

Symptoms.

Dr. HENRY ROBINSON, while agreeing with Sir Bertrand Dawson's description of the disease in the main, alluded to a few striking characteristics. The onset was sometimes acute, slivers being not uncommon. Epistaxis occurred in about 30 per cent. Headache and abdominal pain were the leading symptoms, but backache and vomiting were not rare. There was little abdominal swelling. Although the spleen was not usually palpable, its size, as estimated by percussion, was often increased. Spots often did not appear until the fever had subsided, and were sometimes larger and more lenticular than those of typhoid. The abdominal reflex was frequently absent, though not more often than in typhoid; it was abolished in just under 50 per cent. of the cases of each. Brachycardia was almost the rule during convalescence. The pyrexia varied considerably in duration, lasting from five or six days to two or four months. He did not think that paratyphoid A and B could be differentiated clinically. On clinical evidence, he was of opinion that there were many mild undiagnosed cases. He asked as to which was most reliable, the hanging drop method or that of Professor Dreyer, for estimating agglutination. He had received widely contradictory reports, when the blood withdrawn at the same time had been examined by the two methods, by different competent bacteriologists. He had found that the Widal reaction often disappeared very rapidly after the condition was recovered from.

Bacteriological Examination: Agglutination.

Dr. H. L. TIDY regarded the old and new methods of performing the agglutination test as equally reliable. In a considerable number of the cases of paratyphoid he had obtained no agglutination of the *Bacillus typhosus*, although the men had been inoculated within eight months. Febrile conditions apparently removed the agglutinins to the *Bacillus typhosus* from the blood, and this factor should be taken into consideration by those who were compiling statistics on the persistence of the Widal reaction. A positive Widal reaction was equally valuable in the case of the inoculated and the uninoculated. After having disappeared the agglutinins perhaps returned again, but this was not usual. He thought that the effect of febrile conditions was to convert the agglutinins into agglutinoids. For separating the organisms from the excreta he thought that Carl Browning's "brilliant green" method was preferable to any other, but he had been satisfied with the use of one tube only. He favoured MacConkey's medium for cultural purposes. He had come to the conclusion that Professor Dreyer's arc lamp had no specific value.

Captain KENNY (Canada) gave his experiences of paratyphoid at the Canadian Hospital, Taplow. There were

11 cases probably typhoid, and 22 cases in which the diagnosis of paratyphoid B, and 3 in which the diagnosis of paratyphoid A had been established. Two were cases of mixed infection of paratyphoids A and B. Professor Dreyer's method of testing agglutinating power had proved quite satisfactory. He narrated a case in which at autopsy the lesions both of typhoid and of dysentery were found.

Dr. CARL BROWNING expressed himself as deeply gratified by the favourable expressions which had been used regarding his method of separating the organisms. As modified it had now been reduced to the simplest possible procedure. He agreed with Sir W. Leishman that a careful attitude should be adopted towards small oscillations in the agglutinating power of the blood.

After Dr. SCOTT TEBB and Dr. STOLKING (Moscow) had spoken, Sir WILLIAM OSLER brought the discussion to a close. He stated that paratyphoid was first distinguished by Professor Achard at Paris, and exhibited temperature charts from the original article, and from a case of his own.

ROYAL ACADEMY OF MEDICINE IN IRELAND.

At the first meeting for the session of the Section of Pathology of the Royal Academy of Medicine in Ireland, when Professor McWENNEY took the chair as President for the first time, several interesting cases of infection by *Bacillus paratyphosus B* were related. Professor McWenney described the case of a man, aged 24, who suffered from profuse diarrhoea, severe pains in the stomach, vomiting, and collapse, after eating mackerel at a fried fish shop; there were no other cases in the house or neighbourhood. He was powerless when admitted to hospital, and died within twelve hours of admission after five days' illness. There was suppression of urine, and the patient's aspect was suggestive of the algid stage of Asiatic cholera; the only changes of importance found *post mortem* were in the gastro-intestinal mucosa, which was dark-brown in colour, very rugose, thickened, velvety, and intensely injected. The changes were particularly well marked in the stomach, which contained a little bloody mucus. The intestines were practically empty. There were no ulcers, and the Peyer's patches were not altered. On bacteriological examination, non-lactose fermenting organisms, identical both culturally and serologically with *B. paratyphosus B*, were obtained from the contents of the bowel. The case was important as showing that the pathogenic rôle of *B. paratyphosus B* was not, as generally thought in this country, confined to the production of paratyphoid fever, but that, like the other members of the Gaertner group, it could produce typical food poisoning of the severest type.

Dr. BOXWELL related an instance in which three young men were taken ill after drinking water from a stream grossly contaminated by sewage. In one case admitted to Cork Street Hospital, and diagnosed by Dr. Day as paratyphoid, Dr. SPEARES had no difficulty in recovering the *B. paratyphosus B*. One of the other cases admitted to Meath Hospital suffered a fairly sharp attack which seemed to be typical of typhoid fever, but Dr. SPEARES found the *B. paratyphosus B*. The third man was too ill to be moved to Dublin. Another case Dr. BOXWELL described was that of a woman admitted with a diagnosis of acute gastric ulcer. In this case also *B. paratyphosus B* was found. The symptoms were those of violent gastroenteritis, suggestive of food poisoning, but no such cause could be discovered. At a late stage a few rose spots were seen, and the spleen was enlarged. Professor McWENNEY exhibited the standard agglutination apparatus issued by the Department of Pathology, Oxford, on behalf of the Medical Research Committee. After testing about thirty serums (mostly from inoculated persons) by the method, he could say that it seemed quite effective; the agglutination effects were very striking and the results easily read. Dr. W. D. O'KELLY, while regarding some standard as absolutely necessary, owing to the number of men who had received protective inoculations, considered that the test should be carefully checked by cultural examinations of the faeces before it came into general use. Dr. McWENNEY said that from recent observations he considered that paratyphoid infections were of much more frequent occurrence than had hitherto been generally supposed.

HYPOTHYROIDISM AND HYPERTHYROIDISM.

In an address on the clinical problems of internal secretions, read for him owing to his absence on military duty by Dr. CLOW, Dr. CRAIG, the President of the Bradford Medico-Chirurgical Society, at the opening of the session, related the following interesting case:

A man, aged 57, had complained of weakness of the legs for several months. He could no longer walk to his work, and had lost 3 st. in weight. Pulse small, 120 to 150; no heart murmurs or signs of dilatation. There was no albumin, blood, or sugar in the urine. No exophthalmos. There were marked tremors in both hands. There was a large bilateral swelling of the thyroid which had been there fourteen years. On its first appearance, by the advice of his medical attendant, he had painted it with iodine, and this had been followed by some reduction in size. Six months prior to consulting me there were indications of the gland again enlarging, and of his own accord he had resorted to painting with tincture of iodine. The history and symptoms led to a diagnosis of hyperthyroidism, induced by the absorption of iodine in an apparently simple goitre. With cessation of painting, rest in bed, liberal diet, and a course of iron, strength and weight were gradually regained. In four months he returned to work weighing 13½ st., and in all respects quite well.

Eight months later he complained of being worried by the consciousness of a missing beat in his pulse. On examination the pulse was 44, feeble, of low tension, and missing a beat at irregular intervals. He remained in bed fourteen days without any improvement. I considered the condition to be one of thyroid exhaustion, but, in view of his previous hyperthyroidism, was afraid of attempting stimulation of the gland by iodine, or of giving thyroid extract. It was decided to try potassium iodide. This was given in 3 grain doses thrice daily. In ten days his appetite had gone, he was losing weight rapidly and his pulse was 125. Rest in bed and an iodine-free diet was ordered, and improvement again set in.

In commenting on the case, Dr. CORNISH said that its most interesting feature was the relation of the symptoms of hyperthyroidism to the administration of iodine. The richness of the thyroid in iodine was well known, and it was impossible altogether to escape from the suspicion that treatment with thyroid preparation may after all only be a mode of treatment with organically combined iodine in an easily assimilable form.

OPHTHALMOLOGY.

At a meeting of the Section of Ophthalmology of the Royal Society of Medicine on November 3rd, Mr. PRIESTLEY SMITH, the President, in the chair, Dr. C. W. DANIELS contributed a paper on *Eye lesions as a point of importance in directing suspicion to possible trypanosome infection*. The common manifestation was an iridocyclitis, while a pronounced oedema of the lower lids was not rare. Choroiditis was less frequent. The incidence of the eye lesions stood in direct relationship with the severity of the infection. Thus, in Rhodesian trypanosomiasis the eyes were affected in 83.3 per cent., in Nigerian cases in 40 per cent., and in cases from Uganda and other parts of tropical Africa in 18.7 per cent. The mortality from the disease in those three regions was respectively 100 per cent., 30 per cent., and 18 per cent. Mr. A. HUGH THOMPSON read a paper on *Late results of the operative treatment of high myopia*. Five years ago he had published notes based on his experience of twenty myopic eyes, the clear lenses of which he had needed with the object of making the refraction approximately emmetropic. The degree most suitable for operation was 16 to 22 dioptres. In young children whose myopia was certainly progressive a limit of 14 D. might well be assigned. With a myopia of more than 22 D. the chance of the eye remaining free from destructive processes was small. He had been able to follow up fourteen cases during periods of five to fifteen years. Only one patient was operated upon in both eyes, and he did not think the advantage justified the double operation. In all the fifteen eyes the result of the operation was good, and the subsequent results he tabulated in detail. Two-thirds of the cases, after an average period of eight years, had materially better vision than before the operation. In not one of them had he to deal with a detachment of the retina as a sequela of the operation. He did not think the operative treatment of high myopia tended to counteract the increase in the long axis of the eyeball, though obviously the removal of the lens had the effect of diminishing the result of the lengthening of the axis of the eyeball on the refraction by about one-half.

SKIN GRAFTING IN MASTOID OPERATIONS.

At the meeting of the Section of Otology of the Royal Society of Medicine on November 19th Mr. H. J. MARRIAGE opened a discussion on skin grafting in mastoid operations. The method mostly worked out by Mr. Charles Ballance (1900) was applicable chiefly to chronic mastoid disease. It resulted in a better healing of the cavity, a shorter convalescence, and prevention of stenosis. The graft took well in 99 per cent. of the cases. All cavities in the bone must be closed, so that no septic pockets remained. The graft must be very thin. A disadvantage was that cerumen and epithelium were liable to accumulate and cause ulceration of the skin, but such collections could easily be removed. He gave particular attention to the posterior meatal wall, removing as far as possible any exposed portion of cartilage, as that seemed responsible for delay in healing when such occurred. Of 39 cases, 29 had improved hearing after the operation, in 8 the hearing was worse than before, while in 2 it was unaltered.

Reviews.

DISEASES OF THE SKIN.

IN the preface to *Occupational Affections of the Skin*¹ Dr. PROSSER WHITE modestly claims to have arranged a useful compilation for the ready use of the English inquirer. The work of compilation has been done well, but the author has also added much valuable information drawn from his own experience. It is now many years since Dr. Prosser White's name became associated with trade diseases. His report on the harmfulness to health arising in the manufacture of nitrons explosives was one of the first of the reports of the Departmental Committee which has done so much to improve industrial legislation in this country. His colleague on that occasion was Sir Hamilton Freer-Smith, then one of H.M. Inspectors of Factories. When it is said that about one-fourth of the cases of eczema which receive hospital treatment are due to occupation, the estimate is certainly not placed too high. Of 1,800 operatives examined by Oppenheim, 400 were found to be suffering from skin diseases due to their employment. Recent advances in industrial chemistry and new processes of manufacture of commercial products, especially those obtained from tar, have increased the number of cases of eczema due to occupation. Dr. Prosser White reminds us that the existence and intensity of trade dermatitis depend upon three factors: (1) The potency of the irritant, (2) the resisting qualities, and (3) the reactive capacity of the skin. The chapter on the resistance of the skin is well written. Attention is directed to the differing resisting qualities of the various layers of the skin. The skin is more profoundly affected by alkalis than by acids. Equally interesting are the author's remarks on idiosyncrasy. Heredity, constitutional and dermal conditions play an important part in the determination of skin eruptions. It is astonishing how, even among the members of one family, one individual is found, for example, to be harmfully influenced by handling certain plants while the brothers and sisters escape. The part played by mechanical pressure and friction in causing the skin to become hardened, also the formation of bursae in the case of miners and labourers, is indicated, as well as the influence of streptococcal infection in the development of certain acute rashes, as in intertrigo. The effects upon the skin of exposure to cold and heat, to x rays, and solar rays are fully dealt with, as well as the burns caused by acids and the destruction of the skin by alkalis; in fact, few trade influences are omitted. The winding of raw silk from cocoons is the occasional cause of a vesico-pustular eruption on the hands and forearms of the workpeople. Such a condition of the skin was seen by the reviewer in a large silk works near Milan. There are some well-known chemical compounds of chrome and arsenical derivation which cause ulceration of the nasal mucous membrane and perforation of the septum of the workpeople who

inhale the dust, the remarkable fact in such people being the absence of symptoms and the comparative harmlessness of the lesion. The dust of arsenical compounds is a frequent source of ulceration of the hands and genitalia of workmen employed in colour mixing. It would hardly be thought that in the occupation of a plasterer there would be anything to cause trouble, and yet during the making of Roman cement, owing to the splashing of slaked lime, the skin may suffer. The new method of preparing leather by the use of chrome compounds is also responsible for a certain amount of occupational skin trouble. Many of us are familiar with the acro and pustular eruptions caused by tar and pitch compounds, as well as with the peculiar warts caused by coal distillates, the termination of which is occasionally cancer. Very appropriately, in dealing with this subject the excellent work done by Ross and Cropper is alluded to. Aniline dyes and dyeing play a useful part in the industrial life of to-day. It has been found that in Eastle cancer is more prevalent among the aniline workmen than among men engaged in other occupations in the town. The book closes with an account of the eruptions caused through the penetration of the skin by larvae, such as occurs in ankylostomiasis. The author is to be congratulated on having supplied an interesting and a helpful book—one which ought to be in the hands of all medical men whose practice brings them into contact with diseases of occupation.

The second edition of Dr. SEQUEIRA'S textbook on *Diseases of the Skin*²—though the moment of its publication may seem inopportune, for dermatology is essentially a peaceful specialty—deserves more than mere passing notice. As is commonly the case with second editions, the present volume is considerably larger than the former. Reduced to cold statistics, the growth of the book may be summarized in the addition of 110 pages of text, four new coloured plates, and sixty new half-tone illustrations. The author has kept well up to date with modern advances in dermatology, which may be traced in the additions made; for example, Sambon's work on the etiology of pellagra is adequately noticed, and several additional diseases due to animal parasites, grain-itch, copra-itch, and ankylostomiasis have been included. There is also a special chapter on exotic spirochaetal diseases. Dr. Sequeira has made full use of the great opportunities at his disposal at the London Hospital, and with a few exceptions all the illustrations are drawn from the cases which he has seen at his own clinic. This is a book of some 600 large pages, in the whole extent of which there is hardly a redundant word, and the consequence is that it is a richly stored mine of information upon all the problems of dermatology; the practitioner will find therein the *pros* and *cons* of almost any question which may present itself to him. An omission which we would like to see remedied is the record of Dr. Sequeira's own individual opinion upon some of these questions; for example, the rival theories on the etiology of pellagra are both quite fairly stated, but without any judicial pronouncement in favour of any one of them. Similarly, the fiercely debated subject of the fatalities following the administration of salvarsan is summed up accurately enough, but judgement is still apparently reserved. It would add to the attractiveness of the volume if this reticence were to some extent discarded. There is one point on which we would disagree with Dr. Sequeira—that is, the effects of x rays on the skin. He states that the hair falls fourteen days after the exposure, and that when attended by erythema epilation is permanent. Most workers who have treated many cases of ringworm can recall instances in which the hair has fallen even so soon as eleven days after the exposure and in which there was some erythema but in which the regrowth of hair has been satisfactory. That, however, is probably about the limit, and a dose so powerful is not to be recommended. On the other hand, in the treatment of lichen simplex chronicus pastille doses at intervals of a fortnight are recommended. Are not telangiectases, with atrophy of the skin, likely to follow such a vigorous bombardment? This edition is more strongly bound than the first, and there are not nearly so many misprints.

¹ *Occupational Affections of the Skin: A Brief Account of the Trade Processes and Agents which give rise to them.* By R. Prosser White, M.D. Edin., M.R.C.S. Lond. London: H. K. Lewis, 1915. (Demy 8vo, pp. 175; 5 plates, 7s. 6d. net.)

² *Diseases of the Skin.* By J. H. Sequeira, M.D. Lond., F.R.C.P. Lond., F.R.C.S. Eng. Second edition. London: J. and A. Churchill, 1915. (Roy. 8vo, pp. 661; 48 plates, 238 figures, 25s. net.)

PHARMACOLOGY AND THERAPEUTICS.

The sixth edition of Professor CUSHBY'S well known *Textbook of Pharmacology and Therapeutics*³ has been thoroughly revised and brought up to date, and deserves all the encomiums that have been earned by its previous editions. After a brief general introduction to the action of drugs, the book is divided into four parts. In the first of these Professor Cusby describes the chief drugs characterized by their local action on the tissues, including such substances as bitters, ferments, irritants, purgatives, and antiseptics of all sorts. Part II, in fifty-six sections, forms the bulk of the book, and contains accounts of the substances characterized chiefly by their action after absorption. Part III consists of an account of the pharmaceutical use of the heavy metals among which a chemist will be surprised to find aluminium reckoned. Part IV deals chiefly with cod-liver oil. Professor Cusby writes very clearly, generally preferring to summarize the results of observation and experiment rather than to detail them. His book is packed with information serviceable to the medical student and the practitioner; the information is conveyed in less didactic style and less tabulated form than is the case in Professor DIXON'S shorter volume noted below, its rival as an exposition of the aims and tendencies of modern pharmacology. It may be noted that neither of these authorities makes any use of the outstanding principle of drug action advocated by the late Professor Ehrlich in his fundamental tenet, *Corpora non agunt nisi fixata*; both, indeed, expressly condemn it. Professor Cusby sees no objection to the use of morphine and opium in Bright's disease (p. 254), and is inclined to attribute sudden death early in chloroform anaesthesia to the onset of ventricular fibrillation (p. 204) rather than to vagal inhibition of the heart. A few misprints may be noted; the pyrrol ring of nicotine is not "hydrated" (p. 304), but "reduced" or "hydrogenated"; "cephalic" and "cephaline" (p. 437), words of four syllables, should not be spelt with a diphthong; "phlorizin" should not be spelt "phloridzin" (p. 504), although this error has obtained a very firm footing in British medical literature. These, however, are but trifling defects in a textbook of proved excellence.

The fourth edition of Professor DIXON'S invaluable *Manual of Pharmacology*⁴ has appeared within ten years of the issue of its first edition. The study of drugs has made so much progress during the last three or four years that the author has found it necessary to rewrite large sections of the book. This is notably the case with the chapters on such important drugs as digitalis, strychnine, and morphine. In addition, the production of the new *British Pharmacopoeia* has necessitated much revision of the pages given to materia medica; as Professor Dixon feelingly remarks, "the dual system of dosage now introduced must be for a time tiresome to us all."⁵ The thirty-two chapters of the text give clear and brief accounts of the most important drugs employed in medicine, with insistence chiefly on the physiology of their actions. The illustrations are drawn mainly from tracings of blood pressures, muscle contractions, the actions of the heart or respiratory muscles made in the pharmacological laboratory. The actions of each drug are clearly and tersely summarized under headings in a way that is most attractive to the student. The chemical aspects of the subject are treated briefly; the author appears to have no sympathy with speculations as to the connexion between chemical constitution and pharmacological action with which the pages of such a book as Fraenkel's *Arzneimittelsynthese* are filled. In his account of the organic compounds of arsenic Professor Dixon stops short with the mention of "606," and does not refer to neo-salvarsan ("914"), introduced in 1912, or to the sodium-salvarsan ("1206 A") of a year later. The book is to be commended warmly to medical students who have examinations to pass and practical pharmacological work to do.

The tenth edition of Dr. MITCHELL BRUCE'S well-known little handbook on *Materia Medica and Therapeutics*⁶ has recently appeared, thirty-one years after the first was issued. The new issue of the *British Pharmacopoeia*, introducing a number of new drugs, omitting others, and making important changes in the composition, strength, and name of many preparations, has made it necessary to submit the manual to thorough revision. In addition the employment of the metric system has been extended, and that of the Imperial system of measurement entailed with a view to its total abolition in the course of time. An entirely new section on practical pharmacy has been introduced: many additions have been made to official and non-official synthetic drugs, and the use of vaccines, serums, iontophoresis and the actions and uses of radium are described. Dr. Mitchell Bruce's book, as everybody who has used it knows, is particularly strong on the therapeutic side, and gives an admirable introduction to the rational use of drugs in the treatment of disease such as few living therapeutists could write. The book may be warmly recommended to medical students and practitioners who wish to know how to prescribe the drugs they use with the greatest advantage.

*Potter's Cyclopaedia of Botanical Drugs and Preparations*⁷ now in its second edition, gives a botanist's account of the chief vegetable remedies employed at the present time. It is written, in the first place, for the benefit of those who handle herbs and drugs in either small or large degree; in the second place, it gives a brief but optimistic summary of the medicinal virtues of the plants described. The distinctive characters of the medicinal parts of each herb are given clearly and in brief by Mr. E. M. HOLMES, affording means for the identification of the crude drugs. The book strikes one in many ways as a labour of love, compact of accurate botanical lore, and so far valuable. How far it is a trustworthy medical guide to the student or practitioner is, perhaps, less certain. Thus we find it stated that an infusion of the bark of the slippery elm "makes a very wholesome and sustaining food for infants," while the coarsely powdered bark is said to form "the finest poultice to be obtained for all inflamed surfaces, ulcers, wounds, burns, boils, skin diseases, purulent ophthalmia, chilblains, etc.," as though Lister had lived in vain.

NOTES ON BOOKS.

SEVERAL books have been written upon medical missions since the time when Dr. Livingstone so arrestingly demonstrated some of the wonderful possibilities of the high calling of healing and preaching; but Dr. HODGKIN'S recent work⁸ stands out apart from almost all of them by reason of a fine elevation of thought and diction, combined with an intimate and practical acquaintance with the difficulties of medical mission work. On the one hand, there is his suggestion that for the adventurous spirits of the future the medical missionary's life may supply that moral equivalent for war which is so sorely needed if the world is ever to turn to the paths of peace; and on the other, is his argument in favour of the provision of a native faculty of medicine for China and his consideration of the efforts which are being made to translate medical textbooks into the language of the country and to provide an Anglo-Chinese medical lexicon. Dr. Hodgkin's book deserves to be read thoughtfully by all who are interested in world-wide medicine, whether they agree with him or no in regard to the missionary aspect of the work.

British Medical Journal.

SATURDAY, NOVEMBER 27TH, 1915.

LORD DERBY'S SCHEME AND MEDICAL RECRUITING.

THE Local Government Board, on November 22nd, issued notes and instructions with regard to the formation of local tribunals under Lord Derby's scheme for recruiting. It is now possible for a man either to enlist at once or to join the Army Reserve (Section B) and be placed in a group according to his age, and according to whether he is or is not a married man. Having been attested and placed in his group in the Reserve, he may then return to his civil occupation until his group is called up for service. There are 46 groups—23 for single men (each year of age constitutes a separate group), and 23 similar groups for married men; the first group consists of single men aged 18, the forty-sixth group of married men aged 40. It is proposed to call the men up in the numerical order of the groups, except that men of 18 years will not be called up for service until they have attained the age of 19.

The local tribunals which will be or have been formed by the town and district councils in every area will have the duty of receiving and deciding applications from attested men or their employers, who, for various reasons, wish to have the time at which the men are to be called up for military service deferred. If the recruiting officer, or the local tribunal, is satisfied of the validity of the reasons given, a man may be put back into a later group, provided that the number of groups he is put back on any one claim be not more than ten. When an attested man, or his employer (provided the man is willing to continue in his employment), desires to apply for later grouping, either because the man is indispensable in the industry, or to his employer's business, or because of difficulty in his being released from civil obligations, notice must be sent to the clerk of the local tribunal. If a man is engaged in occupations of importance from the point of view of munition work and is "starred," the case will be referred to the Ministry of Munitions; in the case of men engaged in coal-mining the case will be referred to the Home Office. With regard to men in some branches of railway work and agriculture, and also in what are called "reserved occupations," a long list of which has been drawn up, the local tribunal will investigate the case and report to the Central Appeal Tribunal for decision. Most of the cases mentioned above are those of starred men already provisionally exempted from actual service; but in each case it may be decided later on that it is no longer necessary to retain the man in civil employment.

With regard to the unstarred man, if an application is made to the tribunal, and if the recruiting officer assents to the application, the tribunal notifies the employer that the man has been placed in a later

group. If the military representative does not assent, the local tribunal proceeds to hear and decide the claim. There will be a right of appeal from the decision of the local tribunal to the Central Appeal Tribunal, which consists of Lord Sydenham (chairman) and four other Commissioners. Every man who is attested, in whatever class he may come, will receive an armlet.

With the issue of these instructions on the subject of local tribunals, the decision of Lord Derby to hand over the whole of the recruiting of officers for the R.A.M.C. to the Central Medical War Committee in England and Wales, the Scottish War Emergency Committee, and the Irish Medical War Committee renders it necessary for these committees to undertake at once work of great magnitude and importance. From the outset the policy of the committees has been that every man of military age who is physically fit should either take a commission at once, if circumstances make it easy for him to go, or should enrol himself as willing to do so whenever the Committee tells him that duty requires him to serve. This policy is the basis of Lord Derby's scheme.

Accepting the promise that it is the duty of every fit man of military age to take a commission and serve his country whenever the need arises, and after pressing for the completion of the quota required from each area for immediate service, it becomes necessary to group those who remain in classes according to the ease or difficulty with which they can be set free to join the army. It has been found possible to group medical men under twelve classes, with special arrangements for consultants and specialists. The classification is based on:

- (1) The amount of disturbance in the medical service of the community caused by the removal of practitioners from an area;
- (2) The security of the practices or appointments held by practitioners;
- (3) The question whether a practitioner is married or single.

After the men have been arranged in groups the next duty of each committee will be to find out which men can be spared from each group. Already valuable information on this point has been obtained through the new method of assessing the quota required from each district, and valuable assistance has been given by the Insurance Commissioners. But the ultimate responsibility for assisting the committee in this matter will rest with the local medical war committees.

A matter pertinent to the question of recruiting is the case of medical students in various years of their study. It has recently been announced by the medical authorities of the War Department that "students who at or before the close of the present winter session will be qualified for entry to one of the examinations for the third year students in medicine, and duly enter for the examination for which they are studying, will not be attested until after its conclusion, and if they are successful will be included in the class of fourth year men under Lord Derby's scheme." This decision will go a certain way towards satisfying those critics in the medical profession who had become concerned about the possible shortage of doctors in the future, though it still leaves the younger student, not yet within sight of his intermediate or second professional examination, open to the blandishments of the recruiting sergeant. However, the fact that men in Group I under Lord Derby's scheme will not be called up until they are 19 years of age, may have some effect in reducing the numbers of those who will be taken from their medical studies to serve in combatant capacity.

THE AGE OF RECRUITS.

THE "clastic" age of the recruit is somewhat of a stock joke in the comic papers, but the matter has its serious side, and an attempt is being made to fasten on the medical profession that which does not belong to it.

The attitude of the War Office was defined by Mr. Tennant on November 2nd. After stating that the minimum age at which men are authorized to be taken for service with the colours is at present 19, and that no man is accepted for direct enlistment unless he gives his age on attestation as 19 or over, he said "strict orders have been given to all recruiting officers that unless a recruit evidently has the physique equivalent to his declared age he is not to be enlisted without an examination of his birth certificate. If a recruit enlists who has declared his age to be over 19, but who is actually below that age, the War Office do not consider that to be sufficient cause in itself for discharging him from the army. Under existing arrangements a soldier who is actually below 19 may be sent abroad provided his physique is considered by the medical authorities to be that of a man of 18½. If his physique is below that of a man of 18½ he is retained for training and service at home until he reaches the required standard. In practice, however, the War Office always allow a lad who is under 17 to be discharged provided application is made to his commanding officer whilst he is serving at home. In the case of all soldiers serving overseas the question of discharge or return to this country rests with the Commander-in-Chief, who retains only those who are considered fit for service abroad."

In reply to suggestions that recruiting sergeants should be instructed not to take any boys unless they produced their registration cards, Mr. Tennant said that such a system would take up a very considerable amount of time, and added that he was only aware of two or three cases in which boys as young as 16 had been recruited.

The Honorary Secretary of "National Service" has sent us letters on the subject and a cutting from the press, in which a point which concerns the medical profession is raised. The assertion made is that the whole responsibility for the correct attestation of the age of the recruit rests with the medical officer who examined the recruit, or, in the case of enlisted soldier, with the medical officer of the battalion. He further maintains that the one and only proof that the medical officer should rely upon is the certificate of birth of the recruit. The article he encloses contains the following sentence: "The birth certificate is the best possible preliminary test of a man's fitness to stand the strain of modern war." Put in this blunt and unqualified fashion, the statement cannot be accepted.

In the first place, it must be pointed out that, as Mr. Tennant's statement might have sufficed to show, the doctor is not responsible for the correct attestation of the age of the recruit. The certificate of birth is a document which states that at a certain place and on a certain date a child was born to certain parents, who registered him under a certain name. The certificate may or may not pertain to the bearer of that form. The validity of the application of the document is wholly a legal matter. But the main point is that there is no age at which fitness can be guaranteed. The statement that a recruit is of a certain age does not in any way carry with it a certain indication of growth up to a certain state of physique, and, contrariwise, the known fact that a

given subject has not attained to some marked age does not imply that this subject has not reached a standard of growth and maturity that renders him fit for the most strenuous form of manly service.

The age of 19, as the minimum age for recruits in this country, has been fixed by a process of averaging. It is found on an average that lads of this age are of a certain standard of physical fitness and capable of enduring hard work and severe strain without physical deterioration. Since it is based on an average there are, of course, many above and below this age worse or better than the average.

In the work of selecting recruits the first point that has to be in the mind of the examining medical officer is the likelihood of the man being physically fit for the service which he proposes to undertake. This is made clear by the very form of the attestation paper. Army Form E. 501 is the one in use for recruiting the Territorial Force. On the first page there is a space for questions to be put to the recruit before enlistment—these are purely relating to status; pages 2 and 3 are ruled for data on the training of the recruit and his military history; page 4 is headed "Medical Inspection Report." It is divided into four parts. Of these four spaces the first and the last are the only ones that are pertinent to this matter. In the first space there is a line for entry of name, then one for the entry of the "apparent age," followed by lines for the entry of certain data on height, chest measurement, vision, and physical development. The qualification of the age entry is worthy of note. If it be intended that this space should be filled in by the doctor it is clear that he is there to state the apparent age of the recruit as judged by the only known medical criterion—the judgement of the growth of the recruit. This point would be stronger were it not for a lack of clarity in the military mind, for the "apparent age" of the recruit has to be entered in "years.....months." A medical man of experience may be a fair judge of age in years, but he would be a bold man who would back his opinion on a matter of months. From inquiries at a well-known and central London recruiting station we learn that the age is filled in by the recruit himself, or at his dictation by the military clerks, and that the form so filled in is handed with the recruit to the doctor.

The last major space on this fourth sheet for the medical inspection report is headed "Certificate of Approving Officer." In this the officer certifies "that this attestation of the above-named recruit is correct and properly filled up, and that the required forms appear to have been complied with." There is a note which states that the signature has to be affixed in the presence of the recruit, hence it would seem that this approving officer would be the responsible party in the eyes of the War Office for the declaration of age.

The conclusion is that the medical man who examines recruits has but one duty, that is to discover and certify the fitness or otherwise of the recruit. He is not appointed an amateur detective to question the good faith of the recruit in the statement of his age. He takes that statement for what it is worth. His certificate of fitness is not based upon it, but upon the maturity of flesh and blood before him. To attempt to saddle the doctor with the business of examining birth certificates, which, as has been said, are of doubtful validity in an unsupported state, is ridiculous, and the assertion that such a certificate can establish the fitness or otherwise of a recruit shows a lamentable lack of knowledge on the part of those who put it forward.

SANATORIUM BENEFIT FUNDS.

THE replies in Parliament by Mr. C. Roberts on behalf of the Insurance Commissioners to questions with respect to sanatorium benefit funds are of great importance to panel practitioners. There can be little doubt that a number of Insurance Committees are now engineering attempts to deprive panel practitioners of 6d. out of the 7s. capitation fee. The Ayr County Insurance Committee has passed a resolution to the effect that the 6d. allocated for domiciliary treatment of persons recommended for sanatorium benefit should be discontinued, as it is an unnecessary drain on the sanatorium benefit fund, and that steps should be taken to have the remuneration of practitioners made dependent upon actual attendance and treatment given. This resolution has been sent round to most if not all the Insurance Committees throughout the country with a request that they should pass a similar resolution, which may then be presented to the Government and the Commissioners. It is gratifying to find that many committees have refused to be thus led. In the explanatory letter sent by the Ayr Committee some calculations are made which show a complete ignorance of the true condition of affairs. The calculation takes something like this form in the case of both the Ayr, the Renfrew, and the Kilmarnock Committees: Suppose the 6d. in an area produces £1,000 in a year, and that only ten persons receive domiciliary treatment for tuberculosis, then it is said that the doctors get £100 for each case of tuberculosis treated at home. The specious fallacy of this will undoubtedly captivate many committees and even apparently some members of Parliament, but it is satisfactory to find, as will be seen from our parliamentary report on page 201 of this week's SUPPLEMENT, that Mr. Roberts on behalf of the Commissioners entirely refuses to accept the validity of such calculations. In the first place he quite rightly points out, to quote from the official report, that "the arrangements in respect of the domiciliary treatment of tuberculosis form part of the general terms of remuneration of medical practitioners under the Act." Many committees have considerably over-spent their sanatorium benefit fund, and under Section 17 (2) (3) of the 1911 Act, by the consent of the Treasury and the county council half the deficit will be paid by each of these bodies. This consent must in all cases have been obtained beforehand, and this forms a very salutary restraint on the extravagance of Insurance Committees, which in most cases are only amateurs in dealing with the vast problems of tuberculosis. Accordingly Mr. Roberts also points out that the 6d. specifically allocated to the panel doctors in respect of their responsibility for domiciliary treatment cannot be diverted to meet other expenditure by the committees on tuberculosis. All who are acquainted with the facts know that a very large proportion of insured persons suffering from tuberculosis in its various forms never apply for sanatorium benefit at all, and yet they receive treatment from the panel doctors; and even if they do apply, it is in nearly all cases only after a more or less prolonged course of treatment, and they receive exactly the same treatment so long as they remain at home, though nominally they may not be receiving sanatorium benefit. This being so, it is only right that the sanatorium benefit funds should contribute towards the cost of such treatment. This is attained by the present method, under which, for practical purposes, the 6d. forms part of the general panel fund. The Insurance Committees of Ayr, Renfrew, and Kilmarnock entirely ignore all these facts, and probably it is on this account that Mr. Roberts quite rightly refuses to accept the validity of their calculations. His reply in Parliament is further indirectly supported in the circular of the Commissioners dealing with the commercial tariff, which recognizes in several places that the panel practitioners have a just right to demand that the 7s. capitation fee, which includes the 6d. for domiciliary treatment, shall not be lessened, as would be the case if the contention of the Insurance Committees were granted.

Nevertheless, it is quite evident that the profession will have to present a united front against the attempts to encroach on its remuneration which is now being made by a number of Insurance Committees and indirectly suggested by questions in the House of Commons.

THE ETHNOLOGY OF THE PRUSSIANS.

PROFESSOR J. COSSAR EWART took for the subject of his presidential address to the Scottish Natural History Society on November 4th the question, "Who are the Prussians?" It was, he said, generally assumed that the Germans were Teutonic, or, in other words, that they belonged to a dolichocephalic race of Aryan origin; but De Quatrefages, who made a special investigation of the origin of the Prussians about forty years ago, came to the conclusion that they were not Germans at all, but were related to the Finns and other primitive races of Western Russia, who ruled by the sword alone. Further, an American anthropologist had stated that, whilst North-Western Germany was distinctly allied to the Swedes, Norwegians, and Danes, the remainder, not excluding Prussia east of the Elbe, was less Teutonic in type, Baden, Wurtemberg, and Bavaria being distinctly brachycephalic; the same authority had affirmed that while Northern Germany had a little more Teutonic blood than Northern France, South Germany was not racially distinct from Central France. Professor Ewart referred to the typical and other characters of the Teutonic and Alpine races, pointing out that the Teutons were reserved and independent, and more interested in military and political than in purely intellectual affairs, and that members of the brachycephalic Alpine race were generally characterized by patience and passivity, making them submit easily to autocrats and despots. In origin, the Teutons might be a blend of the dolichocephalic Cro-Magnon and Chancelade races which flourished in Europe at the end of the Ice Age; from such a blend the tall, smooth, oval-faced Teutons might easily come. Finally, Professor Cossar Ewart stated that although German writers had consistently maintained the existence of a radical difference of origin between themselves and the Slavs, yet a comprehensive census of stature and head-form would almost certainly show that though a dolichocephalic race dominated Germany, a round-headed race intimately related to the Slavs formed the bulk of the population.

BOVINE TUBERCULOSIS IN MAN.

THE assertion put forward to an astonished congress in 1901 by the late Professor Koch, that man was practically never infected by bovine tuberculosis, has long since been shown to be erroneous. The actual extent to which the human subject is susceptible to the bovine infection is not so easily demonstrated. Drs. Stenhouse Williams and E. H. R. Harris, a research bacteriologist and a tuberculosis physician respectively, have lately republished an interesting inquiry into the question, with additions, in which the most recent investigations have been taken into account. A vast amount of information has accumulated during the last fourteen years, more especially with regard to the forms of tuberculosis affecting other parts than the lungs. For purposes of analysis the evidence has been examined in two groups—experimental and statistical. It has been proved experimentally that the general tuberculosis which can be produced by inoculation in certain young animals presents the same clinical features and the same pathological lesions whether the infecting material be obtained from a human or an animal source. Statistically it has been proved that tuberculous affections of the alimentary canal and its associated glands, especially the tonsils and the mesenteric

¹ *Bovine Tuberculosis in Man*, by R. Stenhouse Williams, M.D., B.Sc., D.P.H., Research Bacteriologist in Dairying, University College, Reading, and E. H. R. Harris, M.D., B.Sc., D.P.H., Tuberculosis Physician, King Edward VII. Welsh National Memorial Association, University Press, Cambridge, 1915. (pp. 13)

glands, are most prevalent in early life and notably so during the years in which milk forms a large part of the diet. Comparing the death-rate from the pulmonary with the general forms of the disease, it appears evident that there has been steady diminution in both during the past seven years, but that the decrease has been most marked in tuberculosis of the lungs. Examination of the figures recorded in Manchester, under the supervision of Professor Delépine, where the milk supply has been subject to careful control, goes to prove that the percentage of tubercle bacilli present in samples of mixed milk has been reduced in ten years from 17.2 to 5.14. A marked reduction in the death-rate has been effected during the period in which control has been exercised, but it is probable that the bovine type of bacillus continues to be responsible for a large number of deaths from general tuberculosis. The need for continuous and increased effort to preserve the rising generation from this danger has been terribly emphasized by the wastage of young adult life during the past fifteen months.

OBSCURE EPIDEMIC FEVER.

In September, 1914, Quincke and Knoblach¹ observed a small epidemic in a hospital in Frankfurt, where, on two successive evenings, ten patients suddenly developed almost exactly similar symptoms. They complained of pain on respiration in the region of the right costal arch, whence the pain radiated to one or other shoulder, usually the left. The patients were exhausted and febrile; the temperature rose suddenly, and usually reached 39° C. The pain in the lower ribs hampered the respiratory movements, and usually lasted from five to six days, becoming less and less acute in this period. The pain in the shoulders usually began simultaneously with the pain in the chest. In no case were any physical signs found to account for these symptoms, and there was no evidence of food poisoning or a "chill." The authors suggest that the symptoms may have been due to the stings of insects in the liver region, but in no case was any sign of such stings found. They do not, however, seem to attach much importance to this negative evidence, and, assuming that their hypothesis is correct, they point out that the poison from the stings might have reached the liver, where it might have provoked small inflammatory foci in the serosa of the liver. The adjacent parietal peritoneum would accordingly have become involved, as well as the neighbouring intercostal muscles. Such acute epidemics of fever ending rapidly in recovery are exceedingly common. In many cases they represent abortive forms of pneumonia, paratyphus, and scarlatina. In other cases their cause is obscure, and though this group of symptoms is frequently referred to in the textbooks, ignorance of its true cause is betrayed by the multiplicity of titles given to it.

PATHOMETRY.

At the meeting of the Royal Society on November 11th Sir Ronald Ross, F.R.S., read an introductory paper indicating the method he proposed to follow in studying the nature of the functions according to which the number of individuals infected with some disease should vary from time to time, on the supposition that the laws governing the rate of transference of the considered disease were already known *a priori*. He stated the fundamental problem under consideration in the following terms: "If a population is divided into two groups, namely, those who are affected by some kind of happening, such as an infectious disease, and those who are not so affected; and if in unit of time a constant or variable proportion of the non-affected become affected, while simultaneously a constant proportion of the affected become non-affected (that is, revert or recover); and if at the same time both the affected and the non-affected are subject to different birth-

rates, death-rates, and rates of immigration and of emigration, so that the whole population may be incessantly varying during the period under consideration; then what will be the number of affected individuals and also the number of new cases at any moment during that period?" In this first paper the problem was presented in mathematical language, with its solution, and a broad analysis of the curves obtained and of some integrals. Only constant rates of happening (applicable to other happenings besides disease), and rates which varied according to the number of individuals already affected (specially applicable to infectious diseases) were considered. In the latter cases the resulting curves were frequently bell-shaped, declining a little more slowly than they rose—that is, generally similar to the curves frequently seen in epidemics—thus suggesting *prima facie* that epidemics might be largely explicable in the terms of the thesis given.

A METHOD OF EXAMINING TUBERCULOUS SERUM.

An interesting account is given by Hekman¹ of some experiments he has made in the investigation of tuberculous serum by a new method, which has given him results as yet inchoate but perhaps promising. It is similar to one already used by Aberhalden, and depends upon the action of serum upon stained fibrin. If fresh fibrin, which has been stained (the found eosin best, but also used methylene blue) and subsequently thoroughly washed free of all removable dye, be added to human serum, it undergoes an alteration which Hekman assumes to be of a digestive character, and in the course of which the stain is liberated into the surrounding medium. This happens with all human serums, the serum of different individuals varying greatly in this respect, and there seems to be no reason to associate great activity or inactivity with any particular disease. Moreover, it is not only upon fibrin that such action is exerted; coagulated egg albumen, lung or kidney tissue may also be used, though less satisfactorily. There seemed some reason to believe that the serum of chronic nephritis acted much more strongly than other serums upon kidney tissue. The addition of a second unstained protein—for example, egg white—to such a serum-fibrin mixture reduces the activity of the serum to a marked extent, taking to itself apparently some of the active ingredients of the serum, and tuberculin also has a markedly reducing power. The interesting observation, however, is that tuberculin has much less reducing power when the serum in the mixture is derived from tuberculous patients than when it is derived from other sources. This failure of the tuberculin action is accentuated if the serum and tuberculin are left in contact for some time before the fibrin is added. Hekman, who does not appear to have tried whether other proteins behave like tuberculin in this regard, conjectures that the tuberculous serum digests the tuberculin protein so rapidly that it is largely removed from competition with the fibrin, and therefore it may be possible to estimate the tuberculin-lytic power of a tuberculous serum by means of this method. Clinically he has cases even in which the reducing power of the tuberculin rose as the patient improved, and cases where it fell as the disease advanced. There are obvious technical difficulties in such a method, and the variability of normal serum is a source of errors, but Hekman is aware of the difficulties, and is guarded in his estimate of the applicability, and it will be interesting to see whether further development will be possible.

INSURANCE AGAINST THE COST OF ILLNESS.

From time to time we have commented on the additional strain thrown upon members of the medical profession at home owing to the conditions brought about by the war. It has always been prudent to make provision against sickness or accident, with the attendant diminution of

¹ *Beri. klin. Woch.*, August 23rd, 1915.

¹ *Nederlandsch Tijdschr. voor Geneeskund.* 1915, p. 218.

income and increase in expenditure. It is more than ever important to do so to-day, when the ranks of the medical profession are depleted so that it is difficult to get help from neighbours, and when the increased pressure on time and energies renders a breakdown perhaps more probable. As to the increased cost at the present time it is necessary only to remember the increased fees which are now commanded by locumtenents; the prudence, therefore, of ensuring adequate financial assistance when laid aside by sickness is obvious. The Medical Sickness and Accident Society offers an attractive policy designed to meet this necessity; full particulars may be had from the secretary, Mr. Bertram Sutton, 300, High Holborn, W.C.

Medical Notes in Parliament.

War.

Army Medical Services (Advisory Board).—On November 22nd Mr. Shirley Benn asked how many members constituted the Advisory Board of the Army Medical Services; what salaries were paid; and how many meetings had been held in 1913, in 1914, and in 1915. Mr. Tennant replied as follows: There are eleven members, seven military and four civilian. The civilian members are paid £200 a year each for their services on the Board. Two military members receive extra pay of £150 a year; five receive nothing for this duty. The number of meetings of the Board was in 1913 ten, in 1914 seven. No formal meetings have been held in 1915, but all the paid members have been constantly consulted and have given very valuable advice throughout the war.

Invalids from the Dardanelles.—In reply to Sir C. Kinloch-Cooke, Mr. Tennant said that a considerable number of officers and men were being sent home from the Dardanelles suffering from dysentery and enteric fever, and that careful attention would be given in each individual case to the question of the advisability of sending men back to the Dardanelles who had suffered from these diseases and as to whether they might not be employed in some other theatre of the war with less risk of a relapse due to want of suitable food. He was making inquiries as to the rations issued to these invalids on the homeward voyage.

Men Unfit for Service.—In reply to Mr. Morrell, Mr. Tennant said that a soldier who was unfit for active service abroad was not necessarily discharged. If he were fit for garrison duty abroad or for home service he was retained accordingly. If unfit for any of these forms of service he was discharged. A certain number of men had been accepted in the past as recruits who had been found after enlistment not to be in all respects fit for service. These men, if unfit for any form of service, had been discharged. Every endeavour was made to secure efficient medical examination of recruits, and the War Office was not aware that there was now any ground for complaint in this respect.

Dental Treatment for Troops.—In reply to Sir Henry Craik, on November 17th, the Financial Secretary to the War Office said that all grades below officers were now receiving free dental treatment, and officers at the front were treated when necessary by the dentists appointed to the forces. Officers who suffered loss or injury to teeth through wounds were also granted necessary expenses of treatment. In reply to another question, he said that, as far as he was aware, the assistance given by the Colonial and British Governments to their respective officers and men was practically on the same lines. In another question Sir Henry Craik suggested that, owing to the lack of opportunity for operations necessary to supply defects, many officers and soldiers had had to give up much of their short period of leave to the supplying of such defects. Mr. Tennant did not admit the truth of the suggestion. Dental surgeons and dental mechanics were, he said, supplied to the troops at the front as demanded by the authorities. The treatment included not only all that was necessary for the relief of pain, but operations also for officers and men, and the provision of artificial dentures to the non-commissioned ranks. Dental surgeons were given commissions on the unattached list, and not in the R.A.M.C.

Army Rations.—Mr. Butcher, on November 18th, asked the Financial Secretary to the War Office a question with regard to a recent Army Order empowering the general officers to entrust the meat ration within their commands when in their judgement the full ration was not required; whether reductions of varying amounts had been made in seven commands or districts, but none in four others. Mr. Forster said that the subject was receiving careful consideration. He also stated, in reply to Mr. Cathcart Wason, that the army ration of preserved meat was $\frac{3}{4}$ lb., and was contained in a tin known in the trade as a nominal 1 lb. He agreed that it was essential that a meat ration should be available for immediate use, and considered that the tins of bully beef complied with this requirement.

Apothecaries' Hall of Ireland.—On November 18th Mr. Byrne asked a long and circumstantial question with regard to the Apothecaries' Hall of Ireland, and inquired whether the Hall had been hindered in its work of qualifying surgeons for the army by the action of the General Medical Council, which had subjected it to a series of visitations, inspections, and inquisitions, thereby frightening away a number of competent candidates who desired to get qualified to serve in the R.A.M.C.; and whether other medical licensing corporations had been subjected to such visitation, inspection, or inquisition by the General Medical Council since the war broke out. Mr. Tennant replied that the Apothecaries' Hall of Ireland had recently made representations to the War Office with regard to the action of the General Medical Council. He had no information as to any effect which the action of the General Medical Council might have had in frightening away candidates who desired to get qualified to serve in the Royal Army Medical Corps, but it was obvious that the Army Council had no authority over a body such as the General Medical Council, which was responsible for the efficiency of civil medical education, and the Army Council had no information at all regarding the number of inspections which the General Medical Council considered it necessary to make of the various medical licensing corporations.

Milk Supply in Agricultural Districts.—Mr. Field, the member for St. Patrick's Division, Dublin, called attention, on November 18th, by a question in the House of Commons, to the difficulty people in rural districts in Ireland had in obtaining an adequate supply of milk, and asked the Chief Secretary whether, considering the matter in conjunction with the Department of Agriculture and the local authorities, he would institute remedial measures. Mr. Birell, while admitting the difficulty, which he observed had been disclosed in evidence before the Viceregal Commission on the milk supply, said that it was not at present practicable for the Government to take remedial measures; he hoped that creameries and farmers having milk at their disposal would realize their duty to make a portion of their supply available for dwellers in agricultural places, and promised to see what could be done to stimulate creameries and farmers to carry out this recommendation. In reply to Mr. Luodon, Mr. T. W. Russell stated that the estimated value of the total output of butter in Ireland for the twelve months ended June 1st, 1913, was £9,201,000; the corresponding figure for the twelve months ended June 1st, 1908, was £8,879,000.

Grants to Day Nurseries.—In reply to Mr. King, the Parliamentary Secretary to the Board of Education stated, on November 18th, that according to the Board's regulations day nurseries were intended for children under three years of age, but older children might be admitted if proper provision could be made for them. No provision was made by local authorities for children between 3 and 5, except in public elementary schools, but a number of nursery schools for such children had been established by voluntary agencies in different parts of the country; no grant was paid in respect of them.

Midwives (Scotland) Bill.—A bill "to secure the better training of midwives in Scotland and to regulate their practice" was introduced into the House of Commons on November 23rd by the Secretary for Scotland and the Lord Advocate.

THE WAR.

THE EARLY STERILIZATION OF WAR WOUNDS WITH HYPOCHLORITES.

THE views of M. Tuffier, expressed in a recent communication,¹ on the important topic of the sterilization of wounds received in warfare are of special interest, since, in the discharge of his duties as a military medical inspector, he has had unusual opportunities for observing the various methods of treatment followed in ambulances along the whole of the French front, and in the hospitals at the rear. He laid emphasis on the necessity for early sterilization because all wounds in this war are infected, on the localization at first of the infective agents to the neighbourhood of the projectile and other foreign bodies, and on the subsequent spread of infection over the whole surface of the walls of the wound. He pointed out that the necessity for the early treatment of infected wounds was not a new idea, and quoted statistics by Keyser, showing that in the Russo-Turkish war in 1877 the mortality following joint wounds treated in the first twelve hours was 13 per cent., while similar injuries treated at a later stage showed a mortality of 61.5 per cent. After stating that the treatment of wounds in the usual way with ordinary antiseptics was inadequate both scientifically and clinically—a conclusion that has been emphasized recently by Wright and others—Tuffier referred to the treatment of infected wounds by hypertonic saline solution as recommended by Wright. He insisted that the method was inadequate in streptococcal infections, and expressed his own preference for antiseptic treatment based on the use of sodium hypochlorite prepared according to Dakin's formula.² At the *postes de secours* disinfection of the skin is effected with ordinary petrol spirit, the superficial parts of the wound are cleaned, a compress saturated with Dakin's hypochlorite is then applied, and the whole is covered with a layer of cotton kept in position by a loose bandage. He insisted on the importance of getting the wounded to the stationary ambulances or hospitals within the first twelve hours and of ensuring that the services of experienced surgeons were there available for immediate treatment. All cases should, he considered, be kept at these places until their wounds have ceased to be infected. After referring to the inadequacy of present methods of combating shock and the necessity of further research upon this important topic, he said that after the wound had been further cleansed by petrol spirit and with tincture of iodine, carefully protecting the wound proper, the latter was cautiously explored by the surgeon, who should scrupulously observe surgical cleanliness. The wounds should be opened up by moderately free incisions, and only actually dead tissue should be cut away. The mode of dressing the wound was similar to that employed by Carrel and his colleagues, reference to which has already been made in these columns.³

The wound was cleaned mechanically as far as possible and all foreign bodies carefully removed, one or more rubber tubes, 6 mm. in diameter, inserted in the deepest parts of the wound, and a wet dressing soaked in Dakin's hypochlorite solution placed around them. A sheet of ordinary sterile cotton-wool through which the rubber tubes passed was placed around the limb, and the whole was kept in position by a loosely tied bandage. Hypochlorite solution, 5 to 10 c.c.m., according to the dimensions of the wound, was injected every hour, or a constant dropping apparatus was employed. At first a slightly sticky but absolutely clear liquid was secreted from the wound, but there was neither suppuration nor odour. When the temperature had remained normal for several days and the wound was in perfect condition, it might be partially drawn together by adhesive plaster, and union would follow.

The results of this procedure as practised in ambulances of the 11rd, 11th, and 13th French armies successively had, M. Tuffier said, been excellent. In one series of wounds in which the prescribed technique was not adhered to the results were not satisfactory, but a subsequent series of very severe bomb wounds, involving extensive

destruction of muscle and injury to joints, gave results superior to any he had previously seen. Normal temperature and absence of suppuration were the rule. The wounded, who on arrival showed a temperature of 38.5 to 39 C., had a normal temperature after forty-eight hours.

Tuffier concluded by expressing the opinion that this method of antiseptic treatment constitutes an important advance, but that further improvement is desirable. It is not always possible to provide proper surgical treatment for all the wounded within the first twenty-four hours, especially when casualties are very numerous. Occasionally certain gangrenous infections spread so rapidly that antiseptic treatment is too late to be effective. But, given the necessary organization for the rapid transport of the wounded, the hypochlorite method of antiseptic treatment, when properly applied, would prevent a large proportion of the deplorable after-results which are so apt to follow wound infection.

GERMAN EXPERIENCES OF WAR SURGERY.

OPERATIONS ON NERVES.

PAPERS published recently by Steintal, v. Hoffmeister, Heile, and Hezel¹ deal with 64 cases of wounds of the peripheral nerves; most were wounds of the neck and arms inflicted by rifle bullets. It was found that the peripheral nerves were not only subject to direct injury by bullets, but also to indirect injury by the pressure exerted by the wounded soft tissues. The disturbances to the blood supply of the nerves thus provoked often led to the conversion of the structures surrounding the nerves into cicatricial tissue, constricting and limiting the movements of the nerves for a considerable distance. Even in bullet wounds, leaving small wounds of entry and exit, the process of healing was often accompanied by the formation of callous tissue, the amount and distribution of which were frequently a source of great surprise. In this tissue nerve trunks were often found anchored for a considerable distance. To free the nerves from this tissue required much patience and skill. Hoffmeister found the operation greatly facilitated by the endoneural injection of a novocain-suprarenin solution (1 minim of suprarenin to every 10 c.c.m. of a 0.5 per cent. solution of novocain). He also gave this injection after suturing nerves, and found the results very satisfactory and unattended by any ill effects. The injection distended the nerve trunk to double its normal dimensions, and helped to free it from surrounding adhesions, and to break down the endoneural strands of fibrous tissue constricting the constituent parts of the nerve trunk. The injection often brought into prominence hourglass constrictions of the nerve, where the cicatricial tissue had encroached on it. These constrictions were divided so as to give the nerve a uniform cylindrical shape throughout the field of operation. In some cases the injected fluid was arrested at a point where the nerve was apparently healthy, but where an effective constriction had been produced by a little cicatricial tissue. The injection was therefore a useful guide to small constrictions, the freeing of which led to the disappearance of symptoms. A further advantage was the action of the suprarenin, which prevented post-operative capillary haemorrhages, and the consequent development of new adhesions.

In direct wounds of the nerves the authors were repeatedly struck by the frequency with which part of the wounded nerve had escaped injury. In Heile's experience the nerve was only partially severed in four-fifths of his cases. Even when a nerve trunk appeared to be most severely wounded, it was a common experience to find the continuity of substance maintained by a few strands. By the preservation of these strands, and the suture of the divided portion of the nerve by fine catgut ligatures, secured only to the supporting substance of the nerve, good results were obtained. Heile found it advisable, after suture of a nerve, to make longitudinal incisions in the perineurium, so as to secure free drainage for exudate, and thus prevent secondary neuritis. He also made a point of securing the nerve in healthy tissues, which were unlikely to be the seat of post-operative capillary haemorrhage. For this purpose he found the interposition of healthy muscle between the nerve and the injured tissues most satisfactory; when this was not possible, fat or fat could be used to isolate the nerve from the large

bleeding cavity formed by the extirpation of cicatricial tissue. He also employed non-vulcanized rubber tubing to isolate the nerve in cases in which healing by first intention was anticipated. When this was not the case, the use of rubber tubing was contraindicated. Hoffmeister, on the other hand, was sceptical as to the value of isolating the nerve in this manner. Early in the war he had attempted to isolate the nerve in a portion of vein, excised from the same patient, but the results had been disappointing. He had also experimented with fatty tissue as padding for the nerve, again with poor results. He had come to the conclusion that these delicate operations were often rendered superfluous by his method of injecting novocain suprarenin, on which he had learnt to rely more and more. When the nerve was completely divided and extensively imbedded in cicatricial tissue, it was often difficult or impossible to unite the two ends by direct suture after the necessarily extensive resection had been made. But by various devices, including free dissection of both ends of the nerve, and by putting up the limb in a position of extreme flexion, Heile had succeeded in bridging a gap as wide as 6 cm. between the two ends of the nerve. Union of the ends of the nerve by Assaky's suture à distance or by Vauclair's tubulization received little praise; and after a review of the literature of these two methods, Steintal came to the conclusion that the results hitherto published were discouraging.

DOUBLE NERVE GRAFTING.

With a view to overcoming the difficulties caused by extensive destruction of nerves and of the surrounding soft tissues, Hoffmeister had elaborated a procedure aiming at securing a bridge between the two ends of the nerve, which should facilitate early healing and the growth of new nerve fibres. His method was based on Duppe's single nerve grafting, which was first attempted when a divided median nerve was grafted on to a healthy ulnar nerve. This operation has also been performed for paralysis of the facial nerve, which has been grafted on to the spinal accessory or hypoglossal nerve. By grafting the peripheral end of the divided nerve on to the healthy trunk of a motor nerve the growth of fibres from this nerve down to the muscle supplied by the divided nerve was effected. The nerve supply of this muscle was henceforth linked up with the motor centre of the healthy nerve. Hoffmeister had modified the method by using the healthy nerve merely as a conductor between the two ends of the divided nerve. He anticipated that the axis cylinders of the divided nerve would find their way to each other along the trunk of the healthy nerve, and that thus the union of a muscle with a foreign nerve centre, as occurred in single nerve grafting, would be avoided. By this method of double grafting he was independent of the nature of the healthy nerve trunk employed, for it was immaterial whether it were sensory or motor, healthy or paralysed. It was also possible to perform almost an unlimited number of double grafts, provided only one nerve trunk in the limb were healthy. These operations were performed at a considerable distance from the site of the injury, and the ends of the nerve were freely dissected out so that after grafting there should be no pull on them. The ends were often carried through tunnels formed by muscles or behind bones. When a nerve was only partially divided, the divided portion was dissected out from the rest of the nerve for a considerable distance, and then was grafted into the side of this nerve.

Altogether Hoffmeister had performed twenty-two double or multiple nerve grafts, the results of which were promising, although the permanent results were uncertain in many cases. The first operation of this kind was performed on a patient whose upper arm had been wounded by a bullet which had completely divided the ulnar, median, and the cutaneous antibrachii medialis nerves. Three months later, when the wound had healed, extensive cicatricial tissue in the depth of the wound was excised. This operation involved resection of 10 cm. of the ulnar nerve and 12 cm. of the median. The median head of the triceps muscle was detached from the humerus over a small area, the two ends of the ulnar nerve were grafted on to the radial nerve, the two ends of the median nerve were grafted on to the ulnar nerve, and, finally, the cutaneous nerve was grafted on to the median nerve. Thus, the ulnar nerve was bridged by the radial nerve alone, while the median nerve was bridged by the

radial nerve and two portions of the ulnar nerve. The cutaneous nerve was bridged by the radial nerve, two portions of the ulnar nerve, and two portions of the median nerve. Four weeks later there were signs of motor innervation of the area supplied by the ulnar nerve, and six weeks later of the area supplied by the median nerve.

Both Hoffmeister and Heile performed their operations as far as possible under general anaesthesia, although a single operation sometimes took over six hours. The greatest care was taken to prevent haemorrhage, including capillary haemorrhage, and the subsequent formation of adhesions. Heile frequently gave endoneural injections of saline solution during the operation in order to facilitate the liberation of nerve bundles from cicatricial tissue. By this device he was enabled, to isolate nerves which would otherwise have been too securely pinned down by adhesions to be freed. Hoffmeister made considerable use of an antiseptic bipolar electrode, with which he ascertained the distribution of uninjured nerve fibres in cases of partial division of a nerve trunk. The electrode was also useful in slowing to what nerve trunk a given "nerve bridge" belonged, and in testing its functional capacity during the various phases of the operation, without necessitating extensive dissection of the parts involved. As a rule, these operations were not undertaken till the wounded nerve trunks had been given about three months in which to reunite by themselves.

CASUALTIES IN THE MEDICAL SERVICES.

ARMY.

Wounded.

Lieutenant L. J. J. Nye, R.A.M.C. (temporary), Flanders.
Lieutenant A. G. Whitfield, R.A.M.C. (T.F.), Flanders.

DEATHS AMONG SONS OF MEDICAL MEN.

FRASER, Donald Reginald, Sergeant 5th (Lecheil's) Battalion Cameron Highlanders, younger son of Dr. A. Duncan Fraser, Strathcree, Falkirk, killed in France on September 25th. He was educated at Blair Lodge, enlisted at the beginning of the war, and had been previously wounded on June 5th. His elder brother, Major A. W. Fraser, R.A.M.C., is serving in Egypt.

TRESIDDER, Percy Hugh, trumpeter, Wellington Mounted Rifles, eldest son of Dr. Harry Junis Tresidder, of Onehanga, Auckland, New Zealand, killed in the Dardanelles on or about August 27th. He left New Zealand in February, with the third reinforcement.

SLOAN, Geoffrey, Captain Scottish Horse, third surviving son of Dr. Samuel Sloan, of Somerset Place, Edinburgh, died of wounds in France, aged 37. He served with the Scots Greys in the South African war. When the present war broke out he was in Vancouver, where he commanded the Frontiersmen; he returned to Scotland, and was appointed captain in the Scottish Horse from November 14th, 1914. His two brothers are also serving—Colonel Sloan, D.S.O., R.A.M.C., and Captain S. Sloan, Scottish Horse.

HONOURS.

THE VICTORIA CROSS.

THE *London Gazette* of November 18th announced that the Victoria Cross had been conferred on temporary Lieutenant George Allan Maling, M.B., R.A.M.C., "for most conspicuous bravery and devotion to duty during the heavy fighting near Fauquissart on September 25th, 1915. Lieutenant Maling worked incessantly with minding energy from 6.15 a.m. on the 25th till 8 a.m. on the 26th, collecting and treating in the open under heavy shell fire more than 300 men. At about 11 a.m. on the 25th he was flung down and temporarily stunned by the bursting of a large high-explosive shell which wounded his only assistant and killed several of his patients. A second shell soon after covered him and his instruments with debris, but his high courage and zeal never failed him, and he continued his gallant work single-handed."

Lieutenant Maling is the youngest son of Dr. E. A. Maling of Blackwell Hall, Darlington; he is 27 years of age, and was educated at Uppingham, Oxford, and St. Thomas's Hospital, London. He graduated B.M., B.Ch. Oxford last year, and took also the diplomas of M.R.C.S. and L.R.C.P.Lond. He received his commission as temporary Lieutenant, R.A.M.C., on January 18th, 1915. He went to France in June, and was attached to the 12th Rifle Brigade.

Military Cross.

The Military Cross has been conferred upon the two following officers for the services specified in the official notes appended to their names.

Captain Maurice Holdsworth Barton, R.A.M.C.(T.F.), attached 5th Leicester Regiment. For conspicuous gallantry and devotion to duty at Hohenzollern redoubt on October 13th, 1915, in tending and bringing in wounded under fire. He also rallied and sent forward men who had become scattered. This is not the first time that Captain Barton's bravery and good work have been brought to notice.

Captain Samuel Russell Foster, M.B., 2nd North Midland Field Ambulance, R.A.M.C.(T.F.). For conspicuous gallantry and devotion to duty at Hohenzollern redoubt on October 16th, 1915. He went to the relief of an officer and some wounded men who were lying in a trench between the firing lines, passing over a considerable space of open ground in broad daylight under heavy shell, machine-gun, and rifle fire. He spent eight hours in this trench tending severely wounded men.

Captain Barton took the diplomas of M.R.C.S. and L.R.C.P. Lond. in 1914, and was assistant house-surgeon at the Leicester Royal Infirmary. He received his commission as Lieutenant R.A.M.C.(T.F.) on January 10th, 1915. Captain Foster graduated M.B., B.Ch. Queen's University, Belfast, in 1912. He was in practice at Blaina, Monmouthshire, and received his commission as Lieutenant R.A.M.C.(T.F.) on November 27th, 1914.

Distinguished Conduct Medal.

The *Gazette* of November 16th also announced the grant of the Distinguished Conduct Medal to 203 non-commissioned officers and men for "acts of gallantry and devotion to duty." Among them were the following men of the medical services:

Franklin, B. S., Lance-Corporal R.A.M.C., 2nd Field Ambulance.
Halford, R. E., Quartermaster-Sergeant R.A.M.C., 21st Field Ambulance.
Hancock, J. W., Sergeant R.A.M.C.(T.F.), 4th Loudon Field Ambulance.
Holmes, J., Private A.S.C., attached 23rd Field Ambulance.
Parsey, G. F., Quartermaster-Sergeant R.A.M.C., 2nd Field Ambulance.
Sweeney, J., Lance-Corporal R.A.M.C., 42nd Field Ambulance.
Veitch, G. T., Private R.A.M.C., 39th Field Ambulance.

Foreign Orders.

The *London Gazette* announces that the King had granted authority to the recipients permission to wear the following foreign orders:

Lt. (Ralph) Peget, the Grand Cross of the Order of St. Sava, conferred by the King of Serbia for services connected with the British Red Cross hospitals in that country.

Sir St. Clair Thomson, M.D., Commander of the Order of Leopold of Belgium for services in Flanders and England.

Major Herman Stedman, late R.A.M.C.(T.F.), Chevalier of the Order of Leopold of Belgium.

Surgeon E. B. A. Merewether, M.B., R.N., Order of St. Sava, 4th class (conferred by the King of Serbia).

To certain officers of H.M.S. *Jupiter* to wear decorations conferred upon them by the Emperor of Russia. Among them were three medical officers:—

Order of St. Anne, third class: Surgeon W. I. Gerard, R.N.V.R.; Surgeon (temporary) W. G. Biggar, R.N.

Order of St. Stanislas, second class: Fleet Surgeon H. R. Gardner, R.N.

HOSPITAL SHIPS.**Preparatory Falsehoods.**

A wireless message from Berlin, on November 21st, stated that "seventy British transports have passed Gibraltar, heavily laden, and painted like hospital ships, on their way to Greek waters." A German Admiralty official further stated that "in the past few days our U boats have wirelessed that, when British ships reach the submarine danger zone, they drop Red Cross flags over a white space painted on the vessel's side," and that seventy vessels passing Gibraltar, ostensibly hospital ships, "carried heavy cargoes, for they were swimming deep. . . . All these ships carried to the limit of their capacity. Surely England is not sending seventy hospital ships to Greece within a few days with wounded or with hospital supplies? Undoubtedly they are carrying troops and munitions which are being protected by a ruse."

The British Admiralty issued the following announcement on November 23rd:

The constant repetition in the German Wireless Press Messages of falsehoods concerning British hospital ships necessitates a further categorical denial.

There are forty-two British hospital ships working to and from the Mediterranean—not seventy, as stated.

No hospital ship has carried other than sick and wounded, nurses and medical staff, and medical stores.

All are fully ballasted to secure safety and comfort, but are not deeply laden. On the contrary, they are generally some feet higher than deep draught.

All are permanently painted as required by Geneva Convention, and duly notified to belligerents. No temporary arrangements, such as those suggested, exist.

The whole report and its insinuation is absolutely false. Great Britain has strictly adhered to the Geneva and Hague Conventions.

Previous experience suggests that this series of falsehoods foreshadows attacks on British hospital ships by German submarines.

MEDICAL OFFICERS WANTED.**3rd 2nd Home Counties Field Ambulance (T.F.).**

There are a few vacancies for officers in the above unit. Candidates must be fully qualified medical practitioners, and willing to undertake foreign service obligation. Apply, Officer Commanding, Haulton Park West Camp, near Tring, Herts.

57th H.C. Field Ambulance, R.A.M.C. (T.F.).

Medical officers are urgently required for the 57th Home Counties Field Ambulance for foreign service only. For particulars apply to the O.C., 31st Home Counties Field Ambulance, Royal Army Medical Corps (T.F.), Haulton Camp West, Tring, Herts.

Ireland.**THE INSURANCE COMMISSIONERS, THE PROFESSION IN IRELAND, AND SERVICE WITH THE TROOPS.**

At last it would seem that the prolonged differences between the medical profession in Ireland and the Insurance Commissioners on the vexed question of certification were on the point of being settled. This has been stated so often before that one is inclined to be sceptical; however, this time it really seems as if a serious effort had been made on the part of the Commissioners to meet the reasonable demands of the doctors. These proposals provide that certification for the purpose of enabling insured persons to apply to their societies for sickness benefit should be carried out by the medical attendants, the amount of money allotted being based on the number of insured persons in each certification area, and the density, or, on the other hand, the scattered nature of the insured population. It is also proposed that a certain check on certification in the nature of a second medical opinion should be available for the approved societies where they had reasonable doubt as to the degree of care with which medical certificates were given in any area. This would have meant the appointment of a certain number of salaried appointments, but owing to the present needs of the military medical services, it was thought that the hope of obtaining these appointments might hinder suitable candidates from offering themselves for the army. The Insurance Commissioners have therefore come to the conclusion that, while it is practicable to proceed with that part of their scheme which provides for certification, it is desirable to defer the part relating to second opinions until the war is over. This necessitates the abolition of the arrangements at present existing for certification, and the Commissioners propose to hold conferences at an early date for the purpose of discussing the matter with representatives of the various interests affected. They desire that eligible candidates for the Army Medical Service may know at the earliest possible date that certain proposed appointments are now definitely suspended until the termination of the war, and that acceptance of service under the Army Council will entail no disability as regards the appointments in question, but on the contrary, will entitle applications to favourable consideration when such appointments are eventually made. As the medical profession in the country districts of Ireland consists very largely of those engaged in Poor Law work, this notice is of chief importance to them. Already considerable numbers of them have obtained temporary commissions, and the chief hindrance to others is not so much the hope of future appointments as the difficulty of arranging for substitutes to undertake their duties. If, therefore, boards of guardians would make a serious

effort to reduce as far as possible the demands on the time and services of their medical officers, and also allow, where possible, the amalgamation, for the time being, of neighbouring districts, and grant leave of absence, without prejudice, to the medical officers whom it was found possible to spare, a large number of medical men could be set free, who would have no hesitation in offering themselves to the War Office for military service.

DUBLIN UNIVERSITY SCHOOL'S RECORD IN THE WAR.

On Saturday evening, November 20th, the inaugural meeting of the Dublin University Biological Association was held in the Graduates' Memorial Hall, Trinity College. Dr. J. T. Wigham presided and Dr. Charles Benson, the incoming President, delivered an address on "War: its effects upon the medical profession." He expressed the opinion that there would be a great shortage of medical men after the war. Professor Dixon, Registrar of the School of Physic, Trinity College, stated that, of the students who had matriculated during 1909 and 1910 in the Dublin University School of Medicine, 69 had qualified, and of these 65 were known to have taken commissions in the R.A.M.C.; 24 had not waited to qualify, but had joined fighting units either as commissioned officers or as privates; only 19 were left in the school, and they were preparing for their final examinations. Of the students who matriculated in 1911 and 1912, none were yet entitled to enter for their final examinations, but of these, 58 had already joined the regular army. The total number of the medical students of the school on active service was 120.

BOARDS OF GUARDIANS AND POOR LAW MEDICAL OFFICERS' HOLIDAYS.

The relations between the Carrickmacross (co. Monaghan) Board of Guardians and their medical officers have not been of a satisfactory character for some time past. For this undesirable state of affairs their unreasonable attitude as regards leave of absence of their medical officers going on holidays and joining the R.A.M.C. is mainly if not entirely responsible. The custom throughout Ireland is for the boards of guardians to appoint as locumtenent the doctor nominated by the medical officer going on leave, so long as the arrangements impose no hardship on the sick poor—a condition closely inquired into by the Irish Local Government Board before sanctioning the leave of absence. The Carrickmacross Board of Guardians, instead of following the usual custom of boards in Ireland, ignore the locumtenent nominated by the medical officer seeking leave, and appoint one particular doctor to do duty for all their medical officers, who are expected to take their holidays, not to suit their own convenience and private arrangements, but to accommodate the convenience of the locumtenent selected by the board of guardians. That a similar state of affairs to that now existing in the Carrickmacross Union does not arise to a greater extent in other localities in Ireland is due rather to the doctors in these areas observing the ethical rule that no doctor should accept a locumtenent appointment without either the invitation or the approval of the doctor going on leave, than any desire on the part of certain boards of guardians to oblige their medical officers. The Carrickmacross Board of Guardians on a recent occasion also refused to pay any portion of the salary of the locumtenent nominated by their medical officer, Dr. D'Arcy, who intended joining the R.A.M.C.

Scotland.

TUBERCULOSIS SANATORIUMS IN WAR-TIME.

EVERY curative institution throughout the country is feeling the lack of qualified medical men for resident posts. The sanatoriums for the treatment of tuberculosis may perhaps be said to feel the shortage in somewhat less degree than the general hospitals; nevertheless they must needs be hampered in their disciplinary work to a considerable extent when left in the willing but inexperienced hands of substitutes. From the seventh annual report of the Ayrshire Sanatorium, however, it appears that the general average of usefulness has not suffered any decline on this account. The numbers of tuberculous persons treated during the year 1914 show

a steady increase over previous years, and additional accommodation has had to be provided. As in his reports for some years past, the Medical Superintendent finds it necessary to call attention to the prevalent custom in the county (as in many others) of recommending cases for admission at an advanced stage of the disease, many of them coming thus under treatment for the first time. He rightly emphasizes the mischief that must be wrought by such cases, who for many months, and perhaps years, have been scattering the seeds of disease broadcast in the homes or the workshops. Too often the patient refuses to consult a doctor until too weak to carry on his work, and no power exists by which inspection can be carried out to detect and isolate the patient before his disease has advanced beyond the curable limit. The actual death-rate from tuberculosis varies remarkably in different parts of Scotland, but the general tendency to decrease is quite evident. Cases of tuberculosis in soldiers returning from the war are not uncommon. The idea is naturally prevalent that the unrestricted spitting and the general conditions of the life in the trenches is to be held responsible for the infection. It would appear probable, however, that in most cases the seeds of disease were already sown and that the hardships had only served to stimulate afresh the activity of dormant bacilli. Contrary to experience in many kindred institutions, the Ayrshire Sanatorium has not suffered financially during the war. A reduced medical staff and enforced economy in artificial light during the winter months may be held to account for this.

EDINBURGH OBSTETRICAL SOCIETY.

At a meeting of the Edinburgh Obstetrical Society on November 17th, at which the president, Sir Halliday Croom, was in the chair, the treasurer, Dr. John McGibbon, presented the annual financial statement, which showed a balance in bank of £49 ls. 5d., and invested funds which cost £505 6s. 6d. A vote of thanks was heartily accorded. The President then submitted the following motion by the Council:

That meantime, owing to the continuance of the war, no meetings of the society be held until further notice; and that during the period of suspension no subscriptions be called for, and the present office-bearers and council continue in office.

This motion was agreed to unanimously, and it was further decided that notices of the temporary cessation of the society's meetings, of the subscriptions, and of the annual volume of *Transactions*, should be sent to the Fellows of the society. It was also agreed that contributions made by the Fellows to medical journals during the continuance of the war should be considered thereafter by the Council with a view to their possible inclusion in the next volume of the society's *Transactions*.

England and Wales.

THE MIDWIVES ACT IN MANCHESTER.

PROBABLY nowhere is the Midwives Act more carefully carried out than in Manchester, and the Medical Officer of Health gives in his annual report for 1914 an interesting account of special work done for pregnant and nursing women which has arisen owing to the war. The number of midwives in practice during 1914 was 161, of whom over 80 per cent. were certificated. The total births registered numbered 18,697—a rate of 25.3. This is a slight reduction on the previous year, when the number was 19,052, or a rate of 25.64, and, with the exception of the year 1912, when the rate was only 25.09, the rate for 1914 was the lowest on record. Of the 18,697 births, 9,409, or just over 50 per cent., were attended by midwives. This is a considerable drop, as in 1913 the midwives attended 12,251, or 64.3 per cent., while in 1912 they attended 58.6 per cent. No explanation is given of this reduction, though it is probable that since the Insurance Act began to provide maternity benefit many women who formerly had to be content with a midwife have been able to afford to engage a doctor.

During the year 105 cases of puerperal fever were notified; of these, 20 occurred after abortion or premature labour, in 25 cases forceps had been used, and in 22 a

perineal tear was stated to be present. It may be noted, too, that though in the majority of the last ten years puerperal fever occurred more frequently among cases where doctors attended at the birth, on the contrary in 1914 the doctors had a lower proportion of cases of puerperal fever than the midwives. On the other hand, the death-rate among the doctors' cases has been rather persistently higher than among the midwives' cases. The case mortality for puerperal fever was 21.9 per cent. Doctors were summoned to the assistance of midwives in accordance with the rules of the Central Midwives Board in 2,606 cases, by far the greatest number being for tedious labour or rupture of perineum or for inflammation of the eyes in the newborn. Under the Manchester arrangement, by which the Midwives Supervising Committee pays fees in needy cases to doctors summoned to the assistance of midwives, 757 applications for such fees were made. Inquiry was made into every case, and 654 fees were actually paid amounting to £568 14s.; the remaining cases did not fulfil the conditions on which fees are paid. At the beginning of December, 1914, the committee also arranged to pay fees to midwives for attending at confinements of the wives or widows of soldiers or sailors and of other women in need of assistance as a result of the war, the fees payable being 15s. for a first confinement and 12s. 6d. for subsequent confinements. During the month of December 34 fees amounting to £21 15s. were thus paid to midwives, the payments being conditional on the income of the family not being in excess of the same scale as that under which medical practitioners are paid when summoned to the assistance of midwives.

The total number of stillbirths of which there is any record was 638; of these, 406 occurred in the practice of doctors and 232 in that of midwives; 21 of the children who were stillborn were known to be illegitimate. In 1911 two special nurses were appointed, one being for septic work, and visits and investigations have been made with a view to checking the practice of midwifery by uncertified women. When the war broke out it was feared that much hardship and suffering might be entailed on poor pregnant and lying-in women, and the Relief Committee arranged for free meals for a period of two months prior to confinement and during the nursing period, and also for the provision of suitable clothing. The medical officer of health was authorized to administer this relief, and the executive medical officer of the Supervising Committee was entrusted with the arrangements. All the midwives were invited to a meeting to discuss the procedure, and they agreed voluntarily to notify suitable cases. Inquiry into all cases thus notified was made, and those found to be eligible were provided with tickets, which they could present at one of eleven feeding centres which were organized. The food was provided by a large caterer in the city, and delivered daily by the motor bus belonging to the Sanitary Committee; to cases unable to attend at the centres a quart of milk was supplied daily through the nearest dairy, the cost of this being largely borne by the midwives, who combined to provide funds for the purpose. Clothing was received through many agencies, and was distributed direct from the office. In this way relief was given to 2,375 cases, and there can be little doubt that this arrangement, together with the scheme of the committee for the payment of fees to midwives, will have proved extremely beneficial.

Correspondence.

THE SACRIFICES OF CANADIAN PRACTITIONERS.

SIR,—I have just read a very interesting article in your issue of October 9th upon the "Position of general practitioners taking commissions," and in view of the details which are therein given with regard to the "arrangements made by a country practitioner who has recently responded to the call of duty, and taken a commission in the R.A.M.C.," I feel that a statement should be made with reference to the conditions under which, in response to the call of duty, commissions are taken by Canadian practitioners, either in the Canadian A.M.C. or in the R.A.M.C.

Whereas, in the counting of the cost, your correspondent

has been able to work out his financial details so as to reduce the loss anticipated in running his practice during his absence to £8 a year, the practitioner in this Dominion who accepts a commission in either of the above services is unable to make any such arrangement. The conditions of practice in the Dominion make it impossible for a practitioner to receive any remuneration for the loss of his practice, because such a practice is unsaleable, and he who sells commits a fraud, and he who purchases purchases that which is naught. In this Dominion a practice is a purely personal affair, and is worth nothing as a matter of sale, either by himself or by his estate, for patients exercise, and rightly, absolute liberty with reference to their choice of physician, and hold themselves under no obligation, given or understood, to return to any practitioner for a second or third visit. Therefore, when one of the practitioners of this Dominion applies for a commission, he does so in the full knowledge that during his absence nothing will be received by his family in the way of revenue from any practitioner to whom the families which he has professionally attended may resort, and, moreover, upon the end of the war and the return of the practitioner to his former location, should he be fortunate enough to survive, he must look forward to beginning his practice anew, and must not expect, as a right, that any of his old patients seek his aid.

In the hospitals recently sent forth by the universities of Canada, of which I have the more intimate knowledge, the gentlemen who comprised their staffs have with few exceptions abandoned more or less lucrative practices, and only in a few cases are there any others than those who have been for some time in general or special practice, and in most instances these members are teaching members of the university faculties. The senior officers are specialists, professors, or associate professors of the universities, receiving from their private practices incomes varying from £1,000 per annum upwards. These gentlemen left their families dependent upon the insecure revenue derivable from what investments they had been able to make, the separation allowance afforded them by the Government, and whatever portion of their pay they could spare. Their salaries were, of course, continued by the universities, but these are honoraria, and of inconsiderable amount.

From my knowledge of the composition of the units, not one of the staffs regrets for one moment the step he took in volunteering his services, but it is only fair that the facts involved should be made known, and the self-sacrifice acknowledged.

The whole position of the Canadian practitioner who has volunteered for service abroad, as compared with the gentleman mentioned in the article above quoted, who could figure down his actual monetary loss to £8 per annum, makes the self-sacrifice involved in the case of the latter almost a negligible item.—I am, etc.,

IPÉCACUANHA AND ITS ALKALOIDS.

SIR,—The note under this heading, which appeared in your issue of November 13th, gives an account of our knowledge of the chemistry of these alkaloids at the time when Henry's work, *The Vegetable Alkaloids* (1913), was published. Since then, however, the results of several new investigations on the subject have been published, and necessitate some corrections of the earlier statements. The alkaloids of ipecacuanha have been studied in detail in these and the associated laboratories, and the investigation, which is at present suspended owing to pressure of other work, will be resumed here later. In these circumstances, I shall be glad if you will permit me to correct your account in the following particulars:

1. In 1894 Paul and Cownley (*Pharm. Journ.*, 1894 (iii), 25, 111, 373, 690) attributed to emetine and cephaeline the formulae $C_{20}H_{30}O_2N_2$ and $C_{20}H_{30}O_2N_2$ respectively, but shortly afterwards Hesse (*Pharm. Journ.*, 1898 (iv), 7, 98) suggested that the composition of the substances would be better expressed by the formulae $C_{20}H_{28}O_2N_2$ and $C_{20}H_{28}O_2N_2$. The recent investigations, both by Hesse (*Annalen der Chem.*, 1914, 405, 1) and by ourselves (*Proc. Chem. Soc.*, 1915, 29, 226; *Trans. Chem. Soc.*, 1914, 105, 159), confirm Hesse's formula for cephaeline, which may now be regarded as established. We also showed that emetine is the mono-methyl ether of cephaeline, and has, therefore, the formula $C_{20}H_{29}O_2N_2$ which we have confirmed by analyses of the base and several of its salts and derivatives. Hesse has

withdrawn his previous formula for emetine, $C_{20}H_{40}O_2N_2$, and proposed for it the formula $C_{20}H_{40}O_2N_2$, but in view of our work, and in particular of the proved relationship of emetine to cephaeline, this formula cannot be upheld.

2. Emetine sulphate has been prepared in a crystalline form.
3. Whilst the constitution of emetine is still unknown, some progress has been made with its elucidation, and we have shown definitely that this alkaloid is a derivative of isoquinoline; the work of Windaus and Hermans (*Ber. deutsch. chem. Gesell.*, 1914, 47, 1470) leads to the same conclusion.

—I am, etc.,

FRANK LEE PYMAN, D.Sc., Ph.D.,
Director, Wellcome Chemical Research
Laboratories, London.

London, E.C., Nov. 16th.

A COMBINED PHYSICAL TREATMENT FOR DISABLED SOLDIERS.

SIR,—During the last ten months a novel combination of physical methods of treatment has been in operation at the Hôpital Complémentaire at the Grand Palais in Paris.

One of the new features is a hyperthermal *eau courante* bath, which is applied locally to the affected limbs, more especially as a preparation for massage and mechanical treatment. It is found that the *eau courante* bath greatly facilitates both massage and mobilization. This combined treatment is now very extensively employed, both in Paris and in the country in hospitals set apart for it.

According to the latest information several hundred men disabled in their limbs were in October alone returned from the Grand Palais fit for military service, with an estimated saving to the French Government of upwards of £50,000 on account of pensions.

If in Paris why not in London? In England many similarly disabled men are to be seen in the hospitals, and sometimes in the streets. It is claimed that the treatment referred to holds out a fair prospect of recovery in many otherwise hopeless cases. It is recommended, therefore, alike by humanity and by considerations of prudent war economy.

A full account of the results obtained by these combined physical methods in military cases will shortly be published on behalf of a committee of the Royal Society of Medicine (Section of Balneology).—We are, etc.,

R. FORTESCUE FOX,
J. CAMPBELL McCLURE,

Honorary Secretaries to the Committee.

Obituary.

HENRY CHARLTON BASTIAN, M.A., M.D.LOND.,
F.R.C.P., F.R.S.,

EMERITUS PROFESSOR OF MEDICINE AND CLINICAL MEDICINE,
UNIVERSITY COLLEGE, LONDON.

DR. CHARLTON BASTIAN died on November 17th at his residence, Cheham Bois, Bucks. He was born at Truro, Cornwall, in April, 1837. He received his education at University College, and graduated M.A. at the University of London in 1861, and M.D. in 1866. Shortly afterwards he was elected assistant physician to St. Mary's Hospital, and lecturer on pathology in its medical school; he held these appointments until 1867, when he became professor of pathological anatomy in University College, and assistant physician to its hospital. Later he was professor of medicine and clinical medicine. For thirty years he held first the junior and then the full physician's appointment, resigning in 1897. He was also physician to the National Hospital for the Paralyzed and Epileptic, being appointed to the junior office in 1862, and becoming senior physician in December, 1887. He resigned the latter appointment in April, 1902, at the age of 65, but by special resolution was allowed to retain ten beds until he finally retired, having attained the age of 75, in 1912.

The activities of Dr. Bastian's long life were sharply divided into two parts—the one, which occupied his chief energies in the earlier and the closing years of his life, was concerned with the controversy as to the origin of life and heterogenesis; the other was the clinical study of neurology, in which he was chiefly interested during the whole of the middle period of his life, when he was actively engaged as a teacher and physician in London. His friends knew, however, that throughout the whole of

this middle period he never for a moment lost his interest in the other subject, and as soon as circumstances permitted he gave up practice and devoted himself again to experimental investigations with regard to the origin of life and the transformation of organisms. There was, however, another short period of his early life during which it seemed that he would devote himself to pure science. It was during this time that he made researches in parasitology and published (1864) his monograph on the Anguillulidae or free nematodes, in which he described a hundred new species; another work on their anatomy and physiology was published in the following year. It was these researches which led to his election to be F.R.S. when only 31 years of age.

As a physician and teacher he early directed his attention almost exclusively to neurology. As a teacher he attracted a small but select class, who highly appreciated the precision of his methods of diagnosis, the acuteness of his intellect, and his wide acquaintance with neurological literature. He was himself a prolific contributor to it. *The Brain as an Organ of the Mind*, published in 1880, he probably himself considered his most important work in medicine. It was translated into French and German, reached a fifth edition in this country, and was at one time a great deal used as a textbook by men reading for the higher examinations. In 1875 he published his book, *Paralysis from Brain Disease*, being a series of excellent clinical lectures delivered in the previous year at University College Hospital. It was the forerunner of a larger and yet more important clinical and pathological work, *Paralyses: Cerebral, Bulbar, and Spinal*, published in 1886 avowedly as a manual of diagnosis for students and practitioners.

Another clinical work which excited great interest when it appeared in 1895 was entitled *Various Forms of Hysterical or Functional Paralysis*; it was the product of long study in the author's wards at University College Hospital and at the National Hospital for the Paralyzed and Epileptic, in conjunction with his house-physicians and clinical clerks, who drew up full reports of the cases recorded. The most important passage in this treatise contained observations on the nature of hysteria which were well worthy of study, though they did not altogether succeed in dissipating the obscurity which surrounded the subject. Dr. Bastian strongly condemned the practice of using the term "hysterical" as though it were synonymous with "functional." For him, hysterical cases were a special type of functional cases; he urged that if, with Briquet and Charcot, we defined hysteria as a neurosis due to perversion of brain functions, then all the cases of functional spinal paralysis must be placed in some other category.

In the spring of 1897 he delivered the Lumlain Lectures on some problems in connexion with aphasia and other speech defects before the Royal College of Physicians. The lectures were a remarkable analytical contribution to a difficult subject. He held that aphasia depended either upon damage to one or other of the four centres in the cerebral cortex, which, he believed, were concerned in the production of spoken and written language, or to interruption of the commissures connecting them. These lectures, with the addition of a great deal more matter of importance, were published in *Aphasia and other Speech Defects*, issued in 1898. This treatise was dispassionate, scientific work, and in the literature of the subject assumed at once the position of a classic. He contributed many articles on neurological subjects to *Quain's Dictionary of Medicine*, and, in fact, took a considerable part in the production of that work of reference, which revived a method of publication popular a generation earlier, and produced a very considerable effect on the trend of medical opinion in this country by presenting in a convenient form the latest views of acknowledged authorities.

When he finally retired from University College he was appointed Emeritus Professor of Medicine, and shortly afterwards gave up practice in order to resume the studies which had interested his scientific youth. The story is a remarkable example of moral courage and scientific enthusiasm, facing odds which appeared hopeless. Those whose memories go back to the first International Congress of Medicine in London in 1881 will remember the courage with which he faced the meeting presided over by Lord Lister and in which as a speaker he was immediately

followed by Pasteur; afterwards he retired from the field overwhelmed but not defeated, and, as has been said, devoted himself to the practice of neurology. As soon as he had retired, however, he immediately resumed his experiments.

Contrary to generally accepted views—views which seemed to be settled once and for all in the middle of last century by the work of Pasteur and Tyndall on the sterilization of fluids by heat—Bastian denied that life always develops from pre-existing life; for him the aphorism *Omne vivum ex vivo* was not true, and he maintained that not only in the distant past did some fortuitous concourse of atoms presumably give rise to the first beginning of living matter, but that this process has continued ever since, and is continuing at the present day. He held, in fact, the doctrine of spontaneous generation, or, as he preferred to term it, "archebiosis," and carried out a number of laborious investigations in support of his views. Liquids composed of (a) ammonium phosphate, phosphoric acid, and sodium silicate; (b) ferrous sulphate and potassium ferrocyanide; (c) ferrous sulphate, potassium ferrocyanide, and sodium silicate were employed. These were enclosed in sealed glass tubes, sterilized at various temperatures, maintained under certain conditions of light and warmth, and examined after a lapse of months. In a certain number of the tubes micro-organisms—bacteria, torulae, and even moulds—seemed to make their appearance in small numbers. The experiments were laborious and the possible fallacies obviously numerous, but Bastian attempted to meet every criticism and maintained to the last the correctness of his observations. Few have attempted to repeat his experiments, and those who have done so have not had the time at their disposal to study the subject with anything like the minuteness with which Bastian did, for he devoted the last years of his life almost entirely to it. Undoubtedly, in Bastian's tubes, structures were occasionally observed which had all the characters of torulae, except that it seemed impossible to grow them. The MM. Mary in Paris and a correspondent writing in last week's *English Mechanic* claim to have obtained the same results in tubes prepared by themselves, and the MM. Mary state that they have been able to obtain subcultures in media containing lactate of iron. Dr. Bastian was ever attempting to improve his methods and to make use of any new means which might help towards this end. Thus in the spring of this year he published a paper in the *Proceedings of the Royal Society of Medicine* in which he stated that when the organisms had made their appearance in the tubes the addition of tyrosin brought about an enormous multiplication (see also *BRITISH MEDICAL JOURNAL*, January 23rd, 1915, p. 183). His latest results were published in *The Origin of Life*, second edition, 1914, and in *Nature*, January 22nd, 1914, p. 581, and December 24th, 1914, p. 466. Dr. Bastian also held that one kind of organism might suddenly appear as the offspring of another and quite different form. Thus ciliates and flagellates might, he believed, succeed amoebae which themselves appeared out of a bacterial zoogeal mass. This process he termed "heterogenesis," and his observations on this subject were published in a large volume entitled *Studies in Heterogenesis*. All these books were illustrated by photographs taken by himself.

Dr. Bastian was a friend of Herbert Spencer, and one of the trustees under his will, by which he left the bulk of his property in trust for carrying on the publication of *Descriptive Sociology*; as trustee Dr. Bastian was joint editor of Spencer's autobiography. Dr. Bastian received many honours from academic bodies. He was honorary M.D. of the Royal University of Ireland, corresponding member of many foreign scientific societies, and had served as censor of the Royal College of Physicians. He leaves a daughter and three sons, one of whom is in the Royal Naval Medical Service.

In some of the notices which have appeared since his death it has been said that there was something pathetic in the persistence with which he defended and sought to establish the doctrine of abiogenesis and the related hypothesis of heterogenesis. But for himself there was nothing of pathos in his position; he deeply resented, as was natural, the indifference or ridicule which his opinions encountered, but he never for a moment indulged in self-pity. His intellect burned with too clear a flame.

ROBERT MAGUIRE, M.D. LOND., B.Sc. VICT., F.R.C.P.

CONSULTING PHYSICIAN, HOSPITAL FOR CONSUMPTION BROMPTON.
DR. R. MAGUIRE died on Friday, November 12th, aged 58, in Cadogan Street, S.W. He was the son of the late Mr. John Maguire of Manchester and Drummalla, co. Fermanagh, and was educated at the Manchester Grammar School and the Owens College. He graduated M.B. Lond. in 1881, taking the university scholarship and gold medal in medicine, and the gold medals in obstetrics and forensic medicine. He took the M.D. degree in the following year, taking the gold medal. He was for a time physician to the Manchester Southern Hospital, pathologist to the Manchester Royal Infirmary, and assistant lecturer on pathology in Owens College. He afterwards settled in London, and joined the staffs of the St. Mary's and the Brompton Hospitals. As a physician he turned his attention mainly to disorders of the respiratory tract. In the autumn of 1900 he delivered the Harveian Lectures before the Harveian Society of London, which he eventually published in a volume, entitled, *The Prognosis and Treatment of Pulmonary Tuberculosis*. They were reported in the *JOURNAL*, and represented valuable observations made at the Brompton Hospital, and also at St. Mary's, where he was then physician to out-patients. Dr. Maguire advocated asepsis of the lung by intravenous injections of formic aldehyde; he admitted that the procedure was neither easy nor free from danger, yet he found that a solution of formic aldehyde of considerable strength might be introduced into the circulation. He advocated this method for ensuring asepsis because inhalations of vapours could not be of sufficient strength to attack germs in the lung if they were weak enough to pass the glottis, and even if they passed it they would probably go no further than the bifurcation of the bronchi. Subcutaneous injections of germicides were so diluted before they reached the lungs as to be powerless, whilst germicides taken by the mouth were likewise made useless before they could reach the lungs by dilution in the stomach and decomposition in their passage through the liver.

Dr. Maguire contributed to *Quain's Dictionary of Medicine*, and to *Fowler's Dictionary of Practical Medicine*, and published several papers in medical periodical publications. He became a member of the Royal College of Physicians of London in 1883, and was elected a Fellow in 1889. He was honorary physician to the Royal Society of Musicians and to the Benenden Sanatorium.

WE regret to announce the sudden death on November 12th of Dr. J. WRIGHT GRANT at Edinburgh. He was born at Grantown-on-Spey in 1860, and was educated at Grantown, at Aberdeen, and later at the University of Edinburgh, where he graduated M.B., C.M. in 1886. Shortly afterwards he settled in Woburn Sands, and soon had a large practice in that place and in the surrounding district. He wrote the article, *Woburn Sands and Neighbourhood as a Health Resort*, in the *Chimæra and Baths of Great Britain*. He was physician to the Daneswood Sanatorium and the London Boarded-out Children. After some fifteen years increasing deafness caused him reluctantly to give up his practice, but he still continued to take a great interest in his profession. He was a man of marked social gifts, and had a keen sense of humour. His sudden death from angina pectoris at the comparatively early age of 55 is a matter of extreme regret to many.

DR. WILLIAM MELVILLE-DAVISON, Medical Superintendent to the Booth Line, died on October 9th at the age of 46. He studied medicine at Newcastle-on-Tyne, and took the degrees of M.B. and B.S. at Durham in 1890. He practised in Durham for several years, but owing to a failure in health he carried on his profession on the seas for no less than fourteen years, in Chinese emigrant ships, pilgrim ships, and Holt and Booth liners. He also served as a prison doctor in South Africa. When appointed medical superintendent of the Booth Line he wrote his *New and Interesting Points in Ships' Hygiene*. He was one of the pioneers of the mosquito-screening of ships, communicating a memoir on that subject to the Yellow Fever Bureau *Bulletin* in 1911. Dr. Melville-Davison was a total abstainer, and published a work on

Alcoholism, its Cause and Cure, originally a paper read before the Liverpool Council of Voluntary Aid. The Booth Line could not relieve him from his duties in order that he might join in the Red Cross work in France or in England, but he afforded invaluable assistance in fitting out and managing a private hospital. He was much beloved, deservedly popular, and always ready to afford professional or, if necessary, pecuniary aid to those in trouble.

By the death of Dr. GEORGE MILLER STERNBERG, of Washington, which occurred on November 3rd, the scientific world has lost one of the foremost authorities on bacteriology and epidemiology. He was born in Otsego County, in the State of New York, in June, 1838, and was therefore in his 78th year. He graduated at the College of Physicians and Surgeons (Columbia University) in 1860, entered the United States army as assistant surgeon in 1861, and retired with the rank of brigadier general in 1902. He served throughout the Civil War and had command of the American Medical Service in the war with Spain in 1898. He was on special service through several epidemics of cholera and yellow fever, and he was secretary of the Havana Yellow Fever Commission in 1879. To him was due the appointment of the Yellow Fever Commission of 1900 of which Major Reed and Drs. Carroll, Lazear, and Agramonte were members; their work marks an epoch in the history of preventive medicine. General Sternberg also established the Army Medical School at Washington, which has proved itself of signal usefulness to the service. He was the author of *Photomicrographs and How to Make Them*, of a *Manual of Bacteriology*, a treatise on malaria, a work on immunity protective inoculations and serum-therapy, and many reports presented to the Government.

PROFESSOR CARL ANTON EWALD of Berlin, who died on September 20th, after several months' illness, in his sixty-ninth year, was a recognized authority on diseases of the stomach. He took his doctor's degree at Berlin in 1870, and qualified as *Privatdozent* in 1874. He was appointed extraordinary professor in 1882, and later became an honorary ordinary professor. He was the head of the Augusta Hospital and editor of the *Berliner klinische Wochenschrift* from 1881 to 1907, being associated in the later part of this period with Professor C. Posner. He was the author of several books and numerous papers on digestion, diseases of the thyroid, myxoedema, and many other subjects. He was also an authority on forestry. He was librarian to the *Berliner medizinische Gesellschaft* for twenty-five years. He was the financial secretary of the Society for Children's Sea-Coast Hospitals and of the Society for Home Hygiene.

WILLIAM OMAND SCLATER, B.Sc.Edin. 1904, M.B., Ch.B. (1st class honours) 1906, formerly house-surgeon to the Edinburgh Royal Infirmary and to the Palmer Memorial Hospital, Jarrow, died suddenly on October 29th at Ipoh, Perak, in the Federated Malay States.

MAJOR W. M. JENNINGS, T.D., M.R.C.S., died suddenly on November 5th, at the age of 58. He had practised in Jarrow-on-Tyne for over thirty years and was very popular and deeply respected in that town. He began professional life as assistant to Dr. Huntley and at once interested himself in the ambulance movement which was then developing. He was an enthusiastic officer of the Durham Royal Engineers (Volunteers); when the corps became Fortress Companies under the Territorial scheme, Captain Jennings became Major and was commanding officer until about three years ago, when he retired, time expired. Subsequently he became commandant of the Jarrow and Hebburn Detachment of the National Reserve, and did much to bring this body into useful service in connexion with the war. His eldest son, Lieutenant Jennings, R.E., is at present at the Dardanelles. The funeral of Major W. M. Jennings, which took place on November 10th at Jarrow cemetery, was attended by the military and civilian authorities and by a large number of the people of Jarrow, where he was so much beloved. The coffin was

covered with the Union Jack and borne by six non-commissioned officers of the National Reserve.

DEATHS IN THE PROFESSION ABROAD.—Among the members of the medical profession in foreign countries who have recently died are Dr. Albert Malherbe, honorary director of the Medical School of Nantes, in which he was for many years professor of pathological anatomy and histology, corresponding member of the French Academy of Medicine, aged 70; Dr. Oui, formerly professor of clinical obstetrics in the University of Lille, and since the German occupation inspector of military hospitals at Bordeaux; Dr. Johan Ulrik Teodor Quensel, professor of pathological anatomy in the University of Upsala, aged 70; Dr. J. E. Sheppard, clinical professor of diseases of the ear at the Long Island College, Brooklyn, New York, aged 56; and Dr. S. K. Spalding, neurologist to the Omaha General Hospital and professor of nervous and mental diseases in the John A. Creighton Medical College of that city, aged 68.

Medico-Legal.

DUTIES OF GUARDIANS TO ENFORCE VACCINATION IN IRELAND.

THE Lord Chief Justice, Mr. Justice Madden, and Mr. Justice Boyd have given judgement in the King's Bench Division, Dublin, in favour of the plaintiffs in a case brought by the Local Government Board against the Letterkenny guardians for an absolute order for a writ of mandamus compelling the guardians to enforce compliance with the Vaccination Acts within their district.

The Lord Chief Justice, in giving judgement, said the subject of compulsory vaccination first came formally before the guardians on June 23rd, 1913, when a resolution was adopted that the matter should be left open, and that no prosecution should be instituted. To this course the guardians adhered except for a short period during the present year. The guardians had been informed that they were the final and ultimate tribunal to decide as to the enforcement of the provisions of the Vaccination Acts within their union; and the question for the court to decide was whether this was correct. The matter was regulated by the Vaccination Amendment (Ireland) Act, 1877. Section 7 provided for a penalty being recovered from parents having the custody of children who neglected to have them vaccinated. Section 10 provided that the guardians of any union in Ireland might direct proceedings to be instituted for the purpose of enforcing obedience to the provisions of the Vaccination (Ireland) Acts, and that the medical officers of each dispensary district should attend such proceedings, and be entitled to remuneration on a fixed scale for doing so. These provisions were put in force by nearly all boards of guardians in Ireland. The first question for the court was whether Section 10 was or was not mandatory in its operation. It provided, it was true, that the guardians "may" direct proceedings to be instituted, and the guardians contended that this language gave them a discretion in the matter. But it was settled law that provisions in a statute merely of a permissive character might impose a duty. His lordship cited some cases in support of this construction with the view to showing that it was well established and could not now be questioned. With reference to the present case, it was clear to his lordship that when the Legislature enacted that the guardians might take certain proceedings, and when it at the same time provided for the expense of the proceedings being paid out of the rates, it means to cast the duty upon the guardians of enforcing the provisions of the Acts in all proper cases. There was no one else to act in the matter, and if the guardians did not do so the Acts would become a dead letter. For these reasons his lordship was of opinion that the words "may" in the Act of 1877 was mandatory in its character, and that it was the clear duty of the guardians—a duty which could be enforced by mandamus—to take steps to enforce the compulsory provisions of the Vaccination Acts within their district. The powers of control and supervision vested in the Local Government Board over the guardians as regarded their duties under the Poor Law Acts might very reasonably be held to extend to the duty of enforcing the Vaccination Acts. He was of opinion that the Local Government Board had a *locus standi* to interfere where the guardians were not carrying out their duties under the Vaccination Acts, and was a proper relator in these proceedings. The conditional order for a writ of mandamus should therefore, in his opinion, be made absolute. As this was the first occasion upon which it had been decided in Ireland that the duty of enforcing the Vaccination Acts was mandatory upon boards of guardians, and as the Letterkenny Board of Guardians appeared to have adopted the course they did in the bona fide belief that they legally had a discretion in the matter, he did not think that they ought to be required to pay the costs personally. But he would like it to be understood that for the future, if the order of the court in the present case stood, guardians who persistently refused

to enforce the Vaccination Acts within their districts would do so at the peril of being obliged personally to pay the costs of proceedings to compel them to discharge their duty in this respect.

Mr. Justice Madden and Mr. Justice Hoyd concurred. The conditional order was made absolute, each party to abide their own costs.

IMPERSONATION.

The person charged as Henry John Herring at the North London Police Court on October 30th with feloniously giving false certificates of death, as reported in the JOURNAL of November 6th (p. 694) was on November 17th charged before the Common Sergeant with giving false death certificates relating to four persons, and also with bigamy. According to the statement of Mr. Bodkin, who prosecuted on behalf of the Director of Public Prosecutions, as reported in the *Morning Advertiser*, the accused had called himself "Edward Ken Herring, M.B., B.S.," and had personally Dr. Herring, who practises in New South Wales. He had acted as a locum tenens for doctors in London, Cambridge, and Lancashire. Investigation showed that the accused had formerly persecuted Dr. Hoffmeister, who practises in the Isle of Wight, and had been convicted in that name on a charge of manslaughter and sentenced to five years' penal servitude. Further inquiries elicited the fact that he had committed bigamy. Inspector Birch, giving details of the prisoner's career, said that since July, 1906, the prisoner, representing that he was a qualified chemist, had obtained situations at Brighton and at various places in or near London. The Common Sergeant remarked that the prisoner had been guilty of a very serious offence, and sentenced him to four years' penal servitude.

Universities and Colleges.

UNIVERSITY OF CAMBRIDGE.

The following degrees have been conferred:

M.D.—D. W. A. Bull, J. A. Nixon, F. A. Roper.
M.B., B.C.—W. G. Bigger.

UNIVERSITY OF LONDON.

The following candidates have been approved at the examination indicated:

THIRD M.B., B.S.—J. Fanstone, G. C. Linder, Edith Marjorie Hartland, A. Beal, Marion Mildred Fern, W. Burt, Dorothy Chick, J. N. Deacon, C. H. Edwards, Annie Mary Forster, Hilda Grace Johnson, Helena Rosa Lowenfeld, Mary Constance Poonen, G. J. C. Smyth, H. E. Thorn, Mary Woods.

* Passed with honours.

Honorary (War) Degrees.

On November 17th the senate awarded honorary war degrees to eighteen candidates. Of these, fifteen received the B.Sc. (four in engineering and one in economics). Two received the B.A., and one the LL.B. All the new graduates hold commissions or are in the ranks of the army.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.

Annual Meeting of Fellows and Members.

The annual meeting of Fellows and Members was held on November 18th. Sir W. Watson Cheyne presided.

Annual Report.

Some discussion took place on various items in the annual report of the Council. In reply to Dr. S. C. Lawrence, the President said that no action had thus far been taken with regard to removing the names of enemy aliens from the roll. On the subject of special measures to meet the anticipated scarcity of medical men in the future, Mr. George Brown suggested to the Council that it would be wise to return to the old custom of recognizing as part of the medical education of the student a twelve or eighteen months' pupillage with a general practitioner. This would form a better means of education than walking the hospitals, and any such method was preferable to the widespread introduction of women surgeons. The President said that a note would be taken of the suggestion.

Direct Representation of Members.

Dr. George Jones then moved the first of two motions before the meeting:

That this annual meeting again affirms the desirability of admitting Members to direct representation on the Council of the College, which, as now constituted, only represents those Members who also hold the Fellowship; and that it does so in order that the constitution of the Council of the Royal College of Surgeons of England shall be in keeping with modern ideas of true representation.

He said that for twenty-one years the Members had persevered in bringing forward a similar motion, but he wished to make one more direct and personal appeal that the false step represented by the Charter of 1845, which denied to Members their rights and privileges, should be retroactively null and no antagonism to the Council, but so long as the narrow franchise existed so long would there be a restless, dissatisfied body of Members.

Dr. M. I. Finucane seconded the motion, but refused to support the plea of *misericordiam* of the proposer. The

claim of the Members should be put forward not as a request, but as a demand.

On a show of hands, twenty-one voted in favour of the motion, which was carried *unanimously* and *contradictorily*.

Dr. J. Brindley James moved and Dr. Angus Hunt seconded: That this annual meeting requests the President to explain to those now assembled the views of his Council in regard to the representation of Members on the Council of the College.

After some further discussion, in which Lieutenant-Colonel Oldfield, Mr. George Brown, and others took part, this motion also was carried without a dissentient.

The President said that he feared that in any reply he had to make he would disappoint them. This question had been discussed by the Council repeatedly of late years. It was very far from having been disrespectfully shelved, and the members of the Council were quite sympathetic. The only question with which they were concerned was that of the interests of the College. The discussions in the Council had always resulted in a large majority favouring the opinion that to make any change would not be advantageous. The position was fully put forward in the annual report for 1907, and to what was then said he had nothing to add. The whole question turned upon the views entertained as to the function of the College. In the Charter it was defined as scientific and educational, but those who pressed these motions did not have in mind any improvement in the educational and scientific position; they wanted the College made into a political institution. For his own part he detested politics, medical and otherwise. It would be a mistake, in his judgement, to convert the College from a scientific and academic institution into a political one. The President's remarks, which were received with some expressions of dissatisfaction, brought the proceedings to a close.

SOCIETY OF APOTHECARIES OF LONDON.

The following candidates have been approved in the subjects indicated:

SURGERY.—H. M. Arnold, G. T. Baker, W. F. R. Castle, H. C. E. Clarke, W. Fox, L. S. Goss.
MEDICINE.—H. H. Lloyd, J. Remers, A. J. A. Wilson, F. H. Young.
FORENSIC MEDICINE.—E. V. Beaumont, M. J. Byrnes, J. Fox-Russell, B. Gubrial, G. P. K. Grey, W. J. May, J. Remers, A. J. A. Wilson, F. H. Young.
MIDWIFERY.—J. S. Bhajiwalia, M. J. Byrnes, C. G. G. Winter.
Section I. Section II.

The diploma of the Society has been granted to Messrs. L. M. Arnold, G. T. Baker, C. E. Clarke, L. S. Goss, and F. H. Young.

The Services.

EXCHANGE DESIRED.

TERRITORIAL CAPTAIN, Field Ambulance, wishes exchange with officer at Base Hospital.—Address, No. 5720, BRITISH MEDICAL JOURNAL Office, 429, Strand, W.C.

OUR BELGIAN COLLEAGUES AT HOME AND ABROAD.

The following additional subscriptions have been received:

Association of Medical Women in India (per Dr. Mary O'Brien): Dr. Muller, Dr. Shave, Dr. Balfour, Dr. Biobly, Dr. Benson, Mrs. D'Monte, Miss Melita, Miss N. Melita, Dr. Soares, Dr. Ambrose, Dr. Watts, Dr. Houlton, Dr. Blair, Dr. Birch, Dr. Pryor, Dr. G. G. Scott, Dr. Murphy, Dr. Harry, Dr. Mackellar, Dr. Umberstone, Dr. MacLaren, Dr. Lamb, Dr. Rukhmabai, Dr. O'Hara, Dr. Friend, Dr. Periera, Dr. Macmillan, Dr. Lockwood, Dr. Dodson, Dr. O'Brien, Dr. Scott, Dr. Grant, Dr. Graham, Dr. Babaduri, Dr. Gray	£. s. d.
Glasgow Eastern Medical Society (per Dr. C. Wallace Anderson)	5 0 0
Lieutenant-Colonel W. E. Scott Moncrieff	1 0 0
North Yorkshire Pharmacists' Association (per Messrs. Rankin and Horsland)	1 1 0
Subscriptions to the Fund should be sent to the Treasurer of the Fund, Dr. H. A. Des Voeux, at 14, Buckingham Gate, London, S.W., and should be made payable to the Belgian Doctors' and Pharmacists' Relief Fund, crossed Lloyds Bank, Limited.	

THE APPEAL FOR SURGICAL INSTRUMENTS.

Surgical instruments should be sent to the Master of the Society of Apothecaries of London, Blackfriars, London, E.C.

THE October number of the *British Journal of Surgery* contains a short biography of Cheselden, adorned with a reproduction of the portrait of that surgeon by Jonathan Richardson in the College of Surgeons. Mr. Sinclair White and Mr. J. H. Cobb publish in the same number an unusual case of hydatid disease, where it seemed that a kick from a cow caused the rupture of a hydatid cyst of the liver; a few weeks after the injury abdominal section was undertaken, and a laceration in the posterior surface of the liver detected and drained. Two years later a second operation was performed, and extensive hydatid disease of the peritoneum became manifest.

Medical News.

It is announced that the uniform of V.A.D. nurses of the British Red Cross Society and the Order of St. John of Jerusalem will be registered; initiation will be an offence under the Defence of the Realm Act.

The Long Fox Lecture will be delivered by Dr. F. Richardson Cross at the University of Bristol on Wednesday, December 1st. The subject is "The Evolution of the Sense of Sight." All medical men and students are invited to attend.

At a clinical meeting of the West London Medical-Chirurgical Society a number of cases were shown, and Dr. Alastair MacGregor described the Simpson light apparatus, and gave records of some cases treated by this method.

The American Twilight Sleep Association is said to be planning the establishment of a hospital in New York where the method will be applied by experts, and where medical practitioners may obtain instruction in its administration.

The Minister of Commerce in France announces that preference will be given to soldiers maintained in the war in the selection of letter carriers, and that men who have lost an arm may be employed in the proportion of 10 per cent. of all letter carriers in a district.

In a recent case the First Division of the Court of Session, Edinburgh, decided that the duty to make provision for the food, clothing, and lodging of mentally defective children rested upon the parish council and not upon the school board.

The *Times* reports that at Bow Street Police Court on November 22nd Mrs. J. E. M. Walter, of Defoe Road, Totting, was fined £40 with 10 guineas costs for attending women in childbirth otherwise than under the direction of a qualified medical practitioner, she not being certified in pursuance of the Midwives Act, and for failing to give notice to the county council that she had undertaken for reward the maintenance of a child under the age of 7. It was further reported that there was no doubt that the defendant had been carrying on a baby farm. The infants were sent away when they were only a few days old and farmed out to a confederate, to whom the defendant paid a small sum.

It is proposed to raise a memorial fund to perpetuate the memory of Dr. John H. Dauber, who lost his life in the sinking of the transport *Royal Edward* on the way to the Dardanelles in August, 1915. Dr. Dauber was for upwards of twenty years a member of the honorary medical staff of the Soho Hospital for Women, and for many years lecturer to the nursing staff, the theoretical training of the nurses being entirely in his hands. It is hoped to raise about £250 to institute a fund to be called the "Dr. Dauber Memorial Nurses' Prize Fund," and to use the income for prizes to members of the nursing staff for meritorious work in the wards and at examinations. Donations may be sent to the Secretary, Alfred Hayward, Esq., Hospital for Women, Soho Square, London, W.

The National Health Society holds training courses for women desiring to present themselves for the examination of the Sanitary Inspectors' Examination Board and for those who desire to obtain the diploma of the society, which is intended for health visitors, and is recognized by the Local Government Board under the Health Visitors (London) Act. The secretary of the society points out that hundreds of women trained by the National Health Society are already filling posts as sanitary inspectors and health visitors, but the demand for trained women is becoming daily more urgent. The society only desires to receive applications from well educated women, but the question of fees and the cost of living in London often stands in their way. The fees are 12 guineas for the inspectors' course and 15 guineas for the diploma course. An appeal is made for the establishment of scholarships tenable by candidates during their period of training, and also for funds to maintain a hostel. The society is undoubtedly doing good work, and great pains are taken to ensure that the training shall be thorough and practical.

At the meeting of the Central Midwives Board on November 18th it was resolved in reply to a suggestion from the Swansea District Nursing Association that during the war the number of personal deliveries incumbent on candidates for examination should be reduced on account of the decline in the birth rate, to state that the Privy Council had approved the Board's scheme for prolonging the training of pupil midwives to six months, which it was hoped would solve the difficulty. In reply to an inquiry from the M.O.H. Leicester, the Board

stated that according to Rule E.6 a midwife must (after a doctor has been sent for) "await his arrival and faithfully carry out his instructions," and according to Rule E.5 could not attend any other maternity patient without adequate disinfection; but for the doctor to dismiss the midwife because the patient was believed to have puerperal fever, and in the absence of proved neglect, was nowhere sanctioned by the rules. Generally speaking, it was other patients who had to be safeguarded from puerperal fever rather than the patient in question.

MUCH of the military work of the colony of Singapore is carried out by volunteers whose numbers were augmented after the declaration of war, but as the Government did not consider the response adequate, it passed a bill which required every British-born person to train as a soldier, allowing exemptions to be made in certain cases. We are informed that this exemption was not extended to medical men, who were required to drill with the others. We are also given to understand that there is a considerable shortage of British medical men at Singapore; many have joined the R.A.M.C., most of those who remain are doing extra work, and the Government has pointed out that they can best serve by sticking to their posts. The members of the profession had assumed that they would be asked to serve in the Volunteer Medical Corps, and seem to have been disappointed that they were expected to attend ordinary drills.

In a recent Chadwick Lecture, Mr. A. Saxon Snell, F.R.I.B.A., pointed out the desirability of putting a layer of concrete over the whole surface of the ground of the building of a temporary military hospital, otherwise in enclosed wards the ground air was bound to find its way upwards. The necessity was less if the building was raised a few feet above the ground, so as to provide a clear sweep for the air. He stated that the War Office model plan, which provides for a framing of timber, lined on the inside with plaster slabs and on the outside with corrugated iron, with roofs of the same material, was estimated to cost between £60 and £70 a bed. The cost of the open-air hospital at Cambridge and of the Canadian and Glasgow hospitals was about £25 a bed; the cost at Leicester, where the walls are of brick and the floors of concrete, was estimated at £15 10s. a bed for the ward blocks only.

POPE says that:

Index learning turns no student pale,
Yet holds the eel of science by the tail.

The "index learning" sneered at by the author of the Dunciad has with the advance of human knowledge in every direction become almost the only learning possible. As Salomon Reinach has said—a learned man nowadays is not so much one who knows many things as one who knows where to find information about them. The growth of periodical literature in which the fruits of new thought and research and new discoveries are first made known, and in which they are subjected to the fiery test of criticism, has been so vast, that not even a specialist can keep pace with the expansion of his chosen province without the help of the index maker. In this age of omnivorous reading the most methodical and industrious can scarcely note down references to everything he reads, and nothing is more annoying than to remember that one has seen an article containing something that would be useful for work in hand without being able to catch the elusive "eel" of fact, or date, or idea that is wanted. Therefore, we hail the index maker not as the "harmless drudge" Johnson would have called him, but as a recording angel. All serious students will welcome the announcement that the *Athenaeum* has undertaken, at the request of the Council of the Library Association, to issue a subject index to periodicals. The *Index for 1915* will comprise not less than 10,000 entries selected from nearly 400 periodicals, mostly of British origin. Nearly the whole of the indexing and editorial work is being done by the voluntary aid of British librarians: its appearance will be preceded by the publication of a series of twelve class lists dealing with various subjects of general interest, among which we are pleased to note that preventive medicine and hygiene find a place. These lists will be issued as quickly as possible before February, 1916, when, with additional matter, they will be consolidated in one alphabet to form the *Annual Subject Index*. Annotations will be introduced wherever the titles of articles do not seem adequately to indicate the nature of the contents. The publication of monthly indexes will be begun in 1916. Both the class lists and the annual volume will be provided with brief name indexes and lists of periodicals cited. Terms of subscriptions and all further information may be obtained from the Manager, *The Athenaeum*, Bream's Buildings, Chancery Lane, London, E.C.

Letters, Notes, and Answers.

Authors desiring reprints of their articles published in the BRITISH MEDICAL JOURNAL are requested to communicate with the Office, 429, Strand, W.C., on receipt of proof.

The telegraphic addresses of the BRITISH MEDICAL ASSOCIATION and JOURNAL, are: (1) EDITOR OF THE BRITISH MEDICAL JOURNAL, *Medical, Bradford, London*; telephone, 2631. (2) GENERAL SECRETARY AND BUSINESS MANAGER (Advertisements, etc.), *Articulate, Westrand, London*; telephone, 2630. (3) MEDICAL SECRETARY, *Mediscera, Westrand, London*; telephone, 2631. (4) GENERAL SECRETARY, *Mediscera, Westrand, London*; telephone, 2631. The address of the British office of the British Medical Association is 16, South Frederick Street, Dublin.

Queries, answers, and communications relating to subjects to which special departments of the BRITISH MEDICAL JOURNAL are devoted will be found under their respective headings.

QUERIES.

An officer recently serving in France, who has been much troubled by rias in billets and trenches, asks what effectual steps are practically possible to get rid of them. If any reader has practical experience of the use of a virus, or can suggest a good poison containing phosphorus or other ingredient, we shall be glad to hear from him.

Dr. ARTHUR KING (Winchester) raises the question whether, when after trophing a plainly palisating area covered only by sculp is left, a man should be advised that he is capable of undertaking ordinary duties. Does not this deficiency of bone, he asks, expose the individual to extra risks to life, or to failure in a sudden emergency?

INTERMISSION OF ASTHMA DURING PREGNANCY.

Dr. WESLEY WILSON (Hanley) writes: A chronic asthmatic—a woman, aged 35—had been in the habit of having continuous weekly treatment for this disease under the Insurance Act till about a year ago. On her reappearance last week she said: "I have been pregnant, and all the time I was carrying I was perfectly free from attacks; now they have begun again." Is this unusual?

WORK OF A SCHOOL MEDICAL OFFICER.

C. asks for advice on (1) the choice of a book on the duties of a medical officer attached to such schools as a large preparatory or public school; (2) the drafting of a case book suitable for the record of the routine medical examination of children in an orphanage.

(1) We know of no book that deals specifically and solely with the duties of a medical officer to a school. But there are many that deal with the whole subject of school hygiene, and of these there is the well-known book *Health at School*, by Dr. Clement Dukes (Livingtons, London, 1905), which deals particularly with the public school of the type that we are familiar with in England. The study of this book will show any careful medical reader the way his work should lie in the oversight and medical examination of children in such schools. It would be advisable also for the medical officer to join such a society as the Medical Officers of Schools Association (11, Chandos Street, Cavendish Square, London, W.). More than half the members of this society are engaged in public school work, and the journal issued by the society (*School Hygiene*) would prove of great value in his work. The back numbers are worthy of study.

(2) For the record of children's health in an orphanage some such schedule as that used by the London County Council Education Committee (L.C.C. School Medical Officer, 2, Savoy Hill, W.C.) would give a good basis on which to found a case book. Possibly the school medical officer of the county in which our correspondent resides uses a similar form, in which case it would be of interest to follow this scheme, so as to permit of correlation of the work in and out of the orphanage. If the inquirer is particularly desirous of correlating physical and mental characters he might take as his guide the schedule published by the Medical Officer of the Board of Education (Annual Report for 1913, page 321; Wyman and Sons, Fetter Lane, E.C., 1914). General experience goes to show that a card system is preferable to a case book.

ANSWERS.

TREATMENT OF CORNS.

E. G. R. writes to recommend a soft felt zinc oxide plaster now made by most of the plaster makers. If stretched across the sole of the foot it remains so comfortably for some days, and supplies a cushioning often lacking in these cases.

Dr. F. A. BRODIEB writes, in reply to "C. D.," to recommend the following treatment for corns: Soak the feet in hot water till sodden; then cut away all the hard skin till the base of the

corn is fully exposed, taking care not to make the corn bleed. Then rub in a little cocaine and thoroughly destroy the base of the corn with a caustic point. If this treatment is efficiently done the corn does not grow again.

LETTERS, NOTES, ETC.

TEN MINUTE TALKS TO MOTHERS.

In a pamphlet of twenty pages Dr. H. Cameron Kidd, the medical officer of health for Bromsgrove, has reprinted summaries of his lectures under the title of *Ten Minute Talks*, which he delivered in October, 1914, to a class of mothers, conducted under the organization of Lady Chavasse and Mrs. Paterson, and published in the *Bromsgrove Messenger*. The mothers must have benefited, for the advice given is practical and simple and easy of assimilation, and is drawn from the accumulated and large experience of twenty-seven years of general practice. All medicinal men may not, however, be found to agree with Dr. Kidd when he recommends the "daily painting of the nipples with spirit" for pregnant women in the last two months of gestation; some believe that such attentions rather increase than lessen the tendency of the nipples to crack later on. Should the author be tempted to make a hole in the back of his head, he will strengthen it by dealing a little more in detail with the expectant as well as the nursing mother.

FOREIGN PROPRIETARY DRUGS.

MR. HERBERT H. LONG (London, W.) writes: At the present time, when so many medical men are serving their country in the field, might I appeal to you to use your influence so that their fellow practitioners at home may be urged to second their patriotic efforts, if only in a small degree? As a West End pharmacist I am every day called on to dispense or supply glyco-thymoline, dioxigen, Phillips's magnesia, listerin, and a dozen other American or "foreign" proprietary orders or recommended by British medical men of repute. As a patriot I object—especially at this crisis—to contribute to the coffers of foreign manufacturers, more particularly as some of the "Americans" are probably of the hychenated variety. As a pharmacist of experience I fail to see any necessity for the majority of these alien proprietary. If British equivalents are available, either in the *British Pharmacopoeia* Code or elsewhere, what excuse is there for not making use of them? On the other hand, if the existing formulæ do not satisfy the prescribers, is it not in their province to publish others which do? It is useless for English manufacturing chemists to attempt to popularize "all-British" goods when the opposite policy is so consistently fostered by the medical profession, individual members of which would probably be the last to admit that they are grossly unpatriotic.

RARE BOOKS.

A MEDICAL man who is disposing of his library thinks it may interest some readers to know that among the contents are the following rare books: 1. *Lusus in Venere*, by Joannes Secundus of the Hague, Ramusio de Rimini, and others. Paris, M.DCCCXCI. 2. *Martial's Epigrams*, with a comment by James Elphinstone, London, MDCCXXXII. One cover loose. 3. *Suetonius's Works with Commentary*, by Samuel Pitseus, and indexes of editions, authors and subjects, portraits of Roman Emperors, and historical illustrations from ancient monuments. Second edition. Leuwarden, (C) 15 CCXIV. Two volumes, vellum. Good condition. 4. *Horace's Works*. Poetical Translation by Philip Francis. Seventh edition, four volumes. London, MDCCCLV. Vellum; good condition. 5. *Lucian's Works*. Greek Text, with Latin translation by Tiberius Hemsterhuis and Johann Matthias Gesner; scholia and notes by several commentators. Amsterdam, (C) 15 CCXLIII. Three volumes and separate index. Binding not in very good condition. 6. *Terence's Comedies*. Spanish translation by Pedro Simon Abril. Two volumes. Valencia, M.DCCCLXII. We understand that the vendor is open to an offer for these as separate books, or for the whole in one lot.

CHILBLAINS.

LIEUTENANT COLONEL G. H. YORSE, F.R.C.S.I., R.A.M.C., writes to say that he has found the application of phenol ointment (B.P.) a most efficacious remedy in cases of chilblain where the skin has broken.

SCALE OF CHARGES FOR ADVERTISEMENTS IN THE BRITISH MEDICAL JOURNAL.

	£	s.	d.
Seven lines and under	0 5 0
Each additional line	0 3 0
A whole column	10 0 0
A page	10 0 0

An average line contains six words.

All remittances by Post Office Orders must be made payable to the British Medical Association at the General Post Office, London. No responsibility will be accepted for any such remittance not so addressed.

Advertisements should be delivered, addressed to the Manager, 429, Strand, London, not later than the first post on Wednesday morning preceding publication, and, if not paid for at the time, should be accompanied by a reference.

NOTE.—It is against the rules of the Post Office to receive *poste restante* letters addressed either in initials or numbers.

An Address ON GAS POISONING.

READ BEFORE THE MEDICAL SOCIETY OF LONDON,

BY

LEONARD HILL, M.B., F.R.S.,

DIRECTOR, DEPARTMENT OF APPLIED PHYSIOLOGY AND HYGIENE,
MILITARY RESEARCH COMMITTEE.

THE reputation of the use of poison gases by the Germans in war does not lie so much in their actual use as in the fact that the German Government broke, in this as in so many other respects, their word, and secretly prepared before the war this method of offence.

All the propellants now in use set free enormous volumes of gases. The late Professor Vivian Lewes calculated that one of the 15in. guns on a super-dreadnought, with its charge of 400 lb. of cordite, gives off about 2,500 cubic feet of carbon monoxide gas each time the big gun is fired. In every battle hundreds of thousands of cubic feet of this gas must be produced, and yet so great is the diffusive power of the atmosphere that no poisoning from it can be traced. Nevertheless, carbon monoxide is a gas so poisonous that the breathing of 1 per cent. quickly renders a man unconscious. The high explosive nitre compounds such as picric acid and tri-nitro-tolul set free, when exploded, not only carbon monoxide but nitric oxide gas, and the latter when breathed has an irritative effect on the lungs closely comparable to that of chlorine.

The fumes of high explosives set free in close spaces, such as cellars and the interior of warships, where the ventilating power of the atmosphere is absent, may poison those who are not actually put out of action by explosive violence.

Gas poisoning, then, to a limited extent, occurred in modern warfare before drift gases and asphyxiating shells were introduced by the Germans. Much has been said of the suffering produced by gas poisoning, and truly dreadful to behold is the sight for breath of the strong man poisoned by chlorine; but we cannot suppose that the sum of suffering produced by gas is greater than that inflicted by shell wounds with the attendant sepsis, lockjaw, and permanent maiming of individuals.

There are poison gases which kill by cutting off the supply of oxygen—for example, nitrogen, hydrogen; these dilute the atmospheric oxygen below a viable amount—and carbon monoxide, which by combining with haemoglobin prevents the carriage of oxygen to the tissues. There are other gases like cyanogen, hydrogen sulphide, and hydrocyanic acid, which when breathed become absorbed into the blood and paralyse the respiratory centre. There is still another set of poison gases which acutely irritate the respiratory passages, causing exudation of lymph therein, which drowns the subject. This last set of gases the Germans have made use of, and for two reasons—first, because they put a man out of action when breathed for a shorter time and in greater dilution than any other poison gas; secondly, because they are heavier than air, and so suitable for drifting with the wind.

DIFFUSION IN THE AIR.

The molecules of gases, unrestrained by cohesion, are able to intermingle freely, and this diffusive process is very greatly quickened by convection currents set up by differences between the soil and air temperature, by currents due to evaporation of moisture, and still more so by winds and the eddies produced by the friction of wind against the soil. Owing to the immense ventilating power of the atmosphere, and the concentration of the poison gas required, the problem of effective use is very difficult. The drift gas must be considerably heavier than air, or diffusion will disperse it—gases intermingle at a rate which is inversely proportional to the square roots of their densities; it must not be too heavy or it will sink to the foot level; the wind must be of the right strength and direction; the gas must poison in a concentration of at least 1 in 10,000, or the quantities required will be unmanageable. It must be borne in mind that a man can hold his breath for at least half a minute, and that the poison gas cloud must therefore last long enough to

enforce breathing, and this breathing must continue long enough to put the man out of action. Owing fortunately to the enormous ventilating power of the atmosphere there is no reason to fear that Zeppelins will drop poison bombs on London. The German High Staff know perfectly well that no real frightfulness can be effected in this way. The scare about poison bombs which was prevalent in London some months back was unreasonable, and the public ought to have been warned against the purchase of respirators constructed to be worse than useless in a real emergency.

GERMAN EXPERIMENTS BEFORE THE WAR.

EXAMINATION of the back volumes of the *Archiv für Hygiene* shows that poison gases were investigated in Germany for years by Lehmann and his pupils from the ostensible point of view of making safe dangerous trades. From a critical survey of these papers the conclusion is inevitable that if any gases were used in warfare they would be chlorine or bromine. They alone come up to the requirements, namely: (1) that a 1 in 10,000 concentration rapidly puts a man out of action—by asphyxiating him, owing to its intense irritative property; (2) they are much heavier than air; (3) they are manufactured in huge quantities in trade processes; (4) they are easily compressible into cylinders for convenience of transport and handling. Moreover, a respirator is easily contrivable to protect the person who manipulates the brigade gas attack. It is obvious that no drift gas can be used offensively from which the users are unprotected. The density of the various asphyxiating gases which at first were suspected of being used are: sulphur dioxide, 2.21 times heavier than air; nitrogen peroxide, 3.17; chlorine, 2.45; phosgene, 3.49; bromine vapour, 5.53. The power of liquefying a gas by cold or pressure, or a combination of the two, enables the chemist to get into a convenient form large quantities of these asphyxiating gases, but the turning of these liquids back into gases may be troublesome because the heat withdrawn during volatilization may be so great as to freeze the nozzle and stop the outflow.

Special devices are required to produce the expulsion of the gas some distance in front of the trench and to prevent the retardation of flow by freezing. Sulphur dioxide irritates the eyes and air tubes in concentrations of 1 in 2,500; it is liquefied by a pressure of three atmospheres, chlorine by six atmospheres. Of the two, chlorine is a far more powerful asphyxiant, being unbearable in a concentration of 1 in 10,000. Nitrogen peroxide can be liquefied below 26° C. In comparison with chlorine, used in weak concentrations, it has a delayed irritative action on the lungs, and therefore, owing to its want of stopping power, is far less suitable for use. Firemen are sometimes exposed to fumes of nitric acid—for example, after the bursting of carbonyls; they are unaffected at the time but develop a fatal inflammation of the lungs during the next twelve hours. As the oxides of nitrogen play so important a part in the manufacture of explosives, it is unlikely that the peroxide should be used as a drift poison gas.

BROMINE.

Bromine vaporizes at atmospheric pressures and boils at 59° C. It is far heavier than air and as powerful an asphyxiant as chlorine. Germany produces almost the whole of the European supply. It has been said that certain bromine organic compounds have been extensively used by the Germans in asphyxiating and lacrimating shells. The vapours of these substances in concentration as little as one part in several millions of air are said to put a man out of effective action by causing watering of the eyes and inability to open the eyes, so specifically irritating are they to the conjunctiva. They are said also to cause in greater concentrations irritation of the respiratory mucous membrane.

CHLORINE.

Chlorine can be made very easily by heating a mixture of hydrochloric acid and black oxide of manganese, or by electrolytic processes. It can be stored in lead-lined cylinders. The gas above the liquid chlorine exerts a pressure of at least 90 lb. per square inch, so that all that the Germans required to project chlorine was a long tube projecting in front of the trench parapet and a valve. The spray turns into a yellowish-green vapour, and owing to its weight drifts with the wind along the ground. Any one who has watched smoke from a weed bonfire drift over a

could will see how far the chlorine vapour may be carried in poisonous concentration. It will sink into trenches, shell-pits, mine-craters, cellars, and dug-outs. To produce a concentration extending 10 ft. up of 1 in 10,000 during a period of ten minutes in a wind moving uniformly four miles an hour, over 1,000 cubic feet of gas are required for each hundred yards of front. This is leaving out of account diffusion and the ventilating power of the atmosphere. It is clear, then, how large a volume of gas is required for an attack, and how any gas which does not come up to the 1 in 10,000 standard must be ruled out.

LETHAL DOSES.

To estimate the lethal dose of chlorine or bromine special methods have to be devised because these gases combine very readily with the hair of an animal, turning this into a gummy substance. My fellow worker, Dr. Benjamin Moore, found that hair dissolved in bromine into a gummy red-black mass, from which the bromine could be washed away, leaving a white friable substance. This bromo-protein compound gave an intense violet biuret reaction, and on addition of strong nitric acid yielded up its bromine. The effect of 1 in 10,000 chlorine is such that no man would endure breathing it who could escape from its influence. The eyes and the mucous membranes of the respiratory tract are intensely irritated and a watery exudation takes place, the inevitable effort which the living tissues make to dilute so irritant a poison.

Effect on the Lung Structure.

Just as lymph is poured out after a superficial burn of the skin, or the application of a blistering fluid, or in a septic wound under the influence of bacterial toxins or antiseptics, so does chlorine produce an exudation of lymph in the lungs. The epithelial lining, both that of the mucous membrane and of the capillary wall, is damaged by the poison. The osmotic pressure of the damaged tissue is raised—the colloidal lining complex becoming killed and disintegrated with the setting free of crystalloidal substance. This fluid is pulled out by osmotic forces, while through the damaged capillary wall, too, the plasma may actually leak away. The classical first symptoms of inflammation thus appear, ending in stasis of the corpuscles in the capillaries owing to exudation of the plasma. In the earliest stage the salivary glands in the mouth and the mucous glands in the air tubes are stimulated to secrete, just as the tear glands flood the eyes. It is this pouring out of the fluid in a vain effort to ward off the poison which causes the asphyxial symptoms of chlorine poisoning and finally drowns the man. He is as surely drowned by the exudation as he is when he breathes water into his air tubes. The mucous membranes of the nose and mouth, wet with secretion, at first act as a protective respirator, catching much of the poison and preventing it entering the lungs. That this is so is seen by the greater celerity with which serious symptoms arise in an animal when chlorine is administered through a tracheal cannula instead of through the nose and mouth. It is a remarkable fact that while 1 in 10,000 is unbearable to breathe, and 1 in 100,000 is distinctly irritative, yet we find it takes a concentration of as much as 1 in 5,000 of chlorine dissolved in water to stop the movement of the cilia in a preparation of ciliated epithelium observed microscopically. Chlorine is much more toxic when it comes in contact with the moist living membrane in a gaseous state than when in watery solution.

Sir Edward Schäfer¹ has drawn attention to this. "From the chemical nature of chlorine," he writes, "it seems evident that its immediate action must be local. For it is scarcely possible to imagine that it can exist in the free state in such a fluid as blood, which contains many bodies with which it would immediately combine, and which would—unless it were introduced in immense quantities—at once render it innocuous." When 10 c.c.m. of Ringler's solution saturated with the gas were injected by Schäfer into the jugular vein of a rabbit, in a period of 20 seconds there occurred a quite temporary fall of blood pressure and increased depth of respiration. Only in one case when the same amount was injected rapidly and with, therefore, less perfect admixture of blood, did oedema of the lungs and congestion result in the pulmonary vessels, producing a fatal result. The irritative effect of the dissolved chlorine is spent on the blood, or the lung, the first tissue it comes in contact with. When inhaled the

chlorine spends its effect on the air passages and lungs, and we have no evidence that free chlorine or any poisonous chloro-protein complex is formed, which, conveyed by the blood poisons other tissues. Major Walter Broadbent,² in a note concerning nephritis following chlorine poisoning, says: "It looks as if in some cases the chlorine or bromine damages the lung epithelium so severely that it does not allow absorption into the general circulation, while in others the gas passes through the lungs without affecting them permanently, but then sets up an acute nephritis."

It is not possible to uphold this theory. Chlorine gas in every case expands its fury on the lungs. The nephritis, I believe, is due to the intense and prolonged dyspnoea and the struggles for breath. Albuminuria is a common result of the very temporary dyspnoea which athletes suffer in a race. It results in such case from the want of oxygen in the kidney, just as it does when the renal artery is temporarily occluded. It is, I believe, the want of oxygen which produces the increased acidity of the blood observed by Mr. Barcroft in a few cases of chlorine poisoning, including a dog experimentally poisoned by us. No doubt the products of the damaged pulmonary tissue, absorbed during the days subsequent to the poisoning, have a toxic effect, particularly as the damaged lung becomes infected.

SYMPTOMS.

We are told³ that a typical case on admission is cold with a subnormal temperature, conscious but restless, with pulse slow and full (except in the collapsed cases). The face is cyanosed, intensely so in many cases, and the expression strained and anxious. The posture varies. In some cases the patient sits propped up, with head thrown back, gasping for breath; in others, he lies on his side, with his head over the edge of the stretcher in an attempt to aid expectoration. The respirations are jerky and hurried, often numbering 40 a minute, and are associated with a choking cough, accompanied by a varying amount of frothy expectoration. With each inspiration the chest is expanded to its fullest, all the auxiliary muscles being brought into play just as in an asthmatical paroxysm.

This is the first or asphyxial stage, which, if the patient survives, gradually passes off after some thirty-six hours. Can we wonder that such long-lasting intense dyspnoea should produce nephritis, accompanied as it is with convulsive breathing which just maintains the cerebral circulation within viable conditions at the expense of the abdominal circulation? Major Broadbent records a case in which he believes a cusp of the aortic valve was ruptured in the struggles for breath.

"After the first stage the patient falls into a sleep, and awakes feeling much better. But after a few hours of comparative quiet symptoms of bronchitis begin to manifest themselves. In the majority of cases these are not severe"—because, no doubt, nearly all the severe cases die in the first stage. "In the cases which are kept alive with difficulty there is a frothy gaseous stage followed by intense bronchitis. The frothing gives place to greenish mucopurulent expectoration, consciousness to delirium, the temperature rises from subnormal up to 104° F., the pulse becomes of small volume, with its rate increased perhaps to 160, the respirations are less choking but more shallow, and number up to 70 per minute before death."

PATHOLOGY.

Post-mortem examination in the acute cases shows an intense congestion of the mucosa of the trachea and larger bronchi. These tubes are filled with a thin, light yellow frothy secretion, some of which escapes from the mouth and nose when the cases are first laid on the table. The fluid is highly albuminous, solidifying on heating. The larger bronchi only can be traced, the smaller being lost in a condition of intense congestion and oedema which affects the lungs as a whole. The lungs do not collapse in these acute cases, but appear like a solid cast of the thoracic cavity, and are greatly increased in weight. On incision, the lung tissue appears of a deep maroon red colour, and the exudation flows from the cut surfaces in abundance. Light grey patches are to be seen on the surface of the lungs amidst the congested areas. They were found to be due to emphysema. So intense is the obstruction to the entry of air, and so violent the efforts of respiration, that emphysema is produced in these least poisoned parts where air can still enter. We can picture how the violence

of the respiratory efforts, brought to bear on a relatively few small parts of the lungs, distends and breaks down the walls of the alveoli, expelling the blood into surrounding congested areas.

The parts of the lung tissue not affected by emphysema show the intense congestion of the capillaries, and many of the alveoli are seen filled with exudate which takes on the eosin stain. Into some alveoli red corpuscles escape; larger patches of haemorrhage may occur. The heart in these acute cases is congested, particularly on the right side. The stomach shows a condition of catarrh, the mucosa being covered with a thick yellowish mucus and haemorrhages being visible in the submucosa. These changes may conceivably be due to the swallowing of saliva and exudate from the nose and expectorated fluid in which chlorine is dissolved. The venous congestion of the stomach and other abdominal organs and of the brain is due to the asphyxial character of the death.

Experiments made on animals make quite clear the stages of toxic effect. Using bromine in concentration of 1 in 1,000 approximately we find that the mucous membrane of the windpipe, killed by the poison, may be stripped off by the violence of the respiratory efforts, so that drawn down into the large bronchi it forms a tree-like cast therein, suffocating the animal. Chlorine, in our experience, causes a greater exudation of fluid than bromine. Chlorine (1 in 1,000) breathed through a tracheal cannula may shortly cause in a cat such an exudation of fluid that it fills up the trachea. By compressing the chest many cubic centimetres of the fluid can be squeezed out of the lungs into a basin. It is a clear, serous liquid, containing plenty of coagulable protein. That this fluid drowns the animal may be seen by the relief which is given after squeezing it out.

Professor Schafer, experimenting with very high concentrations of chlorine gas—for example, 1 to 2 per cent.—has concluded that death is brought about by stasis in the pulmonary vessels. If this be so for the high concentrations used by Sir Edward, it is not so in the case of the weaker concentrations, such as are breathed on the battlefield.

We have put the matter to the test in two ways: (1) We manipulated the animal so that we could artificially respire one lung with pure air, the other with air containing chlorine. Recording the blood pressure we first of all proved that artificial respiration of either lung sufficed to maintain the circulation in undiminished vigour. We then gave air plus chlorine to the one lung, and observed the gradual production of congestion, oedema, and lessened expansion of that lung, leading to symptoms of asphyxia and failure of the circulation. On carrying out the respiration of the other lung with pure air we observed the complete and immediate recovery of the circulation. On now squeezing the fluid out of the first lung and changing the respiration to that we see that the circulation may continue, the asphyxia no longer being complete.

In the other set of experiments we had the co-operation of Dr. Kuno, of the Physiological Institute, University College, one skilled in the particular technique required. The circulation was confined by Dr. Kuno to the heart and lung preparation and the technical arrangements made so that the output of the heart could be measured at any period of the experiment. The thorax was widely open and the lungs exposed to view. On giving chlorine the first and immediate effect was a very evident diminished expansion, due, we thought, to contraction of the bronchial tubes. Congestion and oedema followed, appearing first in patches on the surface and then spreading; as these grew marked the blood became more and more venous; the output, it is true, was then diminished, but whatever stasis there was in the pulmonary vessels did not markedly affect it.

It is well known that a very large part of the pulmonary vessels can be ligatured and yet an adequate circulation be maintained through the remainder. A very small portion of lung suffices, too, to keep up the oxygen supply to the heart.

These experiments made clear to us how artificial respiration keeps alive the gas-poisoned animal. If fluid be forcibly squeezed out of the lungs of a chlorinated cat, struggling for breath, its condition is greatly improved.

If air is forced by artificial respiration into the lungs emphysema in places may be produced, but the heart is kept going.

SYMPTOMS AND LESIONS OF THE LUNGS IN EXPERIMENTAL ANIMALS.

Animals exposed to chlorine exhibit first of all profuse watering of the eyes and salivation; they make efforts to escape, and if the chlorine in the chamber is not mixed by a fan but sinks to the lower parts, they hold up their heads as high as possible to escape breathing the more concentrated lower stratum. The respiration soon becomes quickened, and then, as the oedema of the lungs and exhalation into the air tubes increases, the respiration becomes slower and laboured. The obstruction to the entry of air becomes great, and in consequence the lower ribs are drawn in with each inspiratory gasp. The mouth gapes open and a frothy secretion hangs round the orifices of nose and mouth. The whole effect of the animal is given up to breathing; finally, it falls over exhausted, the breathing becomes rarer and shallower, and it dies. If in the stage of laboured breathing the animal be removed from the poison, it generally dies during the next twenty-four hours, but may live longer to die within the next few days. One of our animals died as late as a fortnight after the exposure.

Examination of the lungs of those which die in the first twenty-four hours shows an intense congestion of the lungs; they are dark red in colour; a more or less solid oedema prevents their collapse on opening the thorax. The air tubes contain frothy exudation which, on cutting the lungs, exudes in large quantities. When the lung of a rat was kept in a covered dish it shrank like a blood clot, exuding serous fluid, till it floated in it.

The animals which die in the later days show more or less extensive patches of red hepatisation. Those parts of the lungs which were least poisoned appear relatively normal, but are more rosy in colour.

Microscopic examination was carried out on the animals poisoned by us by Professor William Bulloch. The sections show intense congestion and small haemorrhages in places, and an oedema which fills the hardened alveoli with an eosin-stained homogeneous coagulum, reminding one of the appearance of the thyroid alveoli filled with colloidal secretion. The coats of the arteries are enormously distended with exudate, giving a most remarkable picture. The epithelium of the air tubes is in many places detached. The animals die in the early stages from asphyxia, and in the later stages from pneumonia with consequent absorption of toxins and exhaustion.

In those animals which are less severely poisoned the laboured breathing gradually passes away; those that recover appear quite normal at the end of a fortnight. Their fur, which was made sticky, and looked, so to speak, burnt at the ends, becomes glossy again, the damaged hairs being shed. These animals, if killed during the process of recovery, generally show small pneumonic patches. The lungs seem very sensitive to further injury during the period of recovery; inhalation of chloroform may cause acute oedema, and drown the animal.

There seems no reason why recovery of the lungs should be any less perfect after chlorine poisoning than it is after bronchopneumonia. The damaged and shed epithelium of the air tubes can be replaced, and the pneumonic patches resolved by the absorptive action of the phagocytes, until repair is complete.

I have no evidence to offer as to the state of the lungs at any long period after the poisoning.

Irregular Distribution of Lesions.

The remarkable fact that some parts of the lungs are far more severely damaged than others requires an explanation. When chlorine of, say, 1 in 1,000 is driven into the lungs by artificial respiration, and the lungs are exposed and observed from the start, it is evident that the poison reaches and severely damages certain parts in the surface, while other points remain normal. In these experiments the current of air from the pump was driven through chlorine water and then passed into the windpipe. We must suppose either that the chlorine does not uniformly mix with the air, or that certain air tubes are shut up by contraction of the bronchial muscles, and so prevent the poison reaching the alveoli they supply.

There is no doubt that the first effect of concentration such as 1 in 1,000 is to cause contraction of the bronchial muscles and diminish the expansion of the lungs. Using enormously strong concentrations, Sir Edward Schäfer finds no evidence of such contraction—probably the concentrations he used rapidly killed the lining membrane of the air tubes, including the muscle. Some experiments conducted by F. J. Twort and myself on the oxygenation of the blood, in subjects breathing in a shallow way, suggested to us that parts of the lungs may then not be expanded, nor the blood oxygenated in these parts, and that the bronchial muscles may regulate to which part of the lungs the air goes on each inspiration. The results of our chlorine experiments seem to confirm this view.

TREATMENT.

Expulsion of Fluid.

For the severe cases of chlorine poisoning the one object of treatment must be that of getting rid of the exudation in the air tubes which is drowning the victims. Experiments on animals show that the frothy fluid can be easily squeezed out of the lungs and trachea by rhythmic compression of the thorax, and that the dyspnoea which is threatening life can be greatly, if only temporarily, eased by this means. Artificial respiration is reported to have given good results in several of the cases on which it was tried. It must be repeated as often as the dyspnoea becomes excessive. The case is recorded of one man, almost moribund, who was treated in this way on four successive occasions, and ultimately recovered. After squeezing out the fluid, air may be blown into the lungs by mouth to mouth artificial respiration to overcome the resistance of the froth in the smaller tubes and expand enough lung to keep the patient alive. It is true that emphysema may be caused by so doing, but if it is a question of just carrying a man through the threatened asphyxia, one cannot hesitate to get air into the lungs by these means.

I took over to Flanders an apparatus constructed by Messrs. Siebe Gorman called the "Vivator," in which there is a foot-pump which feeds a face-mask through a flexible tube. By each downstroke a measured volume of air or oxygen is pumped into the lungs, by each upstroke a valve is opened which allows the air to escape from the lungs by the elastic recoil of the thorax and lungs. With this apparatus respiration can be kept going in the collapsed or unconscious cases, the fluid now and again being evacuated by squeezing the thorax and by posture.

The inverted posture will help to drain out the fluid. I was told that several of the patients of themselves hung their heads down over the side of the stretcher or table, in order to aid their expectoration.

Emetics.

Emetics have proved very useful in giving relief to the less critical cases. Half a pint of salt and water or 8 grains of copper sulphate, followed by large draughts of lukewarm water, are recommended. A brush or the patient's finger put to the back of the throat will initiate the vomiting without delay. The act of vomiting is reported to cause the expulsion of a large quantity of the frothy liquid.

Oxygen.

Administration of oxygen relieves the cyanosis and improves the condition of the subjects.

Not only does the percentage of carbonic acid in the blood rise in the suffocative condition, but other acids such as lactic acid increase in quantity owing to the lack of oxygen. When the blood is oxygenated by breathing of oxygen these other acids do not appear, and the acid intoxication is therefore so far eliminated. Tests of the power to hold the breath show that a higher percentage of carbon dioxide can be borne when oxygen rather than air fills the lungs. To give oxygen to a man who is struggling for breath and needing to expectorate is no easy matter. It is difficult to get any kind of close-fitting face-mask tolerated. The ordinary clinical method of administering oxygen through an open funnel held near the mouth and nose is of relatively small value; nearly all the oxygen is wasted by escaping into the atmosphere; just at the period of inspiration the stream which reaches the

mouth and nose is not enough, so that the air drawn into the lungs is very slightly enriched. I have found the oxygen in my alveolar air increased by only 1 or 2 per cent. when oxygen was administered to me by a sister in a London hospital. If a loose kind of face-mask be made out of a towel, and the oxygen tube led under that, and the oxygen sent in sufficient stream to blow away the exhaled carbon dioxide, then 70 per cent. of oxygen can easily be obtained in the alveolar air. Down Bros. have made a transparent face-mask to my design, fitted with a curtain which drapes the face, by which oxygen can be effectively given on this plan, but not economically. A 20 ft. cylinder is soon blown away by these methods. To give oxygen economically a well-fitting face-mask, breathing bag, and cartridge for absorbing the exhaled carbon dioxide must be used. The subject breathes through the cartridge in and out of the breathing-bag, which is filled with oxygen from the cylinder as required. The cartridge is loosely packed with small pieces of caustic soda-coke: to prepare these the coke pieces are heated red-hot and dipped into strong caustic soda. They offer a splendid absorbing surface and no appreciable resistance to the breathing. The apparatus—made by Messrs. Siebe Gorman—I took over for use in Flanders. The difficulty in using such lies in keeping the mask over the face of a man who wants to struggle and expectorate. Oxygen breathed between the periods of expectoration will undoubtedly give him relief, and with the above apparatus a 20 ft. cylinder will give a supply lasting many hours.

Compressed Air.

Experiments on animals have shown us that compressed air relieves the dyspnoea to the same extent as oxygen does. On placing a patient in a medical air-lock, such as is used in compressed-air tunnel works, and compressing him to two atmospheres, he would breathe double the concentration of oxygen and at the same time would be able to expectorate and struggle as he pleased. The compression of the air when first applied would halve the size of the air bubbles in the frothy liquid which obstructs the air tubes, and this should give relief by lessening obstruction. Artificial respiration could be applied in the compressed-air chamber and the subject be kept in it for several hours, and then slowly decompressed. The medical locks are fitted with air-locks, through which the medical officer can enter or leave. The difficulty, of course, lies in the provision of such medical locks—heavy cylindrical boiler-like structures, each of which would hold only four or five patients, with the necessary oil-driven compressor engine. A small medical lock and engine would go on a 3-ton lorry, but it is a serious thing to hamper the transport of the army with such a provision. There is another way in which oxygen might be administered without the use of a mask, and that is by drawing over the stretcher containing the patient a cylindrical balloon, say 10 ft. by 4 ft., tying up the end, and then distending the balloon with oxygen.

Verapine, etc.

The giving of atropine has been extolled on the theory that it lessens secretion of fluid and dilates the bronchial tubes. In severe cases of poisoning we have not found it of the least service.

It is claimed that the inhalation of stramonium vapour from cigarettes relaxes the bronchial muscles; this may afford relief in the mild cases, which recover whether so treated or not.

CONCLUSION.

The chlorine poisoning of the lungs is comparable to extensive burns of the skin, and the same general treatment to support strength and lessen shock is required. Just as septic infection of the skin is the sequel of the burn, so pneumonia and bronchitis follow chlorine poisoning. In our experimental animals severe poisoning has in every case had this end, and we know of no means of preventing it. Warmth and good nursing might pull a man through these conditions are difficult to apply to animals.

THE TREATMENT OF GUNSHOT WOUNDS OF THE ABDOMEN.

BY

COLONEL A. W. MAYO-ROBSON, C.V.O., F.R.C.S.,
CONSULTING SURGEON, MEDITERRANEAN EXPEDITIONARY FORCE.

From June to the end of October, while serving in the Dardanelles, it has fallen to my lot to see a very large number of gunshot wounds inflicted by bullets, shells, shrapnel, and bombs, a considerable number being abdominal.

The greater part of my time was spent on various hospital ships anchored from half a mile to a mile from the various landings, my duty being to change from one ship to another as each in turn filled with wounded and steamed off to some base. Many of the cases—such as the efficiency of the R.A.M.C. service ashore—landed on the hospital ship within from two to four hours of being wounded.

At first we were influenced by the experiences of the South African war, which seemed to prove conclusively that opium, starvation, and rest in the Fowler position yielded better results in gunshot injuries of the abdomen than treatment by operation.

In my first six months spent in a base military hospital in London I could not but feel impressed by the absence of abdominal cases in our wards; the explanation is, of course, quite clear—the cases seldom, if ever, reached the base hospitals, as the wholesale expectant treatment was a failure.

In the beginning of this year, while serving with the French army in the Argoonne, I had the opportunity of seeing the treatment of these cases at the front in the field ambulances and hospitals. Owing to the Germans shelling the motor ambulances in the daytime, it was impracticable to collect the wounded until night, so that nearly all the abdominal injuries had been lying out in the cold and wet, sometimes in the snow, for several hours before they could be attended to, and I was told by the surgeons in the various hospitals that nearly all, whether treated expectantly or by operation, had given disappointing results.

It will be seen that at the Dardanelles we were much more favourably placed for the treatment of abdominal injuries, seeing that the cases as a rule were admitted early, and could be treated in theatres equipped for dealing with serious surgical cases. On shore the flies and dust and the general unrest were unfavourable factors; yet success attended operation in quite a number of cases otherwise hopeless.

After some little experience of the course of cases treated by opium, starvation, and rest, I soon came to the conclusion that we might be able to do more for these patients, since a very large proportion, especially of the shrapnel and shell wounds, ended badly. Judgement must be exercised as to the class of cases in which it is wise to operate; for instance, a clean bullet wound through the abdomen, with small wounds of entry and exit, and without evidences of internal hæmorrhage or extravasation, may, if favourably situated, be treated expectantly; whereas a bullet wound with large openings of entry and exit, or with signs of internal hæmorrhage or extravasation, and with absence of liver dullness, should be operated on as soon as possible if seen early and if the general condition is favourable.

As nearly all shrapnel, shell, and bomb wounds are septic and produce great visceral injury, operation will give a better chance of success than expectant treatment if the patient is in a fit condition to bear it and the case is seen early. If the case is seen late and peritonitis has already set in, a small incision above the pubes large enough for the insertion of a drainage tube down to the bottom of the pelvis, and the Fowler position, will give the patient a chance of recovery.

This treatment, by the way, is the best for typhoid perforation; I learnt this in France, where, in the large typhoid hospitals, a good proportion of cases are being saved.

As there are competent surgeons both on the hospital ships and in the hospitals ashore, it naturally follows that the greater number of cases are treated by them, the

opinion of the consultant being asked as to whether operative or expectant treatment is advisable.

The following cases, which, at the special wish of the operating surgeons, I personally operated on, will give some idea of the conditions for which operations may be required:

1. *Shell wound of abdomen* seen between two and three hours after injury; it had occurred shortly after the mid-day meal, the man having been summoned to repel an attack by the enemy as he was finishing his dinner. The wound was in the mid-line between the umbilicus and ensiform cartilage. On opening the abdomen the stomach, which was full of food, was seen to have a rent in its front wall of $\frac{3}{4}$ in., the posterior wall being uninjured. The gastric wound was closed with silk and the abdomen was wiped out with pads soaked in normal saline solution and then closed. The wound through the abdominal wall should have been excised, as it was ruptured and gave rise to some trouble, but the ultimate recovery was quite satisfactory.

2. *Penetrating wound of right side of abdomen with collapse owing to internal hæmorrhage.* The patient was seen within six hours of the injury. On opening the abdomen much free blood was evacuated and a large vessel in the mesentery was ligatured. The abdomen was closed after being wiped out with pads soaked in normal saline solution. The patient recovered.

3. *Shrapnel wound* low down in the caecal region, bleeding freely on admission, about four hours after injury. On opening the abdomen, a large wound was found in the caecum; the spermatic cord was divided and bleeding freely, and the bullet had passed through the bony pelvis into the buttock. The caecum, which was full of faeces, was cut off and the cord was used continuously in two layers, the cord was ligatured, the right testis removed, and a tube passed through the opening into the buttock. The abdomen was wiped out with swabs dipped in normal saline solution and closed around the drainage tube. The patient recovered.

4. *Bullet wound* through right side of abdomen below the costal margin. Liver dullness was absent and there was no effusion in the right loin when the patient was seen, four hours after injury. The abdomen was opened and visceral wounds in colon and duodenum closed by purse-string sutures. The right side of the abdomen was wiped out with pads soaked in normal saline solution and the wound closed. The patient recovered.

5. *Shrapnel wound* beneath left costal margin, free internal bleeding, and collapse. The patient was seen three hours after injury, on opening the abdomen blood gushed out and free bleeding was continuing from wounds of vessels in the meso colon, mesentery, and pancreas; all of these were immediately ligatured, and openings in the colon and in three loops of small intestine were rapidly closed by silk purse-string sutures, and after wiping out the abdomen with normal saline solution the wound was closed. Despite transfusion and saline injections, the patient died of shock and collapse a few hours later.

6. *Bullet wound* in epigastrium, passing through the abdomen and out near the spine. This case was seen about four hours after injury with free blood in the abdomen. On opening the abdomen the bullet was found to have passed through the liver, stomach, and pancreas, and the latter was bleeding freely. The vessels in the pancreas were ligatured, the openings in the stomach were closed with purse-string sutures, the liver bleeding having stopped from pressure with a pad of gauze. The abdomen was wiped out with normal saline solution and the abdomen was closed. He made an uninterrupted recovery.

7. *Bullet wound* through right side of abdomen and bladder. The abdomen was opened. No visceral wound was found except that of the bladder, which was drained above the pubes. The remainder of the wound was closed. The patient recovered.

The above cases are, I think, sufficient to establish the views I have advocated: that operation in gunshot injuries of the abdomen is well worthy of consideration if the case is seen early and if the patient is in a fit condition to bear it and in fit surroundings.

Besides the cases I have related, there are many others in which I have assisted or advised in operations on gunshot abdominal injuries, but I prefer to limit my observations to those cases for which I was personally responsible.

Besides gunshot abdominal injuries, I also operated on several acute appendix cases, in two of which there was general peritonitis, and in a case of peritonitis due to rupture of a large liver abscess. These cases recovered, showing that the means for treatment and subsequent nursing on the hospital ships is so satisfactory that I feel every confidence in advocating a more frequent resort to abdominal section in the class of cases such as those I have briefly reported.

The late Dr. Dudley P. Allen, formerly professor of surgery in the Western Reserve University, has bequeathed the sum of £40,000 as a permanent endowment fund for the Cleveland Medical Library.

FIELD AMBULANCE WORK AT ANZAC.

BY
C. MACKIE BEGG, M.D., F.R.C.S., M.R.C.P.E.,
LIEUTENANT-COLONEL N.Z.M.C.

It may be of interest to your readers to have a short note on the special difficulties and dangers which beset field ambulance work in the duties such a unit has to perform at Anzac.

The facts that all work had to be carried out under continuous shell and rifle fire, that the country is exceptionally rough and precipitous, and that no roads, and consequently no transport except hand carriage, is possible, render the role of the field ambulance uniquely difficult and dangerous.

We soon found that the protection afforded by the barricades of equipment was illusory, as shrapnel bullets came freely through the roof, and finally a shell came through a stationary box and burst inside the dressing station. We then built up the walls with sandbags to the height of about 7 ft., and by breaking up the shattered boats of the first landing party we got enough wood to cover in part of the roof; over this we heaped earth to the depth of about 9 in., and so made a dressing station that was proof against shrapnel bullets but, of course, useless against a direct hit.

We built in the same way other shelters, and after a lot of hard work and improvisation succeeded in making fairly safe cover for sixty stretcher cases. As the cases usually arrived at the beach within an hour or two of being wounded, and as the naval service for evacuating to the hospital ships was so good, no operations, except for the arrest of hæmorrhage, were done on the beach at this time. About fourteen days later, however, on making inquiries at the hospital ships, we found that the results in abdominal wounds were extremely bad. Whether the cases were treated by operation or otherwise seemed to make very little difference. At this time, also, the weather became rougher, and it was often impossible to get the wounded off to the ships at all without considerable delay and knocking about. In these circumstances we determined to erect an operating tent on the beach and try treatment ashore unless the conditions for evacuation were very favourable. From this time till June 16th we operated on almost all cases of penetrating abdominal wound, and kept the patients on shore from twenty-four hours to four days afterwards. The conditions for operating were good, except for shrapnel fire, to which the operating tent was quite exposed. The beach in front was shingly, so there was very little dust.

We found in about 60 per cent. of the cases operated on that the condition was almost hopeless, whether the wound was caused by bullet, shrapnel, or shell fragment. As a rule, the gut was perforated or torn in from seven to twenty places, and several of the mesenteric arterial branches were usually torn across. With shrapnel there was nearly always extensive destruction of tissue round the perforations, so much so that it was usually necessary to resect portions of gut. Most of these cases died in a short time, but a few of them we sent off to the ship some days later in a surprisingly good condition. About 25 per cent. of cases gave good hopes of a favourable result. In these—almost all bullet wounds—two or three clean perforations of the small intestine or stomach were found. These were easily and quickly closed and promised to do well when evacuated. In a few of them no wound of the viscera could be found, though the missile had certainly traversed the peritoneal cavity, usually from side to side. The remainder of these abdominal cases arrived in such a hopeless condition that nothing was done.

We operated on a considerable number of head injuries, principally depressed fractures and ruptured middle meningeal arteries. Of these last we saw a good number, one of which was especially interesting.

A private was brought in showing typical signs of compression of the brain. No wound could be discovered on the head till after it had been shaved. A small spot on the left side of the scalp, over the site of the middle meningeal, was all that could be found. A probe could be passed into this down to the bone, so we decided to turn down a flap and examine the skull. There was a tiny perforation of the skull, and on removing a disc of bone

we found a large clot pressing on the brain and hæmorrhage from the middle meningeal artery. Lying embedded in the dura was a small fragment of steel about half the size of a grain of rice. Speaking afterwards to the man who was beside him in the trench, I discovered that his bayonet had been struck by a bullet and shattered. Evidently a small piece had struck him on the head, but one would hardly have expected such a small fragment to have had sufficient momentum to do so much damage.

The immediate results of operation in these types of head injury are good, and most of them will recover. What the after-results are to be time will show. Most of the head wounds received in the trenches were inflicted at short range, and were very severe. In a large number the whole calvarium and contents were blown right off just as if they had been removed by a saw.

In nearly all cases of long range bullet wounds, which the bullet lodged it was completely reversed—that is, the point was towards the wound of entrance. Some clips of Turkish cartridges were discovered with the bullets reversed, but in the majority of cases the bullet apparently turned over immediately on striking. The nickel coating of the bullet is very thin, and sometimes it bursts and is found two or three inches nearer the wound of entrance than the lead.

Owing to the position of the operating tent, and to the fact that a very large number of men were wounded on the beach within a few yards of it, we were often able to have a man on the table within a minute of the time he was hit. In this way we saved, by ligation of vessels, a good many who otherwise must inevitably have died. One man, struck by a shrapnel bullet near the door of the operating tent, had his jaw broken on the left side, the bullet passed the base of his tongue, and lay under the skin over the sterno-mastoid on the right side. A hæmatoma immediately commenced to form on the right side of the neck, and continued swelling rapidly, just like a toy balloon being blown up. We cut down immediately on the carotid, and found both the facial and lingual arteries cut close to their origin. These were ligated, and he made a speedy recovery. Dyspnoea had been very urgent, and but for immediate assistance he must have died from suffocation.

After cases left the shore it was impossible to get any news as to their progress. They were distributed through the hospitals of Egypt, Malta, and Britain, and could only be traced by a persevering search of the records. Some way by which the results of a particular line of treatment could be traced, and the information made use of, would be the greatest assistance to the medical officers who have the responsibility of early treatment.

The conclusions we draw from our experience of abdominal wounds are:

1. Early operation if conditions are favourable and the operator is experienced in abdominal surgery. By early operation is meant any time up to six hours.
2. Rest at the place of operation for three or four days afterwards.

If these conditions are not available operation is contra-indicated, and ordinary medical treatment must be adopted. In this event, however, our experience would indicate that with Turkish bullets, shrapnel, or shell wounds the results are extremely bad.

By June 26th the operating tent was riddled with bullets and a number of the orderlies and patients had been hit, so we came to the conclusion that cases, and incidentally ourselves, ran so much risk of further injury that operative procedures in the tent were unjustifiable. We set to work to excavate a room underground, as timber was now available, and by the evening of June 26th had an operating room fitted up and lighted with acetylene gas. We considered this comparatively safe, but at 5 a.m. the next morning a 4.7 high-explosive shell penetrated and wrecked it. The beach being enfiladed from both ends, we decided we would have to seek safer quarters for the patients, so we moved up as close as possible to the Turkish trenches. We found a suitable spot protected from bullets by a fold of the ground. It was too close to the Turkish lines to be shelled from long range, and the only discomforts were an occasional sprinkling of shrapnel from a premature burst and a few lumps of iron from high explosives dropping on the cliff

above. Here operations were out of the question owing to the dust and flies. The mules were quartered in a gully close by, and the plague of flies was quite beyond description.

As very many of the men had artificial teeth, and these were constantly getting broken or lost, it was necessary that some steps should be taken to stop the wastage of men from this cause. We had a dentist attached to the ambulance, so we sent to Egypt and got a complete outfit for making dentures. In a small dug-out beside the dressing station the dental officer, with two mechanics, kept the teeth of the whole division in repair, and also made new dentures for those who required them, either from loss or breakage of teeth. The biscuit was so hard that artificial, or sometimes even natural, teeth were liable to injury.

In conclusion, I would like to make quite clear that, so far as we could see, the Turks did not deliberately fire at the medical personnel. The position we occupied on the beach was such that we could not expect to be spared. Indeed, for the greater part of the time we flew no flag, being of opinion that to do so was unjustifiable owing to the proximity of various points of military importance.

The tons of wounded going off to the hospital ships and the hospital ships themselves were never shelled. Only once to my knowledge was a tow of wounded fired on, and that was by a machine gun which was presumably manned by Germans. This incident occurred immediately after a successful attack in which the Turks had lost very heavily and it was not repeated.

THE RECRUIT'S HEART.

BY

SIR JAMES MACKENZIE, M.D., F.R.S.,

LECTURER ON CARDIAC RESEARCH AT THE LONDON HOSPITAL.

After the outbreak of war numbers of young men were sent to me for my opinion, as they had been rejected for the army because of some affection of the heart. Most of them were perfectly healthy, and their rejection was due to the presence of some manifestations, physiological in character, which the medical examiner had taken for a sign of disease. I drew up a memorandum embodying the more prominent signs which were liable to be misunderstood, and giving in brief compass simple methods for differentiating the manifestations of a healthy heart from those due to disease. As I was desirous, like every other man, of contributing what little my special knowledge might help the common cause, I submitted this memorandum to the head of the medical staff at the War Office, scarcely daring to hope that any notice would be taken of it. It came, therefore, as a surprise when Sir Alfred Keogh suggested the issuing of the memorandum to the medical examiners of recruits.

In the memorandum I had endeavoured to give, in clear and concise language, the results of long years of careful investigation, because in the circumstances any more elaborate statement would not be likely to receive much attention. Many people have told me that they have found this memorandum of the greatest service, but others have criticized, and in doing so have contrived to muddle up that which I tried to make clear. Under ordinary circumstances I should not have taken notice of these criticisms, because it was evident that the critics neither understood the grounds on which the statements in the memorandum were made, nor appreciated their practical significance. But in the *JOURNAL* of November 20th (p. 744) Sir James Fowler has felt called upon to muddle up things still more, and as he occupies an official position connected with the War Office, and it seems that doubtful heart cases are referred to him, his remarks call for notice.

In dealing with his comments I must go outside the subject under immediate discussion, and show that Sir James Fowler's views are not based on observations that really bring the essential facts to light.

The manner in which I acquired the information which is summarized in the memorandum was as follows: When I entered general practice in 1879, I did so with the airy confidence of the young man fresh from the medical school imagining that I was well equipped for my work.

In a very short time I realized that I was ignorant of the very essentials of my work. In heart work, like other young men, I flattered myself on my cleverness with the stethoscope in detecting and naming all sorts of murmurs, but when it came to telling their significance, I was completely at fault. I turned to my books for instruction, to find that this very essential knowledge had been ignored. Realizing my ignorance of the meaning of the simplest symptoms, I set myself the task of finding them out.

To do this, I took careful note of my patients who presented any abnormal sign. I carefully differentiated each phenomenon from allied conditions. I noted all associated phenomena. I kept a large number of people under observation, watching them for a great many years, noting how they bore themselves through the strain and stress of life, in their labours and in their illnesses. As years went on, I found it necessary to seek other methods of investigation, and had to devise them. In this work I followed a large number of individuals for ten, fifteen, twenty, or even thirty years to find out the significance of some sign.

I was continually analysing my results and testing my conclusions, so that, at last, out of all this work, some clear issues were perceived. I was able to recognize why certain people with murmurs and irregularities enjoyed perfect health and lived laborious days with no sign of weakness; I was able to recognize also why others drifted to death or lived in a state of impaired health; in other words, I was able, in a great many cases, to make good that deficiency in my education, and was able to estimate the value of many signs and symptoms. I am still engaged in this work, for every day I realize my ignorance.

I want each reader who is capable of reasoning to consider the meaning of the methods I pursued. Knowledge in medicine is not limited to the perception of an abnormal sign, nor to the detection of its cause, but should include the knowledge of what effect the cause of an abnormal sign has on the individual's future life. Every reasonable person must accept that as a prime necessity in a physician. By what other means than that which I adopted could this necessary knowledge be acquired? It is because physicians do not adopt these methods that the profession is absolutely ignorant of the prognostic significance of any sign that may be present for a long period of years.

Compare the method I adopted to acquire a knowledge of the meaning of symptoms with that of Sir James Fowler, as recorded in his article in the *JOURNAL*. At the time he wrote this article (twenty-five years ago) he was placing on record the basis of a belief which has apparently been his guide up to the present. The article itself is characteristic of the writings of that period—vague, immature, insisting on the immaterial, and neglecting entirely the essential. It is evident from the fact that Sir James Fowler now quotes this article that he is aware of the great advance that has been made during the last twenty-five years in affections of the heart.

To bring clearly before the reader the futility of Sir James Fowler's conception, let him consider what is the essential question which the doctor has to answer when the individual presents himself for examination—the recruit for instance. A great many people do not realize what this essential is. If a murmur is detected, the essential question is, What bearing has the cause of this murmur on the recruit's future? Or, more precisely, Does this murmur indicate heart failure or does its presence foreshadow its occurrence? These are really the imperative questions (directly asked or implied) demanded from every medical examiner.

If the reader will turn to Sir James Fowler's article and take that portion written in his youth, or the whole matter with the comments added in his maturer years, he will find that he can get no suggestion of help to answer these essential questions, nor is there the slightest indication how the value of a murmur should be estimated.

As illustrating how firmly established is the superstition that a heart to be normal must be free from murmurs and irregularity, I cite two recent cases, not by any means exceptional.

In August, 1914, a lad of 19 was sent to me by his doctor with the statement that he had been rejected for the

army because of valvular disease of the heart. I examined him, found his response to effort good, the heart normal in size, and a well-marked systolic murmur at the apex. I gave him a certificate saying that the heart was perfectly healthy, and that the murmur was physiological, indicative neither of disease nor impairment. I told him to take this certificate to some other recruiting centre than that at which he had been rejected. This he did, was accepted, joined the army, went through his training, carrying his pack and enjoying his route marches. In course of time he was in Gallipoli in the trenches leading a strenuous life and feeling fit. One day in Maya shell exploded near him and he was blown over and became unconscious; he was picked up and taken into hospital. After he recovered consciousness he felt quite fit, but, unluckily a medical officer auscultated his heart, detected a murmur, and at once diagnosed valvular disease of the heart. He was kept on his back for a considerable time, shifted from hospital to hospital, repeatedly examined by medical men, and given treatment, till finally he was examined by a Board in August, 1915, and invalided out of the service because of valvular disease of the heart. He called to see me a few weeks later: the heart was exactly in the same condition as it was a year before, normal in size, with a physiological murmur, as found a heart as there is in the British army.

A short time ago a highly placed medical official brought his son to see me, as the lad suffered from irregular heart which was resistant to treatment. I found the irregularity to be of the youthful type, and I explained very minutely to the medical official that the irregularity was purely physiological, and I demonstrated to him by what means I separated this form of irregularity from all others, and told him how it was frequently present in the most healthy hearts. A week later he wrote asking me if I could not give him some drug, such as digitalis or strophanthus, to remove the irregularity, as it still persisted. I again wrote, clearly explaining that the condition was a purely physiological one. Nevertheless, he replied that he himself had given the lad a tonic which he hoped might "cure" the irregularity.

NOTE ON

A SUPPOSED SOLUBLE TOXIN, PRODUCED IN ARTIFICIAL CULTURE BY THE BACILLUS OF MALIGNANT OEDEMA.

BY

G. BARGER, M.A., AND H. H. DALE, M.D.,

D.Sc.,

F.R.S.

(From the Department of Bacteriology and Pharmacology, Medical Research Committee.)

SOME months ago we made some experiments on the nature of a toxic substance occurring in the filtrates from cultures of the bacillus of malignant oedema, an organism which has acquired special importance during the war, as being one of the spore-bearing anaerobic bacteria concerned in the production of gas gangrene from soil-infected wounds.

Our observations were limited to the cultural filtrate from one particular strain, for the culture of which, as well as for a quantity of the reputed toxin, with which many of our experiments were made, we are indebted to Mr. J. B. Burton, F.R.C.V.S. The strain was originally obtained from a case of gas gangrene, and its correspondence in all diagnostic points with the true bacillus of malignant oedema has been confirmed by several bacteriologists. From the muscles and areolar tissue of guinea-pigs dying of infection with an organism of this type Roux and Chamberland expressed a juice which, after sterilization by filtration, killed other guinea-pigs with acute convulsant symptoms. Besson prepared a similarly toxic filtrate by growing the organism on sterilized meat, which the digestive activity of the organism rapidly liquefies. The filtered juice of a five or six days culture kills non-flesh guinea-pigs with acute symptoms in a dose of 3 to 5 c.c.m. given hypodermically. It is a juice of this kind which has been regarded by Besson and others as containing a characteristic toxin produced by the organism, and attempts have been made to prepare an antitoxic

serum by immunizing animals against it. A broth culture of the organism, however abundant the growth, will not yield a filtrate of such potency.

The material used by us was obtained by growing the organism for five to six days at 37° C. on minced ox-heart, previously sterilized in the autoclave. The culture was started in hydrogen and provision made for the escape of gases, which the culture soon produced in abundance, by a tube leading from the cultural jar into a trap filled with sulphuric acid. The semifluid, evil-smelling product was filtered first through paper-pulp, and then through a Berkefeld candle. A nearly clear brown filtrate was obtained.

This filtrate produced the acute intoxication described by Besson when injected into guinea-pigs, the fatal dose for an animal weighing about 300 grams varying from 3 to 5 c.c.m. with different preparations. It was at once evident, however, that its toxic constituent had none of the characteristics of a true bacterial toxin. The relatively large volume of the filtrate required for the production of general symptoms and the almost immediate onset of the symptoms, when the dose was sufficient to produce them at all, suggested rather the non-specific action of some product of putrefactive digestion, and the necessity of using solid meat as a culture medium was suggestive in the same direction. The suggestion was confirmed by the observation that the toxicity of the product was but little affected by brief boiling. Dr. Walpole filtered the fluid under pressure through a collodion film, which was impervious to diphtheria toxin, and the filtrate showed the full toxicity of the preparation.

The symptoms produced are both local and general. Locally a large, oedematous, haemorrhagic infiltration is produced in the subcutaneous tissue and underlying muscle, in a considerable area surrounding the site of injection. With a non-fatal dose this local effect may be the only one, except for a vague malaise. To the general intoxication small guinea-pigs are much more susceptible than larger ones. Thus 3 c.c.m. may cause the death of a guinea-pig weighing 200 grams in 10 to 15 minutes, while 6 c.c.m. of the same preparation may cause little more than a local infiltration in a guinea-pig weighing 400 grams. The general symptoms comprise tremors, weakness, and excitability, rapidly passing into extensor convulsions, which usually terminate in death within fifteen minutes of the injection. *Post mortem* the lungs are found to be oedematous, with areas of haemorrhagic consolidation, and the trachea contains a blood-stained froth.

Though the toxic principle resisted brief boiling, it was rapidly lost if boiling was prolonged, and no concentration of the activity could be effected by evaporation, even at a low temperature and under diminished pressure. The toxic substance was evidently very unstable, or highly volatile. Omitting experimental details, we may say at once that we found that the toxic substance could be distilled readily from the fluid if the latter was made alkaline, and could be collected in acid; but that it was held back if the fluid was made acid to Congo red with sulphuric acid. We were dealing, therefore, with a volatile base. We accordingly made a quantity of the "toxin" alkaline with excess of potash and distilled into normal sulphuric acid. The quantity of volatile bases obtained was surprisingly large. From 150 c.c.m. of collodion-filtered "toxin" we obtained volatile bases neutralizing 113.2 c.c.m. of normal sulphuric acid. The mixed sulphates, obtained by evaporation of the distillate, were exhausted with absolute alcohol, in which ammonium sulphate is even less soluble than ammonium chloride. From the part insoluble in alcohol, consisting of ammonium sulphate, we obtained ammonia equivalent to 96 c.c.m. of normal H₂SO₄; the organic bases, with sulphates soluble in alcohol, were therefore equivalent to 17.2 c.c.m. of normal acid. The "toxin" was therefore 0.64 N. in respect of ammonia, and 0.115 N. in respect of other volatile bases. The alkaline residue left after distillation contained large amounts of soaps, and from these, by acidifying and distilling with steam, we obtained volatile fatty acids in quantity corresponding to a normality of 0.75 in the original fluid. This accords with the observation that the "toxin" has but a feebly alkaline reaction.

The question of practical interest was the identification, among the volatile basic constituents, of the toxic principle.

A few experiments showed that the ammonia fraction was entirely responsible for the symptoms produced, and that pure ammonium salts, in dose and concentration equivalent to those of the ammonium salts in the "toxin," produced all the effects described, both local and general, in perfectly characteristic manner. Young guinea-pigs showed, in proportion to their weight, the same excessive sensitiveness to the general, convulsant action of ammonium salts as to those of the toxic culture-filtrate. Neither the organic bases, in the proportion present, nor the fatty acids contributed materially to the effect.

There seems, then, to be no ground for supposing that the bacillus of malignant oedema, in an artificial culture of the type described, produces anything in the nature of a specific toxin. The production by it of a toxic solution from meat depends on its intense proteolytic and desaminating action. The proteins are rapidly broken down to amino-acids, and from these the amino-groupings are then split off, yielding ammonium salts of fatty acids, which accumulate in surprising concentration. To these must be attributed at least the greater part of the acute symptoms produced by the culture-filtrate in the guinea-pig; though doubtless intermediate products of proteolysis may play some part, especially in the delayed death which sometimes follows recovery from the immediate acute symptoms.

The chief interest of the observation seems to us to be the hint it furnishes as to one of the factors favouring spread of infection with the bacillus, in the tissues of an animal in which it has once obtained a hold. It is well known that with washed spores, or even with a broth culture of this organism, it is practically impossible to produce an experimental infection. Some local tissue injury is needed to give the infection a chance of success. This may be mechanical injury, as by contusion of tissue, or irritation by soil particles; or chemical injury, as by lactic or acetic acid. Among such chemical injuries we may now, with some reason, include the effect of the toxic juice formed by the bacillus from meat, which is essentially that of a strong solution of ammonium salts. Given injured tissues in which the growth may start, it is evident that the localized production of ammonium salts will soon be sufficient to create in the neighbouring tissues conditions favouring the spread of the growth, which may then go on indefinitely.

As to how far the production and absorption of ammonium salts, from a large area of infected tissue, may play a part in the general symptoms attending such an infection, we are not in a position to express any opinion. Nor have we studied the production of ammonia in culture by other members of the group.

We hope that these points may receive attention from those who are studying the effects of this group of organisms in the laboratory or at the bedside, and that this publication of observations, so unexpectedly simple in their outcome, may at least save others the trouble of a similar investigation. Our conclusion should, further, make clear the futility of attempting to obtain an antitoxin to the products of the organism with which our observations deal.

Lister Institute of Preventive Medicine, November, 1915.

THE ANTISEPTIC ACTION OF HYPOCHLORITES:

THE ANCIENT HISTORY OF THE "NEW ANTISEPTIC."

BY

H. D. DAKIN, D.Sc., F.I.C.,

OF THE BERTHOLLET LABORATORY, NEW YORK.

The "new antiseptic" announced in the *Times* of August 8th, and subsequently by many other newspapers, was discovered in 1788 by the French chemist, Berthollet.¹ He obtained a liquid with bleaching and disinfecting properties by the action of chlorine upon aqueous alkalis. The composition of the mixture was obscure, but Berthollet presumed that additive compounds were formed between the halogen and alkali—for example, Na_2OCl_2 .

Berzelius in 1808 expressed the view that the product formed was a mixture of a salt of an unknown acid of chlorine with sodium chloride. The discovery of this acid

—hypochlorous acid—in 1834 by Balard² definitely settled the composition of Berthollet's fluid as a mixture of sodium chloride and sodium hypochlorite.

Four years after Berthollet's discovery—that is to say, in 1792—the corresponding potassium salts were made commercially by Percy at the Javel works near Paris by passing chlorine into crude potashes. The product was sold as *eau de Javel*,³ and its use as a disinfectant was advocated by Berthollet and by Guyton de Mourgau.

In 1820 Labarraque⁴ prepared a fluid similar to Berthollet's by the action of chlorine (1 mol.) on an aqueous solution of sodium carbonate (2 mols.). This preparation containing much free alkali became known as "*Liquueur de Labarraque*," or "*Labarraque's disinfecting fluid*." It is related that Labarraque, who was pharmacist first to the Emperor and subsequently to Louis XVIII, achieved great renown on the death of the latter monarch, for, thanks to the disinfecting and deodorizing value of his "*liqueur*," he was able to proceed with the embalming of the royal body, which was so profoundly decomposed that no one was able to approach it until after the application of the hypochlorite solution.

At a later date solutions of the hypochlorites of sodium and potassium were largely replaced by the more stable solid "*chloride of lime*," a combination of calcium chloride and calcium hypochlorite. It is interesting to note that it was with this substance that Seumelweis in 1846 succeeded in eradicating endemic puerperal fever from his clinic.

Subsequently the *liqueur de Labarraque* and *eau de Javel*, as well as the *liq. sodae chlorinatae* of the *Pharmacopoeias*, were generally prepared by the decomposition of chloride of lime with the carbonates or sulphates of the alkali metals, and this simple process has been the subject of innumerable patents applied for long after the process was well established in common practice.⁵

In 1859 Charles Watt discovered that sodium hypochlorite could be formed by the electrolysis of sodium chloride solution, and a similar electrolytic process was patented by Andrews in 1890. Since then scores of different modifications for the electrolytic preparation of hypochlorites have been advocated.

Other hypochlorite preparations, such as "*extrait eau de Javel*," "*esprit de Javel*," "*essence de Boulogne*," "*chlorozone*," "*hermitine*," "*chloros*," etc., need not be referred to in detail, since they represent hypochlorite preparations of varying purity and stability.

Meanwhile the hypochlorites, and by implication hypochlorous acid—for the latter is liberated from its salts by the carbon dioxide of the atmosphere—were finding an ever-extending application as general disinfectants. They were also employed for the sterilization of polluted supplies of potable water, and to a lesser extent for surgical dressings and for oral antiseptics. I am informed that "*Liquor sodae chlorinatae*" has been used at St. Thomas's Hospital as a dressing for amputation stumps as long as sixty years ago. In more recent times weak hypochlorite solutions have been used with more or less success for removing sloughs and for controlling the smell of offensive wounds. As a skin disinfectant for use in pathological laboratories hypochlorite solutions have been used by Professor Delépine for a generation past.

The great drawback to the more general use of hypochlorites as antiseptics has been the strongly irritating character of the commercial solutions. In the early part of the present war some French surgeons made use of the ordinary "*eau de Javel*," but there were many accidents owing to its caustic action. It was for this reason, therefore, that it seemed worth while to try and obtain a solution of hypochlorite with fewer objectionable qualities. This was done in January of the present year, and after the solution had been in constant use for many months a short communication written by me was presented at the French Academy of Sciences. The essential parts of the communication are the following:

"*Parmi les antiseptiques qui ont déjà été étudiés dans le traitement des plaies infectées, les hypochlorites surtout remplissent les conditions qui viennent d'être énumérées. Mais malheureusement les hypochlorites du commerce ont une composition très inconstante et contiennent généralement de l'alcali libre ou du chlorure libre.*

¹ At the present time in France the term "*eau de Javel*" refers usually to sodium hypochlorite solution and not the potassium salt.

De telles solutions sont irritantes. Quand on s'en sert, même sous une concentration modérée, elles peuvent produire des résultats peu favorables... Il était donc utile de trouver le moyen de préparer un hypochlorite de composition constante qui possède une grande activité bactéricide et une faible action toxique et irritante sur les tissus. Ce résultat a été obtenu par la méthode suivante :

The method of preparation already published in this JOURNAL is then described. The principle of the process being the decomposition of chloride of lime with a slight excess of sodium carbonate solution, filtering off the solution of sodium hypochlorite, which is then neutralized with boric acid in such a fashion that the resulting solution reacts acid to phenolphthalein but alkaline to litmus. "On a trouvé que cette solution est un antiseptique très utile dans le traitement des plaies infectées, lorsqu'elle est appliquée suivant la méthode étudiée et employée par le Dr. Carrel."

It will be seen that no suggestion of a claim for novelty in the employment of hypochlorites or hypochlorous acid is made, but distinctly the reverse, as indicated in the first sentence quoted above.

Following this communication of mine to the Academy, the *Times* on August 8th, 1915, announced in the most sensational fashion the discovery of "the new antiseptic" just 127 years after the preparation of sodium hypochlorite by Berthollet.

It might have been thought and hoped that the absurd and extravagant statements made in the lay press would have sunk into oblivion. But this was not the case. The press which had directed so much unwelcome attention to my communication made in Paris had ignored a valuable paper published shortly before by Lorrain Smith and his colleagues,⁶ which also dealt with the antiseptic action of hypochlorites. The *Times* now published a letter from Professor Harvey Littlejohn, Dean of the Medical Faculty of the University of Edinburgh, who, without waiting to read my communication in print, stated that "it was only due to certain members of the university to state that five months ago they recommended for surgical purposes the employment of what appears to be the same antiseptic." The surmise as regards identity of composition was quite incorrect save for the fact that the hundred years old hypochlorites and boric acid were constituents of both solutions. The *Lancet* apparently obtained its information from the daily papers and devoted more than a column of space to the new antiseptic.⁷ Almost the whole of the statements made relative to the solution referred to in the Paris communication are incorrect and misleading. The article ended with the statement that the result of the Edinburgh workers was to confirm the conclusion of various investigators that hypochlorous acid is the most powerful antiseptic known! It is perhaps worth pointing out that such a statement without qualification as to the conditions under which the antiseptic acts is devoid of meaning. Disinfection is a chemical reaction in which the reactive agent acts not only on bacteria but upon the media in which they are found. A large number of antiseptics are known which will kill many microorganisms suspended in water or blood serum at much lower concentration than will hypochlorites and hypochlorous acid. No statement of the relative power of antiseptics is possible except under absolutely comparable conditions. An antiseptic which shows a high relative activity under one set of conditions will often show a low one when conditions are changed.

In France the interesting results of Vincent and Lumière on the use of hypochlorites for surgical dressings were referred to in the lay press, while, as a climax, the announcement was solemnly made in the *New York Times* by Dr. Jenkins, former Medical Officer of Health for New York City, that it was Mr. A. E. Wolff of that city who discovered, some twenty years ago, the application of hypochlorites as deodorants, antiseptics, and germicides.

It would seem as if the time was fitting for a statement to the effect that what we have all been striving for is to find the best means of preparing, preserving, and applying

the powerful antiseptics, hypochlorites and hypochlorous acid, the main properties of which substances were discovered by distinguished French chemists many generations ago.

Lorrain Smith and his co-workers have aimed at a more or less complete liberation of free hypochlorous acid from chloride of lime by the addition of an equal weight of boric acid. Lumière, on the other hand, employed three parts of boric acid to one of chloride of lime with satisfactory results. On the other hand, my own experiments aimed at the preparation of a sodium hypochlorite solution with a low OII ion concentration, sufficiently stable, and containing a balanced mixture of polyborates so that approximate neutrality might be preserved under all circumstances. The amount of free hypochlorous acid in my mixture is much smaller than in Lorrain Smith's or Lumière's preparations. The concentration of available chlorine is less, and it can be more freely and continuously applied.

Recently I have been interested to find that Dr. Heitz-Boyer and the staff of the French hospital ship *Charles Roux* have been making extensive use for surgical purposes of a hypochlorite solution prepared by the electrolysis of sea water in a simple cell using carbon electrodes. The hypochlorite concentration employed varied from 2 to 4 grams of hypochlorite per litre, the lower dilution being used for constant irrigation. The electrolytic hypochlorite is peculiarly unstable.

When suitably applied there seems no doubt that all of these hypochlorite preparations are of genuine value in the treatment of infected wounds.

There is one point concerning the mode of action of hypochlorites that I would like to refer to before closing. It has been repeatedly stated that the antiseptic action of hypochlorous acid is due to its decomposition in the presence of organic matter with liberation of oxygen. I have been unable to find any evidence to support this statement. If it were true that the antiseptic action of hypochlorous acid was due to the liberation of oxygen, it is surprising that many other substances capable of furnishing nascent oxygen should have an antiseptic action far inferior to that of the hypochlorites. Moreover, I know of no evidence pointing to an accelerated liberation of oxygen from hypochlorous acid in the presence of organic matter. The ordinary decomposition of hypochlorous acid with liberation of oxygen is a relatively slow reaction. Furthermore, when strong hypochlorite solutions are added to animal tissues, an evolution of chlorine rather than oxygen occurs.

It appears that when hypochlorous acid or hypochlorites act upon organic matter of bacterial or other origin some of the (NH) groups of the proteins are converted into (NC) groups. The products thus formed—belonging to the group of chloramines—I have found to possess approximately the same antiseptic action as the original hypochlorite, and it appears more probable that the antiseptic action of the hypochlorites is conditioned by the formation of these chloramines rather than by any decomposition with liberation of oxygen. It should be noted that the hypochlorites act upon free ammonia to yield the simplest chloramine NH₂Cl, as first shown by Raschig. The probable formation of this substance during the sterilization of sewage with hypochlorite has already been indicated by Rideal and others.⁸ The chloramines formed from proteins when wounds are treated with hypochlorites are naturally of a much more complicated character.

Inst.*, 1910, xxxi, p. 54.

DR. JOSEPH GOLDBERGER, of the United States Public Health Service, who has been investigating the cause of pellagra, which caused the death of more than 11,000 persons in Mississippi alone last year, has, says the *Medical Record*, been helped in his work by prisoners in the prisons of that State who have voluntarily submitted to experiments. Out of eleven prisoners who were observed, six have developed the disease. The men have all been pardoned, and will be released as soon as a course of treatment on the prison farm has restored them to health.

A. A matter of fact, my communication to the Academy did contain references to some genuinely new antiseptics of the chloramine type, but no comment on these substances was made in the lay press.

A SPLINT FOR COMPOUND FRACTURES OF THE ARM.

By GEORGE M. GILES, M.B., F.R.C.S.,
 LIEUTENANT-COLONEL I.M.S. (RET.), ARINGDON.

The treatment of the ordinary simple fractures of the humerus is a matter of little difficulty, and, in peace, compound fractures of the upper arm are rare. The fractures, however, met with in military practice are compound, and the damage to both soft and hard parts so great that it is difficult to bandage any splints with adequate firmness, and well-nigh impossible to get any proximal point of fixation by means of any of the splints in ordinary use.

These difficulties were brought prominently to my notice in the case of a man nearly recovered from a gunshot fracture of the humerus about 5 in. above the elbow, who, when running up stairs, fell and refractured the arm, at the same time tearing open the well-nigh closed flesh wound on the front of the arm. He was an exceptionally powerfully made man, who had gained high distinctions as a wrestler, in the pursuance of which

sport the arm had been broken six times, so that the present is the eighth fracture. The bone is naturally extremely irregular and a good deal shortened.

Finding I could not get the ends in position with any of the ordinary splints I devised the appliance here described, which can easily be made in less than an hour by any one who is amateur mechanic enough to bend stout wire and clip into shape some scraps of tin.

The essential point of the contrivance is the long narrow extension, which is brought up and bent over the acromion and fixed there in position, directly over the head of the humerus, by means of a pair of body straps. Its form and method of application can easily be understood from the accompanying drawings.

To make the splint the following measurements of the patient's sound arm are required:

- A-B, length from knuckles to olecranon.
- B-C, length from olecranon to acromion, \pm 2 in. for tall and $\frac{1}{2}$ in. for short men.
- D-E, length from anterior axillary fold to the insertion of the biceps, with the elbow flexed to right angles.
- E-F = A-B minus about 4 in., the diameter of the upper arm, allowing for padding.
- G-D, in a direct line, is about 6 in., but as the wire forms a double curve, dropping below the axillary folds vertically, and wrapping round the arm horizontally, about a couple of inches more must be allowed.

All transverse measurements vary with the muscularity of the patient, and the table is merely given as a suggestion for sizes to be kept in stock.

Height of Patient.	A-F	A-B	B-C	D-E	E-F	G-D
	inches.	inches.	inches.	inches.	inches.	inches.
About 6 ft. ...	3 $\frac{1}{2}$	16 $\frac{1}{2}$	17 $\frac{1}{2}$	5 $\frac{1}{2}$	12	3 $\frac{1}{2}$
" 5 ft. 10 in. ...	3 $\frac{1}{2}$	16	17	5 $\frac{1}{2}$	11 $\frac{1}{2}$	3 $\frac{1}{2}$
" 5 ft. 8 in. ...	3 $\frac{1}{2}$	15 $\frac{1}{2}$	16 $\frac{1}{2}$	5	11 $\frac{1}{2}$	3 $\frac{1}{2}$
" 5 ft. 6 in. ...	3 $\frac{1}{2}$	15	16	5	11	3 $\frac{1}{2}$
" 5 ft. 5 in. ...	3	14 $\frac{1}{2}$	15 $\frac{1}{2}$	5	10 $\frac{1}{2}$	3
" 5 ft. 4 in. ...	3	14 $\frac{1}{2}$	15	4	10 $\frac{1}{2}$	3
" 5 ft. 3 in. ...	3	14	15	4	10	3

The short ends A-F and F-A are bound together with binding wire, preferably strengthened with solder.

Some stiff tool, such as a screwdriver, is passed through the loop c and twisted—against the clock for the right arm,

and with it for the left; so that the plane of the loop is turned through rather more than a quarter circle. The frame is then placed in position upon the arm of a person of appropriate stature, with the joint A held in the hollow of the hand, and the loop c bent and manipulated so that it forms an open spiral upwards and forwards, round the back of the arm, and comes to lie against the acromion, projecting from 1 $\frac{1}{2}$ in. to 2 in. above it; this projecting part is bent sharply with a pair of pliers, so as to hook over the top of the shoulder-joint.

The angle E is then twisted forward, so as to lie above the insertion of the biceps with the arm bent, and finally the frame is filled in with a couple of pieces of tin cut to the required shape and bent to fit the arm. These pieces are easily secured in position by bending the edges of the tin round the wire frame; but an even better job can be made by running a little solder into these bent-over edges.

The position and size of the pieces of tin can be varied to suit the position of the wounds, or fenestra may be cut in any required position. A couple of long pieces of bandage, or what is better, lamp-wick, are passed through the loops c and d, and the splint is carefully padded and covered with jaconet, special attention being given to covering the angle E, as this forms the lower point of fixation. The loop c, which, of course, is also padded,

is secured in place over the acromion by means of the lengths of lamp-wick, additional support being gained from the wick looped through d. If these be properly secured, it will be found that a very small amount of bandaging of the upper arm will suffice to keep the bones in position, and that the patient may be allowed to get up and about at a very early stage, as the weight of the arm is a most efficient aid in keeping up extension; it is a

Tracing of radiograph to illustrate relation of acromial loop to the bony parts.

point of much importance, in order to secure this, so to arrange the arm sling as not to support the weight of the elbow too much.

In the figure the lamp-wicks are shown secured to a sort of waistcoat of stout calico, which is a good plan to

prevent the straps from pinching the opposite axilla, but it is quite easy to secure the straps from c and d by crossing them under the opposite axilla and over the shoulder.

If a number of splints are to be made, it is well worth while making a templet arm consisting of 18 in. of 4 in. round pole, into which a piece of inch plank to represent the forearm is mortised. By making the mortise 7 in. deep the templet can be adjusted to suit any stature from 5 ft. 3 in. to 6 ft. 2 in.

AN ADJUSTABLE AND STANDARDIZED SPLINT FOR THE TREATMENT OF FRACTURES.

By W. B. HAYES, M.D., M.Ch.,
PHYSICIAN TO CO. KERRY INFIRMARY.

CURRENT literature, and the large variety of apparatus exhibited at the recent exhibition at the Royal Society of Medicine, impress on one the need for improvement in the methods of overcoming the difficulties encountered in war in the treatment of compound fractures of the limbs. These difficulties have taxed the ingenuity of surgeons.

Three things have to be considered in the circumstances—the immediate treatment at the seat of war, the transport to the base hospitals, and the treatment at these hospitals.

The greatest difficulties seem to have been in connexion with the treatment of compound fractures of the lower limbs. Several essentials are required for a splint for this purpose. Simplicity and efficiency are the first requisites. The perfect splint must be capable of maintaining the limb in a fixed extension and immobilization, and it must be a skeleton splint, to facilitate dressings without disturbing the position of the splint. If to the above requirements are added adjustability, adaptability, and standardization, and the quality of being rapidly fixed, all the needs of an ideal splint are satisfied.

The Thomas splint, as advised by Mr. Robert Jones, is the simplest and most efficient that has yet been thought of, but the more elaborate and complicated the modifications of this splint, the more they are removed from simplicity and efficiency. Observation of Mr. Jones's hospital practice impresses two things on one—first, the remarkably successful results attained, and secondly, the great simplicity of the appliances used by him for that end, all elaborate and complicated apparatus being conspicuous by their absence.

I have found that the splint which I am about to describe fulfils all the requirements of a complete splint. Its ready applicability to any particular case by a simple adjustment gives it a special value under all conditions. It is practically the Thomas splint, which is made completely adaptable. It is adjustable to any size limb and can be adapted to either the right or the left side. Being made from one pattern and in one size, it is therefore standardizable. The ease of application of the splint, which takes a few minutes, is a most important matter for the consideration of the hard-worked surgeon who is obliged to cope with a rush of work. The wounded can be transported with the greatest possible comfort and safety under the circumstances. A great difficulty in the immediate treatment, and transport, of these cases is overcome by the application of this splint.

The illustrations of the splint explain its construction, and no elaborate description is needed.

The truss ring is made of malleable iron, open in front, so that by bringing the open ends together, or separating them, it can be adjusted to the required size. Two tubes are attached to the ring with sufficient play so that the ring can be altered to any angle required to suit the right

or the left side. The lower portion of the splint consists of bent rod iron; the arms of the bent iron are inserted into the corresponding tubes, and by simple telescoping can be fixed by a screw in any position required to suit the

length of the limb. Attached to the lower end of the splint there is a rest, which when turned down raises the limb to any angle required; it will be an advantage in transport, and when not required may be folded up, for it has the shape of the limb and does not interfere with the dressing.

The splint which I have attempted to describe in this short article has been examined by Mr. Robert Jones, who has been good enough to allow me to mention the fact that he personally approves of it.

A NOTE ON THE ELECTRICAL TREATMENT OF DISABILITIES DUE TO WOUNDS.

BY
 JOHN J. GRACE, F.R.C.S.,
CHIEF ASSISTANT IN THE X-RAY DEPARTMENT, ST. BARRICKOCHU W'S HOSPITAL.

It is a truism to say that electricity has a very distinct and useful place in the treatment of those disabilities which follow wounds involving joints, muscles, tendons, and nerves, but it is not sufficiently recognized that the correct application of the kind of current best suited to the condition to be treated is of essential importance. It cannot, of course, be expected that surgeons, in addition to the mastery of their highly technical work, should have all the details of so rapidly advancing an art as electrotherapeutics at their finger-tips, but if the aim of electrical treatment in these injuries be kept in view, it will not be difficult to indicate to the patient the nature of the treatment he requires.

I am moved to write this owing to the considerable number of patients I have seen who have been given electric baths for local injuries to the limbs. How the passage of the constant current or the uninterrupted sinusoidal through a patient could influence such conditions for good or ill I am at a loss to imagine. Such currents often have a good general effect on metabolism. That is all. Some local effect on the molecules traversed by the current there may be; indeed, so far as the galvanic current is concerned, there is undoubtedly some effect, but while we see the results in some cases—for example, of neuralgia—we cannot say to what they are due.

When we come to consider the interrupted currents we are on much surer ground, and there is no difficulty whatever in seeing how their effects are produced.

Whether the injury has affected joints, muscles, ligaments, nerves, or all together, as is perhaps most frequently the case, the object sought is to increase the blood supply to the part, and having done that, or whilst doing it, to contract the muscles of the part so as to drive this increased supply through all the tissues. If this object be thoroughly attained, pain and stiffness will decrease, muscles which have partially lost their function will regain it, torn tendons and ligaments will heal, and the best result obtainable will be achieved in the minimum of time.

To attain these ends we have a considerable number of means at our disposal. We can bake the limb in an electric or gas oven, first wrapping it carefully in towelling to absorb the sweat which would quickly scald the skin if allowed to remain on it, or we can use the high candle-power lamp, or diathermy. As a matter of convenience I use as a rule a 3,000 candle-power lamp, giving an

exposure of twenty minutes or so. In the treatment of joints, however, I prefer diathermy. It seems on the whole to do a little better, and as the greatest heat is developed midway between the electrodes, it should theoretically be more efficient. After twenty minutes, then, of either radiant heat or diathermy a rhythmically interrupted electric current is applied. Of the rhythmically interrupted currents we have—

The faradic as used in the Bergonié apparatus.

The sinuoidal, interrupted by such a device as the Lewis Jones interrupter.

The static wave current.

The static induced current.

The Bergonié apparatus produces very efficient muscular contractions. It is a little troublesome to adjust. The interrupted sinuoidal is a very useful and efficient current. The static induced current penetrates very deeply and gives rise to strong contractions. Any static machine will give them of sufficient penetration for the purpose. The static wave current requires a machine of high efficiency. As a rule, ten minutes of the static induced or twenty minutes of any of the other currents is given at a sitting.

Usually there is very definite and early improvement; my experience is that during the first week of daily treatment the patient is able to detect it, and the increased confidence inspired doubtless helps to increase the effects. I append notes of a few cases:

CASE I.

A man wounded in the shoulder in April last. On July 13th the wound was healed, but he could not use the arm owing to pain and stiffness. There was wasting of shoulder muscles chiefly, but extending also to the arm and in less degree to the forearm. The static wave current was applied to the muscles of the shoulder for ten minutes and to the biceps for other ten. He had fifteen treatments. Improvement was marked from the first. He discontinued treatment to enter a munitions factory, having then complete, but of course not perfect, use of his arm.

CASE II.

An officer, wounded in the right foot in September, 1914, had treatment by massage and electric baths without improvement. The condition on April 19th, 1915, was as follows: Wasting of right calf, 1½ in. less as compared with left. Pain in instep and great toe on walking with two sticks. Bad limp. On walking, great toe dorsally flexed and patient cannot then bend it. The treatment was light to the foot for twenty minutes; static sparks to the sole of the foot for fifteen minutes; and static sparks to the joint and muscles of leg. He had twenty treatments, and discontinued to rejoin his regiment; he walked much better without a stick, but still limped. There was no pain, but the limb was weak. The great toe behaved normally.

CASE III.

A private, wounded at the back of the arm, at the junction of the lower and middle thirds. He was operated on, but afterwards could not extend the third, fourth, or fifth digits, nor flex them when extended. There was wasting of the interosseal and hypotenar eminences. When the hand was forcibly opened there was a dragging sensation along the ninar flexors. He had been treated by electricity (a portable faradic coil?). The treatment instituted was static wave current to the scar, and static vacuum tube discharge to the muscles. After eleven treatments there was marked improvement, and the patient returned home.

CASE IV.

A bombardier wounded on September 27th, 1914, two inches above the elbow-joint, through the soft parts anterior to the humerus. When seen on February 16th, 1915, he could not bend the index and middle fingers beyond a right angle with the palm, and there was numbness of thumb palmar surface and the first and second digits, and loss of tactile sensation. Treatment was by static wave current over the wound, and static vacuum tube discharge to muscles and skin. After eight treatments he was very much better, could flex the fingers fully, and had increased power in the hand, but sensation was not improved.

These cases are samples of a moderate number treated. Some fail quite unaccountably to benefit, but they are the exception.

An officer was wounded on the outside of the thigh. There was loss of sensation on the outside of the leg and foot, most on the dorsum of the foot. When seen he had deep-seated pain in the front and the outer side of the thigh and leg. Pressure on the scar caused local pain. I expected that this case would do well, but failed to afford any permanent relief.

TYPHUS IN SERBIA.

BY

B. WHITCHURCH HOWELL, F.R.C.S.,

HÔPITAL TEMPORAIRE D'ARC-EN-DUBROIS (HAUTE-MARNE), FRANCE.

As a sequel to Dr. Maitland's notes on the epidemic in Uskub, reported in the BRITISH MEDICAL JOURNAL of August 21st, the following observations, gleaned from a much more limited experience of the disease at Vrnjatchka Banja, may be of interest.

Admission of Patients.

It was found essential that the hair of the head and pubic region should be cut short (and in some cases shaved) and then treated with paraffin oil or unguentum hydrargyri. Even then fresh broods of lice made their appearance. The patients were washed in bed, being in various stages of collapse. At the time I was in Vrnjatchka Banja the typhus barracks had no bathroom accommodation.

The Disease.

The majority of patients were Austrians, and, as Professor Morrison pointed out recently, the mortality amongst them was noticeably greater than among the Serbs, owing probably to their being prisoners, of poor physique, and not accustomed, like the Serbians, to live on "pork and beans."

I thought on the whole that the more intense the rash the graver the prognosis—generally the malignant type of case. I noticed also that the rash appeared fairly commonly on the palms of the hands—a fact not often alluded to in the textbooks—generally in the form of faint discrete macules. It seemed to bear no relation to the gravity of the disease.

As a rule the fever fell by lysis, as Dr. Maitland remarked, with, occasionally, "kicks" on the temperature chart; this is contrary to the usual teaching. Some of us thought that the pulse was slowed out of proportion to the temperature. Although I noticed this from time to time it did not seem to be a general rule.

The initial symptoms may be like influenza, as in the case of two of our nurses who contracted the disease; they had aches and pains all over, frontal headache, and pain behind the eyes. The drunken look about the eyes is very characteristic; hence the diagnosis could often be fairly safely made before the appearance of the rash.

When we first took over the fever *Baraque*s pulmonary complications were common, several of the cases dying of a rapid form of bronchopneumonia. Later, as the difficulties in nursing were surmounted, the infections of the lung and parotid gland became less and less frequent. It seemed to me at one time as if the typhus pneumoniae were contagious, as I had side by side, not in the same stage of the fever, three cases in whom the lungs were simultaneously affected.

Deafness was frequently present, and one nurse suffered from it for a long time after she returned to work.

I had only one case of melanuria, in a nurse well over 40; this occurred about the twelfth day, and caused some anxiety, especially as the liver was much enlarged. She rallied, however, and about the sixteenth day it had completely disappeared, and the temperature and pulse were normal.

I saw one case of hemiplegia in the sister of a Serbian general; it came on suddenly during the disease, and lasted some days. The patient recovered from the typhus and from the hemiplegia.

Treatment.

This varied in detail only; in general it was, of course, stimulating. As Dr. Maitland states, the Serbians were not in favour of alcohol; we, on the other hand, used it a good deal in ½ oz. doses, increasing it steadily as the pulse got weaker, especially about the eighth to twelfth day. The most critical period was during and after the lysis.

Digitalis was given by the mouth and hypodermically—we had no digitalin—by the mouth in 20 to 40 minim doses every four hours; subcutaneously in 10 to 20 minim doses. Strychnine also was given hypodermically. I sometimes

prescribed other in 10 to 20 minim doses subcutaneously in very severe cases, generally alternating with strychnine. The other injection sometimes gave rise to local necrosis of the skin, but this was of small moment, as I am sure the patient occasionally rallied as the result when all else had failed.

A CASE OF LEPROSY DIAGNOSED BY X RAYS.

By MAJOR A. NEVE, F.R.C.S.E.,
KITCHENER INDIAN HOSPITAL, BRIGHTON.

THE following case is of considerable interest, as the disease was so atypical as to remain in doubt, even when examined by experts, until the x rays showed clearly the well-marked osseous lesions of leprosy.

Jenadar M. S. was invalided in April, 1915, with the diagnosis of rheumatism. He had served through the winter campaign, and had latterly complained of headache and other ill-defined pains. He also had a widespread papular rash, with some pigmentation in the face; this, he states, has been of many years' duration. His left eye was operated upon four years ago for pterygium, and there is a slight opacity of the cornea in that eye, with injection of the conjunctiva. There is a slight stare, not due to exophthalmos. He has occasional pains in the back, and also in the feet, of a burning character. When he arrived the feet were swollen; this was attributed to exposure in the trenches. From the history it seemed that he might have had syphilis, as potassium iodide had been prescribed years ago with benefit.

The points that raised a suggestion of leprosy were (a) a little clubbing of the fingers, of which the terminal joints were not quite straight and symmetrical; (b) the toes appeared slightly shortened, and one of them was crooked.

He was carefully examined for certain signs, which were all negative:

1. There were no maculae on the back or extensor surfaces of the limbs.
2. No tubercles on eyebrows, ears, or elsewhere.
3. No anaesthetic patches on feet, hands, or body.
4. No thickening of the ulnar nerve.
5. No naso-pharyngeal ulceration or tubercle, and no laryngeal symptoms.
6. No paresis of the lower eyelids.

A radiogram was taken on July 11th by Captain Gale; it showed entire disappearance of the terminal phalanges of most of the toes. The proximal phalanges have also become greatly decalcified; in the right foot the second phalange only is intact and in the left foot the third, while

the big toe of the left foot is only represented by a triangular piece of bone three-quarters of an inch long, and the fifth phalange has quite disappeared.

The distal portions of all the metatarsal bones are extraordinarily thinned.

In the fingers slight changes are perceptible in all the terminal phalanges on both sides. Those of the thumbs

are peculiarly crooked and shaped like pollarded willow trunks, and the terminal phalange of the index finger is a mere stump.

In leprosy it is the osseous framework of the phalanges which first becomes irregularly absorbed. At a later period the metatarsus or metacarpus; the former is more affected, perhaps on account of traumatism, and sepsis spreading from trophic ulcers of the sole of the foot, which also affects the tarsal bones, and spreads to the ankle-joint. Amputation is then resorted to, and it is found that the bones of the foot are so softened as to be readily cut by a knife. It is seldom that a case with slight and doubtful general symptoms shows such extensive osseous changes as to make them the decisive diagnostic factor. Hence the value of the Roentgen rays in this case was peculiar.

I am indebted to Colonel Sir Bruce Seton for permission to publish this case.

DR. HENROT gave recently to the Académie de Médecine an account of the bombardment of the hospital at Rheims. The bombardment did great damage. A breach of about 10 metres was made in the hospital, causing the falling of the façade and the roof. The patients' beds were seen suspended to the walls. The maternity department, situated in a separate wing, by some happy chance was not touched, but by way of precaution the patients were moved to the cellars, as the bombardment was continued every day during half an hour in the morning and half an hour in the afternoon. One night 2,000 shells fell on the town between 9 p.m. and 5 a.m. In the cellars the patients lay on mattresses or on the ground; they were so close together that it was difficult to reach any one. The women pupils, who stuck to their posts, had to give the necessary injections and enemata on their knees. Such was their care and devotion that in spite of privation, fatigue, and mental distress the sanitary condition of the women remained good. During the months of August, September, October, and November (1914) no case of infectious disease occurred. Only two women died—one of eclampsia, the other owing to faulty insertion of the placenta. Some poor women died on their way to the hospital of exposure or want in railway stations, in the train, or in the street. Most of the women were more or less exhausted but they bore their sufferings cheerfully. M. Henrot relates a remarkable case. One day a fine child was presented to him. When he asked for the mother he was told that a fragment of shell had torn open the abdomen and the uterus, and the child had simply to be extracted. As M. Henrot says—this is a form of the Caesarean operation of which there is no previous record.

The Goulstonian Lectures

ON

SPINAL INJURIES OF WARFARE.

DELIVERED BEFORE THE ROYAL COLLEGE OF PHYSICIANS
OF LONDON.

BY GORDON HOLMES, M.D., F.R.C.P.,

ASSISTANT PHYSICIAN TO CHARING CROSS HOSPITAL, AND NATIONAL
HOSPITAL FOR PARALYSED AND EPILEPTIC, QUEEN SQUARE;
LIEUTENANT-COLONEL (TEMPORARY) R.A.M.C.

II. THE CLINICAL SYMPTOMS OF GUNSHOT INJURIES OF THE SPINE.

DURING the past thirteen months we have been able to observe several hundred cases of spinal injury, and at present have clinical notes on over 300; these will form the basis of the remarks and conclusions which will be put forward in the next two lectures.

But even this material is so large and the variety of symptoms is so great that it will be necessary to select only the most striking and special symptoms for consideration. We have found every segment of the cord from the second cervical to the conus affected, but in the cases that have reached the base hospitals the injury has been most common in the middle and lower dorsal segments and in the cervical enlargement; the fourth, the fifth, or sixth cervical segment was damaged, for instance, in 51 cases, while in 65 the lesion lay between the sixth and ninth dorsal segments. It is not proposed to deal at present with injuries of the cauda equina, of which a large number came under observation.

Even an ordinary transverse lesion of a dorsal segment produced directly or indirectly by a bullet, piece of shrapnel or shell casing, presents striking symptoms.

When the patient is seen a day or two after the infliction of the wound, there is usually complete flaccid paralysis of the lower limbs and of the trunk muscles to a level varying with that of the lesion, sensory loss to the corresponding level, absence of all reflexes in the lower limbs, except, perhaps, of the flexor withdrawal reflex in incomplete lesions, and retention of urine.

LOCALIZATION OF THE LESION.

The segmental level of the lesion can be usually recognized as accurately by the extent of the motor paralysis as by the upper border of the sensory disturbance; and since the evidence it gives is less equivocal and as easily interpreted in both military and civil practice, some emphasis may be laid on its importance. The segmental innervation of most of the muscles of the upper and lower limbs is now known, and this knowledge has been applied in clinical work. A paralysis of all the movements of the wrist and fingers as well as of the triceps while the biceps remains strong or only slightly weakened is usually, for instance, taken as an indication of a lesion in the seventh cervical segment, but hitherto little attention has been given to the evidence of the level afforded by the palsy of the trunk muscles. When, however, one of the lower six dorsal segments is involved, the part and the extent of the muscles of the anterior abdominal wall which are paralysed form an easy and certain guide to the segment in which the lesion lies. If, for instance, the eleventh is involved the whole rectus abdominis contracts when the patient raises his head, attempts to sit up, or coughs, but the iliac regions bulge owing to paralysis of the lower portion of the obliqui abdominis, and their failure to contract can be easily recognized by the observer's fingers. Similarly if the ninth segment is injured, it is obvious to the finger that the recti abdominis downwards from about 1 in. above the umbilicus do not contract, but are, in fact, passively stretched by the tension produced on them by the shortening of the upper segments. Owing to the same fact the umbilicus, as Beever first pointed out, rises towards the xiphoid. The state of the intercostals is an equally reliable guide to the level of the injury, and permits a local diagnosis in the upper as well as in the lower dorsal segments. If the fingers are firmly placed in series on the intercostal spaces the unaffected muscles are felt contracting on each deep inspiration, and form a firm shallow floor to the space, while in paralysed spaces no contraction can be felt, and

on deep inspiration the finger sinks deeper between the ribs; in lean subjects this may be, in fact, visible to the eye. As the intercostal muscles have only segmental innervation, and as each receives its nerve supply from the correspondingly numbered dorsal root, the highest space which is paralysed indicates the level of the spinal injury.

The upper limit of disturbance of sensation is the means most commonly used in civil practice to determine the segmental level of the spinal lesion, and if proper care is taken the evidence it gives is reliable, but, as we shall see later, in incomplete lesions, and more especially in those which are wholly or chiefly unilateral, errors may easily occur, and an exact local diagnosis may not be always possible from even an accurate sensory chart; this is due to the oblique course of the decussating sensory fibres in the cord. In a complete or very severe lesion, light contacts are usually felt a short distance below the limit of complete analgesia, but there is frequently some disturbance in tactile sensibility above the level of the latter. The appreciation of moderate temperature is often lost slightly higher than that of painful stimuli.

The disturbance in the appreciation of vibration may be also a valuable indication of the level of the injury, especially in incomplete cases in which the dorsal columns only are damaged and sensibility to touch and pain is unaffected, since the vibrations of a heavy tuning-fork cannot then be recognized below the corresponding segmental area. This can be determined by drawing the base of the vibrating fork upwards over the soft parts. This method is particularly valuable on the trunk when the state of the other elements of sensation conducted through the dorsal columns cannot be investigated; the base of the fork may be simply drawn over the anterior abdominal wall till the level is reached at which the patient feels the vibrations, but, as the thorax can act as a sounding box and transmit the vibration widely over it, it is necessary to apply the fork here only to folds of skin raised gently between the observer's fingers and thumb.

When one of the lower abdominal segments is involved, the level of the lesion may be also accurately determined by observing the segment below which the abdominal cutaneous reflexes cannot be obtained.

It must be remembered, however, that the lesions produced directly or indirectly in the spinal cord by a gunshot wound are often very extensive, and that a clinical examination can, as a rule, indicate only their oral limit.

REFLEXES AND REFLEX TONE.

In all severe lesions the lower limbs are found flaccid at least as early as one day after the infliction of the wound, and within three or four days their muscles become toneless and flabby; if the lesion is complete or almost so they remain flaccid and waste gradually; later the atrophied muscles, especially those of the calf and the flexors of the toes, undergo fibrous contracture. In less severe cases the muscles regain tone and the limbs become slightly rigid, generally within fourteen to twenty days. In one case, however, we observed slight rigidity in a limb five days after the wound was inflicted, but in another spasticity appeared only after eighty-four days. In slight cases there may be no obvious defect of muscle tone, or, if diminished, as it frequently is at first, it rapidly recovers.

In those cases in which some rigidity develops early reflex spasms of the legs of the flexor type are apt to occur; they are, as a rule, seen only a few days after the limbs have become somewhat spastic, but we have observed them occasionally as early as the sixth to tenth day, when the tone of the muscles was not yet exaggerated.

In one interesting group in which pains due to higher spinal lesions occur in the legs, these limbs are often held stiff and rigid, but careful examination shows that there is no true spasticity, and reflex spasms do not occur; in these cases the spinal lesion is not severe, and voluntary movement is either not lost or has recovered rapidly.

The state of the reflexes in the affected parts presents interesting problems. Except when the spinal lesion is slight the knee and ankle jerks are almost invariably lost at first, and in severer cases remain absent during the period in which we have been able to observe them—that is, in some instances, for as long as six to ten weeks. The teaching of Dr. Charlton Bastian that these reflexes are

permanently abolished in total transverse lesions of the cord is generally accepted now, and our experience seems to confirm it, though in one case in which a fragment of shell-casing lacerated the cord in the lower part of the fourth dorsal segment and passed downwards through the next three lower segments, apparently destroying them completely, feeble knee-jerks could be obtained from the fifteenth day onwards; whether or not there was a total transverse lesion has not yet been determined by microscopical examination.

In less severe injuries the knee-jerks return, but generally not earlier than within two or three weeks; the re-appearance of the ankle jerks is always later than of the knee-jerks, but occasionally ankle-clonus could be obtained while the knee-jerks were still absent or much depressed. In a few cases in which paraplegia in flexion developed after the return of the knee-jerks we saw these again disappear as the flexion rigidity increased. In lesions of the upper four cervical segments the arm-jerks are usually lost at first, independently of the severity of the injury, and seem to recover less early than the knee jerks.

Not only are both knee and ankle jerks absent for a considerable time in transverse spinal injuries, but with unilateral lesions of the cervical or dorsal segments neither can usually be obtained in the paretic leg for some days, or they are at least much diminished on this side compared with the normal. The paretic leg is also usually flaccid. In these cases, however, the reflexes return earlier than in transverse lesions of the same degree of severity, but usually not till at least ten to twelve days after the infliction of the wound; in one patient with a unilateral cervical lesion we could elicit only a very feeble reflex after thirty-five days, and it was almost two months after the injury that the jerks of the homolateral limb were as brisk as normal.

On turning to the superficial reflexes we find the abdominal and cremasteric more easily abolished than the tendon-jerks; in fact, when the lesion lies above the mid-dorsal level, both remain permanently absent as long as there is any obvious motor weakness of the lower limbs.

In spinal injuries above the lumbo-sacral enlargement we would expect, on stimulating the sole, to obtain constantly the abnormal type of plantar response originally described by Babinski. When the lesion is complete or particularly severe, however, no movement of the toes may result, and there may be no reflex contraction of the hamstrings or of other muscles; and this holds not merely for the first few days when extensive functional disturbances might be attributed to "shock," but the condition may persist for several weeks at least.

In some cases, however, probably when the transverse lesion is not total, stimulation of the sole produces only a simple flexion of the great toe, often associated with slight flexion and adduction of the smaller toes; this flexion of the great toe can be produced when the outer border of the sole only is stimulated, and consequently it cannot be attributed to direct mechanical irritation or stretching of the small flexor muscles of the sole. The movement differs from the normal flexor response in that it is slower and smaller in range, and in that it is chiefly a flexion at the metatarsophalangeal joint. Occasionally the only effect is contraction of the inner hamstrings, but as a rule this is associated with slight flexion of the toes.

In less severe injuries stimulation of the sole still evokes flexion of the great toe with contraction of the hamstrings, while, if the lesion is still less serious, a withdrawal reflex of the whole limb, in which the hamstrings, tensor fasciae, flexors of the hip, and the dorsiflexors of the ankle are concerned, may be obtained, but still with flexion of the great toe. In many cases, however, an extensor response can be elicited from the sole, but clinical experience and *post-mortem* examinations tend to show that during the first week or ten days at least Babinski's sign occurs only with transverse lesions, which are not complete. We have repeatedly seen a flexor movement of the toes give place to an extensor between the seventh and the twentieth day after the injury, and in certain cases this has been a precursor to improvement. Even in one case in which a unilateral lesion of the fifth cervical segment produced a flaccid paralysis of the limbs of the same side the plantar reflex was absent, or only a slight slow flexion of the great toe could be obtained during the

first two weeks, after which it gave way to a pure extensor response.

SPINAL SHOCK.

This state of the reflexes, more especially the abolition of the tendon-jerks and the absence of Babinski's sign, in severe but not necessarily complete anatomical lesions raises many points of interest. Even if we accept Dr. Bastian's doctrine, we must be surprised to find the tendon-jerks absent, for a time at least, in such a large proportion of incomplete injuries. This differs from what we find in ordinary civil experience, except in cases of fracture dislocation of the vertebral column, and in this condition the medullary injury resembles that produced by gunshot wounds of the spine. The nature of the lesion cannot, however, explain it, and as the reflexes disappear even when the highest spinal segments are injured their absence cannot be attributed to the distant disturbances that have been described in the first lecture. The most obvious common factor is the sudden severance of a portion of the cord from the influence of more orally situated centres by an abrupt section or by a physiological block. This produces the condition which is generally known as "spinal shock." It is recognized in the experimental laboratory, as high transection even in the frog leaves all four limbs flaccid and inactive to stimuli for half an hour or so, and the higher the animal stands in the scale the more pronounced and persistent are the symptoms of shock. In man, in whom the spinal mechanism is most subordinated to the higher centres, the effects of shock are naturally most pronounced, and the caudal portion of the cord is least capable of acting alone as an effective central organ. Our observations, therefore, only extend and confirm the experiences of physiologists, and show that the sudden isolation of a portion of the cord from the rest of the central nervous system leaves it incapable, for a time at least, of subserving even the simplest reflex.

The unilateral absence or depression of the tendon-jerks in cases of unilateral lesion is interesting, as it shows that their abolition is not due to a state of general shock, or to a sudden gross traumatic injury of the cord, but that it must be attributed to an interruption of impulses that descend through the homolateral half of the cord, which produces a functional depression on this side only.

We have not yet had the opportunity of determining whether, in cases in which the structural lesion is not complete, the absent reflexes eventually return, at what date they reappear, and with what other symptoms of recovery their reappearance is associated. We have, however, seen the knee and ankle jerks absent during the first and second week in cases which have recovered sufficiently to stand, and absent for longer periods in patients who later regained some power of movement while under observation.

The inability to elicit reflex movements from the sole in cases of complete transverse lesions must be also attributed to the functional depression, either temporary or permanent, of the isolated segments of the cord. It has been pointed out that in less severe cases only flexion of the toes, or this associated with contraction of the hamstrings, is obtained, and that only in less severe or longer standing injuries can the complete flexor reflex be evoked. This we might expect, for when the activities of the isolated portion of the cord are depressed by shock the relatively complex mechanisms of commissural and intersegmental association naturally suffer more than the simpler and more rudimentary unisegmental functions. And as the sole, from which the reflex is most easily evoked, lies within the sensory distribution of the first sacral root, and the flexors of the toes and the hamstrings are innervated chiefly by the ventral root of the same segment, the contraction of these muscles on stimulation of the sole can be regarded as a unisegmental reflex; additional segments would be concerned in flexion of the hip and knee and the contraction of the tensor fasciae femoris and adductors, which are included in the full flexor reflex. Further, in these cases the receptive field of the reflex is much narrowed, and is in fact almost invariably limited to the sole, where the threshold of effective stimulation is normally lowest.

It might be expected that the effects of shock on the lumbo-sacral enlargement would be more pronounced the lower the lesion lay in the cord, but we find little to

support this view; the lower limbs have been as flaccid and toneless in cases of high cervical injury as when the lower dorsal segments were damaged, and when the lesions have been probably of equal severity there has been no evidence of less shock or of earlier recovery when it lay high rather than low in the cord. This would support the conclusion drawn from the observation of unilateral lesions that shock is not a direct mechanical disturbance of functional activity, but that its effects depend on the interruption of the neuronic impulses that normally flow continuously from the higher to the lower levels of the central nervous system.

Sherrington has pointed out that the effects of spinal shock are seen in experimental animals only in the aboral direction, and it is obvious that in man they are limited to segments distal to the lesion, as in even the rudest transverse lesion no symptoms are found above its level which are attributable to shock.

"AUTOMATIC" MOVEMENTS.

But, though the shock effect of these severe spinal traumata almost invariably abolishes or depresses seriously the functions of the isolated segments, in a group of four cases in which the lowest dorsal or highest lumbar segments were involved, "automatic" movements, such as are observed in certain spinal animals, occurred, and their occurrence can be interpreted only as the result of a reflex over-activity of the isolated segments. In one of these cases the lesion involved the first and the upper part of the second lumbar segment; in another it extended from the lower part of the twelfth dorsal to the middle of the second lumbar segment; in a third it reached as high as the eleventh dorsal segment and probably extended some distance downwards, while in the fourth it was probably limited to the third lumbar segment. In these cases the lesions were severe or total, and as the involuntary movements were identical or very similar in all four, their nature can be best conveyed by describing one case in detail.

CASE II.

Pté. D., 7687, who was first seen on January 6th, 1915, was wounded two days previously by shrapnel while crouching. He fell back and lost power in both legs at once and had some retention of urine. There was a small dry scabbed wound one inch to the left of the tenth dorsal spine.

His legs were flaccid and no voluntary movements of them were possible, but their muscles were not quite toneless. The trunk muscles were unaffected. Sensation was completely lost to the level of Ponpar's ligament on the right side and to a slightly lower level—that is, to the lower margin of the first lumbar root area—on the left. His knees and ankles jerks were absent; an indefinite extensor response was obtained on the right side, but only flexion of the great toe on the left. (In the other three cases only flexion of the toes could be elicited.)

There were constant involuntary rhythmical movements of both lower limbs, which apparently occurred apart from any peripheral stimulation. At first they occurred every four to seven seconds, but their rate later became somewhat slower. They consisted in alternate but not quite regular rhythmical flexion of the knees, with dorsiflexion of the feet, extension of the great toes, and slight flexion and outward rotation at the hips, followed by active extension of all segments of the limb. They were usually more marked in the right than in the left limb and were often grouped—that is, the movements of left and right limbs of the right side alternately. They were not influenced by the position of his limbs, and occurred equally whether these were flexed or straightened out, and whether he lay on his back or side. Stroking or pricking either sole produced a fairly brisk withdrawal reflex; it did not interrupt the sequence of the movements, however, but delayed them when the sole of the limb in which they were next due to appear was stimulated; stimulation of the sole of the limb in which the movements had just occurred had no effect. On the other hand, striking the great toe with a percussion hammer immediately excited the movements, but only when they had last occurred in the opposite limb—in fact, in each limb the movements were followed by a refractory phase, during which they could not be again obtained till they had occurred in the opposite limb; their sequence could not be altered by any movement that was tried, but their rhythm was accelerated for a time by pricking the inner sides of the thighs or the perineum.

Perussion of the patellar ligament did not give a knee-jerk, but was followed immediately by contraction of the hamstrings.

Four days after the infliction of the wound Lieutenant-Colonel Sargent performed a laminectomy. It was noted that the movements of the legs ceased when the chloroform anaesthesia became sufficiently deep to arrest consciousness.

The left side of the eleventh dorsal arch was found fractured, and a small sharp-edged fragment of the articular cartilage,

which measured 1 by 0.5 cm., had penetrated the dura and lacerated the cord at the level of the upper margin of the eleventh dorsal vertebra.

The patient recovered rapidly from the operation, but died fifteen days after receiving the wound. The rhythmical movements and his other symptoms persisted unaltered till death.

On post-mortem examination a laceration was found on the left side of the dorsal surface of the cord in the upper part of the second lumbar segment, and a piece of shell casing, which measured 3 by 4 by 7 mm., was removed from its right side at this level; it had passed through and destroyed the dorsal half of the cord, but a part of its ventral surface seemed little injured. On microscopic examination the dorsal columns were found destroyed in the lower part of the first and the upper part of the second lumbar segment, as well as the dorsal part of the left lateral column. The right lateral column was less extensively injured, but was softened; the ventral columns were not directly affected. There were practically no pathological changes in either the grey or the white matter below the second or above the first lumbar segment.

In another of the cases in which a post-mortem examination was made, it was also only the ventral columns that had escaped total destruction in the lower part of the twelfth dorsal and the upper two lumbar segments.

These alternate flexion and extension movements of the lower limbs obviously represent the rudiments of the lower physiological mechanism of gait, and are very similar to the "mark time" or progressive movements seen in the "spinal" dog; their nature must be the same as these reflex movements which Sherrington has described in the spinal animal.

It is interesting, however, that we have seen such involuntary reflex movements only when the lesion involved the upper lumbar segments of the cord, and that they occurred in a considerable proportion of all serious injuries at this level. In the only two cases in which the spinal cord has been examined there was exceptionally little distant disturbance, and the lower lumbar and the sacral segments were in both almost intact. It is also surprising that they should occur at least as early as the second day. Further observations will be necessary to determine the significance of the absence of direct structural damage in the ventral columns in the two cases which came to autopsy.

We have not observed any "automatic" movements of the limbs when the higher cervical segments were injured; in fact, these are always then flaccid and toneless, and their muscles usually wasted early. We have, however, obtained a reflex—which, as far as we know, has not been yet described—in cases in which the lesion lay in or above the fifth cervical segment, and produced paralysis of the upper limbs. Pricking, pinching, or firm stroking on the inner side of the arm then evoked, generally after a short latent period, a sudden and strong inward rotation and adduction of the arm on the same side, the inward rotation being apparently the prime and chief movement. We obtained this reflex in most of the cases of severe cervical lesions in which we examined for it, provided there was not an atrophic palsy of the arm.

CERVICAL SOFTENING.

Injuries in different portions of the cord naturally produce clinical symptoms differing not only in the extent, but also in nature of the paralysis. One of the most striking types is that which results from an incomplete lesion of the cervical enlargement. Since haemorrhages and secondary changes undoubtedly occur as a result of concussion more readily in this than in any other region of the cord, and since they are more liable to damage the grey than the white matter, the arms are frequently seriously paralysed, though there is fair or unaffected power of movement in the lower limbs. Not infrequently the paralysis, especially that of the arms, develops some time after the infliction of the wound, but, on the other hand, it is not uncommon to meet patients with gunshot wounds of the neck in whom all four limbs were at first paralysed, who had regained power within a week or so, the arms recovering almost invariably later than the legs.

The following case illustrates the chief clinical features of such an injury.

CASE III.

Lance-Corporal G., 11060, was wounded by fragments of a high explosive shell on September 15th, 1914. He found immediately that he had no power of movement in his right arm, but the left was unaffected; he was able to pick up his tobacco pouch with it and put it in his pocket. He walked thirty yards or so, stumbling and faint though his legs seemed quite strong, till he reached shelter. There he lost consciousness, and on

regaining it, twenty-four hours later, found both upper limbs completely paralysed and both legs weak. He had no sphincter trouble, and neither delay or difficulty in passing urine.

He was first seen by us five weeks later. Then there were three small scars on the right side of his neck opposite the spines of the third, fourth, and fifth vertebrae, and an x-ray examination revealed a fragment of shell casing at the level of the body of the seventh cervical vertebra.

Both arms were wasted, the left more than the right, and the only movement possible in the latter was feeble adduction at the shoulder. Practically no movement at the left shoulder or elbow was possible, and flexion of the wrist and of the fingers was very feeble, but the power of extension, adduction, and abduction of the fingers was fair. The trunk movements, as well as those of the right leg, were unaffected, but the left upper limb was somewhat rigid, and its distal movements were slightly feebler than those of the right. He was able to stand and walk easily, and his gait was almost normal.

The right arm-jerks were absent; the left knee and ankle jerks were increased, and stimulation of the left sole gave an extensor response. There was slight loss in the appreciation of pain and light tactile contacts on the left side up to the upper margin of the fourth cervical root area, and complete loss of recognition of posture, passive movement, form, and the compass points in the left arm. The knowledge of position and the discrimination of compass points were only diminished in the left lower limb and unimpaired in the right.

In this case a secondary haemorrhage or softening had obviously occurred in the cervical enlargement as a result of concussion, and the greater affection of the grey thal of the white matter had produced an atrophic palsy of the upper limbs, which is probably permanent, while the weakness of his lower limbs had gradually diminished.

Lesions of certain regions of the cord also produce special local symptoms. We have, for instance, repeatedly seen unilateral paralysis of the diaphragm, and in two cases at least bilateral palsy, due to lesions at the level of the fourth or fifth cervical segment; unilateral palsy of the diaphragm also occurred in two cases in which the main lesion was to the second cervical segment, but it was not observed in any patient in whom it lay lower than the fifth. The occurrence of nystagmus has also been described as a result of lesions in the higher cervical region, but we have observed it in only 3 of the 63 cases in which the cervical segments were injured, in lesions of the second, fifth, and seventh segments. It was slight and ill-sustained in all three, and disappeared rapidly, save in one patient, in whom it persisted at least fifteen days; but as in this case the exit wound was in the neighbourhood of the tip of the mastoid labyrinthine concussion cannot be here excluded.

PARALYSIS OF THE CERVICAL SYMPATHETIC.

Disturbances of the functions of the cervical sympathetic occurred with lesions of all segments between the second cervical and the second dorsal included; they are referred to in our notes on 36 cases, and in the great majority at least of these injury of the sympathetic fibres in the neck could be excluded. The most common and prominent symptom was miosis, or, in unilateral lesions, inequality of the pupils, the smaller being on the side of the lesion, and this, as a rule, failed to dilate, or dilated less rapidly and less completely on shading the eyes. A narrowing of the palpebral fissures in one or both eyes and some enophthalmos was also pronounced in most of the cases. Ptosis was also frequently observed, especially with lesions of the lower cervical and the first dorsal segments.

Disturbances in sweating on the affected side were also present in most of the cases; as a rule, the skin of the face, neck, and shoulders, as well as the hair of the head on the side of the spinal injury, was merely drier and less greasy than on the opposite side; but during the warm weather of the late summer, or in any condition that induced sweating, there was a very obvious difference, for the skin of the face, neck, and shoulder to the level of the second rib remained dry on the one side, while it was moist and covered with beads of sweat on the other. In certain unilateral lesions, too, a diminution of tear secretion was observed on the affected side, the eye being obviously drier and presenting a more staring and glassy appearance than the normal; a few patients even complained of this eye being "stuck" or difficult to open in the morning owing to the lids being adherent as a result of the drying of the undiluted conjunctival secretion.

Definite vasomotor disturbances associated with paralysis of the cervical sympathetic were less common, but

in several cases the face was more flushed and highly coloured on the affected side, especially after shaving.

It is known that the cilio-spinal centre lies in the lowest cervical and first dorsal segments, while the spinal centre of the other components of the cervical sympathetic is found in the two upper dorsal segments, and that these are influenced or controlled by efferent bulbar fibres which descend uncrossed through the cervical cord. It must be to disturbance of the latter that the symptoms just described are due when the lesion lies above the eighth cervical segment, while the spinal centres themselves are injured when the lesion lies below this. It is an interesting question if the symptoms due to lesions in these two sites differ. We have not, however, observed any essential or obvious difference, though both the ocular and secretory disturbances seemed to be on the whole more prominent and permanent when the spinal sympathetic centres were damaged than when the bulbar efferent fibres were involved; in fact, in the latter case the symptoms usually subsided quickly, and often disappeared under observation.

Symptoms of irritation of the cervical sympathetic did not occur in any case in which the spinal cord only was injured.

HYPOTHERMIA.

One of the most interesting types we have observed was due to injury of the lower part of the cervical enlargement, and was characterized by subnormal temperature, slow pulse, low blood pressure, and scanty secretion of urine. All the 10 patients in whom these symptoms occurred died within eight days after the infliction of the wound, and in all the lesion lay in approximately the same region.

On admission to a base hospital, generally one or two days after the injury, the most striking feature was the cold, collapsed condition of the patient. The skin was generally dry and remarkably cold even to touch, and it was noted in some that the superficial temperature on exposed parts, as the face or hands, was apparently no lower than that of covered parts. When the temperature was very low, a touch reminded one forcibly of the coldness of death—this was especially so in a man seen at a casualty clearing station soon after he received the wound. The skin was also generally cyanosed, and the face of a curious slate colour. The temperature varied in different cases, and as unfortunately a special thermometer to register it was not always available, in four of the ten cases we can only say that it was lower than could be registered in a clinical thermometer (that is, 36° C. = 95° F.). In one of the other six it sank to 78.8° F. (26° C.) in the rectum, and did not rise above 80° F. during the twenty-four hours he lived under observation, but in most of those in which accurate observations were made the lowest recorded lay between 80° and 84° F. In a few it rose suddenly before death to above the normal, and in one case which has been already recorded by Lieutenants Oliver and Winfield, actually rose from 80.4° to 105.6° F., that is, 25° F., in twenty-six hours (Fig. 2); in others it remained low till the patient ceased to live. In one case the patient lived at least three days with a temperature not rising above 90° F., and in two it did not exceed 85° F. for twenty-four hours, but as these cases usually did not come under our observation

Fig. 2.—D. Death.

in others it remained low till the patient ceased to live. In one case the patient lived at least three days with a temperature not rising above 90° F., and in two it did not exceed 85° F. for twenty-four hours, but as these cases usually did not come under our observation

till the third day, it is probable that life could be maintained even longer with this low temperature.

The temperature was always taken in both the mouth and axilla, and in a few instances in the rectum too; the thermometer in the mouth generally registered slightly higher than in the axilla, but, except in one case in which it was a few degrees higher, the rectal temperature was approximately equal to that in the mouth.

In all cases, too, the pulse-rate was very slow, while the temperature remained low, and it increased in frequency as this rose; in one case it was only 22 per minute, and in the others ranged between 30 and 50 per minute till the temperature approached normal limits. In one patient it was 32 when the temperature in the mouth was 80.6° F., and rose to 102 when this reached 98.8° F. The pulse was also very soft and of low tension while the temperature remained down; unfortunately, sphygmomanometric observations were possible in only three cases, and in these the pressure registered 56, 72, and 73 mm. of mercury.

As the intercostal muscles were paralysed in every case, respiration was wholly diaphragmatic, but its rate was approximately normal, except in one in which it was only

Fig. 3.—D. Death.

9 per minute, while the temperature remained under 80° F. It must be, however, remembered that when the respiratory movements are much restricted their rate is usually increased, and consequently we may assume a relative slowing of respiration.

The fourth special symptom was the small amount of urine passed. In one man who lived forty-eight hours no urine was secreted; another secreted only 20 oz. in three days; a third probably only 8 oz. in four days; while from a fourth (Fig. 3), whose temperature varied between 87° F. and 105° F. and his pulse-rate between 40 and 104, only 20 to 25 oz. could be drawn off during the first three days, but the daily amount increased to 50 to 60 oz. for the last two days, when his temperature ranged between 100° F. and 105° F. The amount of urea was estimated in two cases in which very little urine was secreted, and its percentage was approximately normal.

The mental state of these patients was another interesting feature: when the temperature was very low, or at least below 85° F., they were stuporose or extremely lethargic, but, with the exception of one case, they could be roused, and then appeared quite intelligent and answered questions rationally, though they always tended to drift quickly again into a lethargic and apathetic state, unconcerned with their condition and immediate wants. As their temperature rose this mental lethargy quickly passed off, and they became bright and fully conscious of their serious condition—in fact, their mental state varied directly with their temperature.

The general appearance of these patients with low temperature, slow pulse-rate, stupor or mental lethargy,

and low metabolic exchange, as indicated by the small amount of urine of normal constitution secreted, reminded one strongly of an animal in hibernation, and as in the hibernating animal the pulse-rate and amount of urine secreted increased and the stupor passed off as the temperature rose to normal limits.

Post-mortem examinations were obtained in nine of the ten cases; in two the chief injury was to the sixth cervical segment, in two to the seventh, in one the seventh and eighth cervical segments were damaged, and in the remaining four the eighth cervical and the first dorsal. In four of these cords there were practically complete transverse lesions; in the others the injury seemed to be only partial, but except in one of these a microscopical examination has not yet been made. Further, from the clinical signs a complete transverse lesion would not be diagnosed in at least three of these cases—in fact, one was able to move both legs from the time he came under observation till his death. In his cord microscopical examination revealed haemorrhages with oedema and foci of necrosis in the seventh and the upper part of the eighth cervical segments, small haemorrhages and swollen axis cylinders above the lesion as high as the fourth, and a cylindrical cavity descending through the dorsal columns from the first to the third dorsal segment.

A condition similar to that above described has been repeatedly produced in animals by section of the cervical cord; this is, in fact, followed by a fall in temperature and

Fig. 4.—D. Death.

diminished secretion of urine, and death within a few days. And the same symptoms have been observed in man when the cervical cord has been injured by a fracture or dislocation of the neck. Parkin,² for instance, records a case of destruction of the fifth to the seventh cervical segments, in which the temperature fell as low as 78° F. and the pulse-rate to 26-37 per minute; and Nieden³ another case of dislocation of the first dorsal vertebra, in which the temperature gradually fell to 80.6° F. before death on the eleventh day, and the pulse-rate sank to 30 per minute. The blood pressure was evidently very low in both of these cases, as the pulse was described as hardly perceptible.

On the other hand, we have seen several cases of complete or very severe injury between the fifth cervical and the first dorsal segment in which these symptoms were not present.

We have some evidence that these patients do react to some extent as cold-blooded animals, and that their temperature may vary with the external temperature: in one patient, for instance, the temperature rose from 84.2° to 95° F. (Fig. 4) when he was placed on a hot-water bed and packed around with hot-water bottles, and another from 85° to 105.6° F., when he was brought into a room heated to 70° F. and also surrounded by warm bedclothes and hot-water bottles. This interpretation of the latter observation is not, however, beyond doubt, as a final rise of temperature occurred in other patients.

In another case an injection of pituitrin brought the temperature for a few hours almost up to normal, and

increased the pulse and respiratory rates, while at the same time the patient, who had been very dull and lethargic, became temporarily bright and intelligent.

The interpretation of these observations cannot be attempted here; they might be taken as evidence of the existence of a heat regulating centre in the lower part of the cervical enlargement, as Dr. Hale White has assumed, or, on the other hand, the fall of temperature might be attributed to diminished heat production consequent on muscular inactivity; a similar fall occurs in curarized animals. Probably the most important factors are deficient thermogenesis and a visceral vasomotor palsy produced by shock in the sympathetic system. Captain Shorten,¹ however, in a short comment on the case published by Lieutenants Oliver and Winfield, suggested that the symptoms may be due to the interruption of descending fibres in the cord which control and regulate the activity of the adrenals, and Professor Harvey Cushing, who kindly saw one of our cases, had suggested previously to us that a cervical sympathetic palsy may disturb the functions of the pituitary and that this may interfere with the correlated activity of the suprarenals. If Captain Shorten's hypothesis is correct we could expect to find hypothermia and its associated symptoms more commonly in cervical and bulbar lesions, and its absence after section of the cervical sympathetics argues against Dr. Harvey Cushing's suggestion. The adrenals appeared normal to the naked eye in one of our cases.

CERVICAL PYREXIA.

Benjamin Brodie, Chossat, and others have described a rise of temperature in animals after injury of the cervical cord, and Sir Jonathan Hutchinson,² Sir Hermann Weber,³ and numerous other clinical observers have observed pyrexia with similar injuries in man. As in most of our patients there were septic wounds associated with the spinal lesion, and as in several cystitis coexisted, particular care is necessary in interpreting our observations on this point, but some are unequivocal. In one patient, for instance, with symptoms of a partial lesion in the fourth cervical segment and a small clean entry wound of a rifle bullet just below the tip of the right mastoid, in which there were no signs of infection, the temperature on several occasions rose to 104° F. and quickly fell again to

injury lies in the middle of the dorsal cord, especially between the fifth and eighth dorsal segments. From one patient with a total transverse lesion between the seventh and eighth dorsal segments an average of 145 oz. was drawn off by catheter during the first six days he was under observation, even 215 oz. in one day. During the next six days and till death the average daily amount secreted was 90 oz. In another patient with a severe lesion of the fifth dorsal segment the average amount drawn off during the first eighteen days was 80 oz.; and in a third, who had sustained a complete destruction of the eighth dorsal segment, the daily average during the first three weeks was 125 oz., but fell during the next three weeks to a daily average of 66 oz. In fact, in the majority of patients with injuries to this region of the cord in whom observations were made, an excessive amount of urine was secreted. Unfortunately, we have not yet obtained a complete analysis of the urine when it is in great excess.

This polyuria is probably due to paralysis of the sympathetic fibres, and especially of the vaso-constrictors, to the kidney. Claude Bernard and Sir John Rose Bradford, it will be remembered, produced it by section of the splanchnics and of the lower dorsal roots.

PULSE-RATE.

While a slow pulse-rate has been one of the characteristic symptoms of severe lesions of the lower part of the cervical enlargement, a marked and persistent acceleration of its rate was often present in partial lesions of this region, especially when the upper two dorsal segments were involved. In one case of partial destruction of the second dorsal segment, for instance, it rarely fell below 100 per minute and was frequently 120, and this independently of any rise of temperature or other obvious cause. In another severe injury of the same segment it ranged between 72 and 140 per minute, and in a third it never fell below 120 per minute. But the most striking alterations are perhaps seen with partial injuries of the four lower cervical segments in which the patient seems in perfect health apart from his spinal injury. In one such patient, who remained three months under observation with an originally slight injury of the fourth cervical segment which later progressed, the pulse-rate constantly

Fig. 5.

normal (Fig. 5). In this and in other patients the pyrexia was not associated with any signs of illness or discomfort, and the pulse-rate did not vary as the temperature rose. In several other patients with partial or unilateral lesions between the third and sixth cervical segments, whom we were able to keep under observation for several weeks, the temperature was frequently above normal, and often reached 102° F. to 103° F. without any apparent cause.

Another interesting observation was persistent shivering of the shoulders, neck, and face without any rise of temperature or disturbance of the pulse-rate, and without any subjective feeling of coldness associated with lesions of the lowest cervical and upper three dorsal segments. This occurred only in severe injuries of this region, and persisted over several days.

POLYURIA.

We have described diminished secretion of urine with lesions of the lower part of the cervical enlargement, but the daily quantity is frequently much increased when the

lay between 100 and 120, and only occasionally in the latter part of this period fell to 90 per minute, and in a similar uncomplicated case of injury to the fifth cervical segment the rate varied between 96

and 130 per minute. It was always regular, however, in these cases and of good volume and fair tension.

VOMITING.

When the mid-dorsal region is severely injured the abdomen is frequently tense and blown out and the patient presents the symptoms of paralytic distension of the intestines. But a more striking symptom which is sometimes associated with it, but which often occurs without any objective symptoms of abdominal disturbance, is vomiting. In the larger proportion of the cases in which it was observed the lesion lay in the sixth, seventh, or eighth dorsal segment.

It was often so persistent that it threatened life, as in severe cases no nourishment could be kept down. In several instances it set in within a few hours of infliction of the wound, and in many severe cases persisted till death or as long as we had the patients under observation. It was generally forcible and projectile, and was apparently associated with much discomfort, but with little nausea, though a few patients complained of the feeling of sickness.

In mild cases it occurred only some time after taking food, and this alone might be brought up in a half-digested state, but when severer it was more or less constant and mucous stuff occasionally coloured with bile, and in a few instances blood-stained, was ejected. In some of our notes the similarity to the vomiting of a tabetic crisis is remarked on.

As in the large majority of cases in which this type of vomiting occurred the lesion lay in the region of the sympathetic outflow to the stomach it might be attributed to irritation or disturbance of the function of these fibres. And there is much evidence that this is its cause. Almost without exception these patients complained of girdle pains around the body, or on one or other side, between the level of the xiphoid and umbilicus, and of great tenderness to light contact, rubbing and other stimuli in the region in which the referred pain and tenderness associated with gastric disease occurs. Further, in several there was a persistent local contraction of a portion of the abdominal muscles between the xiphoid and the umbilicus corresponding to the cutaneous hyperaesthesia, which increased and produced pain when this area of skin was stimulated. In fact, the firm resistance and tenderness of this area to touch occasionally gave rise to the suspicion of a large intra-abdominal lesion. In a few patients the intercostals innervated by the same dorsal roots were also in contraction, and everted the ribs to which these were attached.

Vomiting occasionally occurred after injury to other regions of the cord, too, but in most of these cases it was associated with and probably due to intestinal paralysis, to severe septic infection, or to the cystitis or pyelonephritis which occur so frequently with spinal lesions. In a few cases of cervical injury, however, it was a prominent symptom, and could not be attributed to any of these causes.

When severe and frequent, such vomiting naturally exhausted the patient and induced emaciation. Great loss of flesh also occurs, as might be expected, in severe cases which run a downward course, but it is an interesting fact that it was seen also in patients with relatively slight injuries of the cervical enlargement who took food well and even had excessive appetites. We have observed several patients, for instance, with unilateral lesions of this region producing the Brown-Séquard syndrome, but apparently not affecting their general health, in whom there was extreme emaciation. In some of these the pulse-rate was increased, and there was slight pyrexia, but otherwise the visceral functions seemed unaffected.

PRAPISM.

Numerous other symptoms occurred as a result of spinal lesions, to which time will not permit reference here. Priapism has been frequently described, especially with lesions in the cervical region, but we have observed it in only a small proportion of our cases, and it seemed to occur relatively as frequently with lesions of the dorsal as of the higher segments. It was usually merely a soft turgescence of the penis. If, as is assumed, it is merely due to vascular engorgement, it is interesting to note that it occurred in two of our patients with low temperature, low blood pressure, and a slow pulse-rate; it was present in one man when the blood pressure was only 73 mm. of mercury.

TROPIC DISTURBANCES.

Various trophic disturbances were common in the severer cases, especially bullae and blisters in those parts of the paralysed regions which were subjected to any pressure. Irregular patches of red or strawberry-coloured discoloration, which were scarcely modified by pressure and disappeared slowly leaving a slight mottling of the skin, also occurred frequently in the same parts. Joint changes were not common in the early stages, though there was occasionally effusion with the knees or ankles when the legs were completely paralysed, and in a few patients we observed early arthritic affection of the fingers and wrist when the cervical cord was damaged.

HERPES.

Herpes occurred in nine cases, either immediately above or at the upper margin of the sensory loss. It developed between the third and the fifteenth day, and in three instances recurred in the same area. It usually first appeared as a zone of diffuse erythema with small papules which later became vesicular or pustular, generally in a

region in which there was either pain or tenderness. It usually lasted seven to fourteen days and disappeared, leaving some discoloration and brownish discoloration of the skin. Such larger vesicles as are seen in idiopathic herpes were not observed, and in one case there were only papules and vesicles without any erythema of the skin. In two cases in which *post-mortem* examinations were obtained the corresponding spinal ganglia were found bruised by displaced fragments of the vertebral column, and the clinical symptoms or the course of the missile made it probable that a ganglion was damaged in the other cases too; its pathology is consequently allied to that described for idiopathic herpes by Bäreusprung, and confirmed by Drs. Head and Campbell.

The state of sensation in the herpetic zone was variable; in some cases there was only excessive tenderness to contact, rubbing, cold, and other stimuli, associated with spontaneous pain; in other there were the symptoms of a root lesion, that is, a band of insensitiveness to pin-prick and to moderate degrees of temperature, with loss or diminution of tactility within it. In those cases in which there was definite sensory loss it was found that this was not coterminal or did not correspond with the area of the eruption; Sherrington has shown that the dermatomes are not superimposed in the myomeres, and it is obvious, too, that the peripheral distribution of the radicular fibres, which, when injured, are concerned in the production of herpes, do not coincide accurately with either.

MEDICAL, SURGICAL, OBSTETRICAL.

CONGENITAL ABSENCE OF RADII.

THE publication in the *JOURNAL* of September 11th, by Major Mansel Symptom, of a case of congenital dislocation of the right foot with almost complete absence of the fibula tempts me to put forward a somewhat similar case, in which, however, both upper limbs are affected.

The patient, E. H., aged 16 years, an inmate of Dr. Barnardo's Homes, is an intelligent child whose father, however, is insane and an epileptic.

Both hands are dislocated to the ulnar side, and are at right angles to the forearms; the radiograms—a drawing from one of which is reproduced—show that there is complete absence of both radii. The radiographs were taken by Dr. G. Gushue-Taylor in November, 1910.

In spite of her deformity she can write distinctly, and is being taught to do various kinds of embroidery, which she does very well.

"CHLORINE WATER" AS A DRESSING.

IN the *JOURNAL* of May 8th I published an article on the "Sterilization of Water by Chlorine." It occurred to me over two years ago, when working at this subject, that in addition to using my method for water purification, one might also use the "chlorine water" thus prepared as an antiseptic lotion. By doing this one would have an

service an unlimited supply of antiseptic always at hand. I accordingly brought the use of chlorine as a wash and moist dressing into use in my regimental hospital and had every reason to be satisfied with the results obtained.

The strength of chlorine used by me is somewhat weaker than that used by Captain Fraser. My method of preparing chlorine is by acting on potassium chlorate with concentrated hydrochloric acid, the gas going into solution as it bubbles through water, as described in the article referred to above. In this way a solution of a strength of 1 in 500 of chlorine in water is obtained. As a wash it is used undiluted. As a moist dressing I dilute it 1 in 3, as if used in greater strength it causes irritation, which may even go on to vesication.

Prior to the war it was in general use in my regimental hospital for various septic conditions, such as ulcers, boot bites, lacerated wounds, boils, etc., and as a gargle for septic throats (1 in 5) and a mouth wash in pyorrhoea alveolaris, it proved most efficacious. Since going on service a year ago I have continued to use it in these conditions, and also as an antiseptic wash and dressing for shrapnel and small arms wounds, no other antiseptic being used by me. The results obtained have fully justified its adoption, and, as already stated, the fact that the water sterilizing outfit is also an unailing source of supply of so useful a lotion has proved a great boon. Many cases of flesh wounds have not needed to be sent to the field ambulances, and all have healed by first intention. The fate of the more serious cases, which have had to be evacuated, I am unable to write about, but the large proportion who were very quickly discharged from hospital and returned to the firing line indicates that their wounds also followed an aseptic course.

J. J. HARPER NELSON, Captain I.M.S.

SALINE SOLUTION AS A DRESSING.

I AM interested in the good results obtained from irrigating septic wounds with salt solution, for I have used it frequently for the last three or four years, and lately have been in the habit of dressing ordinary flesh wounds with a saline solution with good results.

The method that I have employed for ordinary surface wounds is by dressing them with a piece of surgical lint soaked in a solution of sodium bicarbonate, the lint being then covered over by a layer of oil silk or jaconet. This method promotes healthy granulations and a speedy repair of the damaged tissues.

W. ROES KEMP, Lieutenant R.A.M.C.

Clipstone Camp, Notts.

Reports of Societies.

GAS POISONING: PHYSIOLOGICAL SYMPTOMS AND CLINICAL TREATMENT.

At a meeting of the Medical Society of London on November 29th Dr. LEONARD HILL read the paper which will be found in full at page 801.

The President (Dr. W. PASTEUR) related a case of a man who had been gassed three times with chlorine, and who arrived in England apparently well, but who every two or three days suffered from attacks of dyspnoea and lividity. It was as yet undetermined whether these attacks were the result of organic causes or were of the nature of a neurosis.

Professor BENJAMIN MOORE said that an investigation of the effects of gas poisoning opened up experimental channels for the elucidation of respiratory diseases. The use by the Germans of the asphyxiating gases must have been premeditated and arranged by previous researches, and it must be our object to prepare offensive and defensive means of countering it. Fortunately, the gas used lent itself readily to means of defence. The oedema produced by it was profound; it was a protective reaction which was overdone, and the exudate practically drowned the patient. The first aim of treatment should be to drain off the exuded fluid; if a means could be devised to keep up the discharge of the fluid and at the same time to leave sufficient lung active much might be achieved. Nearly all the severe cases in animals, if not immediately

fatal, ultimately terminated fatally from septic bronchopneumonia. The attention of clinicians should be drawn to this, so that the risk might be prevented if possible.

Dr. WILLIAM HILL suggested that possibly a combination of tracheotomy and the use of exhaust bottle might allow both of regular drainage and the administration of oxygen. In civilian work it had been found that a drop or two of ether relieved the surface tension of the fluid at once, and the foam about the mucus disappeared.

Mr. C. V. CARGILL referred to a case of retinal haemorrhages in each eye which had followed "gassing." It had cleared up in a few weeks.

Dr. NEWTON PITT pointed out that the effect of obstruction of bronchi was first pulmonary collapse but afterwards over-distension. This had an important bearing on the intense dyspnoea. The lung became more and more over-distended, and air was sucked to its superficial parts while the fluid collected in the deeper. An important factor in treatment was to lower the patient's head and to compress the chest to get the fluid to pass out. Permanent changes seemed to be produced in certain cases. In oedema of the lung and serous exudation in the lung, such as occurred after tapping the pleura, atropine had been found distinctly useful. There was also some evidence in favour of the use of adrenalin and pituitary extract. He disapproved of the use of the term "emphysema" for over-distension produced by mechanical means.

Dr. LEONARD HILL, in reply, said that he could not agree that fluid collected in the most dependent parts of the lungs. Its distribution was somewhat peculiar, and possibly due to the action of the bronchial muscle, which allowed fluid to enter some parts while it prevented it in others. He had restricted his remarks concerning atropine to severe cases; there was no reason why it should not prove beneficial in milder ones.

Reviews.

MATHEMATICAL BIOCHEMISTRY.

In its earliest days chemistry was a purely qualitative science, a matter of tests, colour-reactions, precipitates, and explosions. Towards the end of the eighteenth century it took on a quantitative cast, and proportions by weight or volume came to be regarded as of increasing importance. As a further step in the same direction, physical chemistry became more and more a matter of mathematical analysis and expression in the last quarter of the nineteenth century. It is now the turn of biological chemistry and the chemistry of immunity to be annexed and elucidated by the mathematicians. Eighteen months ago Dr. SVANTE ARRHENIUS delivered the Tyndall lectures at the Royal Institution, choosing for his subject the mathematical treatment of biochemistry. He has now amplified these lectures, and published them in the form of a book¹ containing six chapters. These are cast in the rigid lines of physical chemistry, and deal with various aspects of chemical reactions and chemical equilibrium in their particular applications to the living body and immunization. The author is at pains throughout to show that life is after all a matter of mathematics, and that living processes, like the processes of inorganic nature, are amenable to mathematical treatment by means of graphical representation, logarithms, coefficients, integration, and the like. The book is one for biologists and chemists with mathematical turns of mind; for example, the author expresses (p. 88) the whole progress of the digestion of meat by dogs in the formula:

$$dx : dt = 125 (1 - e^{-0.075x})$$

in which x is the quantity of undigested flesh in grams.

It is very satisfactory to find explained in this book the way in which mathematical analysis has pulverized the "poison spectrum" attributed to certain toxins, such as diphtheria toxin, by Ehrlich. It is only a few years ago that Ehrlich and Sachs, analysing as experimental pathologists the toxicity of various mixtures of toxin and anti-toxin, came to the conclusion that diphtheria poison contained within itself as many as ten varieties of "toxins"

¹ *Quantitative Laws in Biological Chemistry*, by S. Arrhenius, Ph.D., M.D., LL.D., F.R.S., London: G. Bell and Sons, Ltd., 1915. (Demy 8vo, pp. 175; 36 figures. 6s. net.)

and "toxoids," each with its various affinities and toxicities. But, with the aid of mathematical analysis, Dr. Arrhenius is able to show that, by parity of reasoning, the neutralization of ammonia with boracic acid can be made to prove that the ammonia is built up of not less than six components or "partial poisons." This conclusion is obviously absurd in the case of ammonia, and the diphtherial "poison spectrum" must no less go by the board, for it is based only on the relatively great errors of observation inseparable from such biological experiments as were at the disposal of Ehrlich and Sachs as the basis of their calculations. Dr. Arrhenius has been well known to chemists as a profound and original mathematician for thirty years or more. His book is clearly written and as intelligible to the plain man as any such work can be. It should be in the hands of all who are interested in the wide problems of biochemistry.

HANDBOOKS OF SURGERY.

A Textbook of Surgery,² by Mr. RICHARD WARREN, makes a very creditable appearance. It is in two volumes, which is a good plan, as it makes for ease in handling, and the print and illustrations are good. It is stated that the aim of the book is to place before the reader the more practical issues of surgery from the standpoint of the general surgeon. This book does admirably. It may be said to cover the ground completely without reaching the unwieldy bulk of some works on surgery. The arrangement and the grouping of subjects are both decidedly good. Of necessity one textbook on surgery must be very like another, but it often happens that when the practitioner turns to a book for help, the very point that is wanted is either not mentioned or dismissed with the briefest notice. This test of indiscriminate "dipping" is severe, but when applied to this book it was not found wanting. At the present day it is probably easier to write a new book than to bring an old one up to date, as there is a tendency to retain old-world theories and practices to the detriment of the more modern lines of treatment. In the book under consideration Professor Adams's scheme for the classification of tumours has been adopted, which is doubtless a step in the right direction, as this classification is now taught in most schools of pathology. The sections dealing with bones (including fractures), blood vessels, abdomen, and the urinary system are written with due regard to the developments of recent years. The surgery of the ear is placed in the same section as that dealing with the brain and meninges, which is a good plan, as the ear is so often responsible for infections of the latter. The sections on the cord and peripheral nervous system are especially good, and are well worth the attention of candidates for examination. Nerve injuries are common nowadays, and have a way of turning up at examinations. In conclusion, it may be truthfully said that Mr. Warren's book is excellent of its kind and may be most strongly recommended.

A new English edition of the second volume of FÉLIX LEJARS'S *Urgent Surgery*³ has lately been published. The translation from the seventh French edition, by W. S. DICKE and E. WARD, is all that could be desired. The volume contains sections on the genito-urinary organs, the rectum and anus, on strangulated herniae, and on the extremities. The general production of the book and illustrations are excellent. The work is throughout most practical, and the author has the happy knack, only to be gained by long experience, of laying stress on the small details which make the difference. More than half the book is devoted to the surgery of the extremities. Fractures, dislocations, wounds of joints and injuries to nerves are all fully dealt with. The application of plaster splints in cases of fracture is fully described. The author is strongly of opinion that plaster splints should be used as first dressings in cases of compound fracture, so as to

secure absolute immobilization of the fragments. This use of plaster is perhaps the most noticeable thing about French military surgery at the present day. Some of these splints now in use are truly works of art. An outstanding feature of the book is the description of the various forms of strangulated herniae. This is one of the best accounts of the subject that has yet been published. The author rightly points out that the operation for the relief of strangulated hernia is one that any practitioner may be called upon to do, and further that it is an operation that any practitioner can do with ease if the case is not left too long, and the procedure be gone about in a systematic manner. Simple, straightforward cases are first described in detail, and then the various complications are considered. Under this latter heading fall adhesions within the sac, abnormal contents of sac, and cases complicated by previous injudicious taxis. The rare forms of strangulated hernia and their treatment are then discussed, and some most interesting cases mentioned. The book may be most strongly recommended to all, but perhaps more especially to those amongst us who have never held hospital appointments, and thus have had no chance of operating under the direct supervision of a senior.

Under the title *Practical Manual of Bandaging*⁴ Dr. D. C. L. FITZWILLIAMS has brought out a most useful little book. It was written, we are told, in Malta, when the author was medical officer to 1,500 prisoners of war of various nationalities, and while he was actively engaged in preparing orderlies for their duties in the field. The descriptions of the application of the various bandages are lucid and the illustrations clear and easy to follow. As regards the scope of the book all the well recognized roller bandages are described, and space is devoted to the various forms of triangular bandage and their application. Special bandages and the application of plaster are also discussed. In fact, any one who has carefully worked through the book with a suitable subject for practice, should never be at a loss to find an efficient method of bandaging any part of the body. The illustrations, it is stated, were drawn by one of the Hungarian prisoners of war. The frontispiece gives a touch of topical interest to the book, as it depicts the German Crown Prince with his foot and leg swathed in bandages supported round the neck by a sling. In conclusion, one may say that the book should prove of value to many who nowadays take an interest in matters surgical.

CRIMINOLOGY.

THE volume of the literature of criminology is out of all proportion to its importance. Judging by the number of publications and by the immense size of the books on criminology one would suppose that it was, like political economy, a well-established science whose professors, if they do not agree on the solutions of its problems, at least agree on what the main problems are; but familiarity with the literature of criminology soon dissipates this notion. It is filled with pious aspirations; with dogmatic assertions that have no sufficient grounds; with wild speculations that are proposed as hard facts; with crude statistics on matters that cannot be statistically estimated, collected by persons who show violent prejudice, and without any comparison with statistics, collected on a similar basis, of non-criminals. The intelligent outsider has therefore acquired a deep distrust of criminological literature, and it is with no small surprise that he finds a book which is a plain record of facts about individual criminals, collected with great industry and considerable acumen, and utterly destitute of hasty generalizations and crude theories. Dr. HEALY'S *The Individual Delinquent*⁵ is the most valuable contribution to the study of criminals that has yet been published, for the effort of the author, who is attached for the purpose to the juvenile criminal court at Chicago, has been, in every one of the thousand cases whose results are here recorded, to get at the causes, not of criminality in general, but of the criminality of the particular person whose case he is investigating. In this he seems to have been generally

² *A Textbook of Surgery*. By R. Warren, M.D., M.Ch. Oron., F.R.C.S. Vols I and II. London: J. and A. Churchill, 1915. (Roy. 8vo, pp. 755 and 749; 266 and 239 figures. 25s. net.)

³ *Urgent Surgery*. By Félix Lejars. Translated from the seventh French edition by W. S. Dicke, F.R.C.S., and E. Ward, M.A., M.D., F.R.C.S. (Third English impression.) Vol. II, The Genito-Urinary Organs; The Rectum and Anus; The Strangulated Hernias; The Extremities. Bristol: John Wright and Sons, Ltd. London: Simpkin, Marshall, Hamilton, Kent and Co., Ltd. New York: W. Wood and Co. Toronto: The Macmillan Co. of Canada. 1915. (Sup.-roy. 8vo, pp. 597; 601 figures. 25s. net.)

⁴ *A Practical Manual of Bandaging*. By D. C. L. Fitzwilliams, Captain R.A.M.C. London: Baillière, Tindall, and Cox, 1915. (Demy 8vo, pp. 97; 1 plate, 190 figures. 3s. 6d. net.)

⁵ *The Individual Delinquent*. By William Healy, A.B., M.D. London: W. Heinemann. 1915. (Demy 8vo, pp. 845; 10 plates. 21s. net.)

successful, and the reader is much impressed with the openness of mind of the investigator. Dr. Healy has approached his thousand cases with no preconceived views of the causation of criminality, with no theory to support, but simply with the desire to discover; and, as has been said, he has been upon the whole very successful. His conclusions are that the born criminal does not exist; that there is no physique characteristic of the criminal; that there is no criminal subspecies of man; that, while mental abnormality is a causal factor in more than one half the cases he examined, mental deficiency, properly so-called, was present in only about a quarter; that in but few cases was only one factor operative; and the most important conclusion of all is that by careful and patient investigation the causes of a young person becoming criminal can usually be discovered, and when discovered can often be removed.

The book is divided into two parts, of which the first treats of generalities and methods, and the second relates individual cases illustrative both of methods and of causes. Dr. Healy recognizes the desirability and importance of testing and estimating other mental faculties than intelligence and memory, and he has devised a number of ingenious methods of testing such faculties as attention, motor co-ordination, association, perception of relations of form and colour, ability to profit by experience, foresight, and what he calls planfulness, which is what we on this side of the water should call ingenuity, judgement, vocational tests, and so forth. The aim of these tests is extremely praiseworthy, and shows in what an enlightened spirit Dr. Healy approaches his subject; but whether his tests are competent to elicit the information he desires may be doubted. It is, however, much easier to criticize them than to devise better ones, and no doubt as time goes on they will be improved. The important thing is that he does recognize how little value is to be placed on the mere ability or inability to satisfy verbal tests, and how utterly useless for all practical purposes are in this matter the reaction tests and the results of using the algometer and the ergograph and the rest of the armamentarium of the "physiological psychologist." The general result of the investigations shows that a criminal is by no means necessarily deficient in ability, and, in fact, that many criminals are in this respect decidedly above the average.

The greater part of the book is occupied by the records of individual cases as illustrative of the various factors which conduce to the commission of crimes. These factors are very numerous, and rarely act alone; and from Dr. Healy's method of approaching the cases without any theory to support or any preconceived opinion to establish, he succeeds in showing that they are surprisingly various, ranging from defective eyesight to parental neglect, and from epilepsy to puritanic upbringing. One notable discovery is the small part attributed to excess in alcohol in young criminals in contrast with the considerable frequency of excessive indulgence in tea and coffee.

Dr. Healy is no supporter of the view that criminality is a disease, nor is he captivated by any of the many fads that thrive amongst criminologists. He insists on the necessity of punishment, but he insists also that punishment should not harm the offender, as in practice it usually does.

MEDICAL ELECTRICITY AND X RAYS.

THE second edition of Dr. Tousey's massive volume on *Medical Electricity, Röntgen Rays, and Radium*⁶ has been enlarged and brought fairly up to date; the first edition was published five years ago. It begins with a thorough and well-written account of the phenomena and nature of static and dynamic electricity. Next follow chapters on the employment of various forms of electricity in the diagnosis and treatment of nervous and other diseases. The subject of high frequency currents is treated at length in a chapter of 100 pages. In the second half of the volume the x rays receive a no less thorough and scientific consideration; their use in diagnosis is very completely illustrated, and x-ray therapy is equally well described. At the end of the volume some forty pages

are given to the subject of radium, its origin, and its physiological and pathological effects. It may be noted that Dr. Tousey speaks highly of the Coolidge x-ray tube; in this country, we believe, its employment has not been entirely free from disappointment. Dr. Tousey writes very clearly; the book is illustrated with 16 coloured plates and nearly 800 other illustrations. There is a very complete index.

We are disposed to quarrel with Dr. REGINALD MORTON's title-page, for he describes his treatise as *A Textbook of Radiology*,⁷ unqualified even by a subtitle, but the book in fact deals exclusively with x rays, and almost entirely with x rays in diagnosis. The nomenclature in this department of knowledge is hardly yet out of the furnace, but it seems desirable that the term "radiology" should be reserved to denote the science of all the various forms of radiant energy, instead of being narrowed down, as it is in this instance, to only one of them, and to that one merely in its practical applications. This apart, the work is admirably planned for the purpose of the student. The author begins with an explanation of the focus tube, to which every other part of the x-ray outfit is subsidiary, and from this point he works backwards to the question of electrical supply and of accessory apparatus. Photographic and fluoroscopic technique is described very fully, and then there follows, in a series of chapters, a discussion on the use of x rays in medical and surgical diagnosis. Perhaps the most valuable of these chapters is that on the digestive system, which is illustrated by some admirably drawn figures. The last twenty pages are devoted to a survey of the largely unmapped *Hinterland* of x-ray therapeutics; the author seems to approach this part of his task with some diffidence, and carries it through conservatively. Several of the modifications Dr. Morton describes, notably one for completely suppressing the inverse current from the coil, are his own design. A fuller index might be included in those succeeding editions which may be confidently predicted for so useful and authoritative a book.

Dr. A. C. CHRISTIE⁸ has recently published a short account of his x-ray study of gastric and intestinal cases in the laboratory of the United States Army Medical School. He advises the use of barium sulphate rather than bismuth subcarbonate. He uses 10 x 12 plates for photographic investigation of the stomach, and plates 14 x 17 for the colon. He finds x rays of great assistance in the detection of gastric ulcer. Two varieties of gastric ulcer may be directly diagnosed—namely, the penetrating ulcer with a deep crater, and the perforating ulcer with cavity formation. He adds that there are other signs of great value here, although they are not diagnostic of gastric ulcer in themselves. These are the incisures, the six-hour residue, the hour-glass stomach, and a localized point of tenderness on pressure. If the ulcer is on the lesser curvature, the incisure practically always occurs on the greater curvature. Care must be taken not to confuse the cardiac incisure occurring in normal stomachs under the left costal margin, or the angular incisure normally occurring in the angle of the lesser curvature, with those incisures due to gastric ulcer. It must be remembered, too, that incisures may be caused by reflex irritation from an inflamed appendix or gall bladder. Hence to be of value as a diagnostic aid the incisure must be constant in position and accompanied by other signs of ulceration. He attributes the incisure of gastric ulceration to spasmodic contraction of the circular muscular fibres of the gastric wall; its edges are usually quite smooth and its extremity bluntly rounded. A marked residue in the stomach at the end of six hours, amounting to one-eighth of the meal or more, is considered a confirmatory sign of gastric ulcer; it is attributed to pylorospasm. Dr. Christie adds that the hour-glass stomach is of the same value in the diagnosis of gastric ulcer as the incisure, for it is due to the same cause—namely, spasm set up by irritation. As for a localized spot tender on pressure, he says that it must be very sharply circumscribed, constantly present, and accompanied by other

⁶ *A Textbook of Radiology*, by E. R. Morton, C.M. (Trin., Tor.) F.R.C.S., Ed., etc. London: H. Kimpton, 1915. (Demy 8vo, pp. 237 26 plates, 72 figures. 7s. 6d. net.)
⁷ *Studies in Roentgen-ray Diagnosis*, by A. C. Christie, Captain, Medical Corps, 1915. Washington: Government Printing Office. Bulletin No. 7. (Med. 8vo, pp. 35; 45 figures. 30 cents.)

⁸ *Medical Electricity, Röntgen Rays, and Radium*, by Sinclair Tousey, A.M., M.D. Second edition, thoroughly revised and greatly enlarged. Containing 793 practical illustrations, 16 in colours. 1915. Philadelphia and London: W. B. Saunders Co. (Roy. 8vo, pp. 1219, 25s. net.)

signs of ulcer in order to be of value as a diagnostic aid. Dr. Christie also gives the result of his investigations of the small intestine and colon. Here his conclusions are less definite; he gives histories of the more important of his cases and numerous photographic reproductions of his skiagraphs. The pamphlet should be in the hands of all skiagraphers.

Dr. HAROLD MOWAT, Lieutenant (temporary) R.A.M.C., has written a volume on *X Rays: How to Produce and Interpret Them?* which, though of slight compass, will excellently serve its purpose as an elementary introduction to the subject; in quieter times the author will, it may be hoped, write a companion volume on x-ray therapeutics, a subject which at present he has left untouched. His inaccuracies are very few; certain passages in the section dealing with x-ray production might have been a trifle more clearly expressed, and there is a little error on p. 14, where it is made to appear that in a hard tube the rays have a comparatively long wave length, and in a soft tube their wave length is shorter; as a fact, the reverse is the case, the wave length diminishing with increasing hardness of ray. One of the best chapters is that on the localization of foreign bodies; not many writers have found it possible to give an intelligible and workable description of the cross-thread method in so few words. On the other hand, the author takes it for granted that every one knows about the telephone probe as an adjunct to x-ray localization. Many of the excellent illustrations depict war injuries. Perhaps the most striking is one showing a hole made by a bullet which went right through the iliac crest without causing any fracture in that region, and entered the bowel, producing a faecal fistula.

For the use especially of those on active service in the field Mr. T. RANKINE has recently issued in English, and also in French, a brief account of his method of determining the position of foreign bodies in the tissues by means of the x-rays. No additional apparatus beyond a pair of compasses is required; the procedure merely involves the application of the compasses to a table of graphs which is included in his pamphlet.¹⁰ His method may be recommended for its simplicity to the attention of all skiagraphers.

THE HAUSA LANGUAGE.

Mr. ALAN C. PARSONS, the writer of *A Hausa Phrase Book with Medical and Scientific Vocabulary*,¹¹ who was for some time a medical officer in Northern Nigeria, has done good service by collecting and publishing in a handy form a large selection of colloquial phrases such as an Englishman in Hausa is most likely to want, and many of which are not found in the Hausa grammar or in the dictionary published by the Cambridge University Press. A large number of similar books have been issued during the last few years, but this is by far the best and most scholarly which we have seen. In one or two instances (cf. the use of *sami* for *samri* or *sauri*) the author has admitted a form which is only a local variant, but for the most part the Hausa is that spoken in Kano, and more or less generally accepted as the best Hausa. The Hausa language is already the *lingua franca* throughout an immense area in West Africa, and an accurate knowledge of it is likely to become still more essential to Englishmen than it already is if England has to undertake the supervision of Togoland and part of the Cameroons when the present war is over. The volume ends with a carefully selected vocabulary of medical terms which will be of special use to medical officers.

NOTES ON BOOKS.

IN the series *First Books of Science* published by Macmillan, Mrs. CATHCART has written the volume on *Physiology and Hygiene*.¹² There are many good points about

this little book. It is well illustrated, the subject matter is well chosen, and the difficult task surmounted of giving a very elementary account of anatomy, physiology, and hygiene. It is a pity that the author is not more careful in her style. The English is slipshod in many places; for example, "The constipation is cured very often if the muscle be given more work to do by eating food which contains a great deal of waste matter." Some of the statements of fact are erroneous, such as the assertion that the headachy and sleepy feeling in a stuffy room is due to lack of oxygen and too much carbon dioxide. The ill effects in truth arise from the physical qualities of the atmosphere. Discussing the stiffness of the muscles following exercise the authoress says that the beneficial effects of a hot bath are due to the fact that the bath stimulates the little sweat glands to secrete, and they help to rid the body of its waste products. The hot bath really brings more blood to the tired limbs and oxygen to oxidize the waste products. The function of the sweat is to cool the skin by the evaporation of water, its excretory function is of minimal importance. In a passage concerning indigestion Mrs. Cathcart says "the most frequent cause of indigestion is the bolting of food." We know of no proof of this statement; the hungry dog habitually bolts its food, and has a perfect digestion. Soft cooked food requires little mastication, and can easily be dealt with by the stomach. The danger of bolting lies in over-eating; that and lack of open-air exercise are the real causes of indigestion.

We commend the perusal of Miss EDITH L. MAYNARD'S book, *Women in the Public Health Service*,¹³ to those who desire to train for the work of a sanitary inspector, an inspector of milkwives, or a general health visitor. Not only is clear and concise information given as to the way to obtain the necessary education, but the need for the work and its interest are pointed out as well as the difficulties and drawbacks that will be encountered. The question of salaries is also dealt with. Much stress is rightly laid on the need for accurateness, promptness, and courteousness on the part of all public officials. The more highly educated, both in general and technical education, the better will the official be prepared for her work. Yet that alone is not enough, the *suaviter in modo* is indispensable in dealing with the numerous workers, official and voluntary, with whom she will be brought in contact, as well as in dealing with the people she visits in their homes. We are glad to note that it is stated that work with regard to infants calls for much wisdom and for insight into all the conditions of the home, and that dirty sanitary conveniences and the flies they encourage need much insistent and repeated care. A high tribute is paid to the mothers for the way in which they manage the small family income.

Dr. W. T. PROUT'S well-known little book on hygiene and sanitation in the tropics has now reached its fourth edition.¹⁴ It is written in the form of thirteen lectures, and is illustrated by a number of outline drawings and photomicrographs of an unpretentious nature. The lectures include an account of the structure and working of the human body, an outline of the chief diseases met with in tropical climates, and hints as to the general and special hygiene indicated in hot countries. The book is simply and clearly written, and will be very useful to laymen who go to live in the tropics.

Dr. THOMAS BUZZARD'S personal narrative of his experiences with the Turkish army in the Crimea and Asia Minor some sixty years ago forms a book¹⁵ that should be of interest to a wider circle of readers than that for which it was written a few years ago. Dr. Buzzard went out as a member of the British medical staff of the Ottoman army; he writes a most vivid account of his experiences by land and sea in this part of the world during fifteen months of the years 1855 and 1856. The book should be of particular interest at the present moment, when the fate of Constantinople hangs once more in the balance; it is illustrated with reduced reproductions of drawings of the local scenery made by the author on the spot, drawings that recall the early Victorian art of their period with the greatest felicity.

MEDICAL AND SURGICAL APPLIANCES.

Forceps for Suturing.

CAPTAIN H. H. KING, I.M.S., has designed the forceps illustrated in the accompanying drawing. The main point in the design is that the space between the blades is sufficient to allow the free passage of any ordinary needle, so that it becomes possible to suture a little more accurately than with ordinary forceps and with less damage to the tissues, because there is no need to grip the skin or other tissue tightly with the forceps. They might, Captain King considers, be of use also when it is necessary to insert sutures in conscious patients in whom the grip of an ordinary pair of forceps sometimes causes pain, especially where the tissues are tough, as in the scalp. The length of the forceps, the breadth of the blades, and the width of the interval, can be adjusted to meet the wishes of the surgeon by the maker. The idea, Captain King says, may not be new, and is less his own than that of Dr. K. Bremer, of Cradock, South Africa, who firstly suggested the idea as the result of a conversation some years ago on the

disadvantages of the ordinary type of forceps for all occasions.

A Head Fluoroscope.

Dr. FRANCIS HERNAMAN-JOHNSON, Captain (temporary) R.A.M.C., Consulting Radiologist, Aldershot Command, writes: Some foreign bodies which require removal are either so small, so deeply placed, or so numerous as to make it necessary that the surgeon's instruments shall be guided by direct x-ray vision. Some years ago Wullyam introduced a small screen in a wooden box, which could be strapped on the head. This could not be sterilized, did not admit of any change to ordinary vision, and was apt to cause eyestrain. I have now had in use for over six months a "head fluoroscope" having the following advantages:

1. The construction is of aluminium, and a detachable cover of this material is provided for the end containing the screen.

This is sterilized by boiling, and affixed to the fluoroscope after the latter has been bound on to the surgeon's head. It is thus quite safe for him to bend down until the lower surface of the cover is almost in contact with the wound, for if it touches the latter accidentally no harm is done.

2. As the apparatus is generally used where very small fragments are concerned, lenses magnifying three to four diameters are placed inside the instrument and to avoid eyestrain due to convergence, prisms with bases inwards are combined with them. There is also ample room for the surgeon to wear his own glasses should he need any.

3. The instrument is so constructed that the front lifts up as a kind of door. The field of ordinary vision thus obtained is quite extensive,

and enables the operator to change from x-ray direct vision at any moment he chooses, and as often as he chooses.

For use in conjunction with this device a set of forceps is provided having blades at right angles to the handles, and the vertical portions of graduated lengths, differing by steps of $\frac{1}{4}$ in. A pair is chosen of which the vertical portion is slightly longer than the depth at which the fragment is estimated to lie. The general position of the fragment must first be determined, and skin marks made in the usual way. The blades are placed vertically in the wound, when the handles will lie horizontally to the surface of the body, and almost touching it. The surgeon balances the forceps lightly with one hand, and brings down his head gently

until the aluminium cover of the fluoroscope clicks against the shafts. He now opens the blades until the shadow of the foreign body is seen between them. If the blades, when closed, do not now grasp the fragment, the error, provided the previous adjustment has been properly made, can only be a vertical one, and as the gripping portions are $\frac{3}{4}$ in. long, it is limited to insufficient depth. The blades are long ovals and are carefully smoothed, so that it is safe to burrow gently with them in the tissues. In most cases a little manipulation will secure the fragment; at the worst, it will be possible to seize tissue so close to it that it can be seen to move with the blades. If it be encapsuled, no forcible attempts should be made to withdraw it. It should be firmly held by an assistant while the surgeon severs the detaching tissues. This he does by ordinary vision. Should the forceps slip during this process, they must be readjusted. The diaphragm of the tube-box should be cut down until the size of the illuminated patch does not exceed $1\frac{1}{2}$ in. square. As the small screen within the head fluoroscope is protected by lead glass, the operator will run no risk, provided the diaphragm is made of sufficiently dense material. No protective gloves are needed; the handles of the forceps are purposely made long so as to be outside the field of action of the x-rays.

An Improved Spray.

Dr. J. A. KNOWLES RENSIAW (Manchester) writes that he has found the spray illustrated in the accompanying drawing to present the following merits: (1) It is composed of metal throughout, and is therefore readily sterilized and not easily broken. (2) A measured amount of the solution is placed in the receiver, which should be completely emptied on

each occasion that the spray is used, so that there is no waste—a great advantage introduced under similar drugs are used, as exact dosage is possible. (3) It sprays at a low pressure. (4) The swivel nozzle allows the spray to be directed in any direction. It has been supplied by Messrs. Mottershead of Manchester.

MEDICINAL AND DIETETIC PREPARATIONS.

"Chymol."

WE have received from Messrs. Armour and Co., Limited (Atlantic House, Holborn Viaduct), a sample of a new food which is being introduced under the name "Chymol." It is stated to be prepared from red bone marrow, egg yolk, and other ingredients which supply the carbohydrates present, the fats being pancreatized and infants, and in cases of anaemia, indigestion, debility, consumption, diarrhoea, etc. Our analysis of the sample submitted showed it to contain:

Proteins (from the total nitrogen) ...	4.4 per cent.
Carbohydrates, calculated as maltose ...	44.5 "
Fat ...	17.0 "
Mineral matter ...	0.83 "

The fat was present in an emulsified state, while the ash contained an appreciable amount of iron, and evidence was obtained of the presence of haemoglobin. The preparation has the consistence of a fairly thin malt extract, and is very palatable.

THE Co-operative Association for Post-graduate Teaching of Medicine is the name of an organization recently formed for the purpose of making Philadelphia a leading centre in the United States of advanced research and study in medicine. Dr. David Reisman is chairman, and among the members of the executive committee are Drs. F. X. Dercum, W. L. Richmond, and George E. de Schweinitz. A central bureau, with a permanent secretary, is to be established. The preliminary work to be undertaken by the association is the tabulation of lecture courses and hours of laboratory, hospital and dispensary work, and obtaining the co-operation of all medical schools and hospitals in Philadelphia so that their educational advantages may be available for post-graduate students.

Head fluoroscope, showing open front, with door and detachable metal cover made by Messrs. W. Watson and Sons, 131, Great Portland Street, W. The special right-angled forceps are made by Messrs. S. Maw and Sons, Aldersgate Street.

British Medical Journal.

SATURDAY, DECEMBER 4TH, 1915.

NATIONAL ECONOMY IN FOOD.

PROFESSORS HOPKINS AND WOOD have published through the Cambridge University Press a valuable pamphlet on food economy in war time; it can be had for sixpence and may be used to save millions of pounds. They point out that "a generous consumption of protein secures that the maximum muscular power shall be always and quickly available. . . . During exposure to cold protein has again a special function because of its power to quicken combustion in the body. The Eskimo cats much fat as a source of body heat; but only when he has eaten, as he usually does, a large amount of protein also, can he perform such a feat as sleeping without cover in spite of the rigor of his climate. This he frequently does with impunity when well stuffed with seal flesh." The troops, then, in winter must have plenty of meat as well as other foods.

While 1 lb. of protein costs 5s. or 6s. in the form of beef, it costs only 5½d. when purchased in bread, 3d. in oatmeal, and 6d. in such vegetables as peas.

Sedentary workers, apart from the poorest, can make a substantial reduction in their food without injury to themselves, and many by so doing will only be bringing their consumption down to a normal and healthy level. An enormous amount of overfeeding goes on in this country, particularly now when the wages of munition workers are so high. Overeating adds to the work of doctors and makes the fortunes of the quack pill vendors. A "helping" at an eating-house or canteen is not graduated to the work done, but is the same for him who works strenuously in outdoor physical labour and him who occupies a clerk's stool in an overheated office. The daily energy output of the one may be double that of the other, but the clerk may think he has as good a claim to stuff himself as the labourer, and probably believes that he can feed himself strong—a great illusion. Intellectual activity makes very small demands upon food. The well-to-do not only generally overeat, but eat far more animal protein than they require. The need felt for exercise is "in part due to the fact that the food eaten is in excess of what, without the exercise, would cover the needs of the body." Motor-car rides are used to burn off the excess of food eaten and alcohol drunk; the physically indolent thus get the cooling effect of the moving air. Normal food consumption leaves, then, a good margin to draw upon in these times of economic need before the limits of safety are reached. The normal intake of 4 oz. of protein a day can be halved for many months without harm.

In dealing with the price and value of foodstuffs, Hopkins and Wood draw attention to the comparative dearth of prepared breakfast foods compared with oatmeal. The cheapest oatmeal gives more calories and proteins for 1½d. than some breakfast foods for 7½d. The purchaser pays for the advertisement, packing, and fortune of the maker of the latter. In

the case of rice, tapioca, oatmeal, cornflour, the cheapest samples in every case yield per rd. of expenditure more protein and energy than the dearer. The purchaser pays for appearance, whiteness, and other fanciful qualities. The grocer not often, by a trick of the trade, sells the very same article for more money to the well-to-do when asked for a better quality of goods. The well-to-do will pay 3d. for what is equally good at 1½d. A pound of protein taken in milk costs only half what it costs in beef. The protein in skim milk only costs 7d. a pound. The cow is a machine daily turning grass into animal protein, but the ox and sheep are fed up and then killed for eating. "Fresh fish, largely owing to cost of transport, is never a cheap source either of protein or fuel."

Comparing the expenditure of the poor with that of the well-to-do, Mr. Rowntree has shown that for a shilling the former fortunately gets nearly twice as much for their money in the matter both of protein and fuel value. The rich simply pay for rarity and the tickling of the palate.

To secure the required national economy the consumption of luxuries of every kind must be diminished. The energy of the workers must be directed to the making or getting of munitions, fuel, food, and clothing, and the manufacture of articles which can be exchanged with neutral countries for munitions, food, and the raw materials required for the manufacture of munitions and necessities. The consumption of luxuries in food, clothing, and many other articles, induces workers to carry on much uneconomical production. The expenditure of a sovereign roughly means the week's work of some one upon the getting of our luxuries. The producers must be diverted into the army or to factories, coal mines, farms, etc., where either necessities or the articles required for export and exchange are produced.

The general conclusion is that the wealthy classes, aided by the middle and lower classes, could effect a saving averaging 10 per cent. of the national expenditure upon food—a sum of at least £60,000,000. It is in food, the fluff of women's clothing, and personal articles of men's luxury, in which the nation can save, and with not the least hurt to health or happiness.

THE THERAPEUTIC VALUE OF QUININE AND ITS CONGENERS.

A most interesting and valuable clinical investigation of the relative therapeutic worths of five of the chief cinchona alkaloids, and of two laboratory derivatives of the group, has recently been published by Major A. C. MacGillchrist.¹ The alkaloids tested were quinine, which is laevo-rotatory, and its optical isomer quinidine or conquinine, which is dextro-rotatory; cinchonine and its optical isomer cinchonidine, both from the chemical point of view representing quinine without its methoxy group; quinoidine, or amorphous quinine, a tarry, treacly substance obtained from the mother-liquor of cinchona bark after the extraction of quinine and the other crystallizable alkaloids; hydroquinine, which is from the chemical point of view a reduced or hydrogenated quinine, and may be obtained either from cinchona bark or the laboratory; and ethylhydrocupreine or optoquin, a derivative of quinine introduced by Morgenroth and Levy four years ago, which has attracted a deal of attention on the Continent, and has recently been described in this JOURNAL.²

¹ *Food Economy in War Time*, by T. B. Wood, M.A., and F. G. Hopkins, M.A., F.R.S. Cambridge: The University Press, 1915. Demy 8vo, pp. 25. 6d. net.)

² *Indian Journal of Medical Research*, Calcutta, 1915, iii, 1.
³ See BRITISH MEDICAL JOURNAL, 1915, II, 542.

In his previous work with these seven alkaloids Major MacGilchrist had shown that optoquin is the least toxic for guinea-pigs, quinoidine the most toxic, while quinine salts came about halfway between the two. On the other hand, as regards infusoria, optoquin was the most lethal, quinoidine the least, while quinine and quinoidine came low down on the list. In his trials of these alkaloids upon man the author treated the malarial inmates of two large gaols at Alipore. As a preliminary each patient received 4 grains of calomel. The different alkaloids were always given in solution and by the mouth, and a dose was administered every eight hours while the treatment lasted, so as to keep the amount of absorbed alkaloid as constant as possible. The dosage was always made proportionate to the weight of the patient. Every eight hours a blood film was prepared in the usual way, using Leishman's or Giemsa's stain, so that the time of the disappearance of the malarial parasites from the peripheral blood could be approximately estimated; a fall of febrile temperature cannot be trusted as a guide to this disappearance. A measure of the activity of each alkaloid was furnished by the period elapsing between the exhibition of the first dose and the disappearance of the asexual parasites from the peripheral blood. In all, 149 malarial patients were kept under observation for the purposes of these investigations.

In his first series Major MacGilchrist treated 72 patients with benign tertian, malignant tertian, or quartan malaria with one or other of four of the cinchona alkaloids—namely, quinine, quinoidine, cinchonine, and cinchonidine. The other three alkaloids were excluded because the larger doses required might have been dangerous. The dosage was at the rate of one gram to seventy kilograms of body weight, given every eight hours. These massive doses invariably caused the parasites to disappear from the peripheral blood after nine doses; in some instances one dose sufficed, in others all nine were requisite. To give an example of the results registered: in the case of benign tertian fever the average numbers of doses necessary were 4.7 for quinine, 5.0 for quinoidine, 5.5 for cinchonine, and 5.6 for cinchonidine. This amplitude of variation is naturally too small for a comparative test of the value of these alkaloids, and in addition it must be remembered that the results obtained appear to depend more upon the stage reached by the developmental cycle of the parasite at the moment when treatment is begun than upon any other condition.

In a second series of experiments the attempt was made to determine the minimal effective dose of quinine in the three varieties of malarial fever treated. The number of patients was fourteen; the number of doses was not limited to nine, and the treatment was continued while the patient remained in the gaol hospital. As in the previous series, the dosage was proportional to the weight of the patient's body. The second series cannot be regarded as complete or final in any way, but it enabled Major MacGilchrist to conclude, as a working result, that the minimum therapeutic dose of quinine at eight-hour intervals for a patient weighing seventy kilograms is 0.1 gram for benign tertian, 0.15 gram for malignant tertian, and 0.2 for quartan infections. These doses caused the parasites to disappear from the blood in a few days.

Armed with this knowledge, Major MacGilchrist proceeded to his third series of patients, sixty-one in number. The seven alkaloids were administered to them in the minimal doses given above for quinine, according to the variety of malarial infection present;

the medicine was continued as long as the patients remained in hospital. In this series, as in the last, the number of patients with each variety of malaria treated with each of the seven alkaloids is not large enough to justify any final and decisive conclusions. Yet many interesting facts emerge from their consideration. The large doses of the first series acted, as was to be expected, more quickly than the smaller doses of the third series, so that the number of doses given in the latter was larger (but not very much larger) than in the former. On the other hand, the total amount of alkaloid required to free the peripheral blood of asexual parasites in the small dose series was only a quarter to a sixth part of that requisite in the large dose series. Major MacGilchrist's paper contains a great deal of information interesting to parasitologists which must here be passed over; but he gives an interesting comparison of the relative therapeutic antimalarial values of the alkaloids he tested in a tabular statement of the average total amount of each drug, expressed in grams per 70 kilograms body weight, required to free the peripheral blood of asexual parasites in benign and malignant tertian infections combined: Hydroquinine hydrochloride 0.765 gram, cinchonine sulphate 0.915 gram, quinine sulphate 0.95 gram, quinoidine sulphate 1.12 gram, optoquin hydrochloride 1.22 gram, quinoidine 1.79 gram. These figures are calculated for the free alkaloids, not for their salts.

It is interesting to note that clinical experience with malaria thus agrees with the results of experiments *in vitro* with infusoria, so far as the natural cinchona alkaloids are concerned, but not in the case of optoquin. As for the occurrence of by-effects, summed up in the term "cinchonism," these were practically absent in the small dose series. In the large dose series, quinine, cinchonine, and quinoidine were the chief offenders. Apart from their obvious practical applications, it is clear that Major MacGilchrist's valuable results are bound to modify considerably the opinions expressed in the current manuals of therapeutics and pharmacology on the various cinchona alkaloids and their relative values in the treatment of malaria. Not a few of his conclusions support opinions previously expressed by Continental workers in this field.

MARRIED WOMEN'S WORK.

The Women's Industrial Council has been making an inquiry into married women's work, and has now issued a report, edited by Clementina Black.¹ It gives a temperate and graphic account of the lives of working women, and contains notes of the results of actual inquiries into many kinds of work at home, in the workshop or factory, and on the land. It is found that two classes of married women seek work—those who must earn because the family income is inadequate from lowness of the husband's wage, irregularity of work, or his failure in some way, such as sickness, idleness, drink, or desertion; and those who, although the family income is adequate for the supply of necessities, earn to get a few more comforts or luxuries.

With regard to infant mortality, it appears that it is probably less harmful for a woman to work close up to her confinement, if by this means she is able to get more and better food, than to stay at home

¹ *Married Women's Work; being the Report of an Inquiry undertaken by the Women's Industrial Council (unincorporated)*. Edited by C. Black. London: G. Bell and Sons, Ltd. (Cr. 8vo, pp. 292; 1 chart 2s. 6d. net.)

and go hungry. The inquiry does not confirm the generally accepted statement that married women should not go to work because the children are thereby neglected. It is in the dirty homes, whether the mother goes out to work or not, that the mortality amongst the children is frequently high, whereas in a poor but clean home the children seem to flourish. One thing that the report brings out is that a constant result of an inadequate family income is that the elder children are put out to work at the earliest possible moment, and that it is largely in this way that blind alley occupations are fed. Another is that it is the irregular earnings, due frequently to seasonal occupations, almost more than the small earnings, that are harmful to the family welfare, or as one woman puts it, "It is difficult to lay out what you are not sure of getting."

The experience of a certain number of cases brings out the significant point that the domestic work of a hard-working woman in her own home is of the value of 1s. a day, so that unless she earns more than 7s. a week she is probably out of pocket, though she does not recognize the fact; but the poorer the woman and the more unskilled she is the less can she earn, though the amount of labour expended is greater, and this class of woman worker is physically much overtaxed, as she often stays up late at night to keep her house clean and to make and mend for her children. "No driving foreman, no greedy employer, can so spur the efforts of a mother as her maternal affection spurs such a woman. A day's illness is an indulgence she dare not afford herself, while the premature collapse of a child's boots is a disaster that disturbs all her calculations." Among women earners there is a large proportion of intelligent and efficient workers who have good homes whatever their circumstances. It is from amongst the large class of married women whose income is inadequate and yet who do not earn that the gossipers at doorways and the frequenters of public-houses are recruited, and this is explained by the woman being so poor that her furniture and appliances are reduced to a minimum, and she has not enough household work to occupy her time, while the fact of her poverty denies her most of the means by which the better off harmlessly beguile their idle hours.

The contrast between the women of Knowledge, West Worcestershire, who work outdoors, and the women of Wiltshire, who work indoors at glove stitching, is interesting. The former, though working hard all day in the fields, are described as full of vigorous health and spirits, equally ready for work and play, while the latter are depressed and burdened with a variety of small ailments. A number of domestic budgets are given, which must be taken as proof that the food provided is in most cases quite inadequate for the family.

The report is well worthy careful study by the general public as well as by employers of labour. Although it would not be safe to draw definite conclusions from it, yet it is on the lines of such an inquiry as this that wider investigations should be carried out.

GRANDE COLÈRE D'AUGUST MARTIN.

We regret to find, under the heading "Internationale Gynäkologen," in the November number of the *Monatsschrift für Geburtshülfe und Gynäkologie*, an article by Professor August Martin, almost as virulent as the deliverances of Père Duchesne in his "Grande Colère." He begins by asserting that in August, 1914, when war blazed

out in Europe, he, as did most of his countrymen, hoped that scientific and personal relations with foreign colleagues would be maintained. *Das war ein eitler Wahn!*—That was a vain delusion! He is not, he says, surprised that Treub of Amsterdam is incensed against Germany, for Treub, he knows, has ever nourished a temperamental prejudice against *Deutschthum*. Recent events, though Professor Martin does not say so, may not only have confirmed this opinion, but even strengthened it. Martiu complains that Treub displays in his clinic a set of models of malformed fetal heads, labelled "The Prussian in 1815, 1870, 1914, 1915, and 1920," the last being an anencephalus! Professor Martin says that the ill-will displayed in this series was not unexpected; but he cannot understand—though to most of us the problem presents little difficulty—why Professor Jacobs of Brussels is angry with Germany. Jacobs, Martin complains, began from the first to write about German atrocities in Belgium, although a man who knows so much of Germany should never, says Martin, have believed that Germans could do such things, and he asks if the charges are not the monstrous figments of an overheated fancy. Why, Martin asks, should Dr. Jacobs, who formed so many friendships with Tontons in sundry international congresses, believe all these misrepresentations "which the highest ecclesiastical authority of Belgium, even the Holy Father himself, admits do not correspond to the truth? Yet Jacobs supports these unsubstantiated lies! On them are based all the otherwise incomprehensible agitations against *Kultur!*" Then follows the sneer that these lies are hawked about all over the world, especially among those unhappy Belgian doctors who preferred to desert their fatherland instead of remaining at their posts in its hour of need and continuing to perform their professional duties! (Die unglücklichen belgischen Aerzte . . . welche es verzegeben haben, ihr Vaterland zu verlassen, statt in Nothlage auf dem Postem zu bleiben und ihren ärztlichen Pflichten nachzukommen), National prejudice alone can explain so gross a misrepresentation of facts by a man of acknowledged professional standing. Professor Jacobs, for the reason he indicates in the letter published at p. 841, thinks it advisable not to make any detailed reply, but how these Belgian doctors were treated, and why they fled, has been related more than once in the JOURNAL. The ruined and battered houses may be excused as unavoidable results of bombardment justifiable on the ground of military necessity; but the instruments collected by the Belgian Doctors' and Pharmacists' Fund, and classified and put into order by the Master of the Apothecaries' Hall, remind us how the members of the medical profession in Belgium suffered from the confiscation of their instruments, Professor Jacobs being treated, we understand, with special harshness. Professor Martin next turns to Professor Pinard, and quotes the French obstetrician's address to the Paris Obstetrical and Gynaecological Society in November, 1914, in the original language. Pinard found fault with the Kaiser, and exclaimed, "*Honte à jamais aux barbares scientifiques!*" (Shame for ever to the scientific barbarians! we must echo back in the vulgar tongue.) After a diatribe on Pinard, Martin turns to the "Easter neighbour," Professor Stroganof, in whom, he politely observes, we see a reflexion of Pinard's delusions. Bossi, and, lastly, Romolo Sanguinati are rated, the former for his rapid dilator—a gross plagiarism, of course, from the Germans—and Sanguinati for his advocacy, in the *Annales de Gynécologie*, of Latin as distinguished from German culture in Italy. To paraphrase Pope's famous lines on Addison, while we must feel inclined to laugh if there be such a German doctor as would pen an abusive article of this kind, we sorrowfully ask who would not weep if August Martin were he—a distinguished man who in peace time was hospitable to foreigners, and was admitted to be reasonable with opponents in debate.

THE PUBLIC AND THE PROFESSION.

At a recent meeting of the Worcester Division of the British Medical Association a resolution was adopted making an appeal to the public to show special consideration to the medical profession at the present time. The words of the resolution were: "In view of the increased work thrown on the remaining doctors, through the absence of so many of their number on active service, it is earnestly desired that all messages should be sent as early in the day as possible." The Scottish Medical Service Emergency Committee last March made a like request to the public. It pointed out that it would materially help to relieve the great strain now imposed upon the medical practitioners remaining at their posts throughout the country if patients and their friends made a point of sending messages as early as possible in the morning, so that the doctor might arrange his daily round in the way most economical of time. In many parts of Scotland this practice had already been partially adopted. This appeal also pointed out that where the case was not urgent, and a visit on the next day would suffice, this fact should always be stated in the message. A similar appeal was made by the Newcastle-on-Tyne Division of the British Medical Association about the same time. It pointed out the need for the active co-operation of the civilian population if medical work was to be properly accomplished. It asked that calls upon medical men at untimely hours should be restricted as far as possible, and reminded the public that requests for visits after a doctor has left his surgery in the morning take often four times as long to accomplish as when communicated before 10 o'clock. If these simple requests were sympathetically noted and acted upon by the public the pressure on the profession would be materially relieved, and the public would benefit, for, as the Newcastle appeal pointed out, "No doctor can do his best work when unduly fatigued. For this latter reason requests for evening or night visits should only be made when the case is one of extreme urgency, and Sunday visits naturally fall into the same category." In this connexion we may refer to another matter upon which the co-operation of the public is requested, as was explained in a letter issued to the press by the Central Medical War Committee about a couple of months ago. This letter, while clearly stating that the right of every person to consult any doctor he chose was fully recognized, appealed to British citizens not to give up their usual medical attendant on account of his temporary absence on military duty, and to insured persons not to apply for transfer. Those who have entered the military medical services of the Crown not only risk death and injury but also the loss of their means of livelihood on their return. The letter, which was signed by, among others, Sir William Osler, Sir Clifford Allbutt, Sir Alexander Ogston (President of the British Medical Association), the President of the Royal College of Physicians of London, and Sir Rickman Godlee (ex-President of the Royal College of Surgeons of England), stated that in all cases it should be regarded by members of the public as an obligation and patriotic duty to safeguard in every possible manner the interest of the doctors who volunteer for active service, and expressed the hope that patients would inform the practitioner they may consult that their own doctor was absent on military service and that they intended to place themselves again under his care whenever the need arose on his return.

FACTORY LIGHTING.

Nearly three years ago the Home Office appointed a committee to inquire into the conditions necessary for the adequate and suitable lighting, both natural and artificial, of factories and workshops. The committee, of which Dr. R. T. Glazebrook, Director of the National Physical Laboratory, is chairman, has lately issued its first report; there is still another volume to come, which will contain a detailed account of the lighting conditions in the various

factories visited. The report is a noteworthy piece of work, and is relevant to the circumstances of the day, in view of the large number of factories which are working overtime on Government orders. It is recognized, in the first place, that good illumination is necessary for the safety of the worker (which is obvious), also for his general health, and for the efficiency of his work. The relation of lighting to health is a part of the subject which calls for a great deal of further study, and even closer co-operation between the physiologist and the illuminating engineer. As to the effect of lighting upon output and efficiency, there seems to be abundant evidence that where the lighting conditions have been improved there has been a gain both in respect to the quantity and quality of the work done. The committee recommends that there should be statutory power to demand adequate and suitable lighting, and although the problem is so complex that it might seem impossible to formulate a scale of values, the report prescribes a minimum illumination in factory interiors of 0.25 foot-candles. This is not to be the average value, but the legal minimum; and, of course, the special lighting required for particular and localized tasks will, in almost all cases, provide those higher minimum values which are desirable. The avoidance of excessive contrast is met partly by this requirement with regard to general illumination and partly by the requirement that there shall be reasonable constancy over the working area. Outdoor lighting entails a different set of conditions. In large open spaces, docks, etc., the suggested value is 0.05 foot-candles, which, according to a paper read recently before the Illuminating Engineering Society, is about equal to the illumination in St. James's Square in the pre-war days, but at certain working places and points of danger special measures would have to be taken.

NOTIFICATION OF MEASLES AND GERMAN
MEASLES.

The Local Government Board has issued an Order, dated November 27th, making the notification of measles and German measles compulsory in England and Wales. The duty is imposed both upon medical practitioners and on parents or guardians or other persons in charge of the patient, but a medical practitioner is not required to notify if a previous case of the same disease has been notified in the same household or institution during the preceding two months. On receipt of the notification the medical officer of health is required himself, or by an officer acting under his instructions, to make inquiries and take steps for investigating the source of infection, for preventing its spread, and for removing conditions favourable to it. The Order also enables local authorities to provide medical assistance, including nursing, for the poor inhabitants in their districts when suffering from these diseases. The Central Council for District Nursing in London has a scheme (as was noted in the *JOURNAL* of July 24th, p. 156) for supplying nurses to cases of measles, among other diseases, and the Local Government Board hopes that in other areas it will be found possible to arrange for nursing, either by engaging temporarily whole-time nurses or by contracting with county or other nursing associations; but it is realized that in many districts it may be difficult to provide such assistance, and that the local authorities may be reluctant to embark on new expenditure. It is thought, however, that much good may be done if parents can be brought to realize that measles is not a trifling ailment, and are advised as to the care which should be exercised and the precautions which they can take. To this end it is suggested that leaflets should be issued and the services of voluntary helpers enlisted to supplement the work of official visitors. The Board's medical officer has prepared a memorandum on measles,¹ and appended to this is a specimen leaflet. The memorandum sets out steps which local authorities should

¹ To be obtained through any bookseller. Price 1d.

ordinarily take under the Order. It is admitted that the fact that the disease is infectious before it can be diagnosed reduces the possibility of preventing its spread from the first case to other susceptible members of a household, but it is believed that through early notification of recognized cases the medical officer of health will be able to take action to prevent the spread of the disease and to secure improved care of patients, thus reducing the proportion of fatal cases and of disabling complications. One means which will be at his disposal will be the power to give information of cases to school teachers. Each case notified should be regarded as a means of discovering other cases, for it is recognized that cases not seen by a doctor constitute a chief risk of the spread of the infection and of a fatal result in the individual patient. Again, it is recognized that as a large proportion of the fatal cases of measles occur in infancy, removal to hospital is difficult, while the explosive character of epidemics makes it unlikely that the majority of cases can be treated in hospitals. It is thought, however, that all sanitary authorities should make some provision for the hospital treatment of a certain number of cases. It will be remembered that the Board issued a circular on March 31st last, requesting sanitary authorities to take into consideration the question of making measles and German measles notifiable. The average number of deaths occurring annually during recent years in England and Wales from measles was 11,000, the great majority being in children under 5 years of age, but during the first half of the present year the number of deaths was 12,414, and representations have been made to the Local Government Board by the Army Council to the effect that measles has caused a large amount of disablement among the troops in this country, and that accurate information of the presence of the disease among the civil population would be valuable to the military authorities. The Order comes into force on January 1st, 1916.

BACILLUS COLI IN LIGHT BEERS.

Cases of gastro-intestinal disturbance having occurred among the French troops of the north-western line, apparently as the result of drinking the light beers of local production, one of the bacteriological laboratories of the French army was instructed to make an examination of the bacterial flora of the suspected beers. The result of these investigations has been to show that in many cases these beers contain notable quantities of *Bacillus coli communis*. This microbe was found in a third of the Dunkirk brews tested, and in as many as three-quarters of the beers made in the villages and small towns of the neighbouring flat countryside. Over two hundred samples were examined, half of them being collected in the breweries themselves; the conclusion reached is that the beer becomes infected either by the use of contaminated water for cleaning purposes in the breweries, or by the employment of contaminated stocks of top yeast for fermenting the wort. It was noted that the use of an impure yeast did not necessarily result in the production of a beer containing *B. coli*; that microbe was regularly destroyed in three or four days if the yeast was otherwise of good quality and strong growth, and not contaminated with the bacteria of acid fermentation as well as with *B. coli*. Indeed, the light beers of good quality were found to be actively bactericidal to this microbe, when it was intentionally introduced either into the fermenting vat or into the finished product. It is remarked that the water supply of the district is almost entirely drawn from shallow wells, with the exception that Dunkirk is supplied by an excellent spring. The local brewers have to contend with many difficulties, as it is very difficult for them to obtain good malt, and it is impossible for them to secure fresh strains of yeast periodically from Lille, as was their custom before the war. In addition the local demand for light beer is so

great that the temptation to increase production by cutting short the time given to the fermentation of the wort and cleansing operations has apparently proved too strong for the small brewers. Hence the military authority has found it necessary to forbid the sale of the infected beers.

EPSOM ROYAL MEDICAL FOUNDATION.

The Royal Medical Foundation attached to Epsom College has done such good work in helping members of the profession who, owing to misfortune of one kind or another, have fallen by the way in the race of life, or dependants whom they have left in need, that we are sure our readers will be sorry to learn that there is a grave risk of its usefulness being crippled by lack of funds. The numerous urgent demands on doctors made by the war have caused the withdrawal of very many subscriptions; so great has been the loss of income from this source that extreme anxiety is felt by the council lest it should be found impossible to maintain the existing numbers of pensioners and foundation scholars. The situation is made the more serious by the fact that the number of applications for these benefits will, in all probability, increase as the financial pressure of the war becomes greater. Particulars as to the pensions to aged medical men in reduced circumstances or their widows, as to the scholarships given by the Foundation, and as to the educational advantages offered by Epsom College will be found at p. 55 of our advertisement columns. It is earnestly to be hoped that the appeal made by the Honorary Treasurer, Sir Henry Morris, in a letter published at p. 840, will meet with a generous response. The Epsom Royal Foundation is an institution of which the doctors of this country have every reason to be proud. Created by John Probert, a man who was in every way an ornament of the profession to which he belonged, it has during the sixty years of its existence continued to extend its sphere of usefulness till now the College ranks among the most successful of our public schools, while the Foundation has solidly established itself as a harbour of refuge for many who would without its help have been submerged. It would be deplorable if a foundation so excellent in its aims and so efficient in pursuing them were allowed to suffer any diminution in its means of carrying on its work at a time when the need of it is most acutely felt.

THE LEEUWENHOEK GOLD MEDAL.

The Leeuwenhoek gold medal of the Royal Academy of Sciences, Amsterdam, has been awarded to Surgeon-General Sir David Bruce. It is awarded every ten years in recognition of the most remarkable observations made during the decade on the microscopical organisms first discovered by Leeuwenhoek in 1675. The award sets out that it was the discovery of the *Micrococcus melitensis*, the cause of Malta or Mediterranean fever, which first made Bruce's name generally known. The agar plate culture of this microbe from the spleen of a soldier who had died from the disease afforded a sure foundation for the diagnosis of this widespread malady, which occurs throughout the whole of the south of Europe as well as in the subtropical parts of America, Asia, and Africa. His researches led many others to follow similar lines of inquiry, with the result that the history of the disease is now well known, and a new method of treating it provided by the serums produced with Bruce's micrococcus. It was, however, the award proceeds, the very important discovery of the cause of African cattle, or tsetse fly disease, known as Nagana, which made Bruce's name so well known. The life-history of the blood parasite, *Trypanosoma brucei*, was elucidated by him; he proved that the tsetse fly, *Glossina morsitans*, is the transporter of the disease, and his observations indicated the ways

L. Bousquet, M. Hiruté, L. Barat, A. Pierre Marie. *Bull. Acad. de Méd.*, Paris, 1915, xlv, 460.

in which effective steps could be taken against the disease. Afterwards he made careful and extensive researches, with the help of a staff of assistants, into other tropical African diseases caused by trypanosomes, especially into sleeping or Congo sickness caused by the *Trypanosoma gambiense* and transported chiefly by the fly *Glossina palpalis*. Here again his untiring patience and keen observation paved the way for practical results. He is still active in the study of these microscopical parasites, and the award concludes, "It may justly be said that he has worked for the benefit of mankind." The medal will be presented at the meeting of the Academy of Sciences in Amsterdam on Saturday, December 18th.

THE Croonian Lecture for 1915 will be delivered before the Royal Society on Thursday next at 4.30 p.m. by Dr. W. M. Fletcher, F.R.S., and Professor F. G. Hopkins, F.R.S., on "The Respiratory Process in Muscle, and the Nature of Muscular Motion."

WE regret to record the death, at the age of 58, of Dr. F. T. Houston, senior surgeon to the Adelaide Hospital, Dublin. We hope to publish an obituary notice in an early issue.

Medical Notes in Parliament.

War.

Army Medical Services (Advisory Board).—On November 25th Mr. Shirley Benn followed up his question of November 22nd (JOURNAL, November 27th, p. 789) by another, in which he inquired why no meetings of the Army Medical Advisory Board had been held during 1915; by whose authority the paid members had been constantly consulted; and whether a unanimous written opinion of any six out of the eleven members had been obtained during the present year on any question of policy. Mr. Tennant said that he thought it would be agreed that it was desirable to modify administrative machinery created in peace to meet the requirements of war, and it was for this reason that it had been found preferable to use the services of the Board in the manner he had described on November 22nd rather than in the normal and more formal manner. The Director-General A.M.S. was responsible for such consultations. He was not aware that there had been any want of unanimity among the members, save that which was usual and a healthy symptom in mobile minds. He did not think that a board of members of which were always in agreement would command great confidence. In reply to further questions, he said that the duties performed by the Board had been absolutely invaluable, and the medical service which had been so good and so much admired could not have been performed without its help. It was the deliberate policy of the War Office not to hold formal meetings, for no particular purpose; conferences were very useful and absolutely essential, and were constantly being held. In reply to Sir H. Craik, he said that medical advice was more effective if given by the medical members in conference and not collectively by the Board.

Invalided Soldiers.—Sir C. Kinloch Cooke on November 25th asked a question with regard to the food provided on board ship for officers and men invalided home from the Dardanelles with dysentery and enteric. Mr. Tennant said that he was awaiting further information, but could state that hospital ships were supplied with regular hospital diet and medical comforts. Transports were not intended to carry serious cases, but were provided with hospital comforts. At first the supply of such comforts had run short on the transports, but that danger had now been averted.

Cambridge Hospital.—In reply to Mr. Cathcart Wason, on November 25th, Mr. Tennant said that he had received a representation concerning the management of the 1st Eastern General Hospital, Cambridge, and that it had been referred for inquiry and report.

Medical Students.—On November 30th Mr. Snowden asked whether medical students approaching the end of

their third year's course could be exempted from pressure to enlist, and whether first and second year students who desired to continue their training would be allowed to do so. Mr. Tennant replied by reading the communication to the press which was quoted last week (p. 785), and added that he could not undertake that first and second year students should be exempted any more than he could cancel the decision that candidates for holy orders should be regarded as eligible to be canvassed and enlisted or to receive commissions.

Steel Helmets.—In reply to Sir George Scott Robertson, Mr. Tennant said that the supply of steel helmets to the troops in large quantities was being continued in accordance with the recommendations of the Commander-in-Chief, all of whose demands had, he believed, been carried out.

Munition Workers: Effect of Long Hours.—In reply to Sir Courtenay Warner, who asked a question on November 25th as to the effect of the continued prevalence of Sunday labour and as to its tendency to lessen the physical efficiency of munition workers, the Parliamentary Secretary to the Ministry of Munitions (Dr. Addison) said that the whole question of the effect of long hours upon the health of workers and upon production of munitions of war had been engaging close attention, and a committee under the chairmanship of Sir George Newman, M.D., had been appointed to advise on it. This committee had presented an interim report on the question of Sunday labour and it was hoped shortly to lay this report before the House and to state the recommendations of the Ministry. In reply to Mr. Peto he added that steps were being taken to enable workmen engaged at Woolwich on day and night shifts to get an adequate supply of food and temperance drinks in the middle of their working hours. In reply to a further question on November 30th, Dr. Addison said that, in order to encourage the provision of canteens in controlled establishments, the Minister of Munitions was prepared to give full consideration to capital expenditure incurred, with the previous approval of the Control Board, in assessing current profits under the Munitions of War Act. A memorandum on the subject of industrial canteens had been prepared by the Health of Munition Workers Committee, and would be issued with a covering letter, urging the importance of sufficient accommodation being provided.

Supply of Drugs.—On November 24th Mr. Peto, in a question as to the scarcity and high price of aspirin, salicylates, and all coal-tar products, such as phenacetin and antipyrin, and all drugs requiring spirit in their manufacture, asked whether, among steps that might be taken to secure an adequate supply, it was proposed to permit the use of spirit free of duty in their manufacture. Mr. McKenna said that it was not possible within the limits of a parliamentary reply to give any adequate statement of the steps that had been and were being taken. He understood that the position as regards available supplies was, on the whole, improving, and that there was no reason to anticipate any serious shortage in the future. It was not practicable to allow the use of duty-free spirit in the manufacture of drugs generally, but it would be allowed, so far as it was practicable, on certain terms.

Midwives (Scotland) Bill.

As was said by Mr. Barnes, M.P., in the House of Commons last week, a Midwives (Scotland) Bill is overdue. It is thirteen years since the Midwives Act for England and Wales was passed, and although that measure was not perfect, and notwithstanding several difficulties in its working which arose soon after it came into operation, and which cannot yet be said to have been fully removed, it has done much to improve the training of midwives and has given powers of supervision which have had a beneficial effect in regulating the practice of the women who, in the words of the Act, "habitually and for gain attend women in childbirth." In the weeks which immediately preceded the outbreak of war in the summer of 1914 two Midwives Bills for Scotland were before Parliament, one introduced by Lord Balfour of Burleigh into the House of Lords, and the other, under the care of Mr. Barnes, Mr. Ainsworth, Dr. Chapple, and others, in the Commons.

Both these bills omitted the phrase "habitually and for gain," and many authorities regarded this omission as a distinct improvement. During last winter an agitation for a Midwives Act for Scotland began in the north and excited sympathy in the south also, for the nation was beginning to realize the value of infant life with a clearness hardly before attained, the shepherding of the expectant mothers was being accepted as an imperial duty, and the dilliculty of procuring medical men to carry on obstetric work in sparsely populated parts of the country was being more acutely felt with so many of the profession absent on war service. An influential signed memorial was presented to the Secretary for Scotland in August (see JOURNAL of August 28th, 1915, p. 344). At conferences on the maternity benefit under the Insurance Act and at meetings of sanitary associations (see JOURNAL for August 7th, SUPPLEMENT, p. 82, and for September 11th, p. 420), resolutions were passed calling for legislation even in war time, and some weeks later an assurance was given in Parliament that a bill would be shortly introduced. No doubt other influences, and not least Dr. Newsholme's able report on maternal mortality in connexion with childbearing, have been helpful in bringing the pressing need for a Midwives Act for Scotland before the attention of the Legislature.

The measure, which is entitled a bill to secure the better training of midwives in Scotland and to regulate their practice, was presented by Mr. McKinnon Wood and supported by the Lord Advocate, and read a second time on November 25th, with variations to suit special conditions in Scotland. It follows the wording of the English Act somewhat closely; even the phrase "habitually and for gain" is retained, and it does not seem necessary, therefore, to look at the bill clause by clause. But certain salient features may be mentioned. With regard, in the first place, to certification, it is to be enacted that from and after January 1st, 1917—

any woman who, not being certified under this Act, shall take or use the name or title of midwife (either alone or in combination with any other word or words), or any name, title, addition or description, implying that she is certified under this Act, or is a person specially qualified to practise midwifery, or is recognized by law as a midwife, shall be liable on summary conviction to a fine not exceeding five pounds.

Further, that from January 1st, 1920—

no woman shall habitually and for gain attend women in childbirth otherwise than under the direction of a registered medical practitioner unless she be certified under this Act; any woman so acting without being certified under this Act shall be liable on summary conviction to a fine not exceeding ten pounds, providing this section shall not apply to registered medical practitioners or to any one rendering assistance in a case of emergency.

Other paragraphs deal, as in the English Act, with the fulfilment of various conditions prior to certification, with the non-employment of uncertified persons as substitutes, and with the rights and titles under the Medical Acts which this midwives' certification does not confer. Provision, however, is here made for the granting of certain certificates rendered necessary in connexion with maternity benefit under the Insurance Acts. The second clause makes provision for existing midwives in the following terms:

Any woman who, within two years from the date of this Act coming into operation, claims to be certified under this Act, shall be so certified, provided she holds a certificate in midwifery from the Royal Maternity Hospital of Edinburgh, the Royal Maternity Hospital, Glasgow, the Maternity Hospital, Aberdeen, the Maternity Hospital, Dundee, the Obstetrical Society of London, the Royal College of Physicians of Ireland, the Coombe Lying-in Hospital, and Guinness's Dispensary, the Rotunda Hospital for the Relief of Poor Lying-in Women of Dublin, the National Maternity Hospital, Dublin, the Central Midwives Board for England, or such other certificate as may be approved by the Central Midwives Board for Scotland; and produces evidence satisfactory to the last-mentioned Board, that at the passing of this Act she had been for at least one year in bona fide practice as a midwife, and that she bears a good character.

The period of two years may be extended by the Central Midwives Board for Scotland in special cases where any woman is able to satisfy them that she had reasonable excuse for having failed to make her claim within the prescribed time.

A Central Midwives Board for Scotland is provided under Clause 3, to consist of:

1. Three persons to be appointed by the Lord President of the Council, two of whom shall be certified midwives practising in

Scotland, and shall be first appointed when, in the opinion of the said Lord President, midwives so qualified are available in number sufficient to warrant such appointment;

2. Four persons to be appointed, one by the Association of the County Councils for Scotland, one by the Convention of the Royal Burghs of Scotland, one by the Queen Victoria Jubilee Institute for Nurses (Scottish Branch), and one by the Society of Medical Officers of Health for Scotland;

3. Five registered medical practitioners to be appointed, one by the University Courts of the Universities of Edinburgh and St. Andrews conjointly, one by the University Courts of the Universities of Glasgow and Aberdeen conjointly, one by the Royal College of Physicians of Edinburgh, the Royal College of Surgeons of Edinburgh, and the Royal Faculty of Physicians and Surgeons of Glasgow conjointly, and two by the Scottish Committee of the British Medical Association.

All the members of the Board are to retire from office on February 1st, 1921, and on the same date in every fifth year thereafter; but they shall be eligible for reappointment.

The meetings of the Board are to be held in Edinburgh, and the members are to be paid reasonable expenses for their attendances.

Further clauses deal with future revision of the constitution of the Central Midwives Board, with its duties and powers, with provisions as to suspensions, with expenses of midwives and offences by them, with the midwives' roll, with local supervision of midwives, power of entry, notification of practice, penalties, medical assistance in cases of emergency, etc. All these are along the lines of the English Act of 1902.

It is believed that the passing of this bill will be welcomed by the medical profession in Scotland, and in the Highlands and Islands its beneficent effects will soon be evident, whilst in the cities and lowlands it will give a means of bringing under supervision the unqualified or incompletely trained women who are at present attending the poor in their confinements.

OUR BELGIAN COLLEAGUES AT HOME AND ABROAD.

THE WEEK'S SUBSCRIPTIONS.

The following additional subscriptions have been received:

£ s. d.		£ s. d.

Subscriptions to the Fund should be sent to the Treasurer of the Fund, Dr. H. A. Des Voeux, at 14, Buckingham Gate, London, S.W., and should be made payable to the Belgian Doctors' and Pharmacists' Relief Fund, crossed Lloyds Bank, Limited.

DURING a discussion at the Philadelphia Obstetrical Society (*Lancet, Journ. Obstet.*, October, 1915, pp. 624 and 687), after Dr. Buschmann had read a communication on unilateral impairment of the kidney in the toxæmia of pregnancy, the question whether gestation should be interrupted when this complication occurred was raised. It was pointed out that certain methods employed for diagnosis, such as the phenolsulphophthalein test, were not always reliable, even when conducted by experts, and were out of the question when the patient was far from laboratories. Dr. George V. Janvier said that pericæpial clæpsia and renal complications were far graver matters in country than in hospital practice. He had had to do with a large number of Italian emigrant women, and had been struck with the frequency of pathological conditions of the kidney among them during gestation. He showed good reasons for ascribing them to the peculiarly toxic food which they consumed. They kept to their native diet, and during winter had practically no fresh vegetables, such as greens and fruits. They made in autumn a pasty heavy tomato sauce which they used as a relish with their food all through the winter. The food itself was a "horrible fresh, heavy, Italian bread," Bologna sausage, and the savoury but more than suspicious Frankfort sausage, all germ-laden dried meat. The remedy was that such patients should consume milk freely during the last three or four months and eat plenty of green vegetables.

THE WAR.

THE POSITION OF CASUALTY CLEARING STATIONS.

Is the general scheme of evacuation of wounded from a firing line it is provided that they shall be brought in from the regimental dressing stations to the field ambulances by ambulance cars, as a rule motor driven, and from the field ambulance head quarters dispatched in the same way to casualty clearing hospitals.

Owing to the special conditions of the military operations in Northern France—conditions which, it should be remembered, may not recur in the future—the tendency appears to have been to diminish what may be called the hospital side of these units and to make them, more than ever before, places from which wounded are cleared as rapidly as possible to the base. It is for this reason apparently that their name has been changed to Casualty Clearing Stations, although they still retain some of the functions of a hospital, since they may be in the position, if necessary, to retain from 20 to 30 per cent. of the patients brought to them. The remaining 70 or 80 per cent. are usually got away within twenty-four hours by an ambulance train. Nearly a year ago, indeed, Sir Anthony Bowlby, in a paper on the work of the clearing hospitals in France during the preceding six weeks, after pointing out that a clearing hospital is in its conception essentially a mobile unit, consisting really only of a staff with a sufficient amount of surgical and medical equipment for emergencies, said that it was intended in future to call it a "casualty clearing station."

On July 3rd we published an interesting note from our correspondent in Northern France, in which he said that as the army grew in size so had the number of clearing stations increased. They were, he said, never far from the real front. Although at that moment two or three had been left by the rising tide a dozen miles or so from the trenches, others were so close that even in what the army calls "peace time" their occupants could fairly well gauge what was going on merely by the sounds that reached their ears, while others were at intermediate distances. The motor ambulance convoys from the various head quarters of the field ambulances serving the divisions occupying the section of the line nearest the village where the clearing hospital is established usually arrive in the morning bringing in the whole of the wounded gathered between daylight that morning and daylight twenty-four hours previously. Though the convoys usually arrive in the morning there is no absolute regularity, for an ambulance car may at any time go down with a few wounded, who could be collected quickly, and sometimes it is possible to send on in the afternoon men who at daybreak seemed too ill to be moved.

There has recently been some discussion of the position occupied by the casualty clearing stations, and it has been suggested that an economy of personnel might be effected if these stations were pushed up nearer the firing line, so that they might more generally and rapidly relieve the field ambulance stations. As economy of personnel is a matter of great importance, we took the opportunity of consulting a medical officer serving in France, who has replied in the following letter. He begins by expressing his general dissent from the view that the casualty clearing stations could be moved nearer the firing line, for the reason that it "lacks perspective." He continues as follows:

Casualty clearing stations are neither regular hospitals on the one hand nor first aid posts on the other.

Their essential function is to take over the sick and wounded from the field ambulances serving various

portions of a battle line and to treat them until circumstances, including the condition of the patients, permit of their being sent down the line of communications to a stationary or general hospital. They are thus the nodal points in the whole system by which an attempt is made to undo the human damage caused by the enemy's weapons; and that fact must also be borne in mind when questions of their position are raised.

Even on paper that position cannot be varied entirely at will. It must always bear a certain relation on the one hand to a railroad, and on the other to the points—the regimental aid posts (a)—at which the sick and wounded from the portion of the battle line served by the casualty clearing station in question are first collected. With the regimental aid posts the casualty clearing station is connected by the field ambulances, and the relative positions of all three are, speaking in a general way, such as are shown in the diagram.

The field ambulances served by the casualty clearing station each work in co-operation, say, with five regimental or battalion aid posts, and form with them a species of triangle. The apex of each such triangle points in the direction of the casualty clearing station, and consists, say, of the field ambulance head quarters or principal tent section, while its base is in touch with the battalions in action, and is formed by their aid posts; the sides are marked by the advanced dressing stations and bearer sections.

A, B, C, Portion of a battle line. o o o, Aid posts of battalions in action. x x x, Advanced dressing stations. F F F, Field ambulance tent or head quarter sections. X, Casualty clearing station. R, Railroad. —, Line of communication with base. -----, Paths available for bearer parties. ———, Roads.

The three small triangles themselves form the base line of a larger triangle whose apex is represented by the casualty clearing station. Doubtless on paper this apex could be compressed and its position altered so as to push the casualty clearing station very close indeed to the sub-triangles and to the battalions in action which form their real base, but it does not follow even on paper that the ability of a casualty clearing station to fulfil its functions will have been increased thereby. The closer it is placed to one portion of the fighting line the further it may be from the rest.

In fact unless the portion of a fighting line that a casualty clearing station serves happens to be a segment of a true circle, and the casualty clearing station is at the centre thereof, some of the battalions concerned must always be relatively distant from a casualty clearing station—that is to say, more distant than others.

If all this be true as a matter of mere mathematics, it is doubly true in practice. Mathematically, it is conceivable that if a casualty clearing station were pushed up to, say, point Y, it would there be much closer to all points of the line A, B, C, than it was at point X, but practically it may be ten times further off. This would certainly be the case if there were good roads from A, B, and C to X, but no roads or bad ones, from the same point to Y.

It is, in short, not proximity but accessibility that is the point of real importance. The more roads that lead from the fighting line to a casualty clearing station and away from it towards the base the better for all concerned.

Further, accessibility of a casualty clearing station to vehicles approaching it from the field ambulances, and to those which leave it loaded with patients on their way to stationary and general hospitals, is not the point of sole importance.

A casualty clearing station, though always a mobile unit, is a good deal more than a glorified tent section of a field ambulance. It is able to undertake operations of any kind; has a large personnel, which includes nursing sisters; and, while invariably equipped for 200 patients, must be prepared—as experience has time and again proved—temporarily to provide suitable accommodation for five or six times that number. This means that its location must be such that it can always secure at a moment's notice almost unlimited supplies. Consequently it must be fairly near a railroad or a railway siding which is being employed as such.

A third desideratum is that its position should secure it from any but the most deliberate heavy artillery fire. There is not much point in removing the wounded out of the firing line and in making elaborate arrangements to secure them both nursing and surgical assistance which is in every way efficient, if the hospital housing them is placed in such a position that the dozens of vehicles which must daily seek and leave its doors will form a good mark for the enemy, or if it is liable to be accidentally destroyed in the course of an ordinary everyday artillery duel. The lives of combatants even when wounded are valuable, and nurses and doctors cannot be replaced too easily.

All the foregoing facts are strong arguments in favour of not compressing the apex of the triangle which has been mentioned, and thus pushing the casualty clearing stations close up to the battalions in action; while the weight of the sole argument adduced in favour of the latter step is minimized by the fashion in which the patients are transported.

If they had to travel to a casualty clearing station by a country cart or on a jolting supply wagon it might be reasonably concluded that every additional half-mile that they had to be carried would lessen the chance of their recovery. But these means are never now employed; all the patients are transported from the advanced dressing stations to the casualty clearing stations solely on well-sprung pneumatic-tired ambulances, which cover a mile in the space of about five minutes.

Supposing a patient fit to be moved at all, can it really make any practical difference to him whether he remains in such vehicle five minutes more or five minutes less? If the response be that it must make some difference, the reply is that it cannot make half as much difference as that spelt by a patient eventually finding himself in a real hospital instead of in a huge dug-out, or its equivalent, such as is alone conceivable as the habitation of a casualty clearing station which had been thrust quite close up to the line of fire in accordance with the views of your friend.

I am afraid the censor would object if I endeavoured to illustrate the degree to which the authorities have managed by the disposition of their clearing stations to meet the desiderata mentioned in this letter, but in any case the task would be superfluous.

The published despatches of Sir John French and those of sundry newspaper correspondents have disclosed with considerable fullness the position of the British line.

If the facts therein contained be studied by means of one of the very large scale maps now on sale in England, you can note for yourself what towns, villages, or collection of houses seem to be within easy reach of the line by numerous roads, and also within easy reach of a railway by the same means. On some of the maps, indeed, you can even make a fair estimate as to the extent to which certain localities—which seem otherwise suitable for a clearing station—are exposed to the ordinary fire of the enemy, or are protected by hills or rising ground from any but long distance artillery and aeroplane bombs.

When you have thus picked out your possible positions for yourself, I can assure you that you may then safely conclude that each of these localities is either already occupied by casualty clearing stations, or that a casualty

clearing station has been there until driven out by shell fire, or that all the buildings shown are absolutely required as billets for reserve or resting troops, or that the position is one that the military authorities intend to hand over shortly to the French or Belgian troops, or consider likely to be at any moment the aim of a heavy attack by the enemy.

I am afraid that this is all I can say on this particular aspect of the subject beyond expressing what I find to be a general belief—and one which, so far as I am in a position to form an opinion, is also my own—namely, that if the indubitable interests of the great mass of sick and wounded men are not to be sacrificed to the debatable interests of a very small minority, the casualty clearing stations as a whole cannot rightly be advanced any further than they usually are.

This "small minority" is made up mainly of cases of gunshot wound of the chest and abdomen, and of profound shock from hæmorrhage. I have described their interests as debatable because there would be plenty of room for difference of opinion as to their treatment even if they were due to an accident occurring just outside the door of the operating theatre of a London hospital; while when they occur on the field of battle no conceivable, not merely possible, means of dealing with them can be regarded as anything but in the nature of a *pis aller*.

I cannot discuss so many sided a question in this letter, but before winding up what I have to say on its main theme I may mention that these minority cases represent no new problem. It is one which on a glance at any textbook dealing with the medical side of army administration will be perceived to have been carefully studied long before this war, and during this war it has been, and still is being, handled in the light of the most advanced surgical knowledge of the day, and of weekly accumulating experience.

Various means of dealing with it have been tried, but in the main dependence has been placed on the advantage in the way of rapid and easy transport offered by motor ambulance convoys.

Automobile transport is a novel feature in war, and its introduction lies in a measure at the root of the discussions sometimes heard as to the relative utility of various features of the evacuating system as a whole.

Compled with other circumstances—such as the siege-like character of the operations in Flanders, the large number of troops held ready to engage on a comparatively narrow front, the configuration of the ground, and the existence of many possible railheads—it has led on the one hand to the making of medical demands such as would never have been heard had the operations consisted of long advances or retreats; and, on the other, to a superficial obscuration of the principle underlying the work in the evacuating zone, owing to the occasional aggregation and proximity of medical aid posts, advanced dressing stations and casualty clearing stations, and the consequent apparent superabundance and superfluity of some items in the scheme.

As to all this, I can only say that should the eventual consideration of the leading events of this war by tacticians and strategists lead them to a conclusion that the warfare of the future will be trench war, then perhaps we shall see certain more or less radical changes in the existing medical system so far as the evacuating zone is concerned.

But personally I am not disposed to anticipate anything more than some modification perhaps in the equipment and organization of the field ambulance.

It is only in France (and during the last eleven months or so) and in the Dardanelles that the war has been, so to speak, abnormal—that is, has consisted mainly of siege-like operations. Elsewhere—in Mesopotamia, in Russia, and so far in Serbia—the war has been of the kind for which the British evacuating system was primarily invented. I say primarily only because it is mainly when advance movements are rapid and frequent that the merits of the system become readily visible. For its real strength lies in its adaptability to all circumstances and in the fact that it provides a definite backbone for evacuating operations whatever their kind.

For instance, at certain parts of the line during the past few months the two series of triangles shown in the diagram have been coalesced into one, a casualty clearing station practically taking the place of the field ambulance

head quarters shown as forming the apex of the smaller of the two triangles.

But this does not necessarily mean that the organization of field ambulances is out of date or that their head quarters have been useless. There has been plenty of work for their displaced main tent sections or head quarters to do of a most useful kind, in the way of running rest stations, convalescent hospitals, and bathing establishments, and meantime the field ambulances have preserved their unity, and have thus been ready and also able (as comparatively recent events have shown) to fulfil their full normal functions at a moment's notice.

As you know, there are three field ambulances attached to every division, and each consists of three sections subdivided again into a stretcher bearer and tent subsections. These main sections and subsections can act together or separately, and can devote themselves either mainly to running advanced dressing stations, and the connected bearer work, or partly to this and partly to forming and conducting temporary hospitals for the treatment of patients who cannot be moved on.

So far it has been in the former direction that there has been most work for them, but at any moment the scene may change. Should, for instance, any attack such as that on Loos last September, or on Neuve Chapelle last March, prove completely successful the line will move forward so rapidly as to place the advanced dressing stations too far away for the line being from the casualty clearing stations for really serious cases to be sent to them straight away, even if the roads be not too encumbered for good motor convey work. In that case tent section work, which has already been carried on to some extent on different occasions, will come into complete operation, and the advantage of including operating surgeons of first-rate ability among the personnel of the field ambulances will be realized to the full.

On the question of the handling of the abdominal and chest case problem I will try to write to you at a later date, and am meantime happy to be able to conclude now by saying that the completeness with which varying circumstances and different contingencies are anticipated by the existing evacuation system, as also the skilful fashion in which it is being worked, have alike impressed me very considerably.

TYPHOID FEVER IN THE GERMAN AND AUSTRIAN ARMIES.

TYPHOID INOCULATION.

PROFESSOR GOLDSCHNEIDER and Dr. K. Kroner have published¹ a lengthy report on the effect of typhoid inoculation in the German army in the winter of 1914-15. When the Germans invaded France little was at first done to protect the troops from typhoid fever by inoculation, and it was not till late in October that this prophylactic treatment was begun. Extensive inoculation was carried out during November, December, and January. Two to three injections were given at intervals of eight days, the dosage being 0.5, 1.0, and 1.0 c.c.m. When Marx's vaccine was used these doses were doubled. In many cases only one injection was given, owing to ill health or other considerations. It was not till a later date that inoculation with three successive injections was adopted as a routine measure.

The first cases of typhoid fever in the army to which the authors were attached occurred in the second week of September. The number increased in October, reached its maximum in November, and afterwards fell rapidly. There were a few cases in December, and in the following months there were only sporadic outbreaks. The credit for this could not, they considered, be given entirely to the inoculation, for typhoid fever commonly disappeared spontaneously in the late autumn and winter.

The Course of the Disease among the Inoculated.

The authors observed about 300 cases of typhoid fever in patients who had previously been inoculated. In many sufficient data for estimating the effect of inoculation on the course of the disease were lacking. There were 125 cases of typhoid fever among patients inoculated once, 125 cases among patients inoculated twice, and only

39 cases among patients inoculated three times, about which adequate notes had been made. Broadly speaking, the temperature charts showed the same features for the inoculated as for the uninoculated; and there was no temperature curve exclusively characteristic of typhoid fever among the inoculated. But in this class it was relatively common to find a temperature curve with an early tendency to fall permanently or for a short time—a feature indicative of a benign form of the disease. Among the inoculated the temperature sometimes began with an abrupt rise, accompanied by a rigor. The temperature would almost directly fall again more or less abruptly. This type of temperature was most common in patients who had just been inoculated; and it would seem that the inoculation had shortened the incubation period, a slight or abortive variety of typhoid fever being the result.

The Mortality among the Inoculated and Uninoculated.

There were 20 deaths from typhoid fever among the inoculated (6.9 per cent.) as compared with a mortality of 12 per cent. among the uninoculated. Of the deaths among the inoculated, 13 occurred among the 125 patients who had been inoculated once, and only 5 among the 125 patients who had been inoculated twice. In other words, the mortality from typhoid fever among patients inoculated once was as high as 10.4 per cent., whereas it was as low as 4 per cent. among those who had been inoculated twice. There were 2 deaths among the 39 patients inoculated three times, the mortality being 5.1 per cent. The general condition was, as a rule, better among the inoculated than among the uninoculated, and toxic brain symptoms were notably less frequent and prominent among the former. The pulse and general condition of the heart were also more satisfactory. Again, the inoculated developed fewer complications, and myocarditis, thrombosis, plebitis, and intestinal hæmorrhage were relatively rare sequelæ. Respiratory complications were also less frequent and severe among the inoculated. This mildness or absence of complications was most noticeable among patients inoculated more than once, but the inoculation did not seem to check exacerbations and relapses of the disease, yet convalescence was often strikingly rapid among the inoculated.

Complications.

In this connexion it may be interesting to note that J. Matko² has analysed the frequency with which certain complications followed typhoid inoculation in the 64th Roumanian Infantry Regiment. His statistics concern about 3,000 soldiers. The vaccine used was Besredka's, and the dose was 1 c.c.m., followed in six days by a second of 2 c.c.m. Special attention was paid to the temperature, the leucocytes, and the urine, the latter being examined daily with reference to the diazo, the albumin, and the aldehyde reactions. The soldiers were admitted to hospital only when a rise of temperature was accompanied by symptoms of a severe general reaction, such as pain in the head, limbs, and trunk. Many different types of fever were observed. In some cases the temperature rose to 39° C. after the second injection, and fell again to normal next day. In 20 cases the fever lasted for a day or two, after which it fell to normal by lysis. In 3 cases the temperature remained between 38° and 39° for three days and then fell to normal by crisis. In a few cases there was no fever till the second day after the inoculation, when the temperature began to rise slowly, reaching its maximum on the same day and falling again slowly on the third day. With one exception, all the complications followed the second inoculation. The exceptional case was that of a man, aged 24, who had undergone hydropathic treatment for two months for arthritis before he received his first injection. It was followed immediately by a rigor and severe pain in the wrists and ankles, which were much swollen next day. In eight other cases of articular rheumatism the first injection provoked pain in the limbs, but it was not till the second injection that the joints became swollen. In several cases the skin over the joints was hot and red; but with one exception these articular symptoms were transient and disappeared rapidly without treatment. In other cases refractory to treatment by salicylates and electrolol, rapid improvement was effected under hot air treatment. In four cases the inoculation was followed by

¹ *Berl. Klin. Woch.*, September 6th, 13th, and 20th.

² *Wien. med. Woch.*, August 21st, 1915.

acute nephritis, characterized in three cases by haematuria and the presence of numerous erythrocytes, casts and other renal elements in the urine. Pulmonary and intestinal complications were frequent; the most frequent pulmonary complication was cough due to dry, diffuse bronchitis, which disappeared in a few days without treatment. In three cases there were signs of recrudescence of pulmonary tuberculosis, the temperature in these cases remaining high for a long time. One case terminated fatally from miliary tuberculosis of the lungs. In thirty-two cases the second injection provoked transitory colic and diarrhoea. Typhoid bacilli were never found in the stools of these patients.

THE MORTALITY FROM TYPHOID FEVER.

In the opinion of Professor A. v. Koranyi of Budapest² the fate of the patient suffering from typhoid fever was often decided during the first days of the illness. An analysis of 523 cases showed that 45 had died, a mortality of 8.6 per cent. The treatment consisted of careful nursing, a fluid diet, and the free use of chemical antipyretics. In a very few cases only did the treatment include baths, the value of which Professor Koranyi considered very doubtful. The patients were divided into three classes, according as they were admitted within the fourth, seventh, or tenth day of the illness. Although many of the patients in the last class were already convalescent, this classification clearly showed that the mortality was directly proportional to the days of illness which had elapsed before the patients were admitted to hospital. Professor Koranyi argued from this that soldiers suspected of typhoid fever should be spared long journeys as far as possible. In this connexion he pointed out that in determining the value of various forms of treatment physicians were apt to overlook this important factor, yet the great fall in the mortality from typhoid fever which had occurred within the past fifty years was, in his opinion, largely due to the earlier recognition and treatment of the disease.

PULMONARY TUBERCULOSIS AMONG SOLDIERS.

At a meeting of the Medical Society of Hamburg⁴ Dr. Rumpel stated that as early as October, 1914, the medical department of the German War Office took steps to secure beds for tuberculous soldiers in tuberculous institutions. He anticipated that the war would increase both the morbidity and mortality from tuberculosis, but hoped that this change for the worse would be only slight and transitory. Another speaker, Dr. Fahr, gave an account of his observations in the dead-house on the frequency of tuberculosis among soldiers. He had found fatal tuberculosis in as many as 12 per cent., but was inclined to think that this figure was too high for the whole of the German army. The mortality from tuberculosis in the army was, however, disquietingly high, and it was obviously desirable to take more effective measures to keep the disease out of the army. Another speaker, Dr. Prechtl, expressed a more optimistic view, and even denied that the war had increased the frequency of tuberculosis. In the military hospital in his charge he had treated about 5,000 sick and wounded soldiers, only 18 of whom were definitely tuberculous. The military authorities were opposed to the employment of the tuberculous, and the demonstration of tubercle bacilli was sufficient to stamp the patient as permanently unfit for service. Dr. Rumpel argued that the decision whether a man suspected of tuberculosis was fit for military service should not be made on the evidence of the tuberculin test. Many soldiers who were undoubtedly tuberculous had, he said, undergone the strain of active service without breaking down. This, for example, had been the case with a soldier who had been in hospital for two years for tuberculous empyema, which had necessitated extensive resection of ribs. Dr. Rumpel insisted that a careful expert examination of the tuberculous soldier was of primary importance. The necessity for this had been recognized by the War Office in its order that the advice of specialists in tuberculosis should be obtained in doubtful cases. It had also arranged that soldiers should be sent to institutions for the tuberculous as soon as the disease was detected.

CASUALTIES IN THE MEDICAL SERVICES.

ARMY.

Died on Service.

LIEUTENANT COLONEL ALEXANDER AITKEN ROSS, R.A.M.C. (T.F.), died in an officers' hospital in London on November 24th, aged 44. He was the son of the late Lieutenant-Colonel A. A. Ross of the Leicestershire Regiment, and was born at Halifax, Nova Scotia, and educated at Edinburgh University, where he took the degrees of M.B. and C.M. in 1893. He settled in practice in Edinburgh, and, on the institution of the Territorial Force, joined its medical department. On August 15th, 1908, he attained to the command of the 3rd Lowland Field Ambulance, and with it he went last July to the Dardanelles, and had only recently been invalided home. He was married about two years ago, and leaves a widow and an infant child. He was buried with military honours on November 27th, and the funeral procession through the south side of Edinburgh, in which he practised, was witnessed by large and respectful crowds. Among those present were Surgeon-General Bourke, D.D.M.S., and a number of other officers of the R.A.M.C., as well as three hundred men of the Lowland Field Ambulances.

Wounded.

Lieutenant F. T. Simpson, R.A.M.C. (temporary). Mesopotamia.

Quartermaster and Honorary Lieutenant F. O. Chappell, R.A.M.C., Flanders.

Died of Wounds.

Lieutenant James Richardson Spensley, R.A.M.C., died of wounds as a prisoner of war in the officers' prison hospital at Mainz, in Germany, on November 10th. He was at first reported as killed in action, and an obituary notice was published in the BRITISH MEDICAL JOURNAL of October 16th. Later it was stated that he was alive, as a wounded prisoner.

Lost at Sea.

The hospital ship *Anglia*, the vessel in which the King crossed the Channel after his recent injury, was sunk on November 17th, while bringing a convoy of wounded across, it is believed by striking a mine. At the time there were 13 officers and 372 of other ranks on board. On November 29th was published a list of those lost—4 officers, 1 nurse, and 129 men, all of whom, except the nurse, had been previously wounded. The nurse lost was Miss M. Rodwell, of Queen Alexandra's Imperial Military Nursing Service Reserve.

DEATHS AMONG SONS OF MEDICAL MEN.

TOWNSEND, J. W. E., Lieutenant-Commander R.N., younger son of the late Dr. E. R. Townsend, of Cork, died at Parkston on November 19th. He had seen active service, while in the navy, in Crete and in South Africa (medal and clasp), and retired from the navy in 1910. At the beginning of the war he offered his services, which were accepted; and while serving in H.M.S. *Imperieuse* in the North Sea he contracted bronchitis, which proved fatal. He was buried at Parkston on November 22nd with full naval honours.

The notice of Captain Sloan, Scottish Horse, published in the JOURNAL last week, p. 791, requires correction. The name of the officer was Captain George Henry Sloan. He died at Suvla, Gallipoli, of wounds received while attempting to save the life of one of his lance-corporals. He was the son of Dr. Samuel Sloan of Glasgow, and his two brothers serving are Lieutenant-Colonel J. M. Sloan, D.S.O., D.A.D.M.S., and Lieutenant-Colonel S. M. Sloan, Scottish Horse Brigade Ambulance.

MEDICAL STUDENT, PRISONER OF WAR.

Wilkin, Second Lieutenant B. O., of the 6th Battalion Duke of Cornwall's Light Infantry, attached to the Royal Flying Corps, was reported a few days ago as having been made a prisoner of war. He was a medical student at the University of Edinburgh, and took a commission on August 26th, 1914. While reconnoitering over the German lines his machine was damaged, forcing him to come down behind the enemy's lines.

NOTES.

THE CONVERSION OF ASYLUMS TO WAR HOSPITALS.

At the meeting of the Medico-Psychological Association of Great Britain and Ireland on November 23rd the president, Lieutenant-Colonel David G. Thomson, M.D., gave an account of the conversion of the Norfolk County Asylum into a war hospital for sick and wounded soldiers. He said that on January 29th, 1915, the Lunacy Board of Control expressed its willingness to try to provide 15,000 beds in asylums by clearing some entirely of their ordinary patients and distributing them in other asylums. As the result of two conferences twelve asylums were converted

² *Deut. med. Woch.*, September 9th, 1915.

⁴ *Deut. med. Woch.*, August 25th, 1915, and September 2nd, 1915.

into war hospitals, and it was arranged that the receiving asylums should charge the vacating asylums the actual cost of maintenance and make no charge in respect of the building fund—that is to say, rent, upkeep of buildings, and interest on capital. Opinion being strongly against placing sick and wounded soldiers in even wholly separated parts of the same institution as the insane, not even women working patients were retained. It was arranged that the 1,050 patients in the Norfolk County Asylum should be transferred in parties to other asylums. Friends were duly notified, and in sixty instances were encouraged to apply for the patient's discharge under Section 79; in fifty-three cases this was arranged. In making up the parties, due care was taken that each should consist of the various classes—the recent, acute, sick, infirm, epileptic, convalescent, and working. Parties began to leave on March 19th, and by March 31st 960, or an average of one hundred a day, had been transferred without any mishap or accident to nine different towns. Thirteen too little to move were retained for two or three weeks more. To convert the asylum into a hospital many structural alterations were necessary; some of the doors had to be enlarged, and three lifts were installed. In spite of the great demand for hospital furniture and x-ray and electro-therapeutic instruments, the x-ray and operating theatres were thoroughly well installed, the War Office showing uniform courtesy and promptitude in helping on the work. The staff of the Norfolk and Norwich Civil Hospital, which is close by, including the radiologist, ophthalmologist, pathologist, and dentist, were appointed *en bloc* for the Norfolk War Hospital, the remuneration being £1 for each day the hospital was visited. There was difficulty in getting together a resident medical staff. This was achieved by obtaining the services of men medically unfit for active service. A resident woman pathologist was appointed. She has a well-equipped laboratory, and reports upon all clinical specimens sent to or collected by her. The president also described the nursing equipment, and in conclusion paid a tribute to the arduous work of the two commissioners of the Board of Control, Dr. Marriott Cooke and Dr. Hubert Bond, who acted as intermediaries in all the negotiations between the War Department and the asylums.

In a short discussion which followed Dr. Marriott Cooke said that in the twelve hospitals now established 23,996 patients had already been admitted and treated, and 14,776 had, on November 1st, been discharged or transferred, 101 had died, and three remained under treatment 9,120, leaving, at the moment, vacant beds for 4,108. Without the hearty co-operation of those responsible for the administration of the asylums such a work could not have been carried out, and praise was also due to the asylum nurses. Though some of the insane were transferred to distances as great as 150 miles there was no hitch.

Lieutenant-Colonel H. A. Kidd gave an account of the work at the Graylingwell Military Hospital, Chichester. Out of 3,000 patients admitted 1,250 had returned to duty, 1,000 returned to light duty, and 600 were sent to convalescent hospitals, making 95 per cent. of the admissions. At this hospital at the first 490 cases were received in 30 hours.

Colonel Vincent (Wadsley Hospital, near Sheffield) sent an account of his experiences, and Dr. G. M. Robertson (Edinburgh) pointed out that the war and the needs it had brought would teach the speciality more than ever the good policy of having female attendants and nurses for both sexes of patients, a matter he had been interested in for a long time. Sir George Savage also spoke, and the President replied.

CASUALTIES AMONG MEDICAL MEN IN THE GERMAN ARMY.

According to the *Militärärztliche Zeitschrift*, No. 18, 1915, the German army has suffered the following losses of medical men from the beginning of the war to September 22nd, 1915:

Wounded	463
Missing	128
Missing, since returned	35
Killed	139
Prisoners	101
Died of disease	100
Died of wounds	50
Killed by accident	20
Total	1,027

OCTOGONARIAN SCERGONS IN THE GERMAN ARMY.

Two octogenarian doctors are doing voluntary service at the front. Stabsarzt Hertwig, who on October 1st, 1914, celebrated his 80th birthday in the field, where he is serving with a mounted force, and Geheimrath Müller,

who, in spite of his many years, is the energetic superintendent of two reserve hospitals.

CO-OPERATION BETWEEN CIVIL AND MILITARY DOCTORS.

The Danish and German medical press has lately published correspondence on the difficulties which may arise in the relations between the civil and the military doctor. Probably the most frequent cause of friction is the attitude of the military doctor in particular and of the military authorities in general towards certificates of health issued by civilian doctors. In *Igeskrift for Læger*, the journal of the Danish Medical Association, this delicate and complicated matter has lately been handled by correspondents with the gloves off. The origin of this particular discussion appears to have been the publication by a civil doctor in a lay journal of an attack on military doctors in general, in which a military medical officer was alleged to have overlooked plebeitis. This case was put forward as an example of the "depraving influence of militarism," and the doctor in question was accused of "indefensibly frivolous treatment of a dangerously ill patient." In reply to this attack on his colleagues by a civil doctor in a lay journal, a military doctor, in *Igeskrift for Læger*, remarked very properly that such matters should be discussed but not in the lay press. In the correspondence that followed in this journal the civilian's complaint that his certificates of health were "contemptuously flung across the table" was indignantly denied by the military doctor who took up the cudgels on behalf of his colleagues. The correspondence leaves on the reader the impression that, though the civil doctor's complaints may have been exaggerated, they were not altogether baseless. In the German medical press, Professor Schwalbe, editor of the *Deutsche medizinische Wochenschrift*, has complained that the systematic neglect of medical certificates by the authorities has been repeatedly brought to his attention by his colleagues. In this connexion it is interesting to find that the new regulations issued by the medical department of the German War Office to the Army Medical Service, contain the following clause: "The certificate when issued by a doctor in private practice must be authenticated by some official. . . . No comment on the value of such a certificate must be made in the presence of the bearer."

MEDICAL OFFICERS WANTED.

1st Home Counties Field Ambulance.

Surgeons for the front. An opportunity for interesting work at the front is offered to men who are keen on surgery by the Officer Commanding, 1st Home Counties Field Ambulance, Hailton Camp, Tring, to whom applications may be sent; these will be dealt with in the order in which they are received.

2nd South Wales Mounted Field Ambulance.

There is a vacancy for a lieutenant in this unit, which is now stationed on the East Coast. There is also a vacancy for a regimental medical officer in one of the yeomanry regiments of the brigade. All particulars concerning these vacancies can be obtained from Lieutenant-Colonel Herbert Jones, Lyons Farm, Blythburgh, Halesworth.

3rd South Midland Mounted Brigade Field Ambulance.

Medical officers are urgently required for the above unit, at present stationed at Oxford. When trained and efficient they must be prepared to be posted to the second and first lines to replace casualties. Apply to Officer Commanding, 3rd South Midland Mounted Brigade Field Ambulance (T.F.), 1, Ilfrey Road, Oxford.

3rd London Field Ambulance (T.F.).

There are vacancies for medical officers in the 3rd London Field Ambulance (T.F.). Pay and allowances 18s. 10d. daily. Captaincy in six months. Applications for imperial service and period of war only entertained. Apply, Officer Commanding, 3rd London Field Ambulance, Marlow.

Scotland.

GLASGOW HOSPITALS.

THE report of the Western Infirmary, Glasgow, for the year ending October 31st, presented to the annual meeting on November 25th, showed that the deficit was over £21,000, and about £500 more than in the previous year. It had been necessary to draw on capital accounts for over £7,000, reducing the unrestricted capital funds to a little over £4,000. One hundred beds had been placed at the disposal of the military authorities, and the majority of the medical and surgical staff were engaged in military service, either at home or abroad. The number of in-patients was 9,692, an increase of 100 on the previous year. The new connecting block now nearing completion contains an admission and casualty department, three lecture rooms, and three operating theatres. The extension fund, from which a balance of £24,000 was brought forward last year, has been diminished to about £14,000. Much regret was expressed that the Glasgow Corporation threatened to reduce its annual contribution to this and other hospitals in the city to one-half.

GREENOCK INFIRMARY.

The directors of Greenock Infirmary have recently received intimation of a bequest of £2,000 from the late Miss Edgar of Uddingston, and a donation of £1,000 from Mr. Robert Macpherson, C.A., and family, to endow a bed in memory of his son Hugh and of George W. Allan, who enlisted together last year in the Glasgow Highlanders; they fell side by side last May in the fighting at Richebourg.

CIGARETTE SMOKING AMONG WOMEN.

At the thirty-fifth annual meeting of the Greenock Eye Infirmary, Dr. N. Gordon Cheekie, in reporting on the 3,492 patients who had made use of the infirmary during the year, spoke of the harmful effect on eyesight of the excessive use of tobacco, and said it was with deep regret he had to state that this habit was very largely indulged in by females. It led to the premature wearing of spectacles. Dr. Robert Fullerton reported on the work done in the throat, nose, and ear department.

Ireland.

RED TAPE AND THE SENDING OF POOR LAW PATIENTS TO HOSPITAL.

THE Dundalk guardians last week made a strong protest against the action of the Local Government Board in refusing to sanction payment of an account for the maintenance in a Dublin hospital of a patient removed there without having been admitted to the workhouse hospital. The medical officer, Dr. Flood, had certified that the case urgently required operation, and that the patient could not safely be removed to the workhouse hospital. The guardians decided to contest in the court any surcharge that may be made. The usual procedure, in order to have a Poor Law patient in the country sent to one of the Dublin hospitals, is that the medical officer first admits him to the workhouse infirmary and then recommends him to the guardians for transference to another hospital for special treatment; he is then sent to the hospital at the expense of the poor rates, and a small sum is paid towards his keep while in hospital. This method answers well enough in ordinary cases, and perhaps tends to limit the number that might otherwise be sent, but it is not suitable in a case requiring urgent operation, for the doing of which there are no facilities in many of the workhouse infirmaries. If the medical officer or the guardians are not to be allowed to use their discretion in such cases, it simply means that if no charitable person can be found to pay the expenses the patient must be left to take his chance.

MORTALITY OF BOARDED-OUT CHILDREN IN DUBLIN.

At the last meeting of the North Dublin Union a long discussion on the boarding-out of illegitimate children arose on a statement by the chairman that the auditor had threatened to surcharge the guardians for relief given to a woman who had three such children to nurse. A guardian went to the root of the matter when he said that no woman who required Poor Law relief was a fit person to receive boarded-out children. The whole question calls for careful reconsideration. The infant mortality in Dublin is high, and the very high rate among illegitimate infants is occasionally brought to public notice by an inquest. But social workers acquainted with all the facts of the adoption system have little doubt that terrible carelessness prevails. A lady guardian stated that two of these children died under the care of one woman who then took a third. Within the past six months according to the Children's Act Inspector, twenty-eight of these children had died and a sum of £95 had been paid in adoption fees in respect of them. Very few inquests were held, only one in every sixteen deaths. She believed that children were dying in Dublin simply of starvation, cold, and neglect. A resolution was passed directing the clerk to write to the boarding-out associations in Dublin impressing upon them the undesirability of giving children to women in receipt of outdoor relief. Common sense would indicate that an adoption fee should not be paid to a woman who receives a boarded-out child without some sort of guarantee that she is in a

position to take care of and feed the child, and that she will do so. A woman under whose care one such child has died should not be entrusted with the care of a second, unless after searching inquiry she has been proved not to have been to blame for the death of the first. The question has many aspects, and is really only a part of the larger question of the conditions of life in the Dublin slums as well as of that of immortality in Dublin. On both these matters there is need for a stirring of the public conscience.

THE LIBRARY OF THE ROYAL COLLEGE OF PHYSICIANS.

The library of the Royal College of Physicians of Ireland has suffered from the war, as is shown by the report of the committee presented on St. Luke's Day, 1915. It is there stated that there was a considerable decrease in the number of books purchased as compared with the previous year. This deficiency, however, was largely compensated by an increase in the number of books presented to the library. It was found impossible to obtain many of the foreign periodicals which formerly found a place in the library, but here, too, several Fellows had helped by regularly presenting copies of various journals. The report gives a history of the development of the library, the nucleus of which was the collection of books left to the college by Sir Patrick Dun in 1711. At present the library contains 12,934 volumes, not including pamphlets, of which there are 186 bound volumes.

England and Wales.

THE CHRISTIE CANCER HOSPITAL, MANCHESTER.

THE report presented to the annual meeting of the Christie Cancer Hospital on November 25th stated that during the year 128 in-patients had been treated, of whom 71 had been discharged, 39 had died, and 18 remained in the wards. In connexion with the Manchester and District Radium Fund, treatment by radium had been commenced. Advantage had been taken of the proximity of the Royal Infirmary, and out-patients had been treated there. Dr. Burrows, the radiologist to the fund, having been appointed on the honorary staff. The majority of the patients were in such an advanced stage of the disease that no good could be done, but since January, when the new department had been opened, 17 patients had received the treatment. In many cases great relief from pain had been experienced, but it was too early to speak definitely as to permanent results.

Professor Wild, replying to a vote of thanks to the honorary staff, referred to some remarks of the chairman, Mr. E. Tootal Broadhurst, as to the large number of cancer cases in the country and the comparative few that came to the hospital, and said that it was a curious fact that cancer was far commoner in country districts than in large manufacturing districts. Every hospital received operable cases, but Christie Hospital generally received only the worst cases. Dr. Fletcher Shaw expressed the expectation that research would lead to the discovery of the cause of the disease, and then the search for a real cure would be more easy. Dr. Burrows, the radiologist, said that though radium, with improving technique, occasionally cured a case and gave brilliant results just short of cure, it was unfortunately no exception to the general rule that no remedial agent comes quite up to the expectations of its originators.

Sydney.

THE UNIVERSITY AND THE WAR.

A SUGGESTION was made recently that the University of Sydney should consider the possibility of granting a preliminary qualification in surgery to medical students volunteering for active military service, on the understanding that they should return to the university to complete their qualification in medicine. This matter was fully considered by the Faculty of Medicine, which reported as follows:

1. The great demand for Australian medical graduates at the present time is not only for the Australian Army Medical Corps, but also for appointment to the Royal Army Medical

Corps. Before appointment to the Royal Army Medical Corps the War Office requires from each candidate a certificate of registration as a medical practitioner from the General Council of Medical Education and Registration of the United Kingdom. Under the provisions of the Medical Act graduates of Colonial Universities are placed upon the Colonial list of the British Medical Register. His Majesty having previously defined the colonies to which the law applies. "A person who desires to be registered as a colonial practitioner must prove to the Registrar of the General Council of Medical Education and Registration of the United Kingdom that he holds a recognized colonial diploma granted in such a British possession; and that he is of good character, and entitled to practise medicine, surgery, and midwifery in such possession."

2. For the reasons that (a) the War Office requires registration on the British Register before appointment of army medical officers; and (b) the registration implies a recognized diploma in medicine, surgery, and midwifery, the Faculty is of opinion that to issue a preliminary diploma in surgery alone, omitting certain subjects from the last part of the curriculum, as has been suggested, would debar the holder of such a diploma from registration in Great Britain, and from services with the Royal Army Medical Corps, where they are urgently needed.

3. The Faculty also considers that in addition to surgery, a knowledge of the other medical subjects is essential for services in the Australian Army Medical Corps.

4. The Faculty is therefore of opinion that the measures previously recommended, whereby the full course is compressed by making use of the vacations, are the best that can be devised for shortening the course and so accelerating the supply of army medical officers.

At a meeting of the staff of the University on July 26th, under the chairmanship of Professor David, C.M.G., the president of the Professorial Board, it was decided that those present should form themselves into a Committee of National Service of the University of Sydney, that all members of the staff should be invited to join it, and that each member of the staff should be invited to indicate what special work he was able to perform, so that steps might be taken to inform the Commonwealth how the staff of the University might be utilized in this national emergency.

ELECTRIC BELTS.

The following notice has been published in the *Commonwealth Gazette* of July 24th, 1915:

Whereas by the Customs Act 1901 1914, it is enacted that all goods the importation of which may be prohibited by Proclamation, are prohibited imports; and whereas it is desirable in the interests of the public health and welfare to prohibit the importation into the Commonwealth of electric or magnetic belts or any belt which is alleged or intended to produce a therapeutic effect by electric or magnetic influences: Now, therefore, I, Sir Ronald Cranford Munro Ferguson, the Governor-General, acting with the advice of the Federal Executive Council, do hereby prohibit the importation into the Commonwealth of Australia of electric or magnetic belts, or any belt which is alleged or intended to produce a therapeutic effect by electric or magnetic influences.

HEALTH INSPECTORS' CONFERENCE.

The annual conference of the Health Inspectors' Society was opened on September 27th under the presidency of Mr. George Black, the Minister for Health. The secretary in his report stated that the membership of the society had grown from 7 in 1913 to 197 in 1915. At the beginning of the war the society had urged upon the defence authorities the necessity for appointing qualified inspectors to supervise sanitary matters at the various military camps, stating at the same time that a number of inspectors would volunteer their services. This offer, however, was not accepted. During the year the society had tried to secure legislation giving inspectors greater security of tenure of office but without success. The endeavour being made to bring all employees of shire and municipal councils under one wages board should be strenuously opposed. The president referred to the great advance made in sanitary matters during the past few years. Special attention should be paid to country hotels, which in some cases were still little removed from savagery. He spoke of the complaints made that inspectors were sometimes victimized by aldermen, who refused to comply with the ordinances and objected to interference. It would be a most untidy thing if men were discharged for doing their duty fearlessly, and there should certainly be some board of appeal to which cases of alleged victimization could be taken. In conclusion, Mr. Black promised to inquire into the matter with a view to removing this obstacle to the usefulness of the inspectors. Dr. W. G. Armstrong, chief medical officer of the Board of Health, said the outstanding event of the past year was

the passing of the Public Health Amending Act, which gave power to local authorities to close places unfit for human habitation without the necessity for cumbersome legal procedure. He paid a tribute to the late Dr. Ashburton Thompson's splendid work in connexion with health matters in the State. Not only was he one of the greatest authorities in the world on a number of the worst diseases known to humanity, but he was practically responsible for the framing of the health laws of New South Wales, and, together with the Crown Law authorities, drafted the present Act. He always recognized the importance of the work performed by the sanitary inspectors, and did all in his power to raise their status. The following resolutions were agreed to:

That owners of tip-carts should be licensed and a number-plate fixed on the cart, and that the said owners should be responsible for the name and address of the driver.

That Ordinance 39 be amended so as to compel owners of dwellings and tenements to provide and maintain a supply of water of not less than 4 gallons per minute from at least one tap on each floor or story.

That the Minister be asked to extend the definition of "owner" in the Local Government Act similar to that in the Public Health Act, so as to include the agent of person receiving the rent.

That the time is now ripe for the Board of Health to authorize health inspectors to purchase for analysis samples of food other than milk.

That the ordinances under the Local Government Act be amended to provide a penalty for any person refusing to give his name and address when called upon by an inspector.

That the Government be requested to consolidate the Public Health Act of 1902 and the Public Health Amendment Act, and that they should be reissued.

That in an inspector's appointment power should be given to prosecute without a permit from the Mayor, and that the Local Government Act be amended to cover it.

That the time is now ripe when the Health Inspectors' Society should have representation on the Local Examining Board of the London Sanitary Institute.

Correspondence.

THE ROYAL MEDICAL FOUNDATION OF EPSOM COLLEGE.

SIR.—It is again my duty to ask you to allow me to appeal to your readers for contributions in aid of the Royal Medical Foundation attached to Epsom College.

Owing to the loss of many subscriptions as a result of appeals in connexion with the war, the Council are experiencing a period of extreme anxiety lest they should be unable to maintain the existing numbers of pensionerships and foundation scholarships. At the same time, the calls upon the Foundation will most certainly increase. At this year's election the son of a medical man who was killed in action on board H.M.S. *Good Hope* was elected to a foundation scholarship, and the Council anticipate that not a few other appeals will arise directly or indirectly as a consequence of the war.

As is well known, a large number of civilian medical men are serving with the Army Medical Corps, the Red Cross Society, and in volunteer hospitals in France and elsewhere, and those who are carrying on their professional work at home will doubtless consider it both a duty and a privilege to assist any of their brethren or their dependants who may suffer financially in consequence of the sacrifices they have made in the service of their country.

It is earnestly to be hoped that whilst so many generous and munificent gifts are being made by our countrymen to aid Belgians, Serbians, Poles, and others of our allies, our own benevolent institutions will not be allowed to suffer.

May I, therefore, appeal to those of your readers who can do so to increase their contributions to our Medical Foundation, and to those who are not already annual subscribers to come to the assistance of the Council at this particularly anxious time. Although subscriptions of under 1 guinea do not give voting privileges, I may add that smaller contributions are gladly received.—I am, etc.,

HENRY MORRIS,
Honorary Treasurer.

LONDON, W., Nov. 26th.

BROMIDES IN EPILEPSY.

SIR.—Dr. Mercier in his letter in the BRITISH MEDICAL JOURNAL of October 23rd opens up a big subject for

discussion. He deals with the question of giving bromide in epilepsy in a somewhat summary manner. The shortage and prohibitive price of the drug is, in his estimation, seemingly a blessing in disguise. But to some of us who have charge of a large number of epileptic patients the disguise is very thick, and we are sceptical as to the "blessing." Dr. Mercier's name carries such weight that some of us would have liked to have had from him, not a dogmatic statement, but a reasoned opinion based on his great experience. Certainly he deals only with the routine giving of bromide in epilepsy, and I suppose any routine treatment has disadvantages, but I believe that the different bromides, if given intelligently, are very useful drugs in the treatment of idiopathic epilepsy, and aceto is easily avoided by combining them with arsenic.

The following statement shows the average number of fits per patient per month at Lingfield Colony (with nearly 500 epileptics):

1900. No bromide treatment: Fits per patient averaged 13.5 per month.

1907. Heavy doses of bromide: Fits per patient averaged only 1.99 per month, but many showed traces of bromism, and the head teacher complained that they were like "logs" in school.

1914. Moderate doses of bromide, plus individual treatment: Fits per patient averaged 1.5 per month; children showed no signs of bromism. Head teacher reports favourably as to educability.

Of course the arrest of the "fit" does not necessarily mean the arrest of the disease: mental impairment may still go on, but it does mean the prevention of the convulsive habit being formed.—I am, etc.

A. HUME GRIFFITH, M.D.,

Superintendent and Medical Officer, Lingfield Colony.

October 29th.

Sir.—With reference to the use of bromides in epilepsy it may perhaps be of interest to note that of the 73 epileptic aments under care in this institution to-day, not one receives a grain of bromide as a matter of routine treatment.

Bromides, however, are given for three reasons:

1. As a means of control in the increasing frequency and intensity of the convulsive attacks, until the cause of such exacerbation has been determined and, if possible, rectified.

2. As an adjuvant in the status epilepticus. The best means of dealing with this condition is by the immediate induction of general anaesthesia followed by the injection of an emulsion containing bromides with chloral hydrate, so as to ensure good sleep for some hours.

3. Epileptics when temporarily suffering from other diseases are often benefited by the addition of bromides to the mixtures prescribed for those diseases.

Assiduous attention to the diet, the hygiene of the bowels, and the general health of the individual are the essentials in the management of the epileptic, in the endeavour, that is, to guard him against the pernicious effects and the evil results of his disease. But for his own sake let him have his "fits." As Dr. Mercier intimates, the convulsion is to epilepsy what the pyrexia, say, is to acute pneumonia—a protective mechanism.

In conclusion, it remains to state that these principles of treatment, which I have tested to my own satisfaction, have been in practice in this institution for nearly twenty years, being first introduced by the present superintendent, Dr. Caldwell, by whose courtesy they are here published.—I am, etc.,

H. F. STEPHENS.

The Royal Earlswood Institution.
Nov. 15th.

TYPHUS FEVER AND LICE.

Sir.—In connexion with the very interesting paper by Major Davy and Captain Brown (*JOURNAL*, November 20th), I should like to make a remark regarding the lice theory of infection, for I am decidedly of opinion that it would not be wise for any one to regard lice as the only source of danger.

If a person, unprotected by a previous attack of typhus, exposes himself by remaining for some time near a typhus patient in a close, stuffy, unventilated room, I believe that he runs a risk of contracting the disease although there are no lice present. It is to be noted that the writers of the paper in question state (p. 738):

We found evidence that the infective agent resides in the body for at least three weeks after defecescence. Fresh out breaks occurred when patients were returned to their communities after the three weeks' period, though they and their clothes were disinfected and were presumably lice-free in all respects.

Many years ago I had a considerable experience of typhus while Physician-Superintendent of Belvidere Fever Hospital, Glasgow, and I feel it to be my duty to give this word of warning.

While not denying that the infection may be carried by lice, and agreeing that every means should be employed to get rid of them, I have faith in cubic space and a free circulation of fresh air as prophylactics in the case of typhus fever.—I am, etc.,

Bellefield, Lanark, November 22nd.

JAMES W. ALLAN.

PROFESSOR A. MARTIN AND PROFESSOR JACOBS.

Sir.—The Germans having shown the Belgians how dangerous for their fellow countrymen it is to have discussions with them at the present time, I think it my duty as a patriot to abstain for the present from retuning all the nice things¹ which Professor A. Martin addresses to me in the last number of the *Monatsschrift für Geburtshilfe und Gynäkologie* in the name of German Kultur. We shall see after the war that the matters are fully cleared up. Suffice it to say once more that all I have said and written has been seen and proved by me. Professor A. Martin seems to believe that the appeal which I have made in this country on behalf of the Belgian doctors and pharmacists ruined by the war was destined for the unhappy exiles. In that, too, he is deceived. The brotherly generosity of the international corps *médical* mainly helps, and is intended to help, the doctors and pharmacists who have remained in Belgium. The English committee can give a stronger opinion on this point than myself.

The pitiless war overwhelming Europe has created trenches terribly deep between scientific men. It is to be feared that they will be impassable to German *savants* for generations. The unjustifiable attacks which Professor A. Martin directs against me, Professors Pinaud, Treub, and Bossi shows us the course we shall be obliged to take in the future, in spite of the old scientific and friendly relations which we have held with the Germans.—I am, etc.,

C. JACOBS,

Professeur Université de Bruxelles,
Médecin Reg. 1^{ère} Classe, Belgian Army.

December 1st.

Obituary.

ARTHUR HAMILTON WHITE, L.R.C.P. AND S.J.,
LATE PROFESSOR OF PATHOLOGY, ROYAL COLLEGE OF SURGEONS,
IRELAND.

It is with deep regret—a regret which will be shared by many friends in England as well as Ireland—that we have to record the death, from pneumonia, on November 27th, of Arthur Hamilton White of Dublin, at a comparatively early age. White started his early career in the Prisons department of the Irish Civil Service, and while performing the duties connected with this office he found time to study for the medical profession, and took out the night lectures and practical courses conducted by the Carmichael College of Medicine, which subsequently became amalgamated with the school of the Royal College of Surgeons in Ireland. He was a pupil of the Meath Hospital, where he came under the influence of the late Arthur Wynne Foot, and having served in various undergraduate positions in the hospital, he obtained the diplomas of L.R.C.P. and S.J. in 1893.

Later White worked under Sir Victor Horsley in London, and then devoted a considerable amount of time under Kronecker in Berne to the study of the nutrition of the frog's heart. He studied also in Vienna and Freiburg, and coming back to Ireland he obtained the Renben Harvey Memorial Prize for original work on the heart of the frog. He was appointed subsequently pathologist to his old hospital, and to the House of Recovery, Cork Street, and in 1898 was elected to the chair of pathology in

¹The nature of Professor Martin's effusion is indicated in an annotation published at p. 822.

the Royal College of Surgeons in Ireland. These positions he held up to the summer of this year, when he resigned owing to ill health.

In 1893 he became Secretary to the Leinster Branch of the British Medical Association, Honorary Secretary to the Irish Committee of the same Association, and in 1911 Honorary Secretary to the Conjoint Committee of the British and Irish Medical Associations, a committee formed for the furtherance of Poor Law reform in Ireland, and revived, after a period of obscurity, with the passage of the Insurance Act. Firmly convinced that this Act could be turned to good account, White threw himself into the work with all his energy. Mainly owing to his activity a memorial was drawn up and sent to every member of the profession in Ireland, and in this work of organization he succeeded in reconciling the many warring elements with consummate ability and tact. Professor White was a member of the Central Council of the British Medical Association for many years and a very regular attendant at its meetings, and found among its members some very firm friends.

White was an enthusiastic pathologist, as his contributions to various medical journals testify. He had a passion for work and for seeing others work. His own had been a hard and rugged road, and he was impatient of "short cuts." "Aids" of any sort were to him an abomination; the "grinder" was anathema. His own knowledge of the subject was profound—and yet he was not himself a very successful teacher of junior students. He never lectured in the ordinary sense of the word, but while demonstrating morbid changes he made disjointed remarks, the drift of which the average student sometimes found it hard to follow. But those who took the trouble to think about what he said generally came to realize that his observations contained some illuminating principles, some particle of pure gold to be stored up and treasured. He was scrupulously conscientious, avoided dogmatism in everything, and out of fear of misleading students hardly ever committed himself to a definite statement if he could avoid it. He was a devoted follower and believer in the pathological teaching of Sir A. Wright, and his work on the opsonic index showed the patience, industry, and accuracy with which he was endowed.

Outside his work White was a genial companion. He had a keen sense of humour, of beauty in nature and art, and held vigorous views in politics and literature. His disposition was naturally childlike and lovable. He loved children, he loved sunshine, and he loved a good book. But if ever a man had to battle against "the slings and arrows of outrageous fortune" that man was Arthur White. Day and night he carried with him the burden of miserable health. His frequent illness, due to continuous pain, was mistaken by many for senescence, and thus misjudged, or misunderstood, his life would have been a lonely tragedy had there not been a few who had been understood. But it was a tragedy none the less. Maimed, battered, blinded, he worked to the bitter end undaunted, while his hopes and ambitions faded one by one before him. With the resignation of the chair of pathology, his whole life seemed to tumble about his ears; and yet he hoped—hoped for a year, or may be two, of peace in the sunshine that he loved—for a respite to nurse himself back to some degree of health, and then—to work again. To such a life the noble lines of Henley's *Invictus* form a fitting epitaph, and we who knew him well may "thank whatever Gods may be" for his "unconquerable soul."

EVAN WILLIAMS, M.R.C.S., L.R.C.P.

(LATE PRESIDENT OF THE NORTH WALES BRANCH OF THE BRITISH MEDICAL ASSOCIATION.)

It was with deep grief that the news of the death of Dr. Evan Williams was received among the profession and the public of the county of Merioneth, and more especially in Bala and district, where he was well known for upwards of thirty years. He was discharging his duties on October 20th, but when out later in the day shooting he had a seizure and died from cerebral hæmorrhage in about four hours.

Evan Williams was born at Llandderfel, near Bala, in 1860, received his medical education at University College, London, and took the diplomas of L.R.C.P. and M.R.C.S.

in 1882. After acting as assistant to the late Dr. Roge Hughes of Bala, he became his partner. He gained a large practice in Merioneth and was M.O.H. for Bala, and held many other public medical appointments. When a prisoners-of-war camp was established at Froncogh, near Bala, Dr. Williams was appointed medical officer. He took an active part in all the public and social life of the district, was a member of the Merioneth County Council, a county magistrate, and a member of the North Wales Asylum Board. Some years ago he was President of the North Wales Branch of the British Medical Association. He was also a prominent Freemason and a keen sportsman. He inspired more than liking in those with whom he came in contact, and his private friends were innumerable and closely attached to him. The attendance at his funeral at Llanfor Churchyard, on October 23rd, afforded evidence of the love and esteem with which he was regarded by those among whom he lived. He leaves a widow, with whom much sympathy is felt.

Dr. JACOBUS, formerly of Leeds, and recently of Cloughton, near Scarborough, died on November 2nd, at the age of 38. His father was a banker in Cyprus. He was educated at Trinity College, Dublin, where in 1896 he was Vice-Chancellor's Prizeman, and graduated M.B., M.Ch., and B.A.O. in 1903. He practised in the Roundhay and Harcliffe district of Leeds for six years, but his health failed, and he was compelled to retire to Cloughton three years ago. Dr. Jacobus was a classical scholar of some authority, and he undertook the translation of highly important ancient Greek documents. He was married, and his widow survives him.

Dr. JOHN PATERSON of Girvan died on November 24th after a short illness. He was a son of the late Dr. William Paterson, superintendent physician of the Glasgow Hydro-pathic Establishment, Rothsay, and succeeded his father. He received his medical education in Edinburgh, and took the diplomas of L.R.C.P. and S. Edin. in 1870. He is survived by a widow and three children.

Dr. H. B. CURRIE, who died recently in Johannesburg, took the degrees of M.B. and C.M. Glasg. in 1894. Afterwards he held the appointments of assistant medical officer in the Belvidere Fever Hospital, Glasgow; assistant physician at the Crichton Royal Institution of Dumfries, and physician to the Glasgow Western Infirmary. A few years before the Boer war he went to South Africa. He did service as medical officer of the Natal Carbineers through the siege of Ladysmith, and was afterwards appointed Surgeon-Captain to the Imperial Light Infantry. After the peace he was made a major in the Transvaal Volunteer Medical Service Corps. He was also physician to the Johannesburg General Hospital, and on his retirement was placed on the consulting staff.

Dr. JOHN HALLEY, who died at Wentworth Falls, New South Wales, on November 6th, was a son of the late Mr. D. R. Halley, Inland Revenue, Aberdeen, and was the Government medical officer at Fiji. He graduated M.B. at Aberdeen University in 1899. He was 42 years of age.

The death is announced, on November 18th, of Dr. ROBERT BARKER ROBSON of Alwicks, Northumberland. He graduated M.B. Durh. in 1886, and took the diploma of M.R.C.S. in the following year. He was honorary surgeon to the Alwicks Infirmary, and M.O.H. to the urban district.

BRIGADE SURGEON ALEXANDER TURNER, Army Medical Department (ret.), died at Plymouth on October 31st, aged 74. He was educated at Aberdeen University, where he took the M.B. and C.M. in 1862 and the M.D. in 1863. He entered the Army Medical Department as assistant surgeon on September 30th, 1863, became surgeon on March 1st, 1873, and surgeon-major on September 30th, 1875, retiring with a step of honorary rank on October 18th, 1881. The *Army List* assigns him no war service.

Universities and Colleges.

UNIVERSITY OF EDINBURGH.

At the recent medical preliminary examination 54 candidates passed and 21 failed in English, and in mathematics the numbers of those who passed and failed were the same. In Latin 48 passed and 39 failed; in Greek 5 passed and 2 failed; in French 42 passed and 32 failed; in German 3 passed and 3 failed. All those who were examined in Gaelic, Malayalam, Urdu, Sanskrit, Persian, and Yoruba passed.

The number who completed the preliminary examination in the Faculty of Medicine was 133, as against 119 in January, 1914. The total number of first-year students, including women, is 188; the number of extra-academical women students is 111. (The total number of women students in connexion with the university is 613, as compared with 621 last year.)

ROYAL COLLEGE OF SURGEONS OF ENGLAND.

Annual Meeting of Fellows.

LIEUTENANT COLONEL JOSIAH OLDFIELD, B.A.M.C.(T.) writes: Please allow me to correct the report in your last issue as to the meeting of the Royal College of Surgeons. You state: "After some further discussion, in which Lieutenant-Colonel Oldfield took part, this motion was carried." I regret that, owing to my military duties, I was not present at the meeting, and therefore did not take any part in the discussion. My views on the question of admitting Members to a share in the government of the College are wholly opposed to those of Sir Watson Cheyne. What I have claimed time and again at the annual meeting is not that the College should be transformed into "a political institution," but that it should become a real *alma mater*, on scientific, ethical, and protective lines, to all its members. At present it does but the barest minimum instead of seeking to do the highest maximum possible for them. A Council keen on the educational and scientific side would provide a better library; so draughty and wanting is it in the essentials of what a library should be, that wherever possible I go to study at the Lincoln's Inn rather than at the College of Surgeons Library, and it is because this latter library is used for banquets that it cannot be fitted up as a library for study should be fitted up, and yet Sir Watson Cheyne claims he is working for "an educational and a scientific institution." The College has failed to function, too, on ethical and protective lines. In the great fight on insurance, in the great struggle of members to be allowed to use the title of doctor (that is, *doctus*, or learned in the art of healing), in the important questions of equalizing examinations and unifying degrees—to give a few instances of non-political problems which gravely affect the wellbeing of members—the College has given no lead nor taken any care of its members. Surely the Council should be scientific enough to know that the appreciation of evolution is quite different from the fear of evolution, and yet the latter is the annual plea put forward for perpetuating ineptitude.

The Services.

EXCHANGE DESIRED.

CAPTAIN, Field Ambulance, wishes exchange with another Captain, Base Hospital. Address No. 5790, BRITISH MEDICAL JOURNAL Office, 429, Strand, W.C.

Medical News.

DR. GEORGE MINTO JOHNSTON has been added to the Commission of the Peace for Leith.

An electro-therapeutic department for the treatment of gonorrhoea has been established at the Male Lock Hospital, Dean Street, W., and placed in charge of Mr. C. R. Huss, M.B.Lond.

THE Hutterian Society held a clinical meeting on November 24th at the Heart Hospital, Westmoreland Street, London, W., the plans of which were explained by the secretary. A series of cases were shown by members of the hospital staff, and Dr. Hamill and Dr. Strickland Goodall demonstrated the working of the electro-cardiograph and explained the interpretation of electro-cardiograms.

THE drawing-room sale in aid of the funds of the Royal Medical Benevolent Fund Guild, to which the attention of readers was called in the BRITISH MEDICAL JOURNAL of November 20th, took place at Crews House on November 24th, and attracted a crowd of visitors. They showed their sympathy with the cause in aid of which the sale was arranged in a very practical way, with the result that a sum amounting to just over £1,000 has been added to the funds of the guild. It is highly gratifying that the public

should have come to the help of a medical charity in so generous a spirit, and we are sure that the whole profession will join with us in congratulating Lady Tweedy and her fellow workers on the success of their efforts.

AN action for damages, laid at £40,000, was recently brought against the New York Rockefeller Institute for Medical Research and three members of its staff by two former employees at the institute, who alleged that the doctors sued had persuaded them to submit to the injection of a serum, and that as a result of carelessness and negligence they had become infected with a venereal disease. The case came before the United States District Court on November 4th, and was dismissed on the ground that the facts stated were insufficient to constitute a cause of action.

THE committee of the Heritage Craft Schools at Chislehurst, Sussex, reports that seven old boys, once crippled, are now serving abroad, four of them as transport drivers. Since the outbreak of war the boys' workshops have been wholly occupied in the making of war equipment, furniture, and appliances for hospitals. The Princess Louise Military Wards have been established as a relief hospital, in connexion with the London Hospital, for the reception of wounded soldiers. The enterprise is in need of funds, owing to the increase in the cost of provisions and material and to other causes. A handicraft sale of objects made by the children will be held at the Girls' Heritage, Chislehurst Clump, on Saturday, December 4th.

I. MARZINKOWSKY (*Medizinskoje Obzrenije*, No. 20-21) relates that Dr. N., in order to investigate the infectivity of the scarlatinal desquamation, carried out upon himself the following experiment: Having made several incisions over the skin of the shoulder, he applied to the scarified surface a thick layer of an emulsion made of a mass of desquamating cuticle, triturated in a physiological solution, but no infection followed. He then performed the same experiment upon himself with the desquamation of two adults in the second and third weeks of scarlet fever and upon his son, aged 15, who had never had scarlet fever, by applying the emulsion directly to the nose and tonsils with a negative result. Denying the infectivity of the scarlatinal desquamation, the author is of the opinion that the vehicle of contagion is derived from the mouth and nares, and that it is transmitted through "carriers" of scarlet fever as well as through those who suffer from it.

IN the course of his address to the Röntgen Society the new President, Mr. J. H. Gardiner, F.C.S., referred to the suggestion that it might be possible for the medical man of the future to be provided with a set of x-ray tubes, duly labelled for the production of any desired kind of rays. Such a project appeared very enticing, but he doubted whether it would be possible or even desirable. There were too many conditions involved to enable x-rays to be put up in bottles like drugs, and for the purpose of exact research such a plan was unthinkable. Nevertheless, it was now possible to produce and maintain rays of any desired value, and if the immense differences in the effects produced by luminous radiations differing only slightly in their wave-lengths were considered, it did not seem unreasonable to expect that similar special reactions might be due to shorter rays of some definite quality. The investigation called for very great refinement, and the man who was going to make the desired advance would have to combine the qualifications of a pathologist with a thorough knowledge of the physics involved in the passage of electricity through gases. It was now practically certain that Roentgen rays differed from the familiar electro-magnetic disturbances of light, heat, and electricity only in the extreme shortness of their waves, which ranged from about one twenty-millionth to one five-millionth of a millimetre. In the purely physical sphere of investigation the field was equally interesting, but the vacuum tube had not yielded up all its secrets. Vision for most people ended in the blue-violet. Shorter waves than these belonged to the ultra-violet and Schumann region, where chemical and ionizing actions reached a maximum. Beyond this and before the softest radiations were reached there occurred a hiatus, a dark continent of the deepest interest for the physicist, for in that region took place the profound changes which distinguished luminous radiations from those produced in a vacuum tube. At the other side of the vacuum tube rays, beyond what the radiologist called hard rays, and before the gamma rays of radio active substances were reached, there occurred another small gap. Here much work was being done at present, and there was reason to believe that before long it would be possible to construct tubes which would give rays closely approaching, if not corresponding to, gamma rays in wave-length.

Letters, Notes, and Answers.

As above desirable reprints of their articles published in the BRITISH MEDICAL JOURNAL are requested to communicate with the Office, 423, Strand, W.C., on receipt of proof.

THE telegraphic addresses of the BRITISH MEDICAL ASSOCIATION and JOURNAL are: (1) EDITOR OF THE BRITISH MEDICAL JOURNAL, 423 Strand, W.C.; (2) Telephone, 263; (3) Gerard, (2) FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisement, etc.), *Articulate, Westwood, London*; telephone, 263; (4) General, (3) MEDICAL SECRETARY, *Metropolitan, Westwood* of the British Medical Association is 16, South Frederick Street, Dublin.

For queries, answers, and communications relating to subjects which special departments of the BRITISH MEDICAL JOURNAL are devoted will be found under their respective headings.

QUERIES.

INCOME TAX.

PILGRIM writes to say that the surveyor of taxes refuses to allow a deduction of two-thirds of the assessable value of his house under Schedule D, in spite of the fact that the whole of the ground floor is given up to professional purposes. The surveyor will only allow one-third. "Pilgrim" inquires as to his remedy, and as to whether arrears of tax can be claimed against him for more than three years, if the surveyor's contention should be upheld.

The first rule, Cases I and II, Schedule D, provides that no deduction shall be made for the value of any dwelling-house, "except such part thereof as may be used for the purposes of such trade or concern," not exceeding two-thirds. It will be seen that the deduction made by our correspondent is the maximum proportion; whether he is entitled to the full two-thirds is a question on which he is entitled to appeal to the General Commissioners. In the circumstances one-third would certainly seem insufficient, but on the other hand "Pilgrim" is not correct in deducting the ground rent as well as two-thirds of the assessable value, inasmuch as the latter undoubtedly includes the former. The right of assessing arrears extends to the three previous years only (Finance Act, 1907). The surveyor's claim to six years' arrears seems incapable of support, except on the ground that such payment would be by way of compounded penalties (Inland Revenue Regulation Act, 1890). In view of the fact that the question in issue is a debatable one, the Revenue authorities are hardly likely to invoke the penalty sections, though, on the other hand, "Pilgrim" may possibly, not desire to avoid restitution of any tax which may ultimately be found to have been unpaid owing to any misapprehension of his rights of deduction.

ANSWERS.

M. B. M.A.—Chinosol is the trade name for potassium oxychloride for oxyquinoline sulphinate. The salt is readily soluble in water but sparingly in alcohol. The name Chinosol indicated the product of Franz Frische, of Hamburg. For washing out the bladder a solution of 1 in 1,000, increased gradually to 1 in 500, is suitable. Chinosol, we understand, is not highly recommended by authorities for this purpose.

THE DESTRUCTION OF RATS.

MR. ROBERT M. CAPON (Liverpool) sends the following method, which, he states, is adopted by the Chinese: Place a fairly large barrel on end, covering the upper surface with brown paper, on the centre of which place a suitable bait. From the ground to the top of the barrel place one or two planks as a run to the baits. Continue this placing of bait for three or four nights in succession, then on the following night remove the end from beneath the brown paper covering, leaving only the brown paper, on which is again placed the bait. In the bottom of the barrel and in the centre place a brick on end, partly fill the barrel with water until it nearly reaches the top of the brick, and then leave all as before. The results should be as follows: The first rat runs up as usual, falls through the brown paper; the second does the same, and then fights the other for the unremoved brick surface. They both set up such a squealing that all the other rats rush up to see what is going on, as they love a fight, the consequence is a lot are caught; after a few days this can be repeated.

DR. W. E. PAIN (London, S.E.) states that if ordinary gas tar is placed in the runs of rats they will disappear. After trials extending over many years he has never known this plan to fail.

DR. T. RECKEL ATKINSON states that the use of Dantox virus cleared a vicary which had been infested with rats for some years, and the animals did not return.

DR. W. M. MORISON (Anfield Plain) recommends that for a day or two the rats should be well fed to disarm their suspicions,

and then bread or meat poisoned with "rodine" placed near the suspected nest, leaving a plentiful supply of water near, as the poison produces great thirst.

TREATMENT OF CORNS.

DR. W. FELLOWES FISHER (Ramsay, Huntingdon) sends the following suggestion for the treatment of corns on the sole: Make a pad of rubber about $\frac{1}{2}$ in. thick and 1 in. in diameter (a piece of inner tube of motor cycle) and cut a hole in the centre the size of the corn. The rubber will adhere to the skin and relieve pressure on the corn, and has not the disadvantage of adhesive plasters, which have to be renewed each time one washes.

X-RAY APPARATUS.

A. H. F.—(1) It would be quite feasible to run an X-ray and electrical apparatus from a dynamo driven by a gas engine of 3 h.p., but the practice is open to the objection, when working a small set, that there is likely to be considerable flickering and jumping of the current. A slender run could be ensured by the introduction of accumulators, which could be charged by the engine. Two sets of accumulators might be kept, one under charge, and the other in use. (2) Any manufacturer of electro-medical apparatus would give advice on the subject.

"SIMPSON LIGHT."

CURRIOT asks a question as to "S" rays, by which is meant, we presume, what is known as the Simpson light. So far as our information goes, this is a method of using a portion only of the spectrum, or portions in combination, and is based on a somewhat similar principle to the Finzen and other light treatments employed in dermatology. The inventor of the process, who, as understood by a slender, is a medical student, is not commercial. The Simpson light, we believe, is only being employed at present in the electro-therapeutic department of St. Bartholomew's Hospital.

INTERMISSION OF ASTHMA DURING PREGNANCY.

DR. FRANCIS HARE (Beckenham) writes, in reply to a question on p. 500: The cessation of asthma during pregnancy is fairly common, and the freedom from the complaint may be prolonged during the subsequent lactation. The same is true of all the other paroxysmal neuroses—migraine, vasomotor angina pectoris, and even epilepsy (in some cases). Dr. Wesley Wilson will find these occurrences somewhat fully dealt with in my book, *The Food Factor in Disease*, 1905, vol. 1, pp. 234-235. It must also be said that asthma sometimes appears during pregnancy, being absent at other times (*ibid.*, p. 256).

LETTERS, NOTES, ETC.

PASTING FOR DIABETES.

DR. JOHN HADDOX (Denholm, Hawick) writes: I am pleased to see in the JOURNAL a notice of the treatment of diabetics by Dr. Allen, in America, who has been trying the effect of fasting from all food for eight or ten days. Fasting has been had recourse to by the laity in America for many years, and in my book I give cases showing its wonderful power in curing disease. I have seen a man fast for forty days to cure his rheumatism and he succeeded. Fasting, however, in some cases is not safe and ought not to be undertaken except under medical supervision, but the fact that stopping taking food cures disease, or even relieves any symptom, ought to convince the profession that food is the chief cause of disease.

PEPPER IN THE PROPHYLAXIS AND TREATMENT OF FILARIASIS.

DEPUTY SURGEON-GENERAL V. G. THORPE, R.N., writes: It is pepper for prophylactic against filaria, as Dr. J. H. Robertson in the JOURNAL of October 9th, p. 535, states it is, then it is certainly strange that, as I first pointed out in my paper on the Filaria of the South Sea Islands (BRITISH MEDICAL JOURNAL, October 3rd, 1894, p. 189), for every one of the total male population of the Friendly Islands harbour in their blood a non-periodic variety of filaria, apparently identical with *F. bancrofti*, in spite of the fact that the universal native drink is "kava-kava," which is an infusion of a pepper root (*Piper methysticum*), the active principle of which (methysticin) is allied to piperin.

SCALE OF CHARGES FOR ADVERTISEMENTS IN THE BRITISH MEDICAL JOURNAL.

	£	s.	d.
Seven lines and under	—	—	0 5 0
Each additional line	—	—	0 5 0
A whole column	—	—	3 10 0
A page	—	—	10 0 0

An average line contains six words.

All remittances by Post Office orders must be made payable to the British Medical Association at the General Post Office, London. No responsibility will be accepted for any such remittance not so safeguarded.

Advertisements should be delivered, addressed to the Manager, 423 Strand, London, not later than the first post on Wednesday morning preceding publication, and, if not paid for at the time, should be accompanied by a reference.

Notice that the rules of the Post Office to receive *poste restante* letters addressed either in initials or numbers.

THE PSYCHIC MECHANISM OF THE VOICE IN RELATION TO THE EMOTIONS.

BY FREDERICK W. MOTT, M.D., LL.D. EDIN.,

F.R.S.,

PATHOLOGIST TO THE LONDON COUNTY ASYLUMS.

The mechanism of the control of the breath in ordinary speech has become so habitual that, as a rule, one is unconscious of any voluntary effort. It is not so, however, in the arts of oratory, acting, and singing, the conscious management of the breath being of fundamental importance in the expression of the emotions and passions. The correct management of the breathing in the actual technique of vocalization should become a habit, so organized mentally that after a time there is no need to devote conscious attention to the technique of perfect vocalization and clear diction. This fundamental part of the art of dramatic singing can be acquired by careful instruction and practice, so that after a time conscious effort is no longer necessary; for every state of consciousness which is habitually repeated leaves an organic impression on the brain by virtue of which that same state may be reproduced more readily, at any future time, in response to a suggestion fitted to excite it. We can, therefore, readily understand how very difficult it is to cure a bad habit of voice production or diction when once it has become mentally organized; the same applies to any imperfection in phrasing a particular passage in a song. Moreover, consciousness of the difficulty causes nervous apprehension, and a mental struggle may ensue between the conscious right method of rendering and the subconscious habitual wrong method which may make itself apparent to the audience by a faltering and imperfect technique or even a complete breakdown.

A good singer not only pays particular attention to the practising of scales and exercises in order to acquire the habit of correct intonation, but he makes himself thoroughly familiar with the phrasing of difficult passages in classical music as practised by the great master singers, such as Santley and Sims Reeves, for experience tells him that this familiarity will be a mine of wealth which he can constantly utilize not only in the conscious rendering of the particular music in which the passage occurs, but also consciously and unconsciously in learning a new song or operatic part. Not until he has mastered the whole technique of correct vocalization, diction, and memorizing of the words is consciousness relieved of its duties as a watchful censor to prevent mistakes to such a degree that he can devote his attention to the production of all those fine shades of affective tone in the modulation of the voice which are so essential for dramatic singing. The actor and dramatic singer voluntarily expresses the emotions and passions by the conscious control of the force and mode of escape of the breath—for example, the loud outburst of anger and vengeance, the quiver or tremor of fear, the halt of terror, the sob of grief, the sigh of despair, the variations of sympathetic tone and loudness to express the tender emotions of pity and love; and the joyful outburst, tinged with anger, of passionate love, the laughter of joy, the rollicking laugh of mirth, the hiss and sardonic laughter of hatred and jealousy with which he clothes articulate language is the supreme effort of his art.

Sir Charles Bell, who discovered the respiratory system of nerves, pointed out how the lungs from being in the lower animals merely the means of oxygenating the blood, become in the higher animals utilized in the art of expelling air from the body for the production of audible sounds—the elements of human voice and speech.

Likewise, in his great work on the expression of the emotions, he first drew attention to the influence which powerful emotions exercise upon the organs of respiration, including the countenance—for example, the dilated nostrils in anger. Again, he says, when the voice suffers interruption and falters, and the face, neck, and chest are animated by strong passion working from within the breast, language exerts its most commanding influence. But is it necessary or advisable

for the great artist to feel these emotions and passions strongly? He must feel them to a certain degree, for if he expresses them consciously he *must* feel them, and the degree to which he feels them is largely a matter of individual and racial temperament. Darwin pointed out that by voluntarily assuming an expression of the countenance and bodily attitude which an emotion or passion naturally excites, the feeling of that emotion or passion occurs to some degree. But, as Maudsley in his *Mental Physiology* points out, there is a fallacy in the experiment, as, in order to produce the suitable movements of expression, we are compelled to imagine the emotion or passion; but, after allowance has been made for this cause of error, there is still a sufficient reason to believe that the feeling of the emotion or passion is intensified and made more definite by the bodily action. The orator, the actor, or the dramatic singer can consciously assume the expression and bodily action suited to the vocal part, and the feeling tone will be intensified in the voice whether the words are spoken or sung. Every true artist has aesthetic feeling; but he must exercise control of this feeling, for an emotion strongly felt is liable to produce commotion in consciousness and thus interfere with its action, as the censor controlling the automatic subconscious psychic mechanism upon which the successful vocal technique of the artist depends. Such loss of control is very liable to cause imperfections of vocalization, especially faulty intonation, for in anger the pitch of the voice naturally tends to rise, and in fear to fall and the voice to choke. Moreover, he is liable to forget the words. Rather he should aim at keeping a control over his feelings so that his technique does not suffer, and yet be able to arouse in his audience the emotions which he expresses. Thus the art of dramatic singing and acting lies in concealing the art, and the master singer, like the great actor, by the modulation of the voice, by his expression and gestures, feeling himself little or no organic internal disturbance, the essential part of a strong emotion, can nevertheless by his art arouse in the expectant audience that part of the emotion which he does not portray, and probably does not feel, at any rate intensely—namely, the quickening or slowing of the pulse, and respiration, the emotional thrill or shudder of the spine, pallor and coldness or redness and warmth of the skin, tears, and various other manifestations of bodily disturbance. You are all familiar with the passage in *Hamlet* in illustration of this point:

Oh what a rogue and peasant slave am I!
Is it not monstrous that this player here,
But in a fiction, in a dream of passion,
Could force his soul so to his own conceit
That from her working all his visage waned;
Tears in his eyes, distraction in's aspect,
A broken voice, and his whole function suiting
With forms to his conceit? And all for nothing!
For Hecuba!
What's Hecuba to him, or he to Hecuba,
That he should weep for her?

I shall be very interested to hear some of the members of the society on this point. How far they feel the emotions and passions they portray in song, facial expression, gesture and bodily attitudes, and how far the assumption of these outward and visible manifestations assist them in the expression of the affective tone in the voice.

MUTISM.

In my experience at the military hospitals a number of remarkable cases have come under my care illustrating several points in connexion with the psychic mechanism of the voice in relation to the emotions. A large number of men suffering with shell-shock, and having no visible signs of injury, have lost their speech, and yet are quite able to write a lucid account of their experiences. This mutism is really an exaggerated form of hysterical aphonia. A woman owing to an emotional shock may lose her voice; she can, however, as a rule whisper. These men cannot whisper or produce any audible sound. They occasionally show the bodily signs of extreme terror, and in a very few severe cases one is reminded of the lines in Spenser's "Faerie Queen":

He answered nought at all, but adding new fear to his
first amazement,
Starting wide with stony eyes and heedless hollow hue
Astonished stood, as one who had espy'd
Infernal furies with their chains unty'd.

* A paper read before the Society of English Singers on November 17th, 1915, the President, Sir Charles V. Stanford, in the chair.

We may ask, Why should these men whose silent thoughts are perfect, for they comprehend all that is said to them, and are able to express their thoughts and judgements in writing, be unable to speak? The cause of the mutism is clearly not due to an intellectual defect, nor is it due to volitional inhibition of language in silent thought. Hearing, the primary incitation to vocalization and speech, may be unaffected, yet they are unable to speak. They cannot even whisper, cough, whistle, or laugh aloud. Many of these poor fellows, who are unable to speak voluntarily, yet call out in their dreams expressions they have used in battle and trench warfare. Sometimes this is followed by return of speech, but more often not. There has been a severe emotional shock. Is the fear effect still operating on the mind, full as it is of the recollection of the terrifying experiences of the trench warfare they have been engaged in? The frequency with which these cases of shell-shock suffer with terrifying dreams at night, and occasionally even during the day in the half-waking state, points to the conclusion that the emotional shock is exercising an effect on the mind by thoughts continually reverting to terrifying experiences they have gone through at the front; and probably their continuous influence on the subconscious mind accounts partially, if not entirely, for the terrified or vacant look of depression on the face, the cold, blue hands, feeble pulse and respiration, and the sweats and tremors which the severer cases manifest. As these dreams cease to disturb sleep, so these visible physical manifestations of fear pass off and give place to the sweet unconscious quiet of the mind of normal sleep.

The sudden and varied manner in which these mute patients recover their speech is indicative of a refractory condition of respiration in its function of voluntary production of audible sounds in all forms, even the cough, cry of pain, or the audible sound of explosive laughter, for when tickled so as to produce the full measure of the facial expression of laughter no sound comes. Some of these men, however, have suddenly recovered their speech by crying out when unexpectedly feeling physical or mental pain—for example, one man cried out when some boiling tea was spilt over him, another when he was held down and his feet tickled, others have shouted out in their terrifying dreams, and awaked to find themselves speaking, and have continued speaking aloud to be sure that they have recovered. In most cases it is the sudden and unexpected which restores the function of the vocal mechanism. Surprise is an essential element. Thus, a sergeant saw some soldiers larking in a punt, and he suddenly shouted out, "You will be over." Another recovered his speech when a Canadian, who bet he would make him speak, quite suddenly surprised him by seizing him by the throat. He called out, "Leave off." Occasionally the stimulus of a well known chorus has broken down the refractory condition in the psychic mechanism of the voice and the mute has surprised himself and others by finding himself singing. As depressing emotional conditions, including terror arising from the awful scenes of death, exhaustion, and fatigue, play an important part in aggravating the shock effects of shell fire and maintaining subsequently a more or less transitory functional neurosis in the form of deafness, blindness, paralysis, tremors, and mutism, we may suppose the sudden emotional excitement, especially if it be connected with the preservation of the individual, is followed by such a powerful stimulating reaction on these depressed nervous centres that the refractory phase established in them by the shock is suddenly overcome. I believe this mutism is due primarily to an inhibitory functional paralysis of the voluntary cerebral nervous centres which control the management of the breath and direct its mode of escape through the glottis, mouth and nostrils, for I have seen many cases where they have involuntarily and unconsciously in their dreams talked and uttered cries and sweats, but in their conscious state were unable, not only to talk and sing, but to whisper, whistle, utter a cry, cough, or laugh aloud. The worst cases were unable even to blow a candle out. I examined one with the x rays and found the diaphragm hardly moved in respiration; he could not expand the chest necessary to fill the bellows. Latterly he has acquired this power; he can now take a fairly deep inspiration, but yet he cannot talk or even whisper, cry, or laugh aloud; he blows a candle out with the mouth open instead of moulding the lips. Therefore in his case there is an in-

hibition of the whole voluntary mechanism of audible sound production. Now in the cortex cerebri the parts controlling the movements of the lips, the tongue, the jaws, the larynx and soft palate are all contiguous and work together; this, then, is the voluntary nervous mechanism which controls the mode of escape of the breath for the production of audible sounds, whether it be a simple voluntary cry for help or the most complex vocalization. Experiments show that abductors and adductors of the two vocal cords are equally represented in both hemispheres; that there is bilateral representation of the movements of the muscles of the two halves of the larynx. A part of the cerebrum (great brain) controls the voluntary nervous mechanism of the breath in the production of ordinary sounds, and this is represented in both halves of the brain, for the muscles of the two sides of the body which control the breath and phonation never work independently; but the mechanism of phonation cannot say to the breath mechanism, "I have no need of thee," for they are interdependent in the production of audible sound—which reminds me of the story of the organist and the organ-blower. The latter greeted the former one Sabbath morning, "We are going to play as a voluntary, 'O rest in the Lord.'" "We indeed!" said the organist. "Yes, we," said the blower. The service was ended; no sound came from the organ. "Is it *tee!*" was heard. "Yes, confound you!"

SYMBOLIC LANGUAGE AND SOCIAL HERITAGE.

Symbolic language is a social heritage in which auditory and visual symbols have been used, especially by civilized races, to express judgements and feelings. The fact that in all right-handed people it is represented in the left hemisphere shows that it has developed with the specialization of use of the right hand. The feeling tone in symbolic language largely depends upon gesture, facial expression, and modulation of the voice. The mere utterance of articulate language, whether in speech or song, fails to express the emotions and passions, however clear the diction may be. Savages and deaf-mutes are able by mimic and gesture to express the emotions and passions connected with the appetites and desires. This universal language is inborn and not acquired; it is understood by all peoples, as it has its roots in the preservation of the individual and the species; it is not acquired by imitation, like articulate language, but is dependent upon an instinctive pre-organized mechanism in the central nervous system. The effect of emotional shock in the production of mutism is upon this preorganized mechanism which controls the force and mode of escape of the breath in the expression of the emotions and passions. In support of the view of the existence of a preorganized mechanism, I may mention the fact pointed out by Galton in his *History of Twins*—namely, that whereas similar handwriting was seldom observed, similar vocal intonation was usual in identical twins brought up in a different environment. This supports the view that the affective tone of the voice is in great measure inborn and correlated with the temper of the individual.

TERRIFYING DREAMS.

The terror sometimes observed in soldiers suffering from "shell-shock" is contemplative fear; it is fear made more or less permanent by the imagination fixing in the memory past terrifying experiences, repressed in great measure by conscious activity of the mind during the waking state, but evident in the dreams which afflict nearly all these soldiers suffering from "shell-shock" and trench warfare. Shakespeare has not only in his characters shown how a passion steals into the soul, so that it becomes the solo tyrant of the desires, but he has clearly indicated how dreams influence the minds of men, and how they are based upon past experiences. Thus Mercutio in the description of Queen Mab refers to the soldiers' dreams in the following lines, which are as true to-day as when Shakespeare wrote them:

Sometimes she driveth o'er a soldier's neck,
And then dreams he of cutting foreign throats,
Of breaches, ambushes, Spanish blades,
Of healths five fathom deep; and then upon
Dreams in his ear; at which he starts and wakes;
And, being thus frighted, swears a prayer or two,
And sleeps again.

FIXATION OF REPEATED EXPERIENCES IN SONG.

This fixation and organization of repeated experiences in the mind is shown in other ways—for example, a song that has been sung a number of times only requires the first word or note for it to be continued to the finish without any effort of consciousness, the last note or word uttered serving as the appropriate stimulus of the next; as in an instinct, we have what is termed a chain reflex. This was strikingly exemplified in a soldier under my care who suffered with a bullet wound of the brain. The bullet entered the left side of the head, passing through the part of the brain which controls articulate speech, also damaging the structures which control voluntarily the muscles of the right half of the body. It passed through the right orbit destroying the eye, it also in its passage cut the optic nerve of the left eye through, so that he was made totally blind. This poor fellow was very cheerful, comprehended all that was said to him; thus, by feeling my tunic sleeve he recognized my rank for when asked was I a Captain he expressed negation by "oot." Colonel also by "oot," meaning "no," and Major by "ah." He obeyed all commands. Now, curiously enough, although he was unable to express judgements only by "ah" and "oot," which correspond to yes and no, he was able to sing several songs through without difficulty provided the first word or bar of music was given. Thus I stood beside him and hummed "This a long way," and immediately he started the well-known chorus of "Tipperary," winding up with "Are we downhearted? No!" If then said, "Say Tipperary, Tom." He replied, "oot," and he was unable to utter any of the words. It must be concluded either that the song had been repeated so often as to have become organized in both halves of the brain or in sub-cortical lower centres. There is reason to believe that whereas articulate speech is primarily represented in the left hemisphere, phonation is represented equally in both halves of the brain, and therefore music may be also; consequently this may account for the fact that the music and the words of the songs he could sing were organized by frequent repetition in both halves of the brain, especially when it stirs the emotions. It is well known how long melodies can be retained in the memory with comparative ease by countless men and women if words are attached to the tunes. The tune may revive the words, or the converse. A month later, when I saw him, he was able to walk and speak. Thus, given a half-crown, he felt it, then tried the rim for milling on his teeth, and said, "Two shilling bit." When asked again, he corrected it with "Half-crown." Given a penny, he tested it in the same way, and the unpleasant taste left in his mouth caused him to throw it down with all the signs of disgust, saying at the same time, "Copper."

THE PSYCHIC AND PHYSIOLOGICAL MECHANISMS INTERDEPENDENT.

For a perfect performance consciousness should only be employed as the Censor (attention) to watch over and prevent the occurrence of imperfections in the technique of the vocal mechanism, whether it be the control of the breath, articulation, phonation, or the memory of the words. When the technique by constant practice of right methods has become perfect and organized in the subconscious memory as a fixed habit, the dramatic singer can then devote his whole attention to that portion of his art upon which his success will largely depend, namely, the expression of the emotions and passions by voice, countenance, and gesture. Not only will the successful artist be able to interpret the dramatic feeling of the composer, but he may also colour the part with his own personality, by an individual and original feeling tone, which is afterwards associated with his name. There are many happy mortals who have an inborn disposition to the sense of rhythm and harmony, and start well provided with the raw material necessary for the development of the psychic mechanism of the voice. They are what is termed musical, and, provided they possess a good physiological mechanism, are born singers, bound to succeed if they are properly instructed. There is nothing so deadly dull as monotony of tone in an orator or singer. Pleasure of listening comes from sequence of sounds, such as form musical phrases and cadences. Song in this respect has an advantage over speech because a much

wider range of tones is employed. But there must be a sympathetic quality in the voice due to emotional influence.

A perfect psychic mechanism is as necessary as the physiological mechanism for the production of perfect vocalization, especially for dramatic singing. A person, on the one hand, may be endowed with a grand vocal organ, but be a failure as a singer on account of incorrect intonation, of uncertain rhythm or imperfect diction; on the other hand, a person only endowed with a comparatively poor vocal instrument, but knowing how to use it to the best advantage, is able to charm his audience; incapable of vigorous sound production he makes up for lack of power by correct phrasing and emotional expression. We see, then, that the combination of a perfect physiological and psychological mechanism is essential for successful dramatic singing, the chief attributes of which are: (1) Control of the breath, adequate volume, sustaining power, equality in the force of expulsion of air to avoid an unpleasant vibrato, and capability of producing and sustaining loud or soft tones throughout the register. (2) Compass or range of voice of not less than two octaves with adequate control of mental perception of the sounds of the necessary variation in tension of the laryngeal muscles for correct intonation. (3) Rich quality or timbre, due partly to the construction of the resonator, but in great measure to its proper use under the control of the will. (4) The power to express the emotions and arouse the feelings of the audience. This may be acquired, but largely depends upon the inborn artistic temperament. Something is lacking in a performance, however perfect the vocalization as regards intonation and quality, if it fails to arouse enthusiasm or to stir up the feelings of an audience by the expression of emotion or passion, through the mentality of the singer.

Undoubtedly the effects produced upon the mind by song largely depend upon circumstances and surroundings, also upon the association of ideas. Thus I was never more stirred emotionally by the human voice than upon hearing a mad Frenchman sing at my request the Marseillaise. Previously, when talking to him, his eyes had lacked lustre and his physiognomy was expressionless; but when this broad-chested, six-foot, burly, black bearded maniac rolled out in a magnificent full-chested baritone voice the song that has stirred the emotions and passions of millions to their deepest depth, and aroused in some hope, in others despair, as he made the building ring with, "*Aux armes, citoyens, formez vos bataillons*," I felt an emotional thrill down the spine and a gulp in the throat, while the heart and respirations for an instant stayed in their rhythmical course. Not only was I stirred by the effect of the sounds heard, but by the change in the personality of the singer. It awakened in my mind the scenes of the French Revolution so vividly described by Carlyle. The man's facial expression and whole personality suddenly appeared changed; he planted his foot firmly forward on the ground, striking the attitude of a man carrying a musket, a flag, or a pike; his eyes gleamed with fire, and the lack-lustre expression had changed to one of delicious excitement. A pike in his hand and a red cap on his head would have completed the picture of a *sans-culotte*. Dramatic song that does not evoke emotional response in the audience, therefore, is *vox et præterea nihil*.

The second part of the annual report of the New York Rockefeller Foundation, issued on September 25th, gives an account of the work of the Rockefeller War Relief Commission in Europe from August 14th, 1914, to January 1st, 1915. Besides vast quantities of food and clothing sent to Belgium, the Foundation, within a fortnight of the outbreak of the war, made a grant of money to enable Dr. Alexis Carrel, of the Rockefeller Institute, who was mobilized as a medical officer of the French army, to purchase antimeingitris serum and antidyserentary serum. Funds were also provided to be used by the American Red Cross in sending doctors and nurses to Europe. A commission was sent to Belgium and Holland to investigate and report on the organizations for relief in those countries. This commission afterwards visited Poland and Siberia for the like purpose. The Foundation further appropriated funds at the rate of £4,000 a year for the professors of scientific subjects who had been obliged to abandon their laboratories and who had been provided with opportunities of carrying on their work in England.

ORGANIC LESIONS FROM SHELL CONCUSSION.

BY

J. JAMESON EVANS, M.D., F.R.C.S.,

SURGEON TO THE BIRMINGHAM AND MIDLAND EYE HOSPITAL;
OPHTHALMIC SURGEON TO THE 1ST AND 2ND
BIRMINGHAM WAR HOSPITALS.

A LARGE number of cases of shell concussion have been reported since the beginning of the present war. As far as they concern the eyes, the main symptoms are: Impairment of sight, contraction of the visual fields, photophobia, and blepharospasm.

When these symptoms are noted with little or no evidence of injury to the eyes or neighbouring cavities, it is usual to regard them as functional—a form of traumatic neurosis—and in the majority of cases this view is correct.

It must not, however, be assumed that they are all of this nature, and it is the object of this note to draw the attention of the profession in general and military surgeons in particular to the possibility of such symptoms arising from more or less gross organic lesions. The lesions may be present without any superficial sign of injury whatever, or very gross changes may follow such slight surface injuries that it is impossible to regard the latter as the true origin of the organic lesions, and we are compelled to admit that they are probably concussion effects.

The following have been observed among the cases which I have examined during the last twelve months or so:

Hole at the Macula.

In one case the patient gave the history of having been knocked over by the explosion of a shell, and there was no sign that anything had struck him in the region of the head. In the second case the patient said he might have been shot, but there was no sign of a bullet wound or other injury. In both cases x-ray photography showed an absence of foreign bodies, and there was no evidence of fracture of the orbital walls.

Haemorrhages in the Globe: Ruptures of Choroid.

S. P. was admitted into the 2nd Birmingham War Hospital suffering from loss of sight and oedema of the face. There was also a wound, apparently superficial, of the right malar bone, which skiagraphy showed to be punctured, but there was no sign of any foreign body in the head and no wound of exit suggesting that it was a bullet wound. The patient could not enlighten us as to the nature of the projectile which struck him. The cause of the visual defect was found to be multiple ruptures of the choroid with haemorrhages all over the fundus and into the vitreous. Later it was noted that the discs became atrophic, although he still retains sufficient vision to get about.

The appearances of the fundi in this case were identical with those seen after the passage of projectiles of high velocity across the orbits behind the eyeballs.

Mr. Harrison Butler, at a meeting of the Midland Ophthalmological Society, showed a case in which the patient, who had been exposed to shell concussion in August, 1914, had lost the sight of the right eye. There were large membranous opacities in the vitreous the result of haemorrhage, the temporal vessels were reduced to white cords, apparently a little thicker and less defined than the vessels themselves, and the disc was atrophic. Vision = hand movements on the temporal side only.

Optic Atrophy.

Mr. Butler also showed a man suffering from atrophy of the optic nerve on the left side. He had been buried in a trench by the explosion of a shell. He was unconscious for eleven hours; when he recovered consciousness he found that he could not see with the left eye. At that time there was much swelling about the eye, but when admitted to the Birmingham Eye Hospital there was complete absence of any sign of injury. A case with similar history under my care showed optic atrophy and rupture of the choroid, but no sign of injury.

Another case under my care presented right optic neuritis and secondary atrophy with central chorioiditis and vitreous opacities. The only injury was a small superficial wound of the upper lid. There was no fracture or foreign body shown by x rays. Atrophy of the optic nerve, presumably from haemorrhage into the sheath, has also been seen without any evidence of injury.

It is generally assumed, also, that intraocular changes only follow the passage of bullets of high velocity, when they pass through the orbital cavity. This is true in the main, but the following case shows that it is not always so.

Private H. was shot through the left cheek, the bullet passing through the left antrum and the nasal cavities, and emerging through the right zygomatic region. Vision was reduced to $\frac{1}{20}$ in each eye. The macular area in each eye showed marked oedema and the fovea in the left eye showed a red spot almost like the cherry spot of embolism of the central artery. Pigmentary changes in maculae followed.

We have met with other cases in which there is little or no evidence of injury, but which show gross changes such as dislocated lens and detached retina in the eye, but the histories of cases have not been sufficiently definite to ascribe these changes to concussion.

Shell shock also seems capable of bringing out latent ocular defects; squint and nystagmus have become manifest after shell fire, although the patients deny their previous existence.

The cases recorded will, I think, sufficiently indicate the necessity of investigating cases of "shell shock" very carefully in order to differentiate those that are functional from those that are due to organic lesions.

BILATERAL IRIDODIALYSIS WITH AMBLY-
OPIA AND CONTRACTED FIELDS DUE
TO EXPLODING SHRAPNEL.

By F. D. BENNETT, M.R.C.S., L.R.C.P.,

LONDON.

A PRIVATE, aged 37, came to the Royal Eye Hospital on June 12th, 1915. He states that he was wounded in the advance on Neuve Chapelle on March 10th by shrapnel exploding in mud, as far as he could judge some 4 ft. on his left front. He was completely blinded for the time, no doubt by the mud and debris thrown up, as well as the blood from the numerous lacerated wounds of the lids and forehead. From the field hospital he was taken to "E" and rested a night at "M" and "O" before joining the hospital ship *Asturias*. Thence he was conveyed to "N" where he arrived at the "W" hospital, March 16th, and remained till April 22nd.

On arriving at "N" he was unable to see at all, probably owing to extraocular inflammation of lids and forehead, which, judging by the scars, must have been very considerable. He began to see with his right eye after three weeks, and with the left after five, and then at times saw double.

He is a strong, squarely built, thickset, muscular man, with fair complexion and healthy appearance. On admission he had a somewhat dull, apathetic look. His mental cerebration was slow, and he was inclined to be querulous and sullen. Sense of taste, smell, and hearing were normal, and, as far as one could learn, not impaired since the accident. He is married and has three healthy children. He had never had any previous illness or affection of the eyes, was a moderate drinker, but a heavy smoker. There were numerous scars on the forehead, eyebrows, and upper lids, chiefly on the left side, one larger than the rest, involving the whole length of the upper lid, running from the inner canthus up and out to the left external angle of the frontal bone. The mobility of the lids was not impaired.

R.V. = $\frac{1}{20}$ c. + 1.0 ϕ . L.V. = ϕ , not improved.

There was well-marked horizontal astigmatism in both eyes, which on correction did not improve vision. The corneae were clear, and the conjunctivae and sclerotics presented no signs of injury; the anterior chambers normal in depth.

Right Eye.—Pupil of oblique oval shape, 2 x 3 mm. in diameter, with long axis from below in to above out, and parallel with small detachment of the iris for 2 mm. from its ciliary border on the upper and inner side. Reaction very sluggish to light, accommodation, and convergence. Consensual reflex slight. Lens and vitreous clear. Optic disc somewhat hazy and paler than normal; margins, especially the inner, ill defined, and slight oedema of the retina around the papilla. Surrounding vessels appear normal both in size and direction. At the upper and inner quadrant only are numerous foci of pigmentary

choroidal degeneration which seemed of doubtful traumatic origin. These have remained constant since the patient came under observation.

Left Eye. Pupil circular, 3 mm. in diameter, larger than right. Reaction to accommodation and convergence sluggish, but doubtful to light. At the outer margin and slightly above horizontal meridian the iris is detached from its ciliary border for 2 mm., and shows an identical semilunar-shaped opening to the right eye. Optic disc somewhat paler than normal, with ill-defined margins. Surrounding retina shows some effusion. Red reflex present through openings in both irides, but equator of lens not visible.

He was not conscious of any increased illumination through the secondary pupils. There was no evidence of any hyphaemia when he came under observation. X-ray examination and Wassermann reaction gave negative results.

The fields were markedly contracted, especially for red and green.

The diplopia was not constant, and could not be elicited

in examination by the ordinary methods. He stated that it was present at times when lying down in bed and described the one image as being lower than the other. Beyond this it was difficult to obtain information which could be considered reliable, but the evidence pointed to the eccentric pupil accounting for the condition.

The amblyopia, seemingly due to commotio retinae and functional disturbance, improved with rest and treatment. His general condition benefited, and his view of life became considerably more cheerful and intelligent.

Vision now: R. = $\frac{20}{40}$ c. disc $\frac{5}{10}$. L. = $\frac{20}{40}$ c. disc $\frac{5}{10}$.

The fields were taken on admission and twice since, and show no material improvement. This corresponds with Lister's observations on similar cases.

Monocular diplopia can now be elicited in both eyes, but it does not inconvenience him.

I cannot discover any recorded case of a similar binocular condition of the irides, traumatic or congenital. Parsons states that multiple dialyses occur, but presumably means of the same eye. Fuchs states that "he never saw them as a result of injury."

The peripheral zone of the iris adjacent to its ciliary attachment where it lacks the support of the lens behind, and is backed only by the zonule of Zinn, is admittedly the weakest, and the usual situation of these injuries.

The detachment in the left upper angle of each eye would be explained by a blow from the left and above. The head was probably held down in the act of running forward, or automatically ducked on hearing the scream of the shell, as in the case of bullets whistling above.

In the absence of other injuries to the eyeballs the detachments were most probably due to sharp impacts through the upper lids, from lumps of mud and clay from the left front. This explanation would readily fit in with Arlt's explanation of the condition, which says: "The cornea being momentarily flattened, the circle described by the corneal scleral border and the ciliary body, with which it is firmly united, is extended, whilst the sphincter iridis is contracted, the serrated connexion of the iris with the ciliary body is torn to a greater or less extent, and a second communication is formed between the anterior and posterior chambers."

I am indebted to Mr. Stroud Horsford for his opinion on the case, and the kind use of one of his beds.

THE PROPHYLAXIS OF TETANUS:

A SUMMARY.

By A. T. MACCONKEY, M.B., D.P.H.,

BACTERIOLOGIST IN CHARGE OF SERUM LABORATORIES, LISTER INSTITUTE OF PREVENTIVE MEDICINE.

IN THE BRITISH MEDICAL JOURNAL, October 10th, 1914, a short and necessarily incomplete account of the use of tetanus antitoxin was given.

Since then many cases of tetanus have occurred, and many papers have been written on the subject, and a consideration of them should show us where our knowledge has made progress, and where it has been found wanting.

Owing, doubtless, to the exigencies of the times in which we are living, the writers, while expressing definite opinions, have given usually incomplete details of the results upon which their conclusions were based. This want of precision has tended to confusion, and has prevented in many instances the separation of those wounded who had a prophylactic injection of serum from those who had none. The value of the communications is thereby lessened, but in spite of this it is hoped that this further summary of the literature on the prophylaxis of tetanus may prove of interest and of use to those whose duties have not allowed them much time for reading during the past year.

PROPHYLAXIS.

In the *Memorandum on the Treatment of Wounds in War* (July, 1915) there are the following statements:

The prophylactic use of tetanus antitoxin is a proceeding of well established value.

Since, in the first two months of the war, more cases of tetanus occurred than had been anticipated either by ourselves or our Allies, it was decided to direct that a preventive dose of

serum should be given to every wounded man. The results have been excellent, and in the last six months there have been only 35 cases of the disease among those who received a preventive dose of serum within twenty-four hours of being wounded.

The preventive dose of 500 U.S.A. units should be given subcutaneously at a distance from the wound at the earliest possible moment. In severe wounds medical officers not infrequently give 1,500 units; there is no objection to this, but at the same time there is no evidence that the smaller dose is insufficient if given promptly.

Such has been the experience of the British army. Do the reports from other countries confirm it? Walther (1914) records that the action of prophylactic injections has been clear, although they could not in some cases be made until five to eight days after the wound. All the wounded in three wards and ten seriously wounded in another ward received each 10 c.cm. of antitetanic serum. Only one case had tetanus, and this came on the day after the injection—that is, before the serum could have produced its full effect. All the other cases of tetanus were observed among the wounded of three other wards in which prophylactic injections could not be given.

Hartmann (1914) at Besançon and Bourg met with 43 cases of tetanus among 3,373 wounded, and states that at neither of these places did a case occur among the men who had received an injection of antitoxin. He is of opinion that if a prophylactic dose of serum were given in all cases and repeated six to seven days later in intractable wounds tetanus would disappear as a complication of wounds.

Hufnagel (1914) reports that among 2,193 cases received into a hospital at Namur between September 11th and November 30th, 1914, there were 27 cases of tetanus. After October 15th every case had a prophylactic injection of 20 (Behring) units = 800 U.S.A. units, and among the

Chart 1.—Fields: w, White; r, Red; g, Green. Size of object 5 mm. (June 14th, 1915.)

1,195 men admitted after that date (presumably October 15th) there was not a single case of tetanus, though many were severely wounded.

Madelung (1914), speaking of Strassburg where up to October 31st, 1914, there were 15,134 wounded with 101 deaths from tetanus, mentions that no case of tetanus occurred in those who were injected prophylactically before admission into hospital, but that tetanus occurred in some cases though they were received shortly after being wounded and on admission had a prophylactic injection of serum.

Bazy (1915) relates that 200 wounded had to be divided into two lots—each 100 containing cases of about the same degree of severity. The one half had prophylactic injections of serum, and among them there occurred one case of tetanus which developed the day after the injection. Among the other 100 who had no serum, there were 16 cases of tetanus. There were 10,896 wounded with 129 cases of tetanus, of whom 70 per cent. died. One case was admitted into hospital on October 8th, 1914, and had serum the same day. Tetanus began on December 12th and ended fatally on December 18th.

Gasch (1915) describes the usual routine treatment of the hospital with which he was connected as consisting of a prophylactic injection of 20 Behring units in every case of dirty wounds, thorough opening up of the wound and keeping it open. After this treatment there was not a case of tetanus among 700 cases. One case, among a series of 65, was not injected because of the apparent innocency of a wound of the great toe. He developed tetanus and died.

According to Nivière (1915), 14,100 soldiers were admitted into the nineteen hospitals in Vichy between August 17th, 1914, and November 16th, 1914. There were 61 cases of tetanus, and none of them had had a prophylactic injection of serum.

Heile (1915), when reporting his experience of 12 cases of tetanus, mentions that there was no case of tetanus among the wounded who had had a preventive injection. Five severely wounded soldiers were admitted from the same field of battle, and four of them had a prophylactic dose. The fifth man did not seem to be so badly wounded as the others, and so the serum was not given. In his case tetanus appeared on the seventh day, and ended fatally. Ritter (1915) had no more cases of tetanus after prophylaxis with serum was instituted.

Teutschländer (1915) mentions that tetanus bacilli were cultivated from the secretions of the wounds of three soldiers, each of whom had had a prophylactic dose of serum. Except that one man had a slight transient, painless contraction of the sole of the wounded foot, there were no symptoms or signs of tetanus at any time. Notwithstanding vigorous local disinfection, tetanus bacilli, virulent for mice, were cultivated from the wounds several weeks later.

From September 23rd to October 1st, 1914, Goldscheider (1915) had 14 cases of tetanus (one or two a day). Then 500 wounded were admitted in three days and each of them received 20 (Behring) units (= 800 U.S.A. units). Among these there were 4 cases of tetanus, each of whom either showed premonitory signs of the disease when injected or developed it within forty-eight hours. One died of sepsis, one died from the severity of a wound of the lung, and the other two were mild cases. No other case of tetanus occurred, and up to November 5th 1,427 wounded were admitted.

Now Hinterstoisser states (1915) that in the Franco-Prussian war there were, among 95,000 German wounded, 350 cases of tetanus = 0.36 per cent., and F. Stricker (1914) that in the battles of Colomby, Mars la Tour, and Gravelotte, with 29,340 wounded, there were 62 (= 0.21 per cent.) cases of tetanus, and in the battle of Spichern among 3,482 wounded there occurred 20 (= 0.57 per cent.) cases of tetanus.

How does this compare with the incidence in the present war?

If we put together the figures given in the various papers, we get an approximate idea of the percentage of wounded soldiers who have developed tetanus. It is only approximate, as it is impossible to ascertain exactly how much, if any, overlapping there is. It must also be remembered that some of the wounded had received a prophylactic injection.

Percentage of Wounded Developing Tetanus.

	No. of Wounded.	Cases of Tetanus.	Percentage.
Bazy	10,896	129	1.18
Walther	456	20	4.30
Hartmann	3,373	43	1.30
Gasch	700	1	0.14
Hufnagel	2,193	27	1.23
Schoute	242	3	1.20
Nivière	14,100	61	0.43
Goldscheider	1,427	4	0.28
Madelung	15,134	101*	0.66
Hinterstoisser	800	13	1.60
L. Simon	700	8	1.14
Joly	1,798	21	1.62
Siemon (German	1,500	26	1.74
(French	600	2	0.33
Forestier	74	5	6.75
Arzt	26,600	65	0.24
Ennicke	3,000	10	0.33
	83,593	539	0.65

* Deaths.

Hinterstoisser (loc. cit.) also mentions that on the western front during two months of 1914 there occurred among 27,677 German wounded (Madelung's 15,134 may possibly be included in these figures) 174 cases of tetanus = 0.62 per cent. He quotes further:

	Number Wounded.	Cases of Tetanus.
Crimean war	12,094 (English) ...	19 = 0.15%
American Civil War	217,000	505 = 0.2%
Russo-Turkish War	51,700 (Russian) ...	66 = 0.12%

We thus see that the incidence of tetanus in the present war has been greater than would have been anticipated from previous experience.

The figures available with regard to the wounded who received prophylactic injections are very small.

Wounded who received Prophylactic Injections.

	No. of Injected.	Cases of Tetanus.	Percentage.
Bazy	100	1*	1
Gasch	70	0	
Hufnagel	1,195	0	
Heile	4	0	
Teutschländer	31	0	
Goldscheider	500	4*	0.8
Dudgeon, Gardner, and Bawtree	9	0	
	1,881	5	0.26

* It is questionable whether these cases should be included (cf. Bazy, Goldscheider, above), but even if they are, the incidence rate among the injected is less than half the total incidence.

In all these cases tetanus bacilli were found in the secretions of the wounds.

Very much stress cannot be laid upon these figures, but from the "experimental evidence," as it has been termed, quoted above it may be gathered that the surgeons of the armies on the western front have found tetanus autotoxin of extremely great value when used prophylactically.

Thus the estimate of its value formed before the war has been confirmed by the further experience gained from its use during the severe test of active service.

PROPHYLACTIC DOSE.

The next point to be considered is the number of U.S.A. units of antitoxin which should be given as a prophylactic dose. It is necessary to specify the kind of unit referred

to, as the German unit is much larger than the American—1 German unit = 40 U.S.A. units. The mitage of French serum is not given, and one can only presume an average mitage from the results of tests of samples. V. Behring (1915) tested a sample of French serum and found that it contained 40 U.S.A. units per c.c.m. Rosenan and Anderson (1908) estimated the strength of two samples to be 40 U.S.A. units and 66 U.S.A. units respectively. The writer tested a market sample, and found the titre to be more than 50 and not quite 100 U.S.A. units per c.c.m. We may therefore assume that the usual prophylactic dose of 10 c.c.m. of Pasteur Institute serum is equal to some 600 U.S.A. units.

Doses Recommended by Several Writers.

v. Behring (Nov., 1914)	800 U.S.A. units, and repeat if wound not healed, as the preventive injection may merely postpone the tetanus.
v. Behring (Feb., 1915)	800 U.S.A. units, but if the serum can be given immediately the wound is received 500 U.S.A. units may be enough.
Goldscheider ...	800 U.S.A. units.
Kimmel ...	800 U.S.A. units. Must be repeated in some cases.
Grundmann ...	300-4,000 U.S.A. units, and repeat every two weeks.
Weinrand ...	800 U.S.A. units.
Hufnagel ...	800 U.S.A. units.
Gusch ...	800 U.S.A. units.
Aschoff ...	4,000 U.S.A. units, and 800 units eight days later.
Walther ...	10 c.c.m.—about 600 U.S.A. units.
Bazy ...	10 c.c.m.—about 600 U.S.A. units. Thinks that in some cases 2 or 3 c.c.m. might be enough.
English army ...	500 U.S.A. units. No evidence that this dose is too small.
Joachim ...	800 U.S.A. units.
Eucnicke ...	800 U.S.A. units, and repeat twice at weekly intervals.

Here, again, war experience confirms the pre-war conclusion, and it may be accepted that from 500 to 1,000 U.S.A. units of tetanus antitoxin is a sufficiently large prophylactic dose for the *great majority* of injuries, provided it is given early.

ANOMALOUS CASES.

Cases have, however, occurred, and, no doubt, will occur again, in which the injection of from 1,500 to 4,000 U.S.A. units appears to have had only a comparatively limited effect, if any, in preventing the onset of an attack. In some of these cases the interval between the injection and the onset of the disease was too short to allow of the development of the full effect of the antitoxin. As an instance, a case recorded by L. Simon (1909) may be mentioned. A boy aged 5 years, weighing 45 lb., was run over on the evening of August 31st, and brought to the hospital shortly after the accident. It was found that he had a compound fracture of the right leg with a very dirty wound. Amputation at the knee was performed. There was also a compound fracture of the left toe, which was cleaned and dressed. At the same time 20 Behring units, = U.S.A. units, of tetanus antitoxin were injected into the right thigh. At 11 a.m. on September 1st (eighteen hours after the injury) symptoms of tetanus appeared. The attack was moderately severe, and ended in recovery. In the same paper Simon gives details of another case (a boy aged 12 years, run over), in which tetanus developed nineteen hours after the injury. In such cases serum given subcutaneously has no chance of exerting its full effect. But there are some cases in which the seeming failure of a prophylactic injection of antitoxin must be left unexplained until we possess fuller knowledge of the subject. The most remarkable is that recorded by v. Behring (1914):

His assistant H. Sch. was infected:

(1) In 1895, through the nasal mucous membrane when he was preparing dried tetanus toxin.

(2) In 1898, by inhaling dried powdered tetanus toxin; in this attack there was early tetanus of the diaphragm.

(3) In 1902, at 9 a.m. on Sunday November 9th, owing to a litre flask of bouillon culture of tetanus breaking in his right hand, and pieces of glass penetrating deep into the palm. The same afternoon very careful antiseptic treatment was given to the hand, and a plentiful amount of antitoxin was injected into the right arm. On the fourth day there were suspicions of tetanus, and on November 13th there was obvious tetanus

which, in spite of further injections of serum, increased in severity, so that on the sixteenth, as a last resort, the chief nerve trunks in the right axilla were exposed, and as much as possible of Behring's strongest serum was injected into each of them; the result was excellent. The tetanus ceased to progress, and the case gradually but slowly went on to recovery. The use of the right arm was not perfect for a long time.

It is most unfortunate that Behring does not say how many units of antitoxin were given or where it was injected in the earlier stages of the case. He, however, concludes that very shortly after the injury the intramuscular nerve endings had taken up and fixed a minimal lethal dose of the toxin. This, however, is a questionable statement; for if so much of the toxin was absorbed so soon on the 9th, then the lethal dose had not all passed up to the central nervous system by the 16th—that is, in seven days—a rate of travel which is somewhat slow according to experimental evidence (*cf.* Marie and Morax, 1902; Permin, 1913). v. Behring would not, we presume, have given a smaller dose of antitoxin than 20 Behring units, = 800 U.S.A. units, but whatever the dose was the immunity due to it did not last longer than four days.

Duration of Passive Immunity.

The duration of the passive immunity conferred by a dose of antitoxin is a question which has been the subject of investigation but is still unsettled.

In this connexion I may refer to an experiment performed by Meyer and Ransom (1902), though it had a different object in view.

They injected into the left sciatic nerve of a dog about 2.1 U.S.A. units of tetanus antitoxin, and immediately afterwards an equivalent amount of toxin subcutaneously, half being injected into the right fore-leg and half into the left hind-leg. On the third day the right fore-leg was tetanic but the left hind-leg was free. On the seventh day there were signs of commencing tetanus in the left hind-leg, and on the eleventh day it was distinctly involved.

In this case the passive immunity conferred on the left hind-leg by an amount of antitoxin sufficient to neutralize all the toxin injected began to pass off in one week. Ruediger (1913) showed from his experiments that the subcutaneous injection of 1,500 U.S.A. units of antitetanic horse serum into the horse confers a passive immunity lasting from six to eight weeks, and that 250 U.S.A. units of similar tetanus antitoxin injected into guinea-pigs protects them for four weeks against a dose of tetanus toxin in each case fatal to the control animals. If we take the blood volume of an ordinary horse to be about 30,000 c.c.m., and that of a guinea-pig of 500 grams to be 50 c.c.m., then the amount of antitoxin injected was $\frac{1}{60}$ U.S.A. unit per cubic centimetre and 5 U.S.A. units per cubic centimetre respectively. These quantities bring out the difference in the duration of the effect of a homologous and of a heterologous serum. Calculating from the guinea-pig figures, according to body weight only, a man weighing 70 kilos would require some 35,000 U.S.A. units of antitoxin to protect him for a month against a fatal dose of tetanus toxin.

Levin (1909), from experiments made with diphtheria antitoxin, concludes that there is no difference in the rate of absorption of a homologous and of a heterologous serum, but that the former appears to remain about three weeks in the circulation, while the latter has almost all disappeared at the end of a week. He states that of two animals of the same weight receiving the same amount of antitoxin, one may show 50 per cent. higher concentration of antitoxin in its blood than the other (*cf.* Park and Biggs, 1912-13); that if 10, 20, or 40 c.c.m. of heterologous serum be injected into a rabbit, practically all has disappeared at the end of about six days, whether it was given intravenously, intramuscularly, or subcutaneously; also that if it is wished to keep the antibody concentration at a certain height for some time, a series of relatively small doses must be given, and not one very large dose.

L. Simon (1914, *loc. cit.*) mentions the following case:

In a shell wound of the arm, because there was some twitching of the arm and face, 3.0 (presumably Behring) units = 12,000 U.S.A. units, of tetanus antitoxin were given intravenously. As all the symptoms subsided, it was concluded that the assumption of tetanus was a mistake. Thirteen days later the symptoms of tetanus returned in a more severe form, and so another 300 units were given intravenously under chloroform anaesthesia. On recovery from the narcosis the patient became suddenly cyanosed, had a rigor and a temperature of 40.9° C., but the pulse kept good and the respiration was

normal. After this partial shock had subsided there was no return of the tetanic symptoms. Three days later (seventeenth day after the first injection) 100 units were injected intravenously. The patient became totally unconscious for half an hour, there was marbling of the body, the pulse was scarcely perceptible, and the temperature rose to 40.1 C., but the respiration was fairly normal. Recovery was rapid and complete.

Then we have Rowan's (1910) "run over" case:

There was compound comminuted fracture of both bones of the leg, in which five hours after the accident 1,500 U.S.A. units of tetanus antitoxin were given subcutaneously. On the twenty-fifth day after the accident there were "premonitory symptoms" of tetanus, and death occurred on the fourth day of the attack.

In Simon's case we have 12,000 U.S.A. units protecting for only thirteen days, while in Rowan's case 1,500 U.S.A. units conferred immunity for over three weeks.

These results are conflicting, and when considered in conjunction with the general experience that 500 to 1,000 U.S.A. units is a good prophylactic dose make plain the existence just here of a gap in our knowledge which we should endeavour to fill up by taking every advantage of the present opportunity of studying the disease.

The fact that these large doses failed to protect completely, and the experience of the British army that "there is no evidence to show that 500 U.S.A. units is too small a dose" tend to confirm Levin's conclusions that it is better to give a series of small doses rather than one large one. If the dose of 500 units is repeated at the end of a week and of a fortnight after the receipt of the wound we should not use any more serum, and we should probably get a more prolonged immunity than by giving the 1,500 units which some surgeons seem to prefer.

VERY LATE DEVELOPMENT OF TETANUS.

Other cases which are puzzling are those in which tetanus develops very late. One such case is reported by Don (1915). A man was wounded in the shoulder on December 21st, 1914, and received a prophylactic injection (number of units not mentioned) on December 23rd. On March 2nd, 1915, tetanus developed. Tetanus bacilli were found in the pus. Were these tetanus bacilli present from the date of the wound or did infection occur at a later period?

Köhler (1915) and also Grundmann (1915) both suggest that some cases of tetanus arise after admission into hospital, owing to the infection being conveyed from one wounded man to another—most probably by the patients themselves. In 3 cases Tentschländer (1915, loc. cit.) found virulent tetanus bacilli on the secretions of wounds which had been received several weeks previously, and Dudgeon, Gardner, and Bawtree (1915) state that—

"A wounded man may be acting as a carrier of tetanus bacilli for at least two months after the date of the wound, and without any reason on clinical grounds to suggest that these bacteria are present in the tissues."

They cultivated tetanus bacilli from two cases neither of whom had had a prophylactic injection of antitoxin. One of these developed the disease and recovered, whilst the other escaped scot-free.

As suggesting possible sources of late infection, two cases of tetanus recorded by Kirimisson (1914) are not without interest.

The first was that of a girl of 17½ years, who was being treated for dorsal scoliosis. A plaster corset was put on on February 10th, and layers of felt were slipped in underneath the plaster on February 14th and 21st, and on March 7th and 21st. On April 1st there was trismus. The corset was immediately taken off, and a little eschar was found on a right costal projection. Death occurred forty-eight hours later.

The second case was that of a girl of 19½ years, who under similar conditions developed acute tetanus, and died in forty-eight hours.

Kirimisson suspected the felt, and his suspicions were proved to be correct as tetanus bacilli were isolated from it.

Another way in which infection may be brought about is that to which Jacobsthal (1914) has called attention. After meeting with tetanus in two cases in which the East Indian fibre known as Pangawar Djambi had been used to dress the wounds, he examined seven specimens of this fibre, and found tetanus bacilli present in three of them.

Further, it appears that the surgeon may be the cause of the development of tetanus by the use of procedures

which under ordinary conditions would be quite harmless but which are not safe owing to certain peculiarities of the tetanus bacillus. These "vagaries," as they may be called, are well brought out by the results of the laboratory studies of the bacillus carried out by Francis (1914). Eleven vaccine viruses, ten of which contained *B. welchii*, were artificially contaminated with tetanus spores and injected subcutaneously on the back of 26 mice and on the abdomen of 26 guinea-pigs. All the guinea-pigs contracted tetanus after an average incubation period of four days and all died; 17 of the mice had tetanus—average incubation period eight days—and died. The remaining 9 mice showed no signs of tetanus, but each of these 9 mice had a mate which had an injection of the same amount of the same material and each mate, with one exception, developed tetanus from which it died. After forty-five days, in the case of 6 of these mice, and after sixty-six days in the case of the other 3, they were all injected subcutaneously on the back with a twenty-four-hour old agar culture of staphylococcus and all promptly contracted fatal tetanus. Scrapings from the site of inoculation in each instance contained over 500 mouse minimal lethal doses of tetanus toxin.

Again, 93 glycerinated vaccine viruses artificially contaminated with tetanus spores were inoculated in 1 c.c.m. amounts beneath the skin of the abdomen of 93 guinea-pigs weighing about 250 grams each. Seventy-seven died of tetanus, 4 had tetanus but recovered, while 12 manifested no symptoms whatever of tetanus. He showed that tetanus spores may remain in the tissues of the guinea-pig for about four weeks, and at the end of that time may be activated by injections of quinine or of staphylococci. White mice will harbour tetanus spores in the subcutaneous tissues for at least four months, at the end of which time the spores may be activated by staphylococci but not by quinine, and at the site of inoculation there may be produced as much as 10,000 mouse minimal lethal doses of tetanus toxin. Further, Francis mixed 0.5 c.c.m. of glycerinated vaccine virus with 0.5 c.c.m. of a rich suspension of tetanus spores and used the mixture to vaccinate five monkeys, each in five places on the back. There was a good "take" at every insertion, but none of the animals contracted tetanus. In the case of one monkey a portion of the "crust" was removed on the fourteenth day and injected beneath the skin of two guinea-pigs, both of which developed tetanus. This experiment was repeated in the case of three other monkeys with the same result. He then vaccinated a monkey with plain virus, and on the fifth day, when there was a good "take," he rubbed tetanus spores well into the "take." The animal never showed a sign of tetanus.

It would be interesting to compare Francis's animal figures with figures obtained from wounded men, but it cannot as yet be done. The only figures the writer has come across are those of Fleming (1915), who examined bacteriologically 127 wounds within seven days of infliction, and found tetanus bacilli to be present in 22 of them. It is not stated whether the bacilli were identified by microscopical examination only or by cultivation. Unfortunately he does not state how many of the men developed the disease.

The demonstration by Francis that injections of staphylococci may reactivate quiescent tetanus spores and give rise to a fatal tetanus is of great importance when considered in connexion with the experience of C. J. Bond (1915), who states that there are reasons for thinking that cases are occurring in which some slight surgical interference has reignited a violent local reaction in the neighbourhood of a recently healed wound. "I have records of cases in which after all incisions and sinuses round a compound fracture involving the elbow-joint or hip or other joint had completely healed, even simple passive movement of the joint under an anaesthetic has lighted up a violent reaction, the reappearance of the old sepsis and the formation of local abscesses, although no incision was made, nor any solution of skin surface produced."

Confirmation is afforded by Bérard and Lumière (1915), who have encountered a number of cases of tetanus following some operation or trauma affecting a wounded soldier who had had a prophylactic dose of serum, and had long recovered apparently from his wound.

Goldscheider, too, suggests that a case recorded by him

was possibly due to too early and prolonged active movement after a wound had healed.

The case was that of a soldier who received a flesh wound of the left thigh on October 4th, 1914. A dressing was applied by a comrade, and he was admitted into hospital on October 7th. He had no prophylactic injection, and the progress of the wound was normal. On October 30th he was discharged as fit for active service, and he walked 22 kilometres that day, and 5 kilometres the next day with the object of regaining his regiment. On the night of October 31st-November 1st he had pains in the left leg and trouble in eating. He missed his regiment, and had to retrace his steps some distance. The symptoms increased, he was readmitted into hospital, and he died of tetanus on November 7th.

The studies of Francis and the experience of Bond, of Héard and Lumière, and of Goldscheider point out a line along which we may conduct our investigation into the causation of these cases of late development of tetanus.

OPERATION.

As regards operating in cases of tetanus the opinion before the war was against doing so, and nothing has occurred since to change that opinion. This is not to be wondered at considering that it has been shown by:

1. Bolton and Fisch (1902), that toxin makes its appearance in the blood of the horse several days before any symptoms of tetanus are to be observed, and that it gradually increases until about two days before the symptoms become noticeable, and then it suddenly diminishes and may in some cases even disappear. The amount of toxin varies in different cases. In one instance the serum from a diphtheria antitoxin horse about two days before the symptoms of tetanus appeared was sufficiently toxic to kill a guinea-pig in a dose of 0.1 c.cm.

2. Madsen (1908), that five days before the appearance of tetanic symptoms in a horse there was in the filtered serum enough tetanus toxin in:

5 c.cm. to kill a guinea-pig in 8 days	
8 " " " " " 3 "	
10 " " " " " 3½ "	

Serum obtained shortly before the horse's death, on the same day that the symptoms were noticed, killed a guinea-pig in a dose of 4 c.cm.

Nivière (1915) mentions that in 8 cases which had been operated on tetanus developed, in 2 within twelve hours, in 4 within twenty-four hours, and in 2 within forty-eight hours after the operation.

Cobb (1914) reports a case of severe shell wound of the left arm in which amputation of the arm was performed two days after the injury at the base hospital in France. He was admitted into hospital in England on the seventh day with wounds very septic and large sloughs. These latter were cut away, the whole area swabbed with H_2O_2 , and a prophylactic dose of antitetanic serum given. Next day there were twitches in the shoulder, and later in the day the patient developed well-marked trismus. The attack progressed rapidly, and ended fatally on the third day of the disease—the tenth from the receipt of the wound.

As another example, Esau's (1910) case may be cited. A boy of 14 years of age received a pistol shot wound of the left hand. The wound was opened up and cleaned on the third day after the injury. On the seventh day there were slight contractures of the flexors of the left hand, but they passed away, and serum was not given. On the following days the contractures recurred more frequently. They could be overcome with slight force, but this gave pain, and they returned again at once. Not the slightest trouble with the jaws. On the fifteenth day after the injury the wound was opened up again, and some foreign bodies removed. Next day (sixteenth) there was general tetanus, which became moderately severe, but ended in recovery.

It is imperative, therefore, when an operation is proposed in wounded who may have been infected with the tetanus bacillus, to bear in mind that there may be toxin circulating in the body. A large prophylactic injection is consequently necessary, and it should be given in such a way as to ensure that there is no free toxin in the blood at the time of the operation and for some time after. Subcutaneous injections, except as supplementary agents, are out of the question here because of the slow rate of absorption. If the injection be given intramuscularly, then the operation should not take place for several hours. An intravenous injection permits of the operation being performed at once, and as it bears upon the question it is

of interest to note a statement of Ichring's (1915) to the effect that the amount of antitoxin present in 1 c.cm. of blood a few minutes after an intravenous injection of antitoxin remains constant for nearly sixty minutes.

An intravenous injection of serum always raises the question of the possibility of anaphylactic trouble ensuing. E. E. Irons (1915) gives an instance of this and a description of the precautionary measures which were taken. The patient had a prophylactic dose of 1,500 U.S.A. units after a punctured wound of the heel. Ten days later tetanus set in. While arrangements were being made for his admission to hospital 1,500 U.S.A. units were given subcutaneously. This was followed by a moderate urticaria. Eight hours later, on arrival at the hospital, 5 c.cm. of serum were injected intravenously on the assumption that sufficient time had elapsed since the previous dose, which had been followed by an immediate cutaneous reaction, to render him insensitive to further serum. However, an immediate severe serum reaction occurred after this second dose—urticaria, rapid respiration, and rapid pulse. "The severity of the tetanus made us feel that unless something further could be done he would surely die of tetanus. We prepared a 10 per cent. solution of antitetanic serum in NaCl solution, and injected 10 c.cm. intravenously very slowly, watching carefully the pulse, blood pressure, and respiration. There was no further reaction, and the full dose of 20,000 U.S.A. units was then given intravenously and 5,000 units intraspinally without a trace of serum reaction." Surgical treatment of the wound and sufficient sedatives to control spasms completed the treatment. The patient recovered.

CONCLUSIONS.

The experience gained during the first year of the war has confirmed the opinion that from 500 to 1,000 U.S.A. units of tetanus antitoxin is a sufficiently large prophylactic dose for the majority of cases, and that it is advisable, in severe wounds, to repeat the dose once or twice at intervals of a week. Occasionally cases occur in which antitoxin appears to have little preventive effect. These cases should be recorded with minute details, so that our knowledge of them may be increased and an explanation of their occurrence obtained. Those cases of tetanus which develop some weeks after the receipt of an injury may be due to the reactivation of a quiescent focus by too early or too energetic active or passive movement.

NOTE.—It has been assumed that, in all articles published in German, when the expression "A.E." (Antitoxin Einheit) is used it means a "Behring unit."

THE CONTROL OF "DIPHTHERIA-BACILLUS CARRYING"; AND THE JASMIN OIL METHOD.

By WILLIAM EWART, M.D., F.R.C.P.,

CONSULTING PHYSICIAN TO ST. GEORGE'S HOSPITAL, TO THE BELGRAVE HOSPITAL FOR CHILDREN, ETC.

THE revelation of the unsuspected evil of "carriers" arose from a study of the longer and less direct route followed by the dissemination of typhoid, although the recrudescence of diphtheria epidemics at schools had long been identified with a readmission of pupils certified (after an adequate convalescence) as clinically cured. The notion that these were minor relapses after the cure continued to be held for a while after the first observation (by Kayser in 1906) of the spread of typhoid by a "cured-typhoid" bacillus carrier. Since then we have recognized the more subtle and possibly frequent danger from the "typhoid-intact" carrier; and it is now admitted that diphtheria also may have its "cured-diphtheria" and its "diphtheria-intact" carrier, both needing their local internal sanitation, though with a less remote and extensive seat of infection than in typhoid.

That result does not appear to have been achieved. This late publication of suggestions originated and practised long before the "carrier" period has been occasioned by a recent inquiry by a correspondent (*BRITISH MEDICAL JOURNAL*, 1915, vol. ii, p. 459) for a reliable method of curing diphtheria carriers. My first paper in 1897 (*BRITISH MEDICAL JOURNAL*, vol. ii, p. 1564), in conjunction with my then house-physician, Dr. W. A. Hubert, was mainly concerned with tracheotomy dangers—namely, to safeguard the patient against the dangerous suppression of his cough mechanism inflicted for the sake of an air-way; and to help him, less through antiseptics than by the expectoration of the infective material and by a recovery of some of the impaired ventilation and circulation of the lung. It also referred, however, to my antecedent treatment for several years. This contained potentially all the clinical work that followed; practically the "spreading oil-film method" as a mechanical substitute for the unpractical principle of corrosive antiseptics, which is inapplicable to the healthy membrane of the carrier. It is to be regretted that that effort should have passed unnoticed in this country; although in France some reference has subsequently been published to an intranasal instillation of oil which, perhaps, may still be in vogue. Owing to that oversight, and to the lack of systematic institutional opportunities for any test by results, I now offer this method only as a tentative proposition for the purpose of disinfecting carriers. Yet it has not lacked clinical evidence for its feasibility and for its benefits, under active infection.

I had realized the desirability of forestalling any extensive secondary sinus infection, and it possible of suppressing it gradually during treatment, whilst at the same time mitigating the severity of the local trouble. Eventually instructions were given for a systematic toilet at least twice daily in all my cases of diphtheria from the beginning of and throughout their hospital treatment. Antitoxin, which came in as the supreme agent for the clinical cure, did not displace that hygienic indication. I may mention, in illustration of the cleansing power of oil, the benefit derived three weeks ago by an adult patient with bilateral pulmonary phthisis, operated on last February for polypi and still suffering from them, but now unfit for surgical interference. The discomfort was greatly relieved by the first application, and, within three or four days, the

severe factor from which he had suffered for years was completely suppressed. In this instance, however, I had followed up the oil supply with an insufflation of boracic powder, immediately.

The original disinfecting purpose led me to take within the systematic scope of the method practically all the infections including influenza, whooping-cough, mumps, tonsillitis, etc.) which own an ori-nasal origin or extension. Meanwhile the mechanical "oil-film by water carriage" disclosed its ability to reach beyond the feebly moistened glottis and to give relief to an inflamed tracheal or bronchial membrane; though its greatest benefaction is in easing the acute catarrhal upper nasal obstructions, as well as all the acute and chronic catarrhal affections of the naso-pharynx, fauces, and upper larynx.

The method itself has hardly varied from its original form, except for the discarding of carbolic acid (1 in 60) and the substitution of jasmin oil, which is exceptional among flavoured oils in its freedom from the irritating effect of any added essential oil. The mechanism of the method is simple, but needs judgement. It is not free from the influence of the psychical factor, which the sense of relief usually cures provided this is not marred by inexperience in the patient or the nurse. The main idea is still the original one of utilizing to the full the downward action of the cilia, and to sweep the mucous membrane with a continuous moving film. The supply must therefore be from above, not as in spraying, douching or syringing from below. Though introduced at the nostril the oil is collected in the upper fossae. The rapidity of the radiating spread of the film by surface tensions is great in proportion to the moisture of the surface and to the fluidity of the oil. Our main concern is its after movement practically independent in time from the first, and practically uninfluenced in its direction by those evenly centrifugal radiations, which broadly coincide with it in one hemisphere of the field whilst contrary to it in the other. Whether "up or down," the cilia work the transportation towards the external orifice. From a charged frontal sinus it moves downwards, the same way as the massive discharge from blowing the nose, and also backwards. But in the trachea any "descending" film would be moved upwards, the same way as if it arose from an intratracheal injection. The film is, of course, a passing show, easily broken up by absorption. Its full value is in its frequent renewal with adequate charges.

The simple implements are an eggcup to hold a small supply and a penfitter to convey the oil into the nose—namely, for an adult, a charge nearly half filling the tube. The patient reclines on a bed or flat couch with a narrow bolster, and spreads a towel well up to the chin or higher. The essential is to throw the head well back behind the bolster and to maintain it there for half, or the whole of a minute after charging both nostrils. The oil must not be rushed up or run in, but instilled drop by drop. The other essential is the complete lateral movement of the head to the right for a while and then to the left, to favour the irrigation of the sinuses, as that small supply cannot fill them. As the head is gradually levelled the oil is felt to trickle down the back of the naso-pharynx. This is the only unpleasant sensation. But that surplus is not considerable. It may be swallowed; or better, by refraining from swallowing, it may be allowed to find its own way down the larynx and trachea. It is better to have assistance, but most of my patients succeed in their unaided performance on the strength of these simple directions. I believe—but must leave the decision to those with larger opportunities—that this method, with the addition of the insufflation, if duly persevered with, is the most likely one to rid a carrier of his influenza or of his diphtheria bacillus.

The *Medical Record* states that out of 600 applicants for the United States Navy examined recently in Boston only 50 were accepted, the remainder being rejected as physically below the normal or mentally or morally unfitted for the service. From this, Rear Admiral Albert Ross draws the conclusion that America must make its rapidly degenerating citizens into men before they can be made sailors or soldiers.

The Goulstonian Lectures

ON

SPINAL INJURIES OF WARFARE.

DELIVERED BEFORE THE ROYAL COLLEGE OF PHYSICIANS
OF LONDON.

By GORDON HOLMES, M.D., F.R.C.P.,

ASSISTANT PHYSICIAN TO CHARING CROSS HOSPITAL, AND NATIONAL
HOSPITAL FOR PARALYSED AND EPILEPTIC, QUEEN SQUARE;
LIEUTENANT-COLONEL (TEMPORARY) R.A.M.C.

III. THE SENSORY DISTURBANCES IN SPINAL INJURIES.

IN the previous lecture we discussed, as far as time would permit, certain symptoms produced by injuries of the spinal cord, selecting those which were the most important and interesting; in the present lecture the disturbances of sensation, especially those that result from incomplete or unilateral lesions, will be described, and observations that may contribute to our knowledge of the course and grouping of the sensory afferent impulses within the cord will be particularly emphasized.

If you permit me it will be advisable, however, before passing to my own observations, to give a short sketch of the conduction of sensation within the cord as far as it is at present known.

Nearly sixty years ago the first valuable contribution to this subject was made by Brown-Séquard,⁷ who from both clinical and experimental observations concluded that a one-sided lesion of the spinal cord produces motor paralysis, with hyperaesthesia and loss of muscle sense on the same side, and in addition anaesthesia of all other forms of sensibility on the opposite half of the body.

These conclusions have been, however, violently attacked by both physiologists and clinicians, and even Brown-Séquard himself later modified his views, but they have formed the basis of all subsequent contributions, and it has been, in fact, only within recent years that any important additions or modifications have been made to them.

The exact intraspinal course of the various forms of sensation soon began to excite interest. Many workers, following Brown-Séquard and Schiff, held that pain and temperature at least pass upwards through the grey matter, while tactile impressions and those that underlie the sense of position, ascend, according to Schiff, through the dorsal columns. Bechterew's and Bikel's experiments, however, made it probable that impressions of pain are conducted, after decussation, through the white matter of the ventral part of the lateral columns. But it is obvious that neither the grouping nor the course of sensory impulses within the cord could be determined by experiments on animals, and it is not surprising that the most reliable conclusions we have were obtained from clinical observations on suitable cases of injury or disease in man. It is largely to Petróń⁸ that we owe the most accurate and comprehensive summary of clinical observations. From the collation of a large number of cases he has concluded that impressions of pain and temperature pass through the opposite lateral column, "muscle sense" through the homolateral dorsal column, while two paths are open to tactile impressions, one through the uncrossed exogenous fibres of the dorsal column, another in the opposite lateral column. A careful and elaborate analysis by Drs. Head and Thompson⁹ of sensory disturbances produced by spinal lesions confirmed these conclusions, and showed that when the appreciation of cutaneous pain is lost, that produced by pressure is also disturbed, that light touch and heavy touch are lost simultaneously, and that the appreciation of all degrees of temperature is abolished together. They also found that the ability to recognize the simultaneous contacts of two compass points depends on impulses conducted through the homolateral dorsal column. The affection of other forms of sensation by spinal lesions has been also investigated. The French school particularly has been interested in the appreciation of the vibrations of a heavy tuning-fork, and Egger,¹⁰ as well as Seiffer and Rydel,¹¹ have shown that disturbance of this is generally associated with loss of the sense of position, and that it consequently depends on the integrity of the dorsal columns. Finally, working with Dr. Head,¹² I found that in unilateral spinal

lesions the appreciation of weight and the recognition of size and shape are frequently lost in the paralysed side, and from this observation, correlated with other facts, we concluded that the impulses that subservise these functions also ascend uncrossed through the dorsal column; we also confirmed earlier observations that the appreciation of vibration passes by this path too.

The nature of our material and especially the fact that we have been able to investigate most of our cases only in that early stage in which certain symptoms may be attributed to shock and other to partial lesions and incomplete blocking of the passage of sensory impulses makes extreme caution necessary in drawing final conclusions on the mode of sensory conduction within the cord, but the disturbances we observed must have an important bearing on this subject. We have been, however, able to keep certain cases under observation as long as ten to twelve weeks after the infliction of the wound.

BROWN SÉQUARD PARALYSIS.

The description of the sensory changes found in incomplete lesions can be most easily introduced by the history of a typical case of unilateral injury:

CASE IV.

Pte. C., 15417, was wounded on May 12th, 1915, by a rifle bullet, which entered immediately to the right of the fifth cervical spine and made its exit 2 cm. below the right angle of the mouth. His jaw was fractured. He lost all power of movement in both legs and in his right arm at once, and his left arm became weak. He complained of pain in his left shoulder and had retention of urine at first, but this quickly disappeared.

He came under observation three days after the infliction of the wound. An x-ray examination then showed a fracture of the right side of the arch of the fifth cervical vertebra and some damage to the bodies of the fourth and fifth on this side. There was a well-marked palsy of the right cervical sympathetic and his right arm was toneless and completely paralysed. All movements of his left arm were possible, but its

Fig. 6.—Sensory disturbances in Case IV. In this and the succeeding figures the horizontal lines represent tactile anaesthesia, the vertical lines anaesthesia, and the oblique lines thermo-anaesthesia. Interrupted lines indicate partial loss of the corresponding form of sensation. In Fig. 6 the dotted line on the right arm indicates the limit of anaesthesia to heavy touch.

distal segments were slightly weak. There was practically no movement of the right side of his chest in ordinary respiration or on taking a deep breath, and the rectus abdominis and the diaphragm of this side were weak. The movements of his left lower limb were as full and as strong as normal, but the right was flaccid and powerless. The arm-jerks were absent on both sides, and the knee and ankle jerks on the right, but on the left these reflexes were exaggerated; the right plantar response was extensor and the left was flexor.

He then complained of pins and needles in his right leg and of a sharp stabbing pain in his left shoulder. Examination revealed complete loss of appreciation of painful and thermal stimuli on his left side up to the lower margin of his second rib in front and to his first dorsal spine behind, as well as on the inner border of his arm and hand (Fig. 6). Even the highest,

tactile stimuli could be recognized on both legs and on both sides of his trunk, but when a wisp of cotton-wool was drawn over either hairless or hair-clad parts it tickled more, and was "more distinct" on the right than on the analgesic side; when compared with parts above the level of the lesion it was found that this subjective difference was due to non-appreciation of the tickling component in the stimulus on the left side. The extensive sensory disturbances represented on the chart were found on his right upper limb; there was total loss of sensation to pain on the hand and on the radial side of the forearm, loss of appreciation of temperature over a slightly larger area, while cotton-wool and heavy touch could be recognized only on the inner side of the arm; rubbing or scratching, however, produced much discomfort on the area in which sensibility to touch was lost, but that to pain preserved. The sense of position and the appreciation of passive movement were abolished in his right limbs and diminished in his left ulnar fingers, and vibration could not be recognized in his right leg, on this side of his trunk, or below his right elbow. He was also unable to recognize the form of objects placed and moved about in his left hand, but owing to the tactile anaesthesia this could not be then tested in his right hand.

Ten days after the injury his left limbs were almost as strong as normal, and the right reflexes had reappeared, but were feeble; the state of his sensation remained unaltered, except that heavy pin pricks could be occasionally felt on the left side above the level of his fifth rib.

Twenty-four days after the infliction of the wound his general condition had improved and permitted a more complete examination. His right leg was still flaccid and powerless, and his right upper limb was wasted and completely paralysed; the left limbs were now quite strong. He now complained of severe pain in his right leg, especially when it was touched or moved, but there was no local condition to account for this. Apart from his right arm, the lightest tactile stimuli were appreciated as well on one side as on the other; but cotton-wool still appeared smoother and tickled less on the left leg and on this side of his trunk than on the right. Neither pricks nor heavy pressure produced any pain on his left leg or trunk, but strong pricks could be occasionally recognized between the sixth and second rib and in the inner aspect of his left arm. Now pricks and all painful stimuli were "much sorer," and evoked much more reaction than on the right side; in fact, the hyperaesthesia of this side was as pronounced as we have seen it. The appreciation of temperature was still completely lost to the original level. The sense of position was absent in his right limbs and in the three ulnar fingers of the left hand, but vibration could now be recognized in his right leg when the fork was beating strongly. The threshold of discrimination of the compass points was normal on the radial parts of his left arm, but the two points could not be distinguished when 5 cm. apart on the ulnar side of this palm, or on either sole when separated to a distance of 10 cm. (normal threshold 2 to 3 cm.). He was still unable to recognize the form of objects placed in his left hand.

In his right arm the analgesia was now limited to the thumb, index finger, and the lower half of the radial border of his forearm, and the areas of anaesthesia and thermo-anaesthesia had diminished slightly from above downwards.

Fig. 7.

He was transferred to England two months after the infliction of the wound. During the latter half of this time he wasted enormously, and had frequently persistent attacks of vomiting; he regained, however, some power of movement in his right leg, but his right arm remained wasted, flaccid, and powerless. The only noteworthy alterations in the disturbances

of sensation were an ability to recognize strong painful stimuli above the level of the nipple on the left side, though sensibility to pain remained much reduced to its original level, and a further restriction of the anaesthesiae on his right arm, as is illustrated on the chart (Fig. 7); now there was analgesia only on the thumb and the adjacent portion of the hand. The sense of position was still absent in his right limbs and in his left ulnar fingers, and the appreciation of vibration was abolished below his right wrist and diminished in his right leg. The compass points could still not be discriminated when separated to 6 cm. on either sole.

He was admitted to the King George Hospital under the care of Dr. Farquhar Buzzard, to whom I am indebted for the further history of the case. Some secondary changes had evidently occurred during the journey, as when he arrived his right leg was again completely paralysed, and the knee-jerk on this side, which had been brisk, had disappeared; the right plantar response was sometimes flexor, though previously it had been constantly extensor. Otherwise his condition remained unchanged till his death on August 10th. A few days before this occurred his right carotid artery had been tied owing to an aneurysm, and an abscess in connexion with his fractured jaw was drained.

On post-mortem examination no obvious deformity of the spinal column was found, but the fourth, fifth, and sixth cervical segments were softened, and contained numerous haemorrhages.

The sensory disturbances in this case may be divided into "remote," or those due to interruption of the sensory conducting tracts in the cord, and "local"—that is, such as are produced by injury of the sensory root fibres as they enter the cord, or at least before the impressions they carry are regrouped within it.

An elaborate analysis is not possible here, but a short discussion chiefly in relation to the current views of intramedullary conduction of sensation will be interesting. It will be based not on this case alone, but on our notes of 45 cases in which the injury was partial and produced the Brown-Séquard syndrome, or some other form of dissociation of sensation.

REMOTE SENSORY DISTURBANCES.

Anaesthesia to pain and temperature is certainly the most common and prominent disturbance of cutaneous sensibility; in incomplete transverse lesions, for instance, it is frequently found that though tactile stimuli can be appreciated, pricking or the application of heat or cold, even of extreme degrees and over a large area, evoke no sensation apart from that of contact. Both are always lost on the side opposite to the lesion when this is unilateral and lies above the first lumbar segment, and more diminished on this side when the injury is bilateral but more severe on the one side. This crossed relation does not occur when the lesion lies below the twelfth dorsal segment. During recovery from bilateral lesions, too, tactile sensibility usually returns before that to painful or thermal stimuli. As a rule both these forms of sensation were lost together, but in some cases only thermal appreciation was disturbed.

We have not yet observed a case with primary isolated affection of either heat or cold, but during recovery sensibility to either may reappear some time before stimulation with the other evokes any sensation. Some dissociation is, however, common at the upper level of the remote sensory loss, but this will be discussed later when the mode of decussation of the sensory paths will be considered. Many cases seen confirm the conclusion put forward by Drs. Head and Thompson, that when pain cannot be excited by cutaneous stimuli it cannot be produced by excessive pressure; we have, however, seen cases in which heavy pressure gave pain in parts which were completely analgesic to pin pricks, but it must be admitted that in some of these at least sensibility to prick returned within a relatively short period. Their further conclusion that sensibility to all degrees of temperature is affected simultaneously may be accepted if it is borne in mind that when the disease is slight the appreciation of moderate stimuli only may be lost; everything is, however, in favour of their view that thermal stimuli of all degrees pass by the same intraspinal paths, but that, as the study of syringomyelia shows, heat and cold are conducted by separate fibres.

Remote tactile anaesthesia was present in only a very few of our cases of unilateral spinal lesion, and then it generally corresponded with the analgesia—that is, it occurred on the side opposite to the injury. Frequently, however, especially when cotton-wool was used as a stimulus over hair-clad parts, there was a marked

subjective difference in the sensations evoked on the two sides, as contacts on the analgesic area "tickled less" or were "smoother" than on the side of the lesion; this might be, on the one hand, attributed to the homolateral hyperaesthesia or unnatural sensitiveness to various stimuli which Brown-Séquard originally described, but when the sensations were compared with those similarly evoked from normal parts it was evident that the tickling element in the sensation was defective on the contralateral side. On the other hand, this difference was not due to a diminution of tactile acuity, as this could not be demonstrated when other stimuli were employed; in a few cases in which von Frey's hairs were used no definite threshold difference between the two sides was found. Further, on stroking the sole, or on applying any other stimulus which naturally tickles, less reaction was evoked on the side opposite to the injury. It appears, therefore, that of the two spinal paths open to tactile impulses only the crossed fibres which are closely associated with those that carry pain are concerned in the conduction of the affective impressions produced by many tactile stimuli. This observation is particularly interesting, as lesions of certain portions of the optic thalami show that at this level the impulses that underlie tickling are closely related to those of pain.

But though crossed tactile anaesthesia was the rule in our cases, in a few there was greater diminution of sensibility to light touch on the side of the lesion, or on the side of the greater motor paralysis; even homolateral anaesthesia with crossed analgesia occurred in one case.

CASE V.

Pte. J., 15863, was wounded by a rifle bullet which entered slightly to the left of the fifth dorsal spine, on March 11th, 1915. He lost power in both legs at once, but was able to move the right again next day.

When seen four days later all movements of his right leg were possible and fairly strong, but the left was absolutely

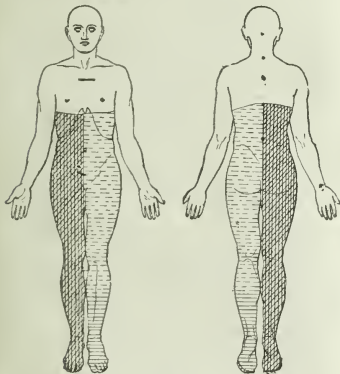

Fig. 8.

paralysed. The left knee-jerk was much depressed, and extensor responses were obtained from both soles. There was complete analgesia and thermo-anaesthesia on the right leg, and on this side of the trunk to the level of the xiphoid and the seventh dorsal spine, but both painful and thermal stimuli were perfectly appreciated on the left side. On the right tactile sensation was unaffected, but there was total anaesthesia to touch on the left leg, and marked hypoaesthesia as high as the xiphoid (Fig. 8). The recognition of position and of passive movement, as well as of vibration, was abolished in the left leg, but normal in the analgesic limb.

A laminectomy was performed by Lieutenant-Colonel Sargent a few days later; the bullet was found embedded in the left articular process of the sixth dorsal vertebra, and a long, sharp spicule of bone which had been driven by it through the dura mater penetrated, as far as could be made out at the operation, this side of the cord. Very little improvement occurred before he left for England, six weeks after the

infection of the wound; the analgesia of the left side became, however, incomplete, and there was less anaesthesia on his left leg.

Another interesting form of dissociation of sensation was represented by a case of incomplete injury due to fracture of the left side of the sixth cervical vertebra by a rifle bullet. There was complete paralysis of the left leg and of the trunk muscles on this side, and all the movements of the opposite limb were weak; on the right side there was complete loss of sensibility to touch, pain, and temperature, while on the less paralysed half of the body pricks and other painful stimuli were appreciated normally, and thermal sensation was only slightly diminished, but there was complete anaesthesia to both light and heavy touches. The sense of position and the appreciation of vibration were completely lost on both sides below the level of the second rib.

In such a case we have the converse of the general rule that tactile sensibility suffers less severely than sensation to pain.

One interesting question that rises from these observations is the mode of decussation of the sensory fibres of the second order which convey impressions of touch, pain, and temperature, and the obliquity with which they cross to the opposite side of the cord. In cases in which the lesion was unilateral the upper limit of the remote anaesthesia to these different forms of sensation varied, and as a rule the upper border of the contralateral loss did not correspond to the segmental level of the injury. If such observations were sufficiently numerous it would be obviously possible to determine the number of segments necessary for the complete decussation of each set of fibres of specific sensory function. To obtain unequivocal results, however, it would be necessary to consider only cases in which the lesion interrupted these fibres after their decussation is completed and in which their interruption is total; unfortunately such cases are rare.

In the mid-dorsal region the crossing of pain and thermal impulses apparently occurs quickly, and is probably complete about one segment above the entry of the dorsal roots that carry them to the cord. Thermal impressions probably cross here less rapidly than those of pain, and as touch, if it is affected, is generally lost to the slightly lower level the fibres of the second order that convey it probably require two segments for decussation. This conclusion is accepted with full recognition of the fact that the peripheral overlap of the tactile root fibres is greater than that of those concerned with pain and temperature. The same order holds for the upper dorsal segments, but here the obliquity of decussation is greater; pain and temperature impressions do not cross for at least two segments after their entry into the cord, and three are frequently required.

The higher we go in the cervical enlargement the slower does the decussation become. At the fourth cervical segment, for instance, the decussation of the pain impulses is not complete till five to six segments after their entry through the dorsal roots, and that of thermal impressions for four to five segments. In the cervical enlargement pain seems to cross within about four segments, thermal sensibility within three to four, and touch somewhat more obliquely than pain; as the upper margin of the anaesthesia to heat is generally slightly higher than that to cold it may be assumed that the afferent impulses that subserve the latter decussate more slowly.

When the lesion is not complete, and especially if it is unilateral, the upper border of the sensory loss frequently retreats caudalwards. In Case iv, for instance, the upper margin of the complete analgesia altered from the sixth cervical to the ninth dorsal root area in two months, and in another case of partial bilateral lesion it retreated from the upper margin of the right cervical root area to the level of the umbilicus within four weeks. A parallel recovery of thermal sensibility may be frequently observed, but it is usually much slower, and heat and cold are then frequently dissociated, the latter recovering as a rule earlier than sensation to heat; but the converse may occur. On the other hand, even when the lesion lies high in the cord, and has produced total or partial loss of sensation to the corresponding level, it is not uncommon to find the area of the lower spinal roots, and especially the skin in the region of the anus, sensitive to one or other mode of stimulation. Further, during recovery it is sometimes

in these regions in which sensation first reappears. In a case of injury of the fourth cervical segment, for instance, which produced thermal, pain, and tactile anaesthesia to the root of the neck, prick could be well appreciated on all the sacral and on the fifth lumbar root areas on the left side. And in another the third, fourth, and fifth sacral areas escaped, though there was otherwise total loss of sensation to the level of the umbilicus. There is generally a remarkable dissociation of sensation in this caudal area; occasionally only pain can be appreciated, but it is frequently sensitive to touch too, and either to heat or cold or to both. The area sensitive to thermal stimuli is, however, generally smaller than that in which pain can be felt. As a rule the caudal anaesthetic part in such cases corresponds roughly to areas of root distribution to the skin.

These two phenomena, the caudalward recovery of sensation and the escape or early reappearance of sensation in the caudal areas, throw light on the arrangement of the sensory fibres of the second order as they ascend through the ventrolateral columns. They indicate a lamellar arrangement in which the fibres that carry any specific form of sensation from successive dorsal roots lie in series; and as there is a general law that the longer ascending fibres lie nearer the periphery of the cord, those that convey impressions from the lower spinal roots are probably placed lateral to those that have later reached the contralateral side. The escape of the sacral root areas would therefore indicate a lesion that involves only the more mesial fibres of the sensory path, while an anaesthesia disproportionately low in relation to the level of the spinal injury would suggest a local destruction of its more lateral fibres. When it becomes possible to correlate the exact histological changes in these cases with the results of careful clinical examinations definite conclusions on the exact course of the fibres that carry various forms of sensation from different regions of the body will be possible.

Microscopical examination has shown that extensive softening and even secondary changes occur frequently in the centre of the cord, especially in the cervical region, and we might consequently expect to find sensory disturbances resulting from interruption of the fibres that decussate at the level of such a lesion; certain of the sensory changes that occur in syringomyelia are due to this cause. The most striking example of this condition that we have seen was:

CASE VI.

Pte. H., 10162, was wounded on February 22nd, 1915, by a rifle bullet which entered just behind the middle of the right sterno-

FIG. 3.—The analgesia is indicated by vertical lines, the thermo-anaesthesia by oblique lines. All forms of sensation were lost on the parts of the right arm coloured black.

mastoid, and made its exit 1 cm. to the right of the first dorsal spine. He lost power in his legs at once, and his arms became

very weak two or three days later. He had no difficulty with micturition.

Both arms were flaccid when he was seen six days later; the right was completely paralysed, but all movements of the left were possible though weak. The right lower limb was weak in all movements, but the left was considerably stronger. His arm, knee, and ankle jerks were absent, and extensor responses were obtained on both sides. Sensation to touch, pain, and temperature were lost over the regions shown on the chart (Fig. 9), and in addition the sense of position and the appreciation of movement and vibration were abolished in his right arm and diminished in his right leg. His general condition and the power of movement, except in his right arm, which remained flaccid, improved during the following three weeks, but the only alteration in sensation was some return of sensibility to prick and temperature on the outer side of his left arm. The complete flaccid palsy and total sensory loss on his right arm was probably due to extensive destruction of the grey matter on this side, the remaining analgesia and thermo-anaesthesia to injury of the decussating sensory fibres.

But the remote disturbances of sensation include also those forms which are affected on the side of the injury, that is the sense of position, the appreciation of passive movement, vibration and form, and the discrimination of compass points. Of these, the sense of position and the recognition of movement were the most commonly lost, and as the dorsal columns through which the impulses that subserve them pass are especially liable to suffer in partial and indirect injuries they were frequently the only form of sensation affected in slight cases; on the other hand, these and the other components of sensation carried by the dorsal columns occasionally escaped, especially in unilateral lesions, though the remote loss of pain and temperature was complete.

The appreciation of vibration, too, was commonly affected on the side of the lesion, though there was frequently no close parallel between this and the state of the sense of position, as the latter was frequently abolished in parts in which vibration could be recognized, but then careful examination generally revealed diminished sensibility to the latter. On the other hand, the discrimination of compass points was, as a rule, more severely affected than either, but we found the reverse in three cases. In a partial injury of the sixth dorsal segment, for instance, even a strongly vibrating fork could be rarely recognized on the right leg, but the two compass points could be accurately distinguished on each sole when only 3 cm. apart, and on the front of each leg when separated to 10 cm. In another case with a unilateral lesion in the second cervical segment there was a marked loss of the sense of position in the right arm, but the threshold to the compass test was the same in both palms and well within the normal. We must consequently conclude that, though the impulses which underlie all these different forms of sensation pass through the homolateral dorsal column, they may be dissociated or affected in different degree by incomplete lesions. They are all independent of tactile sensibility, since they may be all abolished, though the threshold of the latter is unaltered.

In a few cases of high cervical injury we have had the opportunity of testing the power to recognize the form of objects placed in a hand in which tactile sensation is unaffected, and always found it absent if the other symptoms indicated a lesion in the homolateral dorsal column.

Consequently, we may assume that destruction of one dorsal column can produce homolateral astereognosis, which is, as it may be in cortical disease, independent of any tactile loss. This confirms the observations previously made by Dr. Henry Head and myself. The power to recognize differences in the texture of materials placed in one hand is also abolished by destruction of the homolateral dorsal column.

LOCAL SENSORY DISTURBANCES.

The local loss of sensation such as occurred in Case IV must be next considered. Here it was represented by abolition of all forms of cutaneous sensibility over areas of different extent, with absence of the sense of position in the whole limb and of the appreciation of vibration below the elbow. Such local sensory loss may occur with lesions of any level of the cord, but as it presents special features when present in the upper limb, it will be described in detail as it is seen here.

It may result, in the first place, from injuries of the dorsal roots as or before they enter the cord, which, as

might be expected, frequently happens with gunshot injuries of the spine, but as the sensory disturbances then produced are those generally seen with root lesions they require no special mention. Or, in the second place, it may be due to intramedullary lesions which interrupt some or all of the afferent sensory impulses after they enter the cord by one or several dorsal roots, either before or after they have been regrouped in the grey matter. Consequently, all forms of sensation may be affected or certain may escape. The most common type is that seen in Case iv, in which all forms of sensation are involved. Then the tactile loss is the most extensive, and the anaesthesia to pressure is almost coterminous with that to light contact. The thermo-anaesthesia, including loss to all degrees of temperature, is occasionally almost as wide, but it is frequently limited to the area of analgesia; this is generally much smaller. The sense of position and the appreciation of vibration were severely affected in every case, too. In another type only the appreciation of pain and temperature was affected, the impulses carried by the dorsal columns escaping.

But even more remarkable than the character of the local sensory loss on the upper limb is its distribution. In Case iv as well as from the other figures reproduced (Fig. 10), it

FIG. 10.

will be seen that it does not correspond either to the areas of any peripheral nerves or of any dorsal roots; in fact only the peripheral portions of the cutaneous areas of several roots were anaesthetic. On the other hand, it frequently showed a tendency to coincide with the segments of a limb. It has been generally found that when the upper part of the cervical enlargement was involved, the sensory loss extended higher on the radial than on the ulnar border of the arm, and that when it lay in the lower portion of the enlargement the loss was higher on the ulnar side. A similar area in which there is no sensory disturbance is seen on the left arm in Fig. 9.

A local lesion in the lateral part of Burdach's column can, of course, interrupt all the sensory impressions conveyed through this from the roots immediately below it, but the mode of occurrence of the cutaneous sensory disturbance is less obvious.

Its explanation must depend on the anatomical arrangement of the sensory paths. The tone of the muscles, as well as their co-ordinated actions, depends chiefly on afferent impulses that pass from the corresponding segment of the limb to the cord, and act through the grey matter on their final common path. If for the moment we consider only the intrinsic muscles of the hand, we may assume for them a group of cells in the lowest cervical and the first dorsal segments, which, however, receive afferent impressions from the whole hand, through reflex collaterals from at least four dorsal roots, that is, from the sixth cervical to the first dorsal. An interruption of these fibres as they enter this group of motor cells would then cut out all the non-sensory afferents that control the small hand muscles, but would leave intact the connexion of other collaterals from the same roots with the other motor cells that innervate the arm muscles. We would consequently have a segmental reflex palsy. Much the same probably holds for the fibres of cutaneous sensation. Those that convey impressions of pain, for instance, are not all relayed in the grey matter at the level at which they enter, but ascend and descend some distance in Lissauer's zone, and there are probably not grouped according to the roots by which they arrived as they enter the grey matter, but in relation to the segment of the limb from which they come. Thus those that carry impressions of pain from the hand may be relayed at one level, while other fibres of the same roots that carry similar impulses from the forearm

may end in the grey matter at another level (Fig. 11). If such an arrangement exists sensory disturbances similar in distribution to those described may be easily produced by isolated lesions. The type of the sensory loss would depend on whether the sensory afferents were interrupted before or after undergoing relay.

The commonness of these types of local sensory loss would then correspond to the frequency of lesions in the dorsal horns. Fig. M (Plate) represents such a lesion. When the neighbouring part of the dorsal column is also involved the sense of position would be affected in the corresponding limb; occasionally this occurs as an isolated phenomenon—that is, without disturbance of cutaneous sensibility. An interesting example of local loss due to a small lesion in the dorsal column, and probably limited to its root entry zone, was seen in one patient in whom the sense of position and of passive movement was lost at the left elbow and shoulder, though normal in the hand, while on the outer side of this arm he was unable to recognize the vibrations of a tuning-fork when applied to the soft tissues, to discriminate compass points even when separated to three times the threshold distance of the corresponding part of the right arm, or to distinguish texture. All these local sensory disturbances have a tendency to diminish or disappear more rapidly than the remote loss.

SUBJECTIVE SENSORY SYMPTOMS.

Subjective sensory symptoms were not uncommon; pain, for instance, is very commonly present in the parts that correspond to the segmental level of the spinal injury, but here it may be due to irritation of the dorsal roots, or may be only associated with the hyperaesthesia which frequently occurs in this region. Distant pain—in a leg, for instance, when the spinal wound was in the cervical region—occurred, however, in a certain number of cases, and can be attributed only to the spinal lesion. It was frequently only transient or disappeared within one or two weeks, but occasionally persisted as long as we had the patients under observation, in one case for two months. It was generally described as a burning or tingling, which increased when the part was touched or handled. In one patient it was so severe that it prevented sleep and needed morphine. It was generally most severe at night and in some instances increased when the part was exposed or moved, though there might be no demonstrable hyperaesthesia. It sometimes spread over the whole side of the body below the level of the injury, but it was frequently limited to the foot or leg. It occurred only with relatively slight or unilateral lesions, and in the latter case was always on the same side as the injury and on that on which there was no cutaneous sensory loss. In a few instances, however, no sensory loss could be discovered in either side, or, if any existed, it was only a slight diminution of sensibility to pain and temperature.

The condition known as hyperaesthesia was extremely

FIG. 11.—Diagram to illustrate the manner in which sensory impulses enter and are grouped within the spinal cord. The broken lines represent the fibres which carry the impulses that ascend through the dorsal column, the continuous lines those that convey impressions of touch, pain, and temperature. The latter probably ascend or descend in Lissauer's zone before entering the grey matter.

common; it may occur, as was originally described by Brown-Séquard, on the side of the injury when there is a unilateral lesion; or on areas which had been anaesthetic as sensation recovers, or even more commonly as a band on one or both sides of the trunk or down the limbs, at the upper margin of the sensory loss.

A homolateral hyperaesthesia in Brown-Séquard cases is by no means constant, though we observed it occasionally; it extended over the whole half of the body almost up to the segmental level of the injury. Here pin-prick, heavy pressure, and especially scraping, or even rubbing hair-clad parts with a wisp of cotton-wool, produced severe pain and much more reaction than these stimuli on normal parts. The application of cold, too, usually evoked pain, and heat of 45° C. and upwards caused a severe burning sensation. In one case pin-prick not only gave more discomfort than normal, but this persisted abnormally long. This distant hyperaesthesia always showed, however, a tendency to diminish rapidly and disappeared in some cases while they were under our observation. Its pathogenesis has been already the subject of much discussion and experiment. The hypothesis that it is due to section of efferent inhibitory fibres seems very improbable, while the fact that it is generally transient or disappears rapidly is more in favour of the view that it is due to an inflammatory reaction, or rather to oedema and other such changes, at the site of the lesion than to overloading of the afferent tracks that remain open to sensory impulses.

An excellent example of hyperaesthesia in areas in which sensation is recovering was a case in which, owing to a transverse wound across the back of the neck which fractured the sixth and seventh cervical spines as well as the lamina of the sixth vertebra, a complete paraplegia with analgesia and thermo-anaesthesia to the level of the eighth cervical root areas set in at once. Within a fortnight, however, there was complete pain loss only below the umbilicus, and the appreciation of thermal stimuli was only diminished above this level; in the area in which sensation had recovered pricks produced an extremely unpleasant burning sensation, and high and low degrees of temperature gave much more discomfort than on normal parts. He later came under the care of Dr. Head, who found the same condition more than two months after the infliction of the wound.

Finally we come to the hyperaesthesia which is so commonly found at the upper level of the sensory loss on one or both sides, with either complete or partial lesions. On the trunk it is generally associated with a girdle sensation of pain, burning, tingling, or constriction, and on the limbs with pain or paraesthesia over the areas of one or more dorsal roots. It may persist for weeks, but usually diminishes. When severe the lightest contact, or even the approach of any one to his bedside, may be feared by the patient, and the movement of his bedclothes, or the removal of his shirt or bandages, may excite severe pain. Local muscular contractions are frequently associated with it. The state of sensation in the hyperaesthetic area has been carefully worked out in several cases; it is found to be variable. No loss to light contact was ever found, and when they were used no raising of the threshold was discovered to von Frey's hairs, but in three cases contact with No. 4 and No. 5, which only gave a maximal threshold reading on normal parts, produced a sharp stinging or burning, "like a red-hot iron," on the hyperaesthetic zone. Pain was most readily produced by any moving stimulus, as a wisp of cotton-wool, or by scraping with any rough or sharp object, but, on the other hand, moderate pressure generally gave no discomfort.

The state of sensibility to pain and temperature varied; in one group the threshold to pain was, if anything, diminished, while that to temperature was unaffected, but any degree of cold, and heat above 45° C., evoked much pain. In the other class sensibility to pain and temperature were lost or diminished over part of the area that was painful to rubbing or scraping.

The origin of this hyperaesthesia is interesting; it is most commonly attributed to irritation of the corresponding dorsal roots, and this seems to be frequently the actual cause, but there are many facts which prevent us from accepting this explanation in every case. It is often, for instance, much more extensive than it would be if due to irritation of even two pairs of roots in the neighbourhood

of the wound; in one case of injury to the spine of the axis it extended over both upper limbs and to the level of the nipples, and in another patient in whom the fourth cervical vertebra was damaged it spread not only over both arms, but to the base of the xiphoid. But an even stronger argument is the fact that in cases of the Brown-Séquard syndrome, in which there were both hyperaesthesia of the homolateral side and a local area of pain and tenderness at the level of the lesion, no essential difference may be found between them. It is therefore probable that in many cases at least the cause of the pain is to be found within the cord, and that it is due to oedema, circulatory disturbances, or slight diffuse lesions, as Brown-Séquard originally postulated as the explanation of the local contralateral hyperaesthesia he described. Finally, in several cases we have found no injury, on *post-mortem* examination, to the roots which corresponded to the areas that were hyperaesthetic.

PROGNOSIS.

The prognosis during the first two weeks in any one case is extremely difficult, and it must be admitted that there is no one sign or symptom from which we can draw reliable conclusions on the severity of the lesion, or from which we can say, when there is complete motor and sensory paralysis, as there nearly always is in the earliest stages, whether the cord is completely divided or not. It must be remembered that though neither the cells nor the fibres of the spinal cord do regenerate, very considerable improvement may occur, as at least part of the early symptoms are due to oedema, circulatory disturbances, and to incomplete damage. The structural damage is consequently not always parallel to the functional loss. We have seen that the knee-jerks are absent for a time with lesions of all degrees of severity, and this consequently cannot be a guide in prognosis. The most reliable information is perhaps given by the state of tone in the muscles of the lower limbs; after three or four days the legs are generally very flaccid and their muscles toneless when the lesion is severe and irrecoverable, and gradually become more so and waste. The preservation of tone in the muscles is, on the other hand, an indication that some improvement may be expected. Valuable information can be also obtained by stimulation of the soles, as the amount of reflex movement that results varies more or less inversely with the severity of the injury. When this is complete, no reflex muscle contraction can be, as a rule, elicited, while in all stages of slighter damage a brisk withdrawal reflex can be obtained.

Probably no serviceable recovery can be expected if the plantar responses are flexor.

In less severe cases in which all forms of sensation are not abolished, the amount of disturbance of the latter is an indication of the amount of the cord damaged; we have generally seen the promise of useful recovery when tactile stimuli could be felt in the lower limbs within the first two or three days.

When the cervical region is injured the upper limbs are usually more paralysed than the lower, and remain flaccid and waste while these show signs of recovery; histological examination shows that this atrophic palsy of the arms is due to extensive softening of and haemorrhages into the ventral horns, and as the motor cells contained in them are readily destroyed the chance of much improvement is slight.

If recovery sets in early, steadily progressive improvement may be, however, expected, unless complications occur. We know of a few patients, however, in whom the symptoms increased after movement, as Case iv, who lost again the power of movement he had regained in his right leg during his transference to England; and in one other case we observed syringomyelia develop some time after the infliction of the injury.

TREATMENT.

Owing to the nature of the lesions the treatment of these spinal injuries is naturally unpromising. The damage to the spinal cord is done when the wound is inflicted, and we are unable to influence it by treatment. In many cases surgical intervention and the removal of missiles or displaced bone which compress the cord have given a hope of greater recovery, and should be attempted if the symptoms or an x-ray examination make it probable that the cord is

compressed, and that there is any prospect of recovery. But it must be realized that in such cases the symptoms are certainly more dependent on intramedullary changes produced at the time rather than on compression.

Dr. A. R. Allen¹² showed experimentally some years ago that the symptoms produced by severe contusion of the cord can be relieved and recovery made possible by incising the dorsal columns at the level of the injury, thus draining away oedematous fluid and intramedullary hæmorrhages, and allowing the swollen fibres to expand, but it is necessary that this operation should be performed within a few hours of the infliction of the injury. This is rarely possible in warfare, and the early symptoms are so equivocal that if resorted to more harm than good might be easily done.

A large proportion of cases of spinal injury die soon after the infliction of the wound from shock or associated wounds of the chest or abdomen. Among those that survive the greatest danger is from cystitis and pyelonephritis and the development of extensive bedsores. A large part of the responsibility consequently falls on the nursing. When cystitis is threatened or has developed, we have seen excellent results from suprapubic drainage. Finally the danger of moving the patient must be borne in mind; the risk is obvious if the vertebral column is fractured, and if detached pieces of bone lie within the canal these may be displaced and lacerate the cord during transit. Further, we have evidence that secondary changes are more liable to develop after movement; absolute rest is consequently advisable during the first few weeks if the symptoms hold out any prospect of useful recovery.

Memoranda:

MEDICAL, SURGICAL, OBSTETRICAL.

A NEW CATARACT OPERATION.

The following is a preliminary note on a new cataract operation which is now being performed in Delhi. This operation, which embodies several new features, was conceived and perfected by my assistant, Pundit Hari Shanker. The essential feature of the operation is a preliminary conjunctival flap cut so as not to hamper the movements of the knife in making the incision in the eyeball. The lens is removed entire in its capsule either with or without a preliminary iridectomy.

The advantages of the operation, as shown by the results obtained in some 1,500 cases performed this year, are:

1. The wound in the eyeball is closed at once by the flap so that the risk of subsequent infection is nil.
2. Prolapse of the iris and vitreous are prevented from occurring.
3. The flap is firmly adherent to the globe within a few hours, and in a large majority of cases the dressing can safely be then removed.
4. Cataract cases are now treated in this hospital as out-patients, and they can go home immediately after operation, returning next day to have the dressing removed permanently.
5. No photophobia is present subsequent to the operation, even on the second day, when the patients are provided with glasses, and can see well.
6. The usual corneal astigmatism is very much less than is generally found after other operations.

Delhi.

IMPROVED TECHNIQUE FOR INTRAVENOUS INJECTIONS AND REMOVAL OF BLOOD FROM VEINS.

The chief remaining difficulty of this practice is that of properly entering and canalizing the vein, especially when the veins are small or deep, as often happens when the

superficial veins in front of the elbow form a plexus of small veins instead of the relatively large trunks of the textbooks. The application of a bandage in this case produces a series of veins scarcely as large as the needle, and canalization is difficult or impracticable. But by using a sphygmomanometer instead of the bandage, and then compressing to just short of blood pressure point, say 120 to 150 mm. Hg, the hitherto small veins will stand out turgidly, and can easily be punctured and canalized, for the vein stands up to the needle, and will not yield before it. Even in the case of the largest veins the manoeuvre is more easily accomplished by this method.

After the canalization, in the usual way, the cutting or removal of the bandage often causes movement of the arm and endangers the possibility of second puncture. But with the sphygmomanometer all that is necessary is to release the escape cock without disturbing the compression bag. The latter should in the first place be carried right up into the axilla, and in primary and secondary cases at least should have a sheet of Billroth's cambric interposed between it and the skin to avoid infection. The one I have used has been the Herbert French pattern, but any having a similar pressure bag would be equally serviceable.

Reports of Societies.

FIBROSITIS.

At a meeting of the West London Medico-Chirurgical Society on December 3rd the president, Dr. LEONARD DOBSON, in the chair, a discussion was held on fibrositis. Dr. GRAINGER STEWART, in opening it from the medical aspect, said that quite apart from acute traumatism, a large number of soldiers had been invalided with subacute and chronic rheumatism, both articular and muscular. Most of those cases occurred in middle-aged men or in those who had previously been the victims of chronic rheumatism, and there was nothing special to discuss in regard to them. As regards the wounded, it appeared to him that the occurrence of fibrositis was more frequent and the degree more severe than in cases of injury received in civil life. He had been struck by the rapidity with which adhesions formed, not only around and in the joints, but also in the tendon sheaths and muscular structures. He thought that several factors were present which might account for this: (1) Infection from wounds; (2) the effects of chill, strain, or exposure; (3) the protective strain on the muscles guarding the injured part; (4) the complete cessation of functional activity in the wounded limb as the result of its being bound up in splints, and the impossibility of carrying out passive movements and massage of those parts of the limb not directly involved by the injury. Early passive movement and massage would do much to prevent the formation of adhesions, would speed the recovery of the slightly wounded, and would prevent many of the more severely wounded, who would not be fit for further service in the army, from becoming economically a burden to the State in after-years, by keeping the joints supple and the muscles in good condition until the patient had recovered from the primary injury, whether it involved injury to the bone or to the nerves. Personally he regarded immobility as the chief cause of those fibrous adhesions, and, that being so, it was of prime importance to insist on the daily movement of the joints of the affected limb as far as that was compatible with the surgical necessities of the case. Mr. H. S. SOUTTAR, in dealing with the surgical aspects of the question, said that his main contention was that many of the after-effects of injuries and diseases incidental to war, which might be classed under the heading of fibrositis, were preventable, and that, applying the lessons of recent researches in the treatment of fractures, it was of the first importance to avoid anything in the way of too prolonged or too complete immobility of the affected parts. The President, Drs. BRIGHTON, RICKARD LLOYD, F. G. LLOYD, JOHNSON SCOTT, and CLIPPINGDALE took part in the discussion which followed, and Dr. GRAINGER STEWART and Mr. H. S. SOUTTAR replied.

Reviews.

INDUSTRIAL TRAINING FOR DISABLED SOLDIERS.

EVIDENCE of the attention that is now being paid in France to the problems raised by the re-education and professional employment of the wounded soldiers is furnished by a book¹ recently published by Dr. M. CARLE. The subject has been brought before the public by the well-known writer, Maurice Barrès, and Dr. Carle gives a full account of what his society, the Fédération Nationale des Mutiles, and other voluntary associations have done in France to enable soldiers invalided from the army after amputations or other severe injuries to earn their own livings. Such schools for the wounded have been established at Paris, Marseilles, Bourges, Montpellier, Tours, Bordeaux, Pau, Orleans, Nancy, Rouen, Clermont-Ferrand, and many other places. Dr. Carle gives an account of the way in which such establishments should be worked, their objects, the manner in which suitable cases are chosen for them, and the general lines in which artificial limbs and other prosthetic appliances are provided for the victims of the war. The book is short and well written. It should be in the hands of all who have to deal with similar problems in this country.

ANCIENT HINDU SCIENCE.

In his account of *The Positive Sciences of the Ancient Hindus*,² Mr. BRAJENDRANATH SEAL gives a modern exposition of ancient lore dating back to between the years 500 B.C. and 500 A.D., practically speaking. The scientific ideas of the Hindus were founded, naturally enough, on the observation of phenomena; observation, however, was not enough, designed experiment was rarely thought of, and the development of science was handed over to the inductive method and methods of algebraic analysis. Perusal of Mr. Seal's well-written book will show the reader how ill such methods serve the progress of science, however successful their application to philosophy and speculation may have been. Successive chapters are devoted to ancient Hindu chemistry, mechanics, acoustics, plant and animal life, physiology and biology; in the last fifty pages Dr. Seal gives an appreciative estimate of the scientific method of the Hindus, its strength and limitations. It would seem that theoretical considerations and dialectics, logic and inference, possibilities rather than probabilities, were here given undue weight. Hence to the Western mind, which values an ounce of experience more highly than a ton of theory, Hindu science is apt to be disappointing, unpractical, and therefore ineffective. How far Dr. Seal is justified in interpreting the ancient Hindu texts in the terms of the latest scientific views, with the use of such words as "isomers," "infra-atomic vibratory particles," "catalysis," "valency" (as applied to atoms), and the like, is open to question. It seems improbable that the Hindus of the period with which he deals can have had any clear realization of the senses in which such terms are employed nowadays. The book is clearly written, and should be studied by all who are interested in the history of science and philosophy.

DISEASES OF THE RECTUM.

MR. LOCKHART-MUMMERY has written a valuable monograph on *Diseases of the Rectum and Anus*.³ Several works on the subject have been published in the English language during the last few years; this book is both comprehensive and practical, and is in all respects a sound work of reference.

The malformations of the rectum and anus are first described, and there follows a chapter on examination and diagnosis. Mr. Lockhart-Mummery emphasizes the mistakes that are made for want of a proper examination in

rectal complaints; he goes in detail into the methods of examination, and the chapter is one of much practical value. He then proceeds to describe what may be called the general technique of rectal operations, preparation general and local, diet, and after-treatment. Precise instructions are given. A chapter by Dr. Blumfield on anaesthesia completes this preliminary part of the book.

Hæmorrhoids is the first of the rectal diseases considered. For external thrombosed hæmorrhoids immediate removal with scissors under eucaïne anaesthesia is recommended. It is interesting to find that for internal piles the author has almost entirely discarded excision and suture for the older ligature operation. In the chapter on prolapse, the method which Mr. Lockhart-Mummery described in 1910 is recommended for the first and second degrees of the affection. It consists in anchoring the rectum by cicatrix in the posterior rectal space. We believe this to be a reliable procedure, but are not disposed to agree with the characterization of sigmoidoexy as a generally unsatisfactory operation. Several following chapters are devoted to the inflammatory affections—proctitis, ulcer, abscess, and their sequelae. The fact that forty pages are given to fistula shows how completely the author deals with his subjects.

The reader will naturally turn with particular interest to the chapters on malignant disease. It is not possible to analyse these adequately here. There are no dogmatic statements as to choice of operation except a general preference for the abdomino-perineal in view of its superior results. The detailed discussion of this operation will be welcomed by surgeons.

This book undoubtedly counts, if one may use the expression. It is certainly one for all who have to do with rectal disease to add to their bookshelves.

OLD AGE PENSIONS.

The key to this book⁴ is contained in one sentence in the first paragraph, "A practical and human account of the actual working and ascertained results of the Act." It commences with a general account of the Acts, and then proceeds to narrate and discuss the difficulties that arise as to age limit, the conditions of nationality and residence, and the difficulties and methods of ascertaining the annual income of persons who apply for pensions. The various disqualifications for a pension are treated in two chapters, and a long chapter is devoted to a general description of the mode of dealing with claims for pensions. The machinery of the Acts is fully described; and though it is stated that no one authority has undertaken to correlate the statistics that must be available in the various departments concerned, a considerable series of tables is given as to the number and character of claims and the manner in which they are dealt with, and estimates are given as to the effect which the pension scheme must have on the statistics of pauperism and the cost to the rates. A final chapter contains a quantity of suggestions for the amendment of the Acts and for improvements in their administration; and from the intimate knowledge which the author (who has unhappily been killed in Gallipoli) shows of the administration his suggestions must be deserving of careful consideration by the authorities. The book does not claim to be a legal treatise though it is written by a lawyer. Composed in an easy narrative style, it should find many readers among social workers who desire to know the general working and results of the old age pensions scheme, and at the same time it cannot fail to be of great value to lawyers and administrators who want to know in detail the more technical points in administration.

NOTES ON BOOKS.

THE new and revised edition of Sir HENRY BURDETT'S well-known book, *How to become a Nurse*,⁵ tells the reader how and where to train, and is, indeed, a guide to training for the nursing profession, with particulars of the schools and institutions in the United Kingdom and

¹ *Jes Booles Professionnelles des Blessés*. Par le Dr. M. Carle; Préface de M. Edouard Terril. Deuxième édition. Lyons: A. Rey, Paris: J. B. Baillière et Fils, 1915. (Med. 8vo, pp. 132; illustrated.)

² *The Positive Sciences of the Ancient Hindus*, by Brajendranath Seal, M. A., Ph. D. London: Longmans, Green, and Co. 1915. (Med. 8vo, pp. 305, 12s. 6d. net.)

³ *Diseases of the Rectum and Anus: A Practical Handbook*. By J. P. Lockhart-Mummery, F.R.C.S. Eng. London: Baillière, Tindall, and Cox, 1914. (Demy 8vo, pp. 354; 102 figures, 7s. 6d. net.)

⁴ *Old Age Pensions: Their Actual Working and Ascertained Results in the United Kingdom*. By H. J. Hoare, B.Sc., LL.B. With an Introduction by Sir Laurence Gomme, F.S.A. London: P. S. King and Son, Limited, 1915. (Cr. 8vo, pp. 206, 3s. 6d. net.)

⁵ *How to become a Nurse: The Nursing Profession: How and Where to Train*. By Sir H. Burdett, K.C.B., K.C.V.O. New and revised edition. London: The Scientific Press, Limited, 1915. (Cr. 8vo, pp. 336, 2s. net.)

abroad where training in general and special nursing may be obtained. The book is now in its ninth edition. It is complete and up to date in its information, even including pages on the British Red Cross Society, on the Order of St. John of Jerusalem, and on the army and navy as training schools for male nurses.

The eighth edition of Dr. THRESH'S *Simple Method of Water Analysis*,⁶ especially designed for the use of medical officers of health, an excellent manual, has been brought up to date by the inclusion of an account of the purifying of water on the small scale by the addition of almost infinitesimal amounts of chlorine in the form of calcium or sodium hypochlorite. As in our notices of previous editions of this little book, we warmly recommend the latest edition to the attention of those for whom it has been written.

In their little manual of *First Aid in the Laboratory and Workshop*,⁷ Messrs. ELDRIDGE and BRISCOE give outlines of the treatment called for by the emergencies of the workman's life. The text is cut down to a minimum, and errs, perhaps, on the side of excessive brevity.

A serviceable series of diagrams, with the necessary brief explanatory text, for the use of those who have to teach elementary anatomy and physiology to nurses and the like, is provided by *Phillips's Popular Mammikin*.⁸ This is composed of a series of coloured diagrams, superposable, of the human body in various stages of dissection. Both the diagrams and the text furnished by Mr. FURNEAUX appear to serve their purpose admirably.

⁶ *A Simple Method of Water Analysis, especially Designed for the Use of Medical Officers of Health.* By J. C. Thresh, M.D. Vic., D.Sc. Lond., D.P.H. Camb., Eighth edition. London: J. and A. Churchill, 1915. (Cp. 8vo, pp. 69, 2s. 6d. net.)

⁷ *First Aid in the Laboratory and Workshop.* By A. A. Eldridge, B.Sc., and H. V. A. Briscoe, D.Sc., with a Foreword by Surgeon-General Sir A. Keogh, K.C.B. London: E. Arnold, 1915. (Cr. 8vo, pp. 32, 1s. net.)

⁸ *Phillips's Popular Mammikin or Model of the Human Body.* Edited by W. S. Furneaux. London: G. Phillips and Son, Limited, 1915. (9½ x 7½, pp. 16; 5 diagrams, 8 figures. 3s. 6d. net.)

FACTORIES AND WORKSHOPS.*

The report of the Chief Inspector of Factories for 1914 appears almost at the close of the year 1915. The delay is attributed largely to the shortage of the staff caused by the withdrawal to the war of 50 factory inspectors and assistants, 14 clerks from the central office, and 18 from branch offices. At the close of 1914 certifying surgeons to the number of 87 had received long special leave for military service. To-day the number is greater. In the report there appears the announcement that telephones have been provided for all branch offices; this is a remarkable confession. The delay in the introduction of so necessary an appliance must, we presume, be set down to the discredit of officials of the Treasury.

The 1914 report is neither so bulky nor so full of statistics as its immediate predecessors. There were fewer fatal and non-fatal accidents in 1914 than in 1913. During 1914 159,000 casualties were reported, a decrease by 10.5 per cent. when compared with the preceding year. The decrease varied in different districts and is difficult to explain. Usually hurry and speeding up have been regarded as causes contributing to accident, but in some places; for example, Barrow-in-Furness, though much overtime was worked as well as double shifts to very notable increase occurred. In Newcastle-upon-Tyne there were fewer accidents, but a large number of fatalities owing to the men brought into the shipbuilding yards and engineering shops having been comparatively speaking unaccustomed to the dangers. In the textile trades the fewer accidents are probably to be explained by the better fencing of machinery. The fact still remains that many accidents are the result of neglect or of indifference on the part of the workers. It is stated that 30 per cent. of the accidents investigated were the result of such causes. Cleaning machinery whilst in motion is a fruitful source.

The report does not contain reports by the superintending factory inspectors of the various divisions. Some of these inspectors, instead of furnishing reports of divisions, have written upon such subjects as sanitation, safety, and employment. These papers form an interesting contri-

bution to the report. There is slight overlapping, but this is no drawback. Mr. J. H. Rogers draws attention to the comparative absence of suitable messrooms, but, on the other hand, alludes to the improved health and efficiency of the workers in those factories wherein employers have provided facilities enabling the workers to get their meals properly.

The report of the principal lady inspector is, as usual, interesting. Miss Anderson deals with the changes which are creeping over women's labour. Old factories have been adjusted to meet new methods of manufacture, and the women have readily adapted themselves to the new processes. Industrial occupations open to women have changed owing to the necessities created by war. The war has shown how dependent we as a people have been upon Germany for drugs, chemical compounds, and certain types of machinery. In the future this will have to be remedied. Labour difficulties and high wages, also widespread indifference, have been the main reasons why the manufacture of certain products have passed out of the country. Attention is again directed to the unsatisfactory condition of the sanitary conveniences provided for women in factories. We have in previous reviews touched upon this subject. More frequent prosecution and publication of the names of offending employers would tend to improve matters in this direction. It is too soon to attempt to speak of the effect of overtime upon women's health. Women, to their credit be it said, are working with a will and with greater energy than usual because they know that the men at the front require extra clothing and munitions.

Of the 20 fatalities during 1914 from electric shock 18 were caused by alternating currents.

Dr. T. M. Legge discusses the part played by dust in causing diseases of occupation. He ranges himself on the side of those who regard inhalation of lead dust as playing a greater part in causing plumbism than the introduction of the metal into the body by food eaten by workmen with unwashed hands, or its possible passage through the skin. Mention is made of Dr. Shuttleworth's interesting series of cases of plumbism occurring in lead workers after the men had joined the army—a circumstance probably to be explained by the increased metabolism due to the altered conditions of life. Poisoning by gases developed in various industries receives considerable attention, as also the subject of dermatocosis, especially industrial eczema. Carefully prepared tables of industrial lead poisoning are submitted by Dr. Legge, who remarks that the continued diminution in the number of cases of plumbism notified has not been accompanied relatively by a corresponding fall in the number of deaths reported. A special chapter is devoted to tetrachlorethane poisoning. This material is an ingredient of varnish used for covering the wings of aeroplanes so as to make them impervious to moisture and air. One of the effects of poisoning is jaundice. The report covers interesting ground, and quite maintains the reputation of its predecessors.

HEALTH OF MUNITION WORKERS COMMITTEE.

The Committee appointed by the Minister of Munitions of War, with the concurrence of the Home Secretary, "to consider and advise on questions of industrial fatigue, hours of labour, and other matters affecting the personal health and physical efficiency of workers in munitions factories and workshops," is constituted as follows:

- Sir George Newman, M.D. (Chairman).
 Sir Thomas Barlow, Bt., K.C.V.O., F.R.S.
 Mr. G. Bellhouse, Factory Department, Home Office.
 Professor A. E. Boycott, M.D., F.R.S.
 Mr. J. R. Clynes, M.P.
 Dr. E. L. Collis, M.B., Factory Department, Home Office.
 Dr. W. M. Fletcher, M.D., F.R.S., Secretary of Medical Research Committee.
 Dr. Leonard E. Hill, M.B., F.R.S.
 Mr. Samuel Osborn, J.P., Sheffield.
 Miss R. E. Squire, Factory Department, Home Office.
 Mrs. H. J. Tennant.
 Mr. E. H. Pelham is secretary; to him communications may be addressed at the offices of the Board of Education, Whitehall, S.W.

The memorandums on Sunday labour and on industrial canteens mentioned below are the first of a series on

* Annual Report of the Chief Inspector of Factories and Workshops for the year 1914. [Cd. 8051.] Price 1s. 2d.

matters of immediate practical importance which the Committee will submit to the Ministry of Munitions. They will deal with such subjects as welfare supervision, hours of labour, the employment of women, and sickness and accidents. It is anticipated that they will eventually be incorporated in a single report, which will also deal with other matters affecting the health and physical efficiency of munition workers, and will include summaries of evidence and other material.

Sunday Labour.

The memorandum on Sunday Labour (No. 1) which is of the nature of a preliminary report, contains certain conclusions, together with an outline of the evidence upon which they are founded. The main conclusion is that Sunday labour should be everywhere discontinued, and by all classes of workers, except in the tending of furnaces and other work which must necessarily be continuous. In such cases, and also in respect of repairs, special arrangements should be made to give a corresponding rest during some other part of the week. Exceptions may occasionally be necessary to meet sudden emergencies, including the making up of arrears in particular sections. Except for quite short periods, continuous work is, in the opinion of the Committee, a profound mistake, not only on social and religious grounds, but also economically, since it does not pay, the output not being increased. The output is not increased partly because men become bored and wearied with the monotony of the work, and partly, apparently, because the actual number of hours worked may be larger when the average weekly hours are reduced. In one case the reduction was from 73½ to 65½ hours, and, though the normal hours were thus reduced by 13, the average number of hours worked during the three months preceding the change was 60, whereas the average number of hours worked during the six months preceding the change was 59½. The Committee express the opinion that the foremen and the higher management require definite periods of rest even more certainly than the manual workers. They never spare themselves, carry a heavy burden of responsibility, and cannot be replaced.

Industrial Canteens.

The memorandum on this subject, which is numbered 3, deals first with the general problem of nutrition. It is pointed out that, speaking generally, more importance is to be attached to the food being fresh, digestible, and appetizing than to its chemical composition or proportion. The relative value of food to the individual is affected by the nature of the employment, whether sedentary or active. With an increase of work there must be proportionate increase in quantity and in nutritive value of the food. A man who has to work hard, or long, or steadily, needs a proportionately ample food supply, composed of highly nutritive ingredients, if he is to withstand the strain. A woman requires on an average about four-fifths of the food supply of a man, and an adolescent about seven-tenths. The Committee considers that industrial alcoholism is in part due to the lack of cheap, good food. It found evidence that workers are getting a better type of food than formerly, but that large numbers of both sexes are not getting such a diet day by day; difficulty arises mainly where the workman or workwoman must have meals away from home. After referring to the custom of bringing food to the workshop, where sometimes facilities for cooking or warming are provided, and to the improvement in the character of cook-shops and coffee-houses, the Committee expresses the opinion that by far the most hopeful enterprise has been the establishment by employers of industrial canteens or workpeople's dining-rooms in or near the factory. The general scope of such a canteen is, perhaps, best expressed and explained in the following statement of an employer, which, the Committee says, expresses its conviction:

In answer to your inquiry as to the effect which our canteen arrangements have had upon the health and efficiency of our own workpeople, we were so fully alive to the importance of this as to erect a complete installation, separated from the factory proper, for the use of those who live too far away from the works to dine at home. From 1,500 to 2,000 workpeople make use of these rooms daily.

The building has a well equipped kitchen, but the majority of those who dine at the works, although buying tea and light refreshments, bring their own dinner. This habit obtains elsewhere. We make a point, however, of having, in addition to other things, one or two cheap and very nutritious dishes—for example, a 1d. basin of soup or stew, of which some hundreds are sold daily. In planning the dining block, we felt it was not merely a question of supplying food, but of doing so under restful and comfortable conditions, in rooms well lighted

and ventilated and properly warmed. A great deal more was done than was required for bare efficiency, and it is not necessary to bring about costly a result. At the same time, as there is a moment's doubt as to the importance of a comfortable dinner hour for our people from the point of view of their efficiency in the afternoon.

The health of our workpeople has unquestionably improved in recent years, and we feel sure that the dining-room has helped to bring about this result. At the same time, as there are many factors which have come into play, it is not possible to vaive with any approach to accuracy the part that each of these has played. The proper ventilation of the workrooms, medical and dental attendance freely given at the works, with facilities for those in poor health getting to a convalescent home, are among the many factors which have each exercised an influence.

The Committee has been impressed with the consensus of opinion as to the substantial advantages both to employers and workers following the establishment of an effective and well-managed canteen. These benefits have been direct and indirect. Among the former has been a marked improvement in the health and physical condition of the workers, a reduction in sickness, less absence and broken time, less tendency to alcoholism, and increased efficiency and output; among the latter has been a saving of the time of the workman, a salutary though brief change from the workshop, greater contentment, and a better mid-day ventilation of the workshop. The Committee is satisfied that the evidence of these results is substantial, indisputable, and widespread.

ROYAL MEDICAL BENEVOLENT FUND.

At the November meeting of the Committee 39 cases were considered. One applicant was elected to an annuity of £20 and £273 granted to 23 cases, and the others were either postponed for further inquiries or found unsuitable. The following is a summary of the cases relieved:

Daughter, aged 27, of L.R.C.P. Irel. who practised in Ireland. Applicant had nursed her mother, who had died recently, through a long and serious illness, and required a change and rest. Mother's income derived from charities ceased at her death. Voted £3 to enable her to take a holiday.

Widow, aged 57, of M.D. Glasg. who practised at Glasgow, and died in 1911. Only certain income £7 per annum. Son who helped to keep the home going had joined the army. Applicant endeavoured to make a living by taking lodgers, but this has not been a success of late. The Glasgow Branch of the Guild reported very favourably of this case. Voted £10.

Widow, aged 62, of M.D. Dubl. who practised at Elgin and died in 1904. Husband prior to his death was for some years an annuitant of the Fund. Applicant left totally unprovided for, and obtained post as manageress of a boarding-house in London, but owing to the war the house has been closed, and she is now out of work. Has one son who is a permanent invalid. Voted £12 in twelve instalments.

Widow, aged 67, of M.D. Dubl. who practised at Widnes, Lancashire, and died in August, 1915. Applicant had been separated from her husband for some years owing to his habits. Was left totally unprovided for at his death. Is an invalid and has lost the sight of one eye. Has two daughters, aged 22 and 9, and one son aged 16. The eldest daughter is a nurse. Applicant has a home temporarily provided by friends. Voted £10 in two instalments.

Daughter, aged 68, of M.R.C.S. Eng. who practised at Cambridge and Cheltenham and died in 1887. For some years has just managed to earn a living by keeping a boarding house at Westcliff, but owing to the war has not had any visitors, and has had to sell her home to provide rent and other expenses; only income £35 per annum. Voted £12 in twelve instalments.

Daughter, aged 65, of M.D. Edin. who practised at Spalding and died in 1896. Has only a very small permanent income, and relatives who have helped her in the past are now unable to do so. Voted £12 in twelve instalments, and referred to the Guild.

Daughter, aged 64, of M.D. Edin. who practised at Newark-on-Trent. Applicant lives in own house, which is heavily mortgaged, and the little investment she has is not paying dividends owing to the war. Has a lady boarding with her who only pays a nominal amount. Voted £10, and referred to the Guild.

Daughter, aged 22, of M.P., C.M. Aberd. who practised at Methick and died in 1909. Mother of applicant died this year. The applicant is the oldest of six children, the three youngest of whom are at school. Of the other two, one boy aged 19 has joined the army, and the elder is a clerk earning £1 per week. Only permanent income £27 10s. per annum. Applicant is desirous of keeping the home together. Voted £10 in two instalments, and referred to the Guild.

Widow, aged 50, of M.R.C.S. Eng. who practised at Bexhill-on-Sea and died in 1912. Was left unprovided for with two daughters, now aged 20 and 11. The eldest earns about £1 per week as a clerk. The applicant's health is very bad, and she is quite unable to undertake any employment. Relieved three times, £30. Voted £10 in two instalments.

(To be continued.)

British Medical Journal.

SATURDAY, DECEMBER 11TH, 1915.

REST AND FOOD OF MUNITION WORKERS.

LAST September the Minister of Munitions, with the concurrence of the Home Secretary, appointed a Committee on the Health of Muniton Workers, to consider and advise on questions of industrial fatigue, hours of labour, and other matters affecting the health and efficiency of workers. The Committee intends to issue a series of memorandums dealing with such questions as hours of labour, industrial canteens, the employment of women, and sickness and accidents. The members of the Committee have taken evidence in London and other important centres from employers and representatives of the workmen, and have visited a large number of controlled factories and workshops. In another column the constitution of the Committee is stated, and a short account is given of the two memorandums on Sunday labour and on industrial canteens respectively, which have already been issued.

As soon as the war began overtime was prolonged in muniton factories, so that men worked even fifteen hours a day and seven days a week. Night and day shifts were instituted, and the change from night to day was made in many factories by the men working an eighteen-hour shift—for example, from 6 p.m. on Saturday to noon on Sunday, the other shift working from noon on Sunday to 6 a.m. on Monday. Such pressure of work might be sustained for a short period, the workers being keyed up by the high wages earned—double pay on Sunday—and the country's need of their exertions, but it is physiologically impossible that such hours should be endured for the long period which the war has, and will, occupy. Tired nature compels the workers to lose time, and then nothing is gained by the long hours; there may even be loss owing to staleness and a general lowering of health and efficiency. It must be remembered that not only has Sunday labour been the rule, but the usual holidays have been greatly curtailed. It is on the highest skilled workers, such as the toolmakers—most in demand—and on the executive—the brains and organization of the work—that the continuous labour and excessive hours of work have most heavily told. "These individuals have never spared themselves, they carry a heavy burden of responsibility, and they cannot be replaced." So topsy-turvy, too, are the present economic conditions that we have heard of piece workers earning half as much again as their charge hands, who are on a fixed salary. The representative of one important firm told the Committee that it had recently extended the relief at the week-end and reduced the average weekly hours from $78\frac{1}{2}$ to $65\frac{1}{2}$ hours. Though the normal hours were thus reduced by 13, the average number of hours (60) worked during the three months succeeding the change had, he said, exceeded the average number of hours ($59\frac{1}{2}$) worked during the six months preceding the change. Moreover, in his opinion, the output was improved. The employers have been coming to the view that

Sunday work does not pay. If the workers lose time in the week, they have to be stopped from earning double pay on Sundays, and thus the Sunday rest is given to those who need it least. The evidence obtained from trade union officials is that the men are getting "fed up," and that much of the time lost is to be attributed to the fact that the men feel they want more rest. They would rather have the Sunday holiday and lose the double pay. The Committee justly considers "that the discontinuance of Sunday labour should be of universal application and should extend to all classes of workers, except that where the work must necessarily be continuous special arrangements will be necessary." The employment of women and boys and girls on Sundays is particularly deprecated. Should it prove difficult, if not impossible, to bring about the early stoppage of all Sunday work, it should, it is considered, at least be practicable to lay down the principle that Sunday labour is a serious evil to be steadily and systematically discouraged and restricted. The Committee suggests several ways in which present conditions may be mitigated, even if the full return is not made to the one day off in seven. We trust that the Minister will not content himself with merely circularizing the advice of the Committee, but will give it the necessary power to ensure that its recommendations are carried out. The workers, from all the accounts that have reached us, have responded with praiseworthy and extraordinary zeal to the long hours of labour demanded of them. They work in the face of the greatest discomfort in crowded factories which, since they are occupied continuously, can never be thoroughly scoured out with fresh air, for they are now occupied during the hours of night when under normal conditions they would be empty. It must be remembered also that both men and women suffer also because means of transit are slow and the vehicles crowded.

Moreover, housing difficulties are very great in some districts, and in such neighbourhoods, and perhaps even more in places where the working population has been very largely increased owing to the setting up of muniton factories, the facilities for getting nutritious meals in comfort must often be inadequate or altogether deficient. This consideration has led the Committee to issue another very interesting memorandum—on industrial canteens. The problem is to supply suitable food at a low price for large numbers of persons at specified times. Independent enterprise has provided improved coffee-houses and refreshment rooms, and philanthropic effort has done something, but in existing circumstances, at any rate, much more is necessary, and the Committee considers that the most hopeful plan is the establishment by employers of industrial canteens or workpeople's dining-rooms in or near the factory itself. Various partial expedients may be successful when circumstances are specially favourable, but the need can only be effectively met, at least in many instances, by establishing a dining-room supplying cheap hot and cold dinners in association, if possible, with an institute or club affording facilities for rest and recreation, including rest rooms, baths, and perhaps a gymnasium, a roof garden, and even education classes. It is estimated that a dinner consisting of meat or fish, with two vegetables, pudding, and bread and cheese, can be supplied for 6d. to 1s., and non-alcoholic beverages for from $\frac{1}{2}$ d. to 1 $\frac{1}{2}$ d. It is recognized that any canteens which may obtain permission to sell alcoholic beverages will require particularly careful supervision. On this point, however, the Committee says that it has been impressed not only by the improved nutrition

manifested by the users of a canteen, the prevalence of a spirit of harmony and contentment, and an increase of efficiency, but also by a lessened tendency to excessive consumption of alcohol.

The Committee has a great opportunity not only to remedy the grosser defects produced by the existing pressure and shifting of work, but to make what ought to be a permanent advance towards the scientific management of manual labour and the greater efficiency and happiness of manual workers. We welcome the practical nature and good sense of its first memorandums.

MUSIC, EMOTION, AND MUTISM.

THE power of music to evoke emotions and memories is well known, but as Dr. Ormerod observed in the discussion which followed the delivery of the philosophical and suggestive address by Dr. Mott before the Society of English Singers (p. 845), the process may in some instances be extremely subtle and difficult to understand. Dr. Mott shows that a perfect psychic mechanism is as necessary for the production of perfect vocalization as is a perfect physiological mechanism thoroughly under control. For successful dramatic singing the perfect and co-ordinated action of the series of mechanisms necessary include the control of the breath in the manner he indicates, an adequate compass, rich quality, due partly to the construction of the resonator, but in great measure to its proper use under the control of the will, and the power to express the emotions and rouse the feelings of an audience.

Dr. Ormerod pointed out that the reaction in the mind of the hearer might go beyond that at which the singer or, indeed, the composer aimed, and he mentioned the case of a lady, the pupil of a distinguished composer, whose mother would beg her not to sing one particular song of his. Yet the daughter had no notion what distressing emotion was evoked by it or why. Music in its appeal to the hearing, like odours appealing to the lower sense of smell, might open up obscure labyrinths of feeling—the "vestigia intercommunia sensus."

Dr. Aikin, the honorary secretary of the society, observed that Dr. Mott's work, which came so near to the very source of artistic expression in song, seemed to establish a psychic technique controlling the emotions which express themselves naturally in the breath. The breath in its turn, as the physical source of sound, supplied the foundation of phonological technique which carried out the natural and educated uses of the organs in vocalization and diction. While the phonologist can only follow the phenomena of the voice down to their breath foundation, Dr. Mott has carried his investigations from the emotions up to their influence on the breath. Thus continuity is established and it is shown that the meeting place of the psychic and physical forces is the breath. This important principle calls for careful consideration and shows clearly the necessity of psycho-physiological inquiry in matters concerning education.

Incidentally Dr. Mott dealt at some length with the subject of mutism produced by shock, and discussed the problem in the light of some remarkable cases he had observed among men suffering from shell shock, who, though they had no visible signs of injury, had lost their speech while yet quite able to write a lucid account of their experiences. Dr. Ormerod expressed the opinion that the condition thus produced by violent emotion in men presumably

healthy corresponded exactly with that which lesser emotions could produce in neurotic patients, which we are wont to call hysterical mutism. Why such emotion should particularly affect the function of speech was, he thought, hard to explain. But the fact had long been known. Virgil described the condition of terror in the well-known line:

Obstupui, steteruntque comae, et vox faucibus haesit.

The Bible phrase is, "My tongue clave to the roof of my mouth." Excellent instances of emotional mutism could, he added, be found in the Bible and in Herodotus. The return of the lost speech, which could as a rule safely be predicted, was often sudden and complete, and might take place during a dream, as Dr. Mott had pointed out, or from some emotion in the waking state, or in circumstances which seemed quite trivial and inadequate. This is a problem of no less psychological interest than the original loss of speech.

The analogy of such cases to those of loss of sight, or at any rate the power of interpreting visual images which apparently must be formed upon the retina, will occur to every one. Such cases are commonly regarded as functional, and are characterized by impairment of sight, contraction of the visual fields, photophobia, and blepharospasm. The symptoms are, in the majority of cases, due no doubt to functional derangement—a form of traumatic neurosis—but, as Dr. Jameson Evans of Birmingham points out in a paper published in this issue, this is not always the case, and he enumerates a number of definite lesions which may be present without any superficial sign of injury, or following such slight surface injuries that it is impossible to regard the latter as the true origin of the organic lesions of the eye.

TUBERCULOSIS AMONG SHOEMAKERS.

IN an article giving an account of the first year's work of the Medical Research Committee, published on November 20th (p. 754), it was stated that though the Committee had felt that its most urgent duty was to co-operate with the War Office by conducting researches into problems raised by the war, the research work done on its behalf in other directions though diminished had not been altogether discontinued, and special reference was made to inquiries into the incidence of phthisis in particular occupations and industries. It was stated that a special investigation committee, with Dr. Addison, M.P., as chairman, and as members Dr. Leonard Hill, Dr. Benjamin Moore, and Dr. Brownlee, of the Committee's scientific staff, and Dr. E. L. Collis, medical inspector of the Factory Department, Home Office, had begun an inquiry into the incidence of phthisis among workers in boot and shoe factories, leather and hide works, and printing shops.

A report has now been issued on the boot and shoe industry. Statistical returns have for many years past pointed to this particular industry as being associated in too high a degree with tuberculous disease, and the double purpose of the inquiry has been to ascertain the contributing causes of the fact and to suggest any possible amendments by which they might be counteracted.

The Committee in its report explains in detail the conditions under which bootmaking is carried out at the present time, and the changes of method which have followed the introduction of machinery to replace hand work. The strain upon the physical

powers of the workers has undoubtedly been considerably relieved in some of the operations of bootmaking that formerly involved a cramped position for many hours in the day, but it would seem that there is still room for improvement in this respect. The machines used in one department are for the most part small and numerous, and there is an attendant upon each. The work requires little active exercise, and the workers, in their desire to keep warm, do not carry out the prescribed rules for ventilation. The rooms become hot and stuffy, the machines in many cases produce a good deal of dust, and the windows, when kept tightly closed, are usually semi-opaque with accumulated dirt; the net result is to produce the very conditions under which it is believed that tuberculosis may most easily be spread if there should be a case of active disease among the crowd of workpeople of either sex. Sitting in close proximity and often facing one another, the operatives must be at all times liable to infection from any of their fellows who suffer from frequent coughing, even if there be no actual distribution of sputum. It is shown that a direct relation subsists between the departments where sedentary work is carried on and the incidence of phthisis. In some other workrooms, where larger machines are used and heavier work is undertaken, the hygienic conditions are better and proper ventilation is observed, the fear of chills and draughts being less marked owing to the more active nature of the work. In most of the factories reported upon it would seem that proper means are provided, but that the operatives themselves will not consent to make right use of them.

It follows from this that educational rather than structural amendments are called for, and with this object in view the Committee makes several valuable suggestions, which deserve very careful consideration on the part of factory managers and others responsible for the conditions under which large numbers of operatives are required to work for long hours in enclosed premises. A system of compulsory exercise is recommended, for a definite time each day, in the form of easy drills or other combined movements, and the avoidance of long four-hour spells of work without a break, more especially for girl workers. In some factories such a system has been found to be of advantage in every respect. More and better work is done, while the standard of health is raised. By the introduction of electric fans to keep the air of the workshops in movement, and by placing the whole system of ventilation out of the control of the occupants of the room, and by the compulsory cleaning of windows, much of the present defect may be removed, but there still remains the individual sufferer from chronic cough to be dealt with. While still able to tend his machine and to turn out his due proportion of work, such a person may be a constant source of danger to others. Compulsory powers to remove a consumptive patient to a sanatorium or otherwise segregate him do not exist, and the pregnant idea is mooted in the report that a sanatorium might be affiliated to the factory, in which the consumptive workman might continue his work, within limits to be prescribed by medical authority, but at the same time be under constant supervision and compelled to live a strictly hygienic life. This idea is one capable of very wide application, and doubtless there are many other trades where small machines are employed and where the work could be carried on by consumptives in various stages of disease, if only the requisite accommodation could be supplied in a sanatorium as a part of the factory itself. Already many large industrial undertakings

are provided with their own hospital accommodation, but the patients do not return to their work until their convalescence is complete. Very many of these would be quite equal to a moderate amount of work each day if the means for doing it were provided, and in the case of the consumptive, where the convalescent stage is of necessity prolonged, the opportunity for earning a little money and for occupying the mind would undoubtedly be welcome.

The adoption of such a scheme would naturally require some adjustment as regards the terms of insurance and sickness benefit, but the difficulty should not be insuperable.

A CLASSIFICATION FOR MEDICAL RECRUITING.

THE scheme of classification which has been under the consideration of the Central Medical War Committee for some time past is published in the SUPPLEMENT for this week, together with an explanatory letter addressed to the secretaries of local Medical War Committees in England and Wales. The scheme is comparable to that elaborated by Lord Derby, but the groupings are different in character and are to be used in a somewhat different way. The size of the armies now contemplated in this country makes the problem of the future very serious; and it is by no means certain that it may not be necessary for almost one-half of the medical profession to be in military service next year. To prepare for this possibility it is essential that every man of military age who is physically fit should declare his readiness to place himself at the service of his country if called upon to do so. The only method by which he can achieve this is by placing himself unreservedly in the hands of the national Medical War Committees, which, with the assistance of the local Committees, are able to decide, in as equitable a manner as the circumstances allow, in which direction each individual's duty lies. In the opinion of the Central Medical War Committee, patriotism demands that every eligible man, whatever may be his views as to the value of his own work, should sign an application for a commission in the R.A.M.C., and hold himself in readiness to make every sacrifice in his power for his country whenever it becomes plain that the holding up of his application is no longer justified by the nature of his employment in civil life. To talk about waiting until he is taken under the compulsion of conscription is unworthy of a member of the medical profession. Far better to show at once that he is willing to go without further question as soon as those in touch with the authorities are convinced that his services are needed in the army. Since the meeting of the Central Medical War Committee a fortnight ago, several important interviews have taken place between representatives of that Committee and various Government departments. In so large a scheme it is obviously necessary that all parts of the work throughout the country should be co-ordinated. It would not be politic to let the patriotic feelings of the doctors of one area run away with them to such an extent that they would forsake the necessary medical services of the civil community to go to war whilst there were a considerable number of medical men left in other districts who were not called upon to do their share. It is obvious that the difficulty of sparing medical men differs considerably in different parts of the country and in different types of practice. A man who has an appointment at a fixed rate of pay generally has some sort of goodwill attached to his post which he is able to retain even though he is temporarily absent and his work is carried on by a deputy. On the other hand, a practitioner who does work amongst private people, particularly in town districts, is wholly dependent for his goodwill on his continual and personal application; no

substitute can wholly make up for his absence. It is obvious that the first class of man can go to the war more easily than the other, and between these there are all grades. It is as the result of the recognition of these difficulties that the Central Medical War Committee has prepared a scheme to be a guide to the local committees. The Committee particularly wishes it to be understood that this classification is not to be regarded in any sense as a time-table; by that it is meant that those put in the early classes need not necessarily be on service before any in the last classes should be asked to consider the desirability of volunteering. The position of men in public services must, of course, be considered in relation to the Government departments responsible for their work; the views these departments take, and, indeed, have expressed, both in circulars and by the way they have dealt with applications for leave of absence by individual medical men, has been exemplary. The Central Committee is urgent in its request that the canvass of medical men under Lord Derby's scheme should be undertaken without fail in every area of the country. This is being done already by some local committees, who have put the actual canvassing in the hands of senior medical men of the district. This matter should not go by default, for it is likely that if the medical profession fail to seize this opportunity of arranging its own affairs the work of canvassing may fall into the hands of lay canvassers either under Lord Derby's scheme or whatever other scheme may follow it. All these efforts of the Committee are directed to the future; provision must be made for the continuance of a supply of medical men for the military services as the necessities of our growing armies increase the demand, but the Committee hopes that those men who can go now or at an early date will send in their applications for commissions without delay. All the rest, to whom the difficulties of freeing themselves seem insurmountable, should place themselves unreservedly in the hands of the Central, the Scottish, or the Irish War Committee, as the case may be, feeling assured that the Committee will not call upon them for service until such time as the demands of the war render the need for them imperative.

MAGNESIUM CHLORIDE AS CYTOPHYLACTIC.

LAST September Delbet and Karajanoğlu reported to the Académie de Médecine the results of their most recent researches into the influence of magnesium chloride in stimulating phagocytosis. From observations *in vitro* they found that the action of a solution of 12.1 per 1,000 of anhydrous magnesium chloride in stimulating phagocytosis was 75 per cent. greater than that of a solution of sodium chloride (8 per 1,000), which itself caused 63 per cent. more than Ringer's solution, and 154 per cent. more than isotonic sea water. They next ascertained that this cytophylactic action of magnesium chloride was to be observed when an intravenous injection was made during life. Their first experiment consisted in injecting 150 c.c.m. of the 12.1 per 1,000 solution into the saphenous vein of a dog weighing 16 kilograms. On comparing the phagocytic action of the blood taken before and thirty-five minutes after the injection they found that in the first specimen 500 polymuclear corpuscles took up 245 microbes, and in the second 681, an increase of 180 per cent. They then by a rather elaborate experiment, details of which were not explained, ascertained that an even more marked result occurred when the phagocytosis took place in the circulating blood itself; the increase in the case of the *Bacillus coli* was 333 per cent., and in the case of the *Bacillus pyocyaneus* and cocci 129 per cent. The injections did not produce any toxic symptoms, but they had not made them in man, although they had used the solution of magnesium chloride for dressings and subcutaneously with good results. At the meeting of the

Académie on November 23rd² M. Pinard reported very favourably on the use of a solution of magnesium chloride in the treatment of wounds; owing to the difficulty of obtaining the anhydrous salt he had used the crystallized salt in corresponding proportion, which was calculated to be 17.5 per 1,000. The solution actually used was made by dissolving 18 grams of crystallized magnesium chloride in 1,000 grams of sterilized water. In treating the wounded from the battle of the Marne Pinard had used antiseptics, but after October 12th, 1915, he had entirely abandoned their use, and all the wounded from the Champagne actions were treated solely with the magnesium chloride solution. All the cases when received had infected wounds, which were suppurating freely. The wounds were irrigated with the solution and covered with a thin layer of sterilized absorbent wool impregnated with the solution. All cases which were suppurating, or which presented anfractuons wounds of the muscles or bones, were dressed during the first five days twice a day, after that once a day. No drains were used, and any counter openings considered necessary to afford free exit to the pus were small. The results, Pinard stated, were such as he had never before witnessed. Alike in wounds of muscles and those which involved bones, suppuration diminished very rapidly and the foul odour progressively grew less. Amputation wounds did extremely well; the epidermis extended from the edges with astonishing rapidity, as the neck of a bag is drawn in by a string, and in no case was it necessary to cauterize exuberant granulations. The stumps in some of the cases in which the amputations had been performed on September 25th, 26th, 27th, were completely cicatrized on November 23rd, but in a few there was a small fistulous opening leading down to the bone; in such cases the wound was irrigated with the solution every day, and the amount of excretion diminished daily. In wounds involving bones suppuration diminished rapidly, and the exposed bone either became detached in small fragments, each irrigation bringing away particles, or the bone became red and covered with granulations. If all the intricacies of the wound were thoroughly irrigated, the offensive odour of the discharge disappeared generally in a few days and callus formed rapidly. Only one case went wrong—a case of amputation through the thigh. In that the stump was very short, and it was difficult to keep the dressing in position; erysipelas developed. Two subcutaneous injections of 80 c.c.m. of the solution were made, one at the back of the stump, and the other at the upper margin of the erysipelatous blush on the skin. The temperature fell within twenty-four hours. The injections were repeated on the next and following day, the general symptoms disappeared, and the temperature fell to normal after, on the third day, a small abscess containing inodorous pus at the back of the stump had been incised. In another case of severe wound of the knee, with a temperature of 104° F. and abundant offensive suppuration, in which arthrotomy appeared urgent, the joint was thoroughly irrigated, every pocket being carefully washed out until the fluid returned limpid. The irrigation was repeated daily, and on the ninth day after admission suppuration had stopped and the temperature had fallen to normal. "When I compare," Pinard said, "the results I obtained with the wounded from the battle of the Marne, which I treated with antiseptics, with those I have recently obtained with the wounded from the battle in Champagne treated with the solution of magnesium chloride, the conviction that a great advance has been achieved is forced upon me."

GLANDULAR PARTIAL HERMAPHRODITISM.

DR. BLAIR BELL³ has had an opportunity of studying a case in which a patient commenced life and passed puberty as a normal woman, menstruating regularly for

² *Bull. Acad. de Méd.*, November 23rd, 1915, p. 577.

³ So-called Hermaphroditism, with the Report of a Case, *Proc. Roy. Soc. Med.*, vol. xiii, 1915, p. 77.

¹ *Bull. Acad. de Méd.*, September 7th, 1915, p. 266.

eighteen months. The catamenia then ceased, and masculine characteristics developed. At the age of 19 the voice had become deep, a small moustache had developed, and the distribution of hair on the surface of the body was noted to be of the masculine type. An exploratory operation was performed. The left genital gland was enlarged to the size of a plum, and a wedge-shaped piece of tissue was excised for examination. The right genital gland presented the appearances of a rather small normal ovary. After a piece had been excised, a graft taken from an ovary removed from a patient under operation a few minutes previously was implanted in the uterus. The wounds in the genital glands were closed with catgut suture. There was no evidence of disease of the suprarenal glands. The microscopic appearance of a section of the piece taken from the enlarged left genital gland simulated columnar-celled carcinoma. In consequence, Dr. Blair Bell removed both genital glands and Fallopian tubes, with the fundus of the uterus. The after-history was remarkable, for the patient, who had ceased to menstruate for about three years, all menstrual molimina having disappeared as well, nevertheless became subject to slight menopausal symptoms. The right genital gland proved to be a small normal ovary, not in a highly active condition. The left genital gland was a true ovo-testis. The naked-eye appearance was instructive, the gland on section showing a pale cortex presenting all the appearances of an ovary, and a dark medullary portion. On microscopic examination the cortical part was seen to be made up of true ovarian tissue, with normal Graafian follicles; the more central portion was testicular tissue, made up of seminiferous tubules and testicular interstitial cells. No spermatogenesis, however, was seen. Dr. Blair Bell classifies this case under the head of "glandular partial hermaphroditism." We have had occasion to describe cases of gynandry and androgyny within the last few years, but recently the subject has been investigated with the indispensable aid of perfect microscopic technique. Total hermaphroditism—the power of self-fertilization or at least of fertilizing others and of being fertilized—is limited to invertebrates. Partial hermaphroditism, on the other hand, is known to exist in man. As judged by the strict standard of histological investigation, all the recorded cases except one of glandular partial hermaphroditism have been found to possess mixed gonads or ootestes with or without irregularities in the sex characterization of the genital ducts, external genitalia, and secondary characteristics. Dr. Blair Bell agrees with Pick and Tuffier and Lapointe in holding that all cases reported and accepted as "true hermaphroditism" should be called "glandular partial hermaphrodites." The ootestis has been detected in ungulates, moles, and other mammals, as well as in man.

RIVERS OF DAMASCUS.

SINCE the earliest days of civilization mankind has been in the habit of resorting to natural mineral waters for the cure of disease, by either internal or external application. Nowadays, it need hardly be said, spa treatment and treatment by draughts, baths, douches, sprays, and other applications of spring waters have become a necessity for the holidays and medical welfare of the upper and middle classes, and a highly valuable medicinal luxury for the poorer members of society to whom they are prescribed by medical advice. Many of the European springs of natural mineral waters hitherto most frequented are within the boundaries of the Central Powers with whom we are at war. For the present, therefore, they are not available for our invalids, and it seems likely that in the future also their utility will be seriously restricted so far as we are concerned. What are we to do about it? Obviously the time has come to give our own natural spring or mineral waters the more extensive trial their

merits have long deserved. Whatever may have been true of Syria in Naaman's time, there is good reason for believing that our own insular Abanas and Pharpar will prove on trial at least as valuable to invalids as many of the German and Austro-Hungarian waters of Israel. Dr. Sutherland has written an interesting historical account of the spas, baths, and wells of London,¹ in which he shows that for the most part the Londoner's rivers of Damascus, never of any great medical potency, have now, alas! dried up or become impoverished to such an extent as to render them medicinally valueless. Before it was built over and drained in the eighteenth and nineteenth centuries, the London area seems to have been as rich in natural springs as was many fountains' Ida in the time of Enone. Dr. Sutherland catalogues no less than twenty-three holy springs and wells, or sources dedicated to saints, in Old London; nineteen wells used for drinking purposes; two score public wells with pumps; and half a score bathing pools supplied with natural water of more or less medicinal properties. In addition he gives details of some nine medicinal springs in London itself, and over twenty more in its suburbs and vicinity, that have had their vogue during the last two hundred and fifty years. Many of these furnished chalybeate waters, the others contained larger or smaller quantities of magnesium sulphate in solution. In many instances spas were established and exploited at these medicinal wells or springs from the latter half of the seventeenth century onwards, but by the end of the eighteenth century the prosperous and palmy days of the majority of the London spas—or "spaws," as Dr. Johnson wrote the word—were over. No less than eight London spas existed within a mile of the present King's Cross. Dr. Sutherland enumerates twenty-five others that flourished for a time in and around London, including the celebrated spas of Hampstead, Kensington, Kilburn, Marylebone, Bayswater, Richmond, Shooter's Hill, Streatham, and, last but not least, Epsom. It is sad to have to record the fact that at the present time the spas of London and its environs have decayed, leaving but a couple of decrepit survivors south of the Thames. Abana and Pharpar have, in fact, dried up or become demineralized to such an extent as to rob them of medicinal value. Their day is passed, but Dr. Sutherland points out that there are plenty of other spas of sterling worth in England, Scotland, and Wales to which patients may be sent with the utmost advantage. In many of them the various forms of treatment necessary may be carried out quite as efficaciously and satisfactorily as at the foreign stations now closed to our invalids. The Londoner can no longer get spa treatment in or near London, it is true, but he will find himself excellently served at twenty British spas in the country.

THE SOLDIER'S DIET.

PROFESSOR FILIPPO RHO has published recently an essay on the feeding of soldiers in peace and war. The two chief points in it are—first, the repeated statement that the ration is too rich in nitrogenous content; and, secondly, that alcohol should be prohibited, although it is admitted that it may be an occasional addition to the dietary, but only with meals and when work is done, not as a preliminary to work; tea and coffee, well sugared, are, Professor Rho considers, much more useful in this respect. Although alcohol provides some calories, it is always rather an anarchic element—"consuming like a burning faggot, and not like charcoal, in a slow and lasting fashion." Like many writers on dietetics, he is much influenced by Clittenden's results; for the soldier, who is often still growing, he would allow 100 grams of nitrogenous food, 70 grams of fat, and from 300 to 600 grams of carbohydrate, according to the work required, the

¹ *Old London's Spas, Baths, and Wells*. By S. Sutherland, M.D. London: John Bale, Sons, and Danielsson, Ltd. 1915. (Demy 8vo, pp. 280; 35 illustrations. 7s. 6d. net.)

minimum diet giving 1,934 calories and the maximum 3,378 calories. He considers that the diets of practically all armies err on the side of providing an excessive amount of nitrogenous food, and the English are, he thinks, amongst the worst. It is even suggested that some of the so called trench diarrhoea is due to excess in nitrogenous food. Professor Rho realizes that the modern scientific results seem to suggest a reduction in the nitrogenous content of the diet as advisable, yet it is necessary to proceed slowly in making radical alterations when dealing with masses of men, for the majority are still believers that to be strong plenty of strengthening things such as meat must be taken. He gives this as a reason for not making detailed recommendations, but contents himself with explaining the results of recent work in dietetics, and how far practical experience has borne them out. It is interesting to read that according to calculations recently made, the rations of the old Roman legionary worked out at 123.57 grams albuminoids, 25.22 fats, 429 hydrocarbons, and 25 alcohol, giving a total of 2,482 calories.

ANTITYPHOID VACCINATION IN NORTH AFRICA.

The bacteriologists of the Algerian Pasteur Institute have been actively employed during the last sixteen months in preparing antityphoid and antiparatyphoid vaccines for the French North African army, using Vincent's method of preparation, and also finally heating the vaccine to 55° C. for an hour.¹ In Algiers, what is commonly known as typhoid fever has been very carefully studied by Roussel. In two and a half years between 1911 and 1913 he made 303 positive cultivations from the blood of typhoid patients. The microbe grown was the *Bacillus typhosus* in 227 cases, *B. paratyphosus* A or B in 72, the A variety being more often met with than the B; in the remaining four cases Roussel found two new intermediate types of paratyphoid bacillus which he terms C (three cases) and D (one case). The vaccine employed was designed to protect against the first three of these. Each cubic centimetre contained 400 million typhoid bacilli, and 200 million paratyphoid A and B combined. Four inoculations were made, containing respectively $\frac{1}{2}$, 1, 1 $\frac{1}{2}$, and 2 c.c.m. of the vaccine, in each case. Over 100,000 soldiers were treated in 1914-1915; it was noted that the local and general reactions were no more severe with the mixed vaccine than they had been up to October, 1914, when a simple antityphoid vaccine was in use. The results of the employment of the mixed vaccine are described as most satisfactory throughout the North African army. In Algiers itself both typhoid and paratyphoid A and B fevers are endemic among the unprotected civil population; several hundred cases are treated yearly in hospital. But no case has occurred among the fully inoculated soldiers of the garrison at Algiers; nine have been recorded among the few non-inoculated soldiers, and five among those who were in process of being inoculated.

STATISTICAL PSYCHOLOGY.

Those who have dissented from the belief so industriously propagated that modern science is mainly a product of "Kultur" must view with satisfaction the recent history of statistical methods. The school founded by Galton, and developed by Karl Pearson, composed, as far as its most distinguished members are concerned, exclusively of British and American citizens, has profoundly modified the technique of workers in apparently unrelated fields of investigation. In biology and anthropology, even those who decline to adopt the conclusions of the biometricians have been forced more or less unconsciously to use their methods. On medicine and pathology the researches of Sir Ronald Ross, Brownlee, Greenwood and others, not to speak of those of Professor Pearson himself, have left impressions, while in the study of sociological and economic

phenomena the modern English statisticians have had matters very much their own way. No subject, however, has been more affected than psychology, and Dr. Edward Webb's thesis, entitled, *Character and Intelligence*,¹ is a conspicuous illustration. Dr. Webb has applied statistical methods to data derived from two groups of students at a training college, numbering 98 and 96 respectively, and to four groups of school-boys totalling 140. From an analysis of a large number of coefficients of correlation, Dr. Webb reaches the following main conclusions: In the first place, he considers that the existence of a common central factor of intellectual energy—a factor to which attention was first directed in recent times by Spearman—is demonstrated by his results, which fully confirm those of Spearman and his co-workers. In the second place, he thinks that another general factor more specially prominent on the "character" as distinct from the purely intellectual side of mental activity, must also be postulated. He puts forward the tentative suggestion that this second factor stands in some close relation to "persistence of motives." We cannot attempt here to discuss the method adopted; it must suffice to say that everything turns upon the significance of certain coefficients of total and partial correlation. Dr. Webb has very properly been on his guard against various sources of material error, and has brought to light certain fallacies which might not have been expected *a priori*. The value of his work is unquestionable, although it is open to attack on the purely mathematical side. It appears to us that Dr. Webb has not fully grasped the nature of the criticism to which some of Professor Spearman's work has been subjected by, for instance, Professor Pearson and Dr. William Brown. Some of Professor Pearson's criticisms of Professor Spearman's approximate methods of computation are indeed unanswerable, and it cannot be said that the processes of eliminating "observational errors," which Dr. Webb appears to regard as unimpeachable, are really so. A still more important question is the computation of a "probable error." Dr. Webb gives the ordinary formula for the "probable error" of a coefficient of correlation; but we doubt whether he has altogether realized the essential limitations of that formula and the difficulties involved in the evaluation of random errors when we have to deal with small samples, even if random, especially when the correlation is very high or very low, not to speak of the complications introduced where clustering is a possibility. The recent papers of Soper, "Student," Fisher, and others are of importance in this connexion, while, with regard to clustering, Soper has justly observed, in a recent letter published in *Nature* (September 9th), "In all cases where a space or time content is taken as the sample it is necessary, owing to unknown clustering, to repeat the sample many times over before a just estimate of the statistical constants and of their probable errors can be obtained." These remarks may seem hypercritical, but the importance of Dr. Webb's conclusions is so great that the steps by which they are reached merit the closest scrutiny. Dr. Webb is to be congratulated on the performance of a valuable and laborious piece of work.

AMOEBAE IN PYORRHOEA ALVEOLARIS.

DENTISTS have hitherto looked on pyorrhoea alveolaris either as a general disease with local manifestations or as a local disease of bacterial origin. Lately, however, it has been suggested that it is a local disease of amoeboid origin. In particular Bass and Johns are exponents of this view, and in a short memoir,² which gives evidence of much thought and careful study, they maintain that both the

¹ *Character and Intelligence* (British Journal of Psychology, Monograph Supplements No. 3), (A Thesis approved for the degree of Doctor of Science to the University of London). By Edward Webb. Cambridge: At the University Press, 1915. (Pp. 99. 8s. net.)

² *Alveolar Pyorrhoea*. By C. C. Bass, M.D., and F. M. Johns, M.D. Philadelphia and London: W. B. Saunders Co. 1915. (Roy. 8vo. Pp. 167; 42 figures. 12s. net.)

¹ L. Sergeant and L. Nègres, *Bull. Acad. de Méd.*, Paris, 1915, lxxiv, 469.

cause and the cure of what they prefer to call alveo-dental pyorrhoea have been established beyond dispute. The cause is the *Entamoeba buccalis*, and the cure emetic, which causes rapid disappearance of the amoeba. They have found the parasite in more than 300 cases in which the disease had developed to an extent which permitted it to be diagnosed, but have always failed to find it in microscopic preparations that contained no pus. The special "habitat of the organism is the dying tissue at the bottom of the lesion (the pocket) where bacteria and other agencies are few or absent . . ." Other evidence that the entamoeba is the specific cause of alveo-dental pyorrhoea is "the very certain and rapid results that follow treatment with a specific amoebicide, whether applied locally or given hypodermically." They believe that the *Entamoeba buccalis* finds a suitable habitat in tissues injured by trauma, such as misuse of the toothpick or dental silk, and that by its motile activities it implants into these tissues the bacteria which adhere to it. It thus ensures a constantly deepening infection. Once the amoebae are destroyed the tissues are given a fair chance of healing, but pockets must be mechanically destroyed, since reaccumulation will keep up the irritation and prevent healing. Whatever may be the part played by the entamoeba, there is no doubt of its presence, though the fact that it is found most abundantly in the depths of the pockets, that is, in the well-developed lesion, may suggest to some that it is rather a secondary than a primary factor. It has, indeed, been regarded as a scavenger. Further, the trauma which is postulated as necessary for its implantation (by providing injured tissue) is by no means a necessary factor to the development of the disease, which habitually attacks the most secluded spots. The results of using emetic are said to be very good, but we are not told of any cases treated by this drug alone. A statement as to the local treatment accompanying its use ought to have been given, since by thorough local treatment the disease may always be cured—so far as cure may be spoken of in a recurrent condition—and the use of a rather uncomfortable drug avoided. But the opinion expressed is worthy of consideration, and it is to be noted that they have been able to fix the entamoeba by heat. The essay contains many good illustrations.

HYPPOCHLORITES AS PROPHYLACTIC DISINFECTANTS.

We understand that trials have recently been made on the use of electrolyzed sea water containing hypochlorites for the disinfection of hospital ships carrying infectious cases. The tests, which were made under the auspices of the Medical Research Committee, seem to have been highly satisfactory. The disinfectant was chiefly used for application to the walls and floors of the wards; it was not used in the latrines on account of possible risk of corrosion of steel pipes. The condition of the wards as regards freshness and absence of odour following the use of electrolyzed sea water appears to have been excellent and the absence of secondary infection among the ships' staffs has also been noted. The cost of the necessary apparatus and of its maintenance in use is low.

Medical Notes in Parliament.

War.

Total Casualties.—In a written answer to Mr. Molteno, the Prime Minister gave the following statistics of the total casualties in the main fields of operation respectively up to November 9th:

	France.	
	Officers.	Other Ranks.
Killed and died	4,529	69,272
Wounded	9,754	240,283
Missing	1,583	54,446
Total	15,866	379,983

Mediterranean.

	Officers.		Other Ranks.	
	Killed and died	1,504	21,551	
Wounded	2,860	70,148		
Missing	356	10,211		
Total	4,720	106,610		
On the Trenches.				
Killed and died	227	2,052		
Wounded	537	5,587		
Missing	76	3,223		
Total	840	11,862		
Naval and Marines All Fields.				
Killed and died	589	9,928		
Wounded	161	1,120		
Missing	52	310		
Total	702	12,160		
Grand total	5,422	510,230		

Mr. Tennant stated on December 2nd, in reply to Mr. Lynch, that the casualties on the whole of the west front, as far as British, Canadian, and Indian troops were concerned, during the last three months, amounted to approximately 95,000 of all ranks. In the Gallipoli Peninsula the Australians, as distinct from the New Zealand forces, had sustained approximately 25,000 casualties since their arrival. Mr. Chamberlain, on December 8th, said, in answer to Sir E. Cornwall, that the casualties in the fighting at and about Ctesiphon were 4,567. These included 643 killed, 3,330 wounded, leaving 594 not yet accounted for. He had not yet received details as to the distribution of the losses in the retreat, but the total, according to his present information, was under 300. Sir J. Nixon reported that the general condition of the wounded was very satisfactory, and that the medical arrangements worked well under circumstances of considerable difficulty.

Picric Acid.—In reply to Mr. W. Thorne, who asked a question as to the injurious effect on workmen of picric and nitric acids at Woolwich Arsenal, Mr. Lloyd George said: I am informed that as regards picric acid no ill effects are caused except a discoloration of the skin, but that workmen engaged on trinitrotoluene are sometimes injuriously affected, the degree of susceptibility varying greatly, many workers being immune. Various expedients of a sanitary and medical character are in operation to counteract the difficulty, and a weekly medical examination of all workers is carried out with a view to the transfer to other work of persons specially susceptible.

Naval Dental Surgeons.—On December 2nd Mr. R. McNeill asked why dental surgeons employed afloat were given commissions and those ashore not given commissions; and whether under Lord Derby's scheme dental surgeons employed ashore by the Admiralty were held to be indispensable and not eligible for enlistment. The Financial Secretary (Dr. Macnamara) said in reply that there were obvious differences in the conditions of service of dental surgeons afloat and ashore. The services of dental surgeons employed on shore were indispensable, and they had been granted the Admiralty war service badge, and would be given a special certificate stating that their services could not be spared, and that it was their duty to remain at their present posts.

Asylum Attendants.—In reply to Sir John Lonsdale, Mr. Birrell said that the appointment of attendants in district asylums in Ireland was vested in committees of management, whose discretion as regards the age limits was not restricted further than that the regulations could not be altered without the approval of the Lord Lieutenant. Any alteration empowering committees to require that candidates must not be of military age or fit for army service would be sympathetically considered.

Claret.—Several questions were addressed to Mr. Tennant on December 6th with reference to the issue of claret to the French troops. All he could say was that the Army Council had no information as to the comparative immunity from sickness of the British and French troops at Gallipoli, nor as to whether the ration of claret had proved a preventive of disease, but he added that it had not been shown that like results would follow if claret were served to British troops. He seemed to countenance the suggestion that Pasteur had established that claret had germicidal properties.

Midwives (Scotland) Bill.—The Midwives (Scotland) Bill passed through the House of Commons on December 2nd, and was read a third time without amendment.

THE WAR.

VENEREAL DISEASE IN THE GERMAN ARMY.

Incidence.

At a meeting of the Verein für Wissenschaftliche Heilkunde¹ in Königsberg, Dr. Scholtz stated that the incidence of venereal disease was, in his opinion, not much greater than in the war of 1870. The conditions were somewhat worse in the West than in the East; and among certain bodies of troops stationed in large towns in the West the disease was prevalent. He, however, estimated the incidence of venereal disease in the German army at as low a figure as 3 per cent. a year. This figure was, he said, all the more striking as the incidence of venereal disease among German civilians in time of peace was as high as 25 per cent. for students in large towns; it was 16 per cent. among business men and 8 per cent. among workmen. There was, however, one important exception in the case of married soldiers, among whom the incidence of venereal disease was at present higher than among married civilians in time of peace. He, as well as other surgeons, had found that a third of the soldiers suffering from venereal disease were married men.

Dr. L. Halberstaedter,² attached to the system of military railways, has described the measures which have apparently been adopted with considerable success against venereal disease among the troops. During the rapid advance of the Germans in the early phases of the war there was, it is said, little opportunity of infection, and the active hostility of the invaded districts was a further barrier to sexual indiscretions. These restrictive factors ceased as the occupation of hostile territory continued and hostilities assumed a stationary character which afforded time and opportunity for the men to have relations with the civilian female population. Particularly in large towns and industrial centres, in which even in times of peace prostitution was widespread, did the vicissitudes of the war and lack of employment pave the way for wholesale prostitution.

Preventive Measures.

In the devising of measures for the prevention of venereal disease it was recognized that facilities for indiscriminate sexual intercourse must be reduced, and that the men must be taught the dangers of venereal disease, the risks they ran by attending certain resorts, and the consequences of over-indulgence in alcohol in this connexion. Steps were also taken to provide entertainments and comforts which would help to replace home comforts. These measures, however, did not effect any marked improvement. More severe regulations were accordingly put into force. The subjects of venereal disease were to a certain extent treated as if they had contracted one of the ordinary infectious diseases, and resort was had to early diagnosis, isolation, the detection and suppression of the source of infection, and, finally, prophylactic devices. The combination of all these measures, effectively supported by the co-ordination of various authorities, including the *Sitten Polizei*, kept the disease within moderate bounds.

The Educational Campaign against Venereal Disease.

Great importance was attached to the educational work of the army medical officers. In the course of an educational campaign among the soldiers, Halberstaedter was struck by the widespread ignorance of venereal disease, its causes and consequences, among his audience. An overwhelming majority of the men did not understand the significance of the first symptoms. He had little faith in leaflets of advice, which were often too windy to be very instructive, and could not be a substitute for oral instruction. The most effective educational influence was the parade of awe-inspiring examples, such as severe cases of gonorrhoea with complications, and neglected cases of syphilis.

Inspection and Supervision of the Infected.

Second only to the educational campaign in persuading the infected to notify themselves, was the systematic

medical inspection of the men; for they realized that they would be punished if this inspection revealed unnotified venereal disease. Not only did this measure lead to the detection of the disease in an early stage, but it also contributed largely to the suppression of amateur treatment and quackery. In the first months of the war, when this systematic medical inspection was not carried out, many cases did not come under medical treatment till the victims of amateur treatment had developed severe complications. Such cases were seldom seen after the introduction of medical inspection. In one area 22 per cent. of all the cases of venereal disease were not voluntarily notified at once. This relatively high percentage of concealed cases fell rapidly; it was 22 per cent. in December, 1914, 14 per cent. in January, and only 11 per cent. in February, 1915. These concealed cases were brought to light either by an unexpected medical examination or by the development of complications which forced the infected to go on the sick list. In the middle of February, when systematic medical inspection was made effective, this state of affairs ceased almost at once; and owing to the early "voluntary" notification of infection, hardly a single case was detected at the regular inspection. During the following five months there was scarcely one case in which notification was deferred till the development of complications. The author was, therefore, greatly impressed by the efficiency of this measure, which, to be of real service, must be carried out every fortnight, no exemption from inspection being permitted. An essential condition for success was the thoroughness with which it was carried out. Each soldier should be examined by himself, both for ethical reasons and in order that the examination might be the more thorough. All the manipulation necessary should be performed by the soldier himself. When it was noticed that the soldiers had passed water just before the examination, they were referred to a later examination. This inspection led to detection of the disease at an early stage, and it was only by this measure that the detection of the source of infection and the early treatment of the disease were rendered possible.

Tracing Venereal Disease to its Source.

Within the last few months the source of infection in almost every case had been discovered in the author's district. At first, when notification of venereal disease was largely evaded, many sources of infection remained hidden, and in many cases misleading information was given. When, however, instruction in venereal disease was combined with penalties for silence, information was usually forthcoming as to the source of infection. This was most easily discovered when the patient himself accompanied the patrol or the police in search of the source of infection. Thanks to the efficiency of the *Sitten Polizei*, the discovery and internment of infectious women was greatly facilitated, and by the prompt action of the police an appreciable reduction in the incidence of venereal disease was effected.

Treatment of the Infected.

Although the diagnosis was at once followed by treatment, most of the cases of gonorrhoea had, unfortunately, already reached the stage of profuse discharge, with numerous intracellular gonococci. There was therefore seldom an opportunity for early abortive treatment. On the other hand, syphilis was often detected in the early stage of chancre. In this connexion the examination for spirochaetes was the most valuable aid to early diagnosis at a stage in which a negative Wassermann reaction was valueless. The treatment adopted was a combination of salvarsan and mercury, the opinion being generally held that the ultimate fate of the syphilitic depends on the first course of treatment. With regard to the much-debated question whether the subjects of venereal disease should undergo treatment while on active service or be sent to a military hospital, two principles should be kept in view. Isolation during the infectious period must be as effective as possible, and skilled examination and treatment must be available. In most cases it was difficult for the regimental doctor to fulfil these two conditions, and it was therefore advisable for him to co-operate with a special department devoted to venereal disease in a military hospital

¹ Berl. Klin. Woch., August 16th, 1915.

² Dent. med. Woch., October 14th, 1915.

Every patient in the infectious stage should, as a rule, be transferred to a military hospital, and should remain there till the symptoms had disappeared. Later observation and intermediate courses of treatment could be arranged for outside the hospital without materially interfering with the soldier's duties. Unfortunately syphilis were often discharged as "cured" from the military hospitals after the completion of a course of treatment; and it was very difficult in these cases to convince the patient that further observation and treatment were necessary, and that they were still a source of danger. A negative Wassermann reaction was also apt to give the patient a false sense of security. As a result of early scientific treatment the incidence of gonorrhoeal complications, notably epididymitis, was much reduced. Thus, in the first five months, October, 1914, to February, 1915, there were in one area 24 cases of gonorrhoeal complications, 20 being cases of epididymitis. In two cases gonorrhoeal arthritis had supervened, and one of the patients had developed a febrile gonococcal septicaemia with endocarditis. In the same area in the next five months, March, 1915, to July, 1915, there was only one case of epididymitis, and no other complication of gonorrhoea.

Prophylactic Treatment.

The equipment of soldiers with antiseptic preparations for the prevention of infection, was accompanied by the warning that these preparations did not constitute an absolute guarantee against infection, nor did they imply that the authorities countenanced incontinence. Considerable tact and discretion were required in connexion with the supply of these prophylactic preparations to applicants, many of whom were elderly married officials, sensitive to the chaff of the young men in the Army Medical Service. On the whole, these prophylactic measures proved successful, and it was certain that the use of mechanical protective devices constituted a valuable protection against syphilis. In the case of gonorrhoea, the protection afforded by chemical preparations was very effective, and during the last few months practically all the patients who had contracted gonorrhoea had dispensed with these preparations, or had not used them properly. Halberstaedter considers that the adoption of prophylactic measures should be enforced by penalties.

CASUALTIES IN THE MEDICAL SERVICES.

Killed in Action.

CAPTAIN FRANCIS SHINGLETON SMITH, I.M.S., was killed in the battle of Ctesiphon, in Mesopotamia, on November 22nd-24th, aged 36. He was the son of Dr. R. Shingleton Smith, consulting physician to the Bristol Royal Infirmary, and was born on October 10th, 1879. He was educated at Cambridge, where he took the degree of B.A. He graduated B.C. in 1906 and M.B. in 1914. He studied also at the Bristol School and took the diplomas of M.R.C.S. and L.R.C.P.Lond. in 1906. After acting as house-surgeon of the Weston-super-Mare Hospital he entered the Indian Medical Service as Lieutenant on July 27th, 1907, becoming Captain on July 27th, 1910. Since February 8th, 1913, he had been Medical Officer of the 120th Rajputana Infantry, formerly the 20th Bombay Infantry.

Lieutenant Maurice Mackenzie, R.A.M.C., was killed in France, aged 28, while attending a wounded officer under fire on November 28th. He was the youngest son of the late Sir Stephen Mackenzie of 18, Cavendish Square, London, and a nephew of the late Sir Morell Mackenzie. He was educated at Elstree and Repton, and at the London Hospital, where he was house-surgeon, house-physician, and receiving-room officer, and showed every promise of success in his profession. He took diplomas of M.R.C.S. and L.R.C.P.Lond. in 1912, and at the beginning of the war took part in the organization of a hospital at Chateau Laversine, which was placed at the disposal of the British Red Cross Society by Baron Robert de Rothschild. After the advance to the Aisne this hospital was evacuated, and he then took a temporary commission in the R.A.M.C. He was posted to the 43rd Field Ambulance, and, after a period of training at Aldershot, went with it to France in April. In August he was attached as medical officer to the 2nd Battalion Royal Irish Rifles,

was with them in the advance on September 25th; and remained with them at the front till his death.

Died on Service.

Lieutenant John Cunningham Bell, R.A.M.C., died of dysentery in No. 17 General Hospital, Alexandria, on November 22nd, aged 39. He was born on July 9th, 1876, the eldest son of Mr. George Bell, of Blackheath, educated at University College Hospital, London, and took the diplomas of M.R.C.S. and L.R.C.P.Lond. in 1900. He had been in practice for thirteen years at West Coker, Yeovil, Somersetshire, when he took a commission as temporary Lieutenant in the R.A.M.C. on September 16th, 1915. He went with the 7th Battalion Royal Scots to the Dardanelles, whence he was invalided to Egypt.

Quartermaster and Honorary Lieutenant Henry Robinson, R.A.M.C., is reported to have died in France. He was born in November, 1876. After eighteen years' service in the ranks he was promoted to Sergeant-Major in August, 1914, and got his commission in June, 1915.

Wounded.

Lieutenant-Colonel H. O. Browne-Mason, R.A.M.C., Mesopotamia.

Captain R. W. S. Murray, R.A.M.C., Special Reserve, France.

Captain D. Arthur, I.M.S., Ctesiphon, Mesopotamia.

Captain R. Knowles, I.M.S., Ctesiphon, Mesopotamia. This is the second time that Captain Knowles has been reported wounded.

Captain G. Tate, I.M.S., Ctesiphon, Mesopotamia.

Captain W. J. Powell, I.M.S., Ctesiphon, Mesopotamia.

Lieutenant W. C. Spackman, I.M.S., Ctesiphon, Mesopotamia.

Lieutenant M. B. Patel, I.M.S., Ctesiphon, Mesopotamia.

DEATHS AMONG SONS OF MEDICAL MEN.

Brocklehurst, James Edward, Private 6th Battalion Sherwood Foresters, Notts and Derby regiment, second son of the late T. H. Brocklehurst, M.R.C.S., killed in France, November 24th, aged 35.

Dane, Victor Louis Yate, Captain 22nd Punjabis, son of the late Colonel A. H. C. Dane, I.M.S., killed in the battle of Ctesiphon, Mesopotamia, November 22nd-24th, aged 28. He was born on February 17th, 1887, educated abroad and at Berkhamsted School, and entered the army as Second Lieutenant on August 5th, 1905. He joined the Indian army on October 25th, 1906, became Captain on August 5th, 1914, and since May 10th, 1914, had been Adjutant of his regiment.

Irvine, Paget George, Captain 16th Battalion Gloucestershire Regiment, son of the late Major George Nicol Irvine, R.A.M.C., killed in France on November 26th. He was a solicitor by profession, having been admitted in November, 1901, and was in practice at Bristol. His commission as Lieutenant was dated September 18th, 1914; he reached the rank of Captain in 1915.

MEDICAL STUDENTS.

The annual report of the Edinburgh University Union, dated November 25th, 1915, contains a list of members of the Union who have fallen in the service of their country during the war.

Sixty-three names are given; of these eighteen were medical officers of the various services. Obituary notices of all these eighteen officers appeared in the BRITISH MEDICAL JOURNAL at the time of their death. Thirteen more were medical students. This list is not exhaustive. Many students are not members of the Union. Of these thirteen, obituary notices of seven—R. B. Buchanan, R. N. Bunce, F. Chilton, A. H. M. Henderson, J. E. B. Millar, D. P. Thompson, and R. A. Wilson—have already appeared in the JOURNAL. The other six are:

Anderson, David, Private 4th Battalion Royal Scots, killed in Dardanelles May 27th.

Crozier, James C.B., Second Lieutenant 2nd Battalion Royal Munster Fusiliers, killed August 27th, 1914, in Flanders.

Hudson, R. G., Second Lieutenant Royal Field Artillery, Special Reserve, died in London September 13th, 1914.

Mackenzie, G. A., Second Lieutenant 8th Battalion Gordon Highlanders, killed in Flanders, September 26th-27th, 1915.

Ritchie, Charles A., Cadet, Artillery Unit O.T.C., killed by a fall from his horse, February 8th, 1915.

Smith, J. M., Lieutenant 5th Battalion Royal Scots, killed in Dardanelles, May 5th, 1915.

NOTES.

WATER SUPPLY AT SUEVA BAY AND ANZAC.

The extensive nature of the arrangements which must be made for the supply of potable water to troops is well illustrated by a telegram dated November 8th, 1915, from General Headquarters, Mediterranean Expeditionary

Force, to the War Office. The telegram has been published as a White Paper, and is as follows:

1. When Suvla operations were first planned information available pointed to a considerable amount of water in the Biyuk Anafarta valley and Suvla plain. The correctness of this information has been proved by subsequent experience. But the following preparations were made to guard against risks of not finding water or of inability to develop local resources in the first instance:

On June 17th War Office was asked to dispatch with each reinforcing division water receptacles for pack transport. On June 21st the War Office replied that they were only able to provide 250 eight-gallon receptacles. In consequence steps were taken to procure the balance of the requirements from India and Egypt, and eventually portable receptacles consisting of petroleum tins, milk tins, camel-tanks, water-bags, and pakhsas were provided as follows: On *Dundrenn* receptacles for 42,027 gallons, on *Wiltshire* 32,475 gallons, on *Grampian* and *Southland* receptacles for 11,400 gallons, on *Prah* receptacles for 2,000 gallons. Of the foregoing this amounting to two-thirds of the total gallons were tins, and bags, etc., totalling one-third of the total were to be filled before leaving ship or beach, as it was found that the bags did not hold water for long.

2. Dealing with arrangements at Anzac. A high-level reservoir was built with a capacity of 50,000 gallons, pipe system, and distribution tanks. A stationary engine capable of filling the reservoir was brought from Egypt, but it broke down at one period.

3. A further supply was to be secured from lighters and water ships. These were under naval control and details as to the numbers arranged are not immediately available here. By arrangement with the Admiral the responsibility of the army was confined to the emptying of the lighters and the distribution of the water to the troops; while the navy undertook to bring the full lighters to the shore to replace empty ones. The arrangements made by the Admiral were considered adequate to provide a continuous supply.

4. Engineer stores and tank pumps. The *Prah* carried tanks and troughs, with a capacity of 195,000 gallons, for erection on the beach or at local wells, and 300 water buckets and 6 lift-and-fall pumps, and other pumps, however, were not a vital part of the water scheme.

5. The total number of miles ordered up for Suvla and Anzac was 3,700, together with 1,750 water-carts. This number was in addition to 950 miles already at Anzac. Representatives of the Director of Supplies and Transport at Suvla and Anzac were to allot this transport, which was to be used for carrying up whatever was most needed by units ashore, whether food, water, or ammunition.

OCCUPATION FOR CONVALESCENTS.

Dr. W. R. Dutton has published a serviceable little book¹ on the simple games, occupations, and domestic crafts that may be taught convalescents, hospital patients, or other patients in the charge of them. Partly these will serve to while away the time, partly they will enable the patient to earn a few pence or shillings while he is disabled. Dr. Dutton also provides a full American bibliography of the subject that should be of service to those who wish to pursue the subject, or any of its special branches, further.

"KENT'S CARE FOR THE WOUNDED."

An interesting account of what the County of Kent has done to care for the wounded in the present war has recently been published, and has a preface by Sir Gilbert Parker, Bt.² The first part of the book is copiously illustrated with photographs of Kentish villages, hospitals, and the like; the second part gives a detailed account of the work of the separate detachments of the Kent T.F.A., with lists of the chief workers in each. The volume gives a strong impression of successful effort, and may be commended to the generosity of the public. All profits on its sale will go to the Kent County War Fund. We wish it all the success it deserves.

MEDICAL OFFICERS WANTED.

31st North Midland Field Ambulance.

Three officers are urgently required for the 31st North Midland Field Ambulance. Candidates for commissions must be physically fit for service overseas. Full details as to pay and allowances will be sent on application to Captain Holmes, R.A.M.C.(T.), Officer Commanding 31st North Midland Field Ambulance, Belton Park Camp, Grantham.

21st South-Eastern Mounted Brigade Field Ambulance

R.A.M.C.(T.F.)

Three medical officers are urgently required by this unit. They must be willing to take the Imperial Service obligation. Pay and allowances as in the regular army. Full particulars on

¹ *Occupation Therapy: A Manual for Nurses*. By William Rush Dutton, Jr., B.S., M.A., M.D. 1915. Philadelphia and London: W. B. Saunders Company. (Demy: 8vo, pp. 240; 43 figures. Price 6s. 6d. net.)
² London, New York, and Toronto: Hodder and Stoughton. 1915. (11 illustrations. Paper, 1s. net; cloth, 2s. net.)

application to Major Hamilton, Commanding 21st South Eastern Mounted Brigade Field Ambulance, Cricket Ground, Canterbury.

Welsh War Hospital, Netley.

Applications are invited for the posts of Commanding Officer and of four medical officers for the above hospital, as the present staff is proceeding overseas. Applicants must be above the age of 45, or medically unfit for overseas service. One of the medical officers must be a pathologist. Further particulars from the Honorary Secretaries, Welsh Hospitals, 47, Princes Street Buildings, Cardiff, to whom all communications should be addressed.

England and Wales.

WELSH HOSPITAL FOR OVERSEAS.

At a meeting held at Cardiff last week it was resolved, while maintaining the Welsh Hospital at Netley, to organize a Welsh hospital of 1,040 beds for overseas service. Dr. James Robinson, who presided, said that when the Welsh Hospital was started in August, 1914, it was intended that it should be an overseas hospital. Lieutenant-Colonel A. W. Sheen, the present commander of the Welsh Hospital at Netley, said that it was proposed to raise the personnel of the new overseas hospital in Wales; the War Office would meet all expenses, but there were many things which might be provided for it by the people of Wales, including a portable operating theatre, motor ambulances, and additional equipment. Sir William James Thomas, the honorary treasurer, said that the total sum received from church collections was £3,945, and that by the addition of the 5 per cent. he had promised this was increased to £4,145. He said also that he would be glad to present a motor ambulance for the hospital overseas. We are informed that Lieutenant-Colonel Sheen has been appointed to the command of the new general hospital, and that with him will go four medical officers at present at Netley. Among the staff of the hospital will be a pathologist, and specialists for the eye, ear and throat, and radiography. Owing to the transfer of the commanding officer and four other medical officers, there are vacancies on the staff of the Welsh Hospital at Netley. Applications are therefore invited for the posts of commanding officer, pathologist, and three other medical officers. Applicants should be above the age of 45—the limit of age for overseas service—or should be medically unfit for such service.

BACTERIOLOGICAL DIAGNOSIS IN TYPHOID INFECTIONS.

Professor E. Glynn, at the first pathological meeting of the Liverpool Medical Institution for the session, read a paper on bacteriological problems of intestinal cases from the Dardanelles. He thought that many of the cases diagnosed as typhoid were really paratyphoid A, or paratyphoid B, or dysentery. He considered that, from a statistical point of view, the results of examination of the blood for the specific bacillus could alone afford proof of typhoid being present. The value of serum reactions in diagnosis of convalescents from typhoid fever and the disturbing effects of previous typhoid vaccination were touched upon. The burden of his remarks seemed to be the importance of bacteriology in effecting a correct diagnosis, and with this object in view he expressed his satisfaction that the War Office was sending competent bacteriologists to all base hospitals.

LEASOWE HOSPITAL FOR CRIPPLED CHILDREN.

The city of Liverpool has not delayed long in perpetuating the memory of Nurse Edith Cavell. The Leasowe Hospital for Crippled Children, built by the Liverpool Invalid Children's Association, is to have a memorial ward of twenty-two beds, to be known, with the sanction of Miss Cavell's mother, as the Edith Cavell Ward. This hospital is an excellent institution, and, apart from the fact that suffering children ever stimulate pity, it is most attractive. Situated on the sea and exposed to its health-bestowing breezes, the hospital consists of four blocks with open-air wards. Each block contains forty-four beds. Two of the blocks, known as Faith and Hope, were opened in July, 1914, and have been occupied regularly since. The third block is to be known as the Honour block. Beds in this block, by a donation of

£200, may be named after officers or men who have given their lives for their country in the war. A generous donation of £1,000 has enabled the committee to begin with the Edith Cavell Ward in this Honour block.

MEDICAL INSPECTION OF SCHOOL CHILDREN.

At the meeting of the London County Council on December 7th, the reapportionment of the duties of medical officers of schools was discussed in view of the Council's policy of retrenchment in the educational service. The Chairman of the Education Committee said that hitherto there had been three medical inspections of the children—namely, an entrance, in the middle of the school career, and on leaving school. The proposal was to continue the second and third of these inspections as before, but to require a less detailed inspection of entrants, only those children who on a cursory examination appeared to require it being thoroughly examined. It was also announced that the medical officer of the Board of Education had approved of the change on behalf of the Board. The school medical officers had agreed also that the disturbance caused by medical inspection should as far as possible be limited to one week during a term in any one department.

RULES OF THE CENTRAL MIDWIVES BOARD.

The Central Midwives Board having intimated to the Midwives Act Committee of the London County Council that they proposed to revise the existing code of rules, which will expire on June 30th next, the Committee submitted to the Council certain amendments of the rules which they (the Committee) deemed advisable. The more important alterations suggested were: That the examination of candidates for certificates should embrace the subject of the local manifestations of venereal disease in its effects, not only as hitherto on the newly-born, but on the mother as well; that the duties of the midwife should be more strictly stated by the insertion of the requirement that she should "properly wash and cleanse the mother and child after the birth and during the lying-in period, which shall be held for the purpose of these regulations and in a normal case, to mean the time occupied by the labour and a period of ten days thereafter"; that the abnormalities to be notified in the case of the child should include "increasing jaundice, persistent blueness, rapid breathing with a rise in temperature"; and that a new regulation should be made requiring the midwife to send notice as soon as possible on the prescribed form to the local supervising authority in all cases in which she herself was a source of infection, or in which she had been in contact with any infection.

REGISTRATION OF LYING-IN HOMES AND MASSAGE ESTABLISHMENTS IN LONDON.

The London County Council has issued abstracts of the principal provisions of Part IV (Lying-in Homes) and Part V (Establishments for Massage or Special Treatment) of the London County Council (General Powers) Act, 1915. These provisions make it necessary that any person conducting for payment or reward a lying-in home or an establishment for massage or special treatment in London shall register himself and his premises with the Council. A lying-in home is defined as a place used, whether regularly or occasionally, for the reception of women for childbirth. In the case of massage establishments, the conditions are extended to cover premises in which manicure, chiropody, light, electric, vapour, and other baths or similar treatment is provided. Recognized hospitals are exempted in both cases, as are also, in the case of lying-in homes, approved institutions for the training of midwives, and homes in which only relatives of the person carrying on such a home are received. Lying-in homes and establishments for massage or special treatment which are carried on by a duly qualified medical practitioner are similarly exempted, but in these cases annual certification by two independent practitioners is necessary, to the effect that, in the case of a lying-in home, both premises and equipment are suitable, and in the case of a massage establishment, that it will not be used for any immoral purpose, and in both cases that the practitioner is a fit and proper person to carry on the establishment. Penalties are provided not only for carrying on unregistered establishments, but also for publishing or displaying an advertisement of such an establishment

after the prescribed notice that registration has been refused or cancelled. The date on which the provisions come into operation is February 1st, 1916, but applications in the case of existing lying-in homes must be made before December 28th next, and in the case of massage establishments before December 23rd.

The London County Council has decided that the inspection incidental to registration of the lying-in homes and also of the massage establishments should be undertaken by the chief officer of the public control department. It was understood that the medical officer of health would co-operate with him in any case in which medical questions arose.

Ireland.

LONGFORD COUNTY INFIRMARY.

As was noted in the JOURNAL early this year, Dr. Mayo was dismissed by the committee from his position as surgeon to the Longford County Infirmary, which he had held since 1877, on the ground that he had refused to allow a Dublin surgeon to operate in the County Infirmary on a soldier stationed in the local barracks. The Local Government Board refused to approve the dismissal of Dr. Mayo, and the Irish Medical Association adopted a resolution affirming that in refusing to admit another surgeon to operate in the infirmary Dr. Mayo acted correctly, prudently, and in accordance with the rules of the institution. It appears that Dr. Mayo's salary, which was at the rate of £94 a year, had been paid quarterly up to June 30th, but not since. The rules required a certificate signed by five governors of the County Infirmary, and in May last Dr. Mayo obtained a certificate signed by four governors at a meeting, and by a fifth outside the meeting. On this he obtained a decree in the county court for the amount against the county council, but at the assizes the decree was reversed, on the ground that the five members had not signed it at a meeting of the body. Since then, although meetings had been summoned, there was never a quorum. An appeal was heard in the King's Bench Division in Dublin, and a conditional order of mandamus was made directing the members of the committee to sign a certificate.

Correspondence.

THE MEASLES NOTIFICATION ORDER.

SIR,—I am writing as a country M.O.H., and my grumble is this, that the powers above issue these orders, which may or may not be useful as far as large towns go, but are of very doubtful utility in the country. They entail a great deal of work, trouble, and clerical labour, for which there is no extra remuneration.

Now, my point is that when the Local Government Board issues a new order, it should also name a definite increase of pay for those who have to work it.

We were all pretty hard worked before, then came the notification of tuberculosis (for which I did manage to get an increase of salary); then the war, causing a great increase of gratuitous work; then notification of births; and now measles follows.

It hardly seems the time to introduce all this new legislation and expense, at least in rural districts, where so much time is taken up in travelling; why not try these experiments in the large towns first for a year or two, and see the results before making the orders general? Ten thousand deaths from measles, at a 1 per cent. death-rate, means 1,000,000 cases a year, or £125,000 for notification fees, leaving out German measles, health visitors, stationery, postage, etc.—I am, etc.,

J. POLLOCK,

December 5th. M.O.H. Tiverton Rural.

TYPHUS FEVER AND LICE.

SIR,—The quotation made by Dr. James W. Allan in the JOURNAL of December 4th, p. 841, from the article on typhus by Captain A. J. Brown and myself has shown me that that portion of the article is—possibly owing to a certain clumsiness of construction—somewhat ambiguous.

What we wished to convey is that the men who returned to their companies free of all lice immediately became infested with lice anew; and being still infectious, infected a new generation of lice, with the result that, in due course, a recrudescence of the epidemic occurred. In fact, the contention we wished to make is that the analogy between the spread of typhus and the spread of malaria is a complete one. We recognize that we have offered no proof of this, and indeed it may be that the louse—such a predominating feature of the picture—has warped our judgement in this, our sole experience of the disease.

While on the subject may I elaborate the point we made in regard to the class of case we call "high tension type"? In this it is quite common for the pulse-rate never to go above 90 during the entire pyrexial period and to remain between 70 and 80 while the temperature remains on a plateau of 103 to 104 for several days. It is a feature so peculiar as to impress itself on the notice. "The exigencies of the service" prevent me from communicating with my late collaborator before writing this, but I feel sure he will concur with me.—I am, etc.,

P. C. T. DAVY,
Maj r R.A.M.C.

London, W., Dec. 7th.

BROMIDES IN EPILEPSY.

SIR.—Whether epilepsy is one disease or several diseases cannot be decided, cannot even be discussed, until we have some clear understanding of what is meant by a disease; and there is no such understanding. It is the business of our lives to treat diseases, but we none of us know what we mean by diseases; at least I know of no satisfactory definition of the term. Some months ago I offered to open a discussion on the matter at the Royal Society of Medicine, but that society was at the moment engaged in discussing something much more important and more practical—I think it was, "What is good for a cough?"—and my offer was courteously but firmly declined. I know what I mean by a disease, but I cannot explain it within the limits of a letter, and therefore it is from want of space, not from lack of courtesy, that I am unable to satisfy Dr. Humphrey Davy, and I trust he will forgive me.

Dr. Hume Griffith's statistics are scarcely convincing. His experience is that in 1900 a set of patients, whose number and the peculiarities of whose cases are not specified, were not treated with bromide, and had fits averaging 13.3 per month. In 1907 a set of patients, whose number is not specified and the peculiarities of whose cases are not specified, and who may or may not have been, but probably were not, the same set of patients as were observed in 1900, were treated by heavy doses of bromide, and the fits averaged 1.99 per month. Again, after seven more years, another batch of patients, some or all of whom may have been different from those in the previous batches, were treated with moderate doses of bromides, plus individual treatment, and the fits averaged 1.5 per month. I am afraid that from these data no trustworthy conclusion whatever can be drawn. The frequency of the fits varies in different patients from scores in one day to one or two in a year. It is clear that the presence in the first batch of a single case of unusual frequency and its absence from the later batches would account for the whole of the average difference, supposing the bromides to have had no influence whatever on the fits, or even supposing that it increased their frequency.

Dr. Stephens finds bromides of use in three ways: First, as a means of controlling the increasing frequency and intensity of the attacks: this, of course, assumes that the bromides do exercise this control. My case is that there is good evidence of the exercise of such control in some cases, but no evidence of any such control in other cases. Second, he uses it as an adjuvant in status epilepticus. Thus used, it certainly does no harm, but I could never satisfy myself that it increased appreciably the effect of the chloral. Third, he finds that epileptics, when temporarily suffering from other diseases, are often benefited by the addition of bromides to the mixtures prescribed for those diseases. But, in the first place, Dr. Stephens does not say that they are always benefited, and thus does not contravene my assertion; and, in the second place, it is, if not impossible, extremely difficult to disentangle the several effects produced by several drugs prescribed in a single mixture.

I do not deny, on the contrary, I strongly assert, that in some cases of recurring convulsion, which is what we mean by epilepsy, the discreet administration of bromides is followed by great diminution of the frequency of the fits, without any discernible ill effect; but I assert also that in the majority of cases either the fits are not diminished in frequency; or if they diminish in frequency they are increased in severity; or the diminished frequency of the fits is accompanied by a deterioration of mind which is too high a price to give for the lessened convulsions. My own practice, therefore, is to begin the treatment of most cases of epilepsy by administering bromides, but to watch their effect narrowly; to leave them off from time to time, and watch the effect of the omission; and unless I can satisfy myself that there is a clear gain from their administration, to leave them off altogether, and trust to careful regulation of the diet, attention to the bowels, regulation of exercise, and so forth.

I am surprised to hear from Dr. Hume Griffith that bromide acne is easily avoided by the administration of arsenic. My experience is that the combination of arsenic with bromides delays the appearance of acne, and lessens its severity, but does not prevent it; and it has seemed to me that in proportion as the acne is delayed and lessened, the other effects of the bromides are delayed and lessened.

In estimating the improvement or otherwise of a case of epilepsy, it is not enough merely to count the number of the fits. We must take into consideration also their severity, the increase or decrease of physical energy and of mental capability, the feeling of well-being or the reverse, and other factors; and it is only when all these factors are taken into account that we can strike a balance and say whether the life of the patient is really improved, is better worth living, is more advantageous upon the whole to himself, his family, and the society in which he lives. It is not easy to strike such a balance, but it is to this that our efforts should be directed. Diminution in the frequency of the fits, important as it is in itself, is not the only thing to be considered, and even if we can effect it, it may be bought too dear.—I am, etc.,

Parkstone, Dorset, Dec. 4th.

CHAS. A. MERCIER.

SIR.—Our knowledge of the action of bromine and the bromides upon man can hardly be regarded as adequate and satisfactory. On the one hand a distinguished authority like Dr. Mercier regards the war shortage of bromides as possibly a "blessing in disguise." On the other hand, as testified by general practice and tradition, and more particularly by the correspondents in your issue of December 4th, bromide undoubtedly exercises a considerable control over epilepsy. The main point at issue, I take it, is whether on the whole the bromides may not do more harm than good.

Apart from any special experience in epilepsy, most medical men meet with more or less severe cases of bromism—that is to say, bromism as described in the textbooks and familiar to our observation. Can we be sure, however, that we recognize at all adequately the remote evil effects of bromine compounds upon the human body? Bromine is a powerful drug, and it may be that by its use we are actually setting up various tissue degenerations and other results of unrecognized chronic poisoning. Dr. Hume Griffith mentions the fact that patients treated in the Lingfield Colony with heavy doses of bromide were like "logs" in school. Do the textbooks warn us against such a phenomenon as a result of bromide administration? It would be interesting to ascertain, were it possible, what is the terminal state of patients who have been dosed over long periods with bromides. It has always seemed to me that the last state of many epileptics may have been in reality attributable—in some degree at any rate—to the bromides which form the classical remedy in that malady. In some cases of unconsciousness or what may perhaps be described as cataleptic conditions under my own observation I have been able to trace a history of prolonged bromide administration.

At any rate, in the bromides we are using a powerful drug of whose remote action after prolonged dosage we cannot be said to have an adequate knowledge. Comparative pathology has long ago shown its destructive effect in small doses on internal organs.—I am, etc.,

London, W., Dec. 6th.

DAVID WALSH.

SIR.—Regarding the question of the treatment of epilepsy by means of bromides, I think one class of case has been overlooked by those who do not agree with this treatment—I refer to the patient who develops epilepsy in young adult life and comes under treatment before the habit is firmly established. If this kind of case is treated by bromides for a period of one to two years, with careful supervision a cure will often result. I personally have found the treatment very satisfactory, with no return of fits after an interval of two to three years.

I feel sure that many general practitioners have had the same experience, and that it would be a great pity if the use of bromides fell into disrepute.—I am, etc.,

Bridgwater, Dec. 5th.

RICHARD COATES.

SIR,—I consider Dr. Mercier's views on the bromide question a reasonable reminder to the profession. The routine practice of administering potassium bromide has led some of us in the past to value it too royally. Without wishing to advance any wild speculations with regard to the causes of epilepsy, yet the asphyxial problem of the convulsive seizure deserves a special line of thought. Do we conceive that the central nervous system bursts forth into unconscious fury without a physical agency at work? And of what does the hereditary weakness in each individual case of epilepsy consist which attracts the physical agency? If we believe the arterial vascular system is closely linked to the cerebro-spinal system through the medium of the ganglionic sympathetic system and controls the blood of the brain, then we may promulgate the idea that epilepsy may be set up by an instability of some part or parts of the arterial circuit. This is what I considered in a pamphlet some years ago, *On the Asphyxial Problem of Convulsive Seizures*. In sending these few remarks I do so from some practical experience of epilepsy, having found the preventive dietetic treatment of it most helpful, even when we have to assist with drugs like the bromides or chloral.—I am, etc.,

Bournemouth, Dec. 4th.

JOHN FREDK. BRISCOE.

A COMBINED PHYSICAL TREATMENT FOR WOUNDED SOLDIERS.

SIR,—In your issue of November 27th I notice a communication on the above subject. In plain English I assume that "hyperthermal eau courante" is "hot running water." About the application of this in one form or another there seems nothing very novel to a humble balneologist like myself, even when combined with massage and movements. I speak with all submission to Drs. Fortescue Fox and Campbell McLure.

To take a very localized injury—such as a sprain of ankle or wrist—hot douching (or cold) is a very old and well-recognized form of treatment. Also, every day do I see joints, rheumatic or traumatic, sprayed by the Aix or Vichy method and manipulated concurrently or subsequently, which, of course, the heat makes easy. I think I am not assuming too much in stating there must be all sorts of douches and methods of applying "eau courante" in London, from the pump and kitchen tap upwards, and some of them are probably in use unless the Zeppelins have mishandled the water mains.

One is therefore rather at a loss for a reason for the official utterance of the secretaries of the Balneological Section of the Royal Society of Medicine.—I am, etc.,

Peebles, Dec. 7.

T. D. LUKK, M.D.

THE late Sir James Matthew Moody, medical superintendent of Cane Hill Asylum, Coulsdon, Surrey, left estate valued at £6,981.

In the October number of the *Revue de gynécologie et de chirurgie abdominale* is an article on Professor Gross of Nancy and Professor Koerberlé of Strassburg containing an impartial account of the share which Koerberlé played in establishing ovariotomy as a legitimate surgical operation. A photograph is given of the first set of pressure or haemostatic forceps, made for him in 1855. A note on the development of the pressure forceps, on the testimony of published records between 1853 and 1879, appeared in the *JOURNAL* of March 27th, 1915, p. 555. Koerberlé's monograph, *De l'hémostase définitive par compression excessive*, published at Strassburg in 1877, is a classical work.

Public Health AND POOR LAW MEDICAL SERVICES.

REFORM OF THE POOR LAW MEDICAL SERVICE.
IN a supplement published in the *Medical Officer* of October 30th, 1915, there is set out in full a recent memorandum on the office and duties of workhouse and district medical officers, presented to the Departmental Committee appointed by the Local Government Board to examine and report with regard to the Poor Law orders affecting these officers, and as to amendments of the same.

The memorandum deals with the seven following grievances. Most will be seen to be very real grievances, but as to a very few there may be room for doubt.

1. Tenure.

The claim for a security of tenure for the increasing number of assistant whole-time medical officers who act on the staff of the infirmaries, particularly in London, and carry out the duties of the old district medical officers is particularly well founded. They have to contribute to superannuation funds, but have none of the security to the benefits that the men they replace had.

Hardship is said to have arisen owing to the order which makes it necessary for the doctor to be resident within his district; the alternative proposal is that he should be resident within his district or within a short distance therefrom. That is the suggestion we think most dubious. The doctor for the destitute poor must live where the poor live, otherwise his services may not be available when most wanted. "A short distance" is a very elastic term, even if it were the rabbinical Sabbath day's journey. The citation of London, where the definition is of the desired sort, is not a strong argument, for means of locomotion are exceptional in London.

2. Remuneration.

Guardians add to the duties of their medical servants, but forget to add to the pay. The Local Government Board may make representations, but the guardians ignore them. So far as we can discover, the difficulty arises from the absence of any monetary contributions by the Board to the guardians; it is the old saw, "He who pays the piper calls the tune." The Board can compel the dismissal of an unpaid doctor and the substitution of a properly paid officer, but who will take the risk of such a clumsy process?

3. Duties.

Strong exception is taken: To the demand that certificates necessary under the Mental Deficiency Acts should be given without pay; identical certificates for lunacy are paid for. To the practice of the guardians in recovering fees for attendance on bogus "poor" without sharing these with the men who did the work. To the refusal of guardians to pay for attendance on boarded-out children for which sanction has been given by the Local Government Board.

A very real grievance is found in the practice of police officers of hunting up the Poor Law doctors to attend street accident cases; the public may suffer gravely by the delay caused.

Exception is taken to the requirements for the treatment of school children reported defective. There are stronger grounds for objection to this practice. It is most undesirable that work of State compulsion should be associated with pauperism. In the annual report of the Medical Officer, Board of Education, 1913, p. 96, it is written, "It cannot be considered that this (Poor Law treatment) is satisfactory from any point of view. . . . Nor have the boards of guardians any special facilities." A somewhat similar difficulty arises with adults. The complexity of modern medicine does not allow a man to be an expert in every branch of work; apparently some guardians do expect this, and at the flat rate for ordinary service.

4. Divided Control of the Sick Wards in Non-separated Workhouse Infirmaries.

The claim is that the workhouse master should have no administrative duties in the sick wards, but might act as steward under the medical officer. It is a just one. A case is cited where the patient suffered because the master had control; the Local Government Board strongly condemned, but the local officials condoned.

5. Extra Fees of District Medical Officers.

Such fees are allowed for exceptional services, operations, etc.; the list was drawn up in 1847. It is surely a modest request that it be brought up to date.

6. Provision of Drugs by District and Workhouse Medical Officers.

The claim is that the Poor Law doctors should be put on exactly the same footing as the panel practitioner. Numerous political speeches might be quoted in support of this reform.

7. Periodic Increase in the Salaries of Poor Law Medical Officers.

It is suggested that every Poor Law medical officer, unless it can be shown that his work has diminished considerably, should be entitled to a definite increase of salary every five years up to a fixed maximum. Such increment to be dependent on good behaviour and efficiency. The effect would be to improve the service to the benefit of the public.

Throughout the memorandum there runs evidence of a want of control by the Local Government Board of a large spending authority; until this is obtained, and by that most effective measure, "grants in aid," we see little hope of getting more than a piecemeal rectification of the more glaring anomalies of the work of such local authorities.

Universities and Colleges.

UNIVERSITY OF LONDON.

At a meeting of the Senate on November 17th it was decided that students who have performed clinical service for not less than six months during the continuance of the war be admitted to the M.B., B.S. Examination at an interval of not less than two and a half years from the date of their passing the second examination for medical degrees in anatomy and physiology, provided that they be not admitted to the M.B., B.S. Examination within five and a half years from the date of their matriculation. It was decided also not to transmit gold medals to students to whom they are awarded during the continuance of the war and for one year thereafter, but that such students should be entitled to receive the equivalent in money if they so desired, and to receive the medal awarded on retirement of that sum at such period after the termination of the war as the Senate shall determine.

The following intercollegiate courses were recognized as advanced lectures which a candidate at the B.Sc. Honours Examination in Physiology may name for part of his examination: At University College, Professor Blyden, physiological applications of physical chemistry; at King's College, Professor Halliburton and Dr. Rosenheim, physiological chemistry of the animal fluids; at Guy's Hospital, Dr. Pembrey, respiratory exchange; Dr. Hertz, investigation of movements of the alimentary canal by x rays; at Bedford College, Dr. Edkins, advanced practical histology.

Mr. H. L. Eason, M.D., M.S., ophthalmic surgeon to the British expeditionary forces in the Mediterranean, and Sir Wilmot Herringham, C.B., M.D., consulting physician to the British expeditionary forces in France, have resigned their membership of the Senate as representatives of the Faculty of Medicine. Sir David Ferrier, M.D., F.R.S., was elected Chairman of the Physiological Laboratory Committee.

The Paul Philip Reitinger Prize, founded by Mr. Albert Reitinger in memory of his son, a student of St. George's Hospital Medical School, was offered this year for the best essay on "The Economic Condition of the People of England in 1815 in comparison with the Present Day," has been awarded to Herbert Roland Hodges, of the London School of Economics. The prize next year will be awarded for the best essay embodying the result of some research on a medical subject carried out by the candidate.

UNIVERSITY OF BRISTOL.

At the recent meeting of Council the degree of M.Sc. was awarded to Major F. Percival Mackie, R.A.M.C., M.D.

ORMSBY of Chicago (*Journ. Amer. Med. Assoc.*, November 6th, 1915) reports a group of twelve cases of self-inflicted dermatitis noted during recent years in the experience of himself and two other practitioners. He considers it probable that the majority of the cases described as "pemphigus gangrenosus," "zoster gangrenosus atypicus" (Kaposi), and "dermatitis symmetrica dysmenorrhoeica" are in reality examples of factitious dermatitis. While the disorder is believed to be comparatively rare, he thinks it probable that it would appear more common if recognized more generally. Dr. Norman Walker, in the clinical lecture on dermatitis artefacta published in the *JOURNAL* of June 18th, 1910, p. 1481, gave some coloured illustrations of the appearances observed in certain cases, and published a rather entertaining correspondence which shows the truth of Dr. Ormsby's statement that the family physician is often loth to admit, even to himself, the possibility that his particular patient should deliberately produce the lesions.

Obituary.

KENNETH WILLIAM MILLICAN, B.A. CANTAB., M.R.C.S. ENG., L.R.C.P. EDIN.

We much regret to announce the death on November 28th, at the age of 62, of Mr. Kenneth William Millican, until recently the assistant editor of the *Lancet*.

He was born at Leicester, where his father was an architect of high position, a leading member of the Conservative party, and a colonel in the Volunteers. He was educated at the Atherstone Grammar School and Emmanuel College, Cambridge, and graduated with honours in the classical tripos. He entered St. Mary's Hospital with a natural science scholarship; he took the diploma of M.R.C.S. Eng. in 1879, and that of L.R.C.P. Edin. in the following year. After acting for a time as surgeon in the service of the Ocean Steamship Company, he settled in practice in Kington, Warwickshire. Afterwards he moved to London, and became surgeon and laryngologist to the Infirmary for Consumption in Margaret Street, and also to the West End Hospital for Paralysis. While in London he wrote two volumes of verses—*Smoke Clouds* (jointly with the late Dr. A. B. Clarke) and *Passion Spray*. He produced, in collaboration with C. H. Stephenson, a domestic drama entitled *Fettered Freedom*, and became well known as an amateur actor. In 1883 he wrote a small book on *The Evolution of Morbid Germs*, in which he anticipated opinions now held by many. He was a captain in the 9th Battalion of the King's Royal Rifle Corps, and took great interest in the Volunteer movement and in military administration.

He left London in 1892, and after again acting as a ship surgeon for a short time, became successively medical officer to mining works in Mexico and in California; in 1897 he was appointed associate editor of the *New York Medical Journal*, a post which he held for six years, leaving it to become the editor of the *St. Louis Medical Journal*. Two years later he joined the staff of the *Journal of the American Medical Association*, and in 1911 that of the *Lancet*. His health broke down last summer, and after some weeks of increasing disability he died of heart failure.

He was twice married, and leaves by his first wife a grown-up son and daughter who are settled in the United States, and by his second wife, who survives him, one daughter 12 years of age.

NICHOLAS PERCY MARSH, M.B. LOND.,

PHYSICIAN TO THE LIVERPOOL INFIRMARY FOR CHILDREN.

It was with great regret that the medical profession of Liverpool and district learnt that Dr. N. Percy Marsh passed away on November 28th, in his 56th year, after an illness of a few days' duration. His death came as a shock to many of his friends, who were not aware that he was indispensed. The immediate cause of death was cerebral haemorrhage. He was the elder son of the late Dr. N. K. Marsh, a well-known Liverpool medical man and city councillor. Dr. Percy Marsh was one of the leading specialists for diseases of children in Liverpool, and during the last ten years had acquired an extensive consulting practice in this branch of medicine. He was one of the physicians to the Liverpool Infirmary for Children, with which he had been connected since 1886. From the very beginning of his professional career he devoted himself to the speciality. He received his medical education at St. Bartholomew's Hospital, took the diploma of M.R.C.S. in 1882, and graduated M.B. Lond. in the following year. He held successively the posts of clinical assistant to the East London Hospital for Children, and resident medical officer to the General Hospital for Children at Pendlebury, before settling in private practice in his native city. In the last few years Dr. Marsh published various observations on children's diseases, more particularly meningitis in its protean manifestations. "Meningitis and lumbar puncture," "Treatment of cerebro-spinal meningitis with Flexner and Jobling's antiserum," "Encephalitis," "Epidemic poliomyelitis," are papers which set forth not only correct clinical observation but reveal critical acumen of a high order.

Dr. Percy Marsh was chairman of the Liverpool Division,

and during the incubation period of the Insurance Act had ample opportunities of showing his ability in conducting the numberless meetings held during those months of medical unrest.

At the last meeting of the Medical Institution Dr. Hope, in proposing a vote of condolence with the relatives of the late Dr. Marsh, who had been a member since 1886, alluded to the loss not only that the institution had sustained but the medical profession in and around Liverpool. He said that many members were personally indebted to Dr. Marsh for the professional help he had so willingly rendered to their families, and that he should be cut off at the zenith of his career was all the more poignant. Dr. Hope touched on the character and amiability of Dr. Marsh, whom he had known intimately for many years. Dr. Peter Davidson, a colleague of the late Dr. Marsh, added a few words, expressing in feeling terms how much he would miss his colleague, with whom he had been associated for so many years.

The funeral took place on November 29th at Childwall Church in the presence of a large number of his professional brethren and friends. On all sides his untimely death is deplored, and many a medical man will miss Dr. N. Percy Marsh for his courteousness, kindness of heart, and professional skill.

He leaves a widow, with whom much sympathy is felt, a son—Captain E. Bertram Marsh, R.A.M.C.—and two married daughters to mourn his loss and to cherish his memory.

FRANCIS T. HEUSTON, M.D., M.Ch., F.R.C.S.I.,

CONSULTING SURGEON, ADELAIDE HOSPITAL, DUBLIN.

We announced last week the death on November 27th of Mr. Francis T. Heuston of Dublin. He was born in 1857, the son of Mr. Robert Heuston of Ballykisteon, Tipperary, and was educated at Queen's College, Galway, and at the Royal College of Surgeons of Ireland. He was at one time professor of anatomy in the Carmichael College and the Royal College of Surgeons, Ireland, and, in addition to his appointment at the Adelaide Hospital, was consulting surgeon to the Rotunda and Coombe Lying-in Hospitals, and to the Cripples' Home, Bray, and surgeon to the London and North Western Railway. He was honorary secretary of the Adelaide Hospital, and governor of the Rotunda Hospital. He was a Fellow of the Royal Academy of Medicine in Ireland, and at one time chairman of its section of anatomy and physiology. He contributed several papers to medical periodicals, including one describing a method of excision of the rectum, published in this JOURNAL in 1895. Dr. Heuston was appointed surgeon to the Adelaide Hospital in 1886, and, as the board noted in a resolution passed shortly after his death, threw himself heartily into its work, and made the interests of the hospital his first object. The board expressed to Mrs. Heuston and to her son and daughter its sincerest sympathy in their bereavement, which came so soon after the loss of a son and brother killed in the war. In this expression of sympathy all those who knew Dr. Heuston will desire to share.

COLONEL FRANCIS JAMES DRURY, Bengal Medical Service, died suddenly of heart failure at Ranchi on November 30th, 1915, aged 55. He was born on May 17th, 1860, and educated at the Adelaide Hospital, Dublin, and at Trinity College, where he took the B.A. in 1881, the M.B. and M.Ch. in 1883. He entered the Indian Medical Service as surgeon on April 1st, 1885, became surgeon-major on April 1st, 1897, and lieutenant-colonel on April 1st, 1905; he was promoted to colonel from April 1st, 1912. His first five years' service were spent in military employ, during which he served in the Burma war from 1886 to 1888, taking part in the operations of the Fourth Brigade, and on the western frontier with the Poonk column, receiving the medal with two clasps. He then went into civil employ in Bengal, and after holding the post of civil surgeon in various districts, Balasore, the 24 Parganas, and Chitragong, he succeeded the late Major Evans, when he died of plague on March 13th, 1899, as Professor of Pathology in the Calcutta Medical College. Subsequently he became principal of the college, professor of medicine, and first physician of the Medical College Hospital. When the new province of Bihar and Orissa was constituted, from April 1st, 1912, he was appointed Inspector-General

of Civil Hospitals therein, with the rank of colonel. But though he took up the post at once he was not formally confirmed in it, and gazetted full colonel (from the original date, April 1st, 1912), till some two years afterwards.

DR. C. W. SESSIONS BARRETT died on November 4th aged 58, at his residence, Appleton House, Hinckley Leicestershire. He was the eldest son of Dr. Charles Albert Barrett, of Wallingford, Berks, and received his professional education at the University of Aberdeen, where he graduated M.B., C.M. in 1886. After holding appointments in the Huntingdon County Hospital and the Doncaster General Infirmary, he settled in Hinckley, where he became medical officer to the Cottage Hospital, to the Hinckley Workhouse, and to the Children's Home, Burbage, Leicestershire. He was interested in the question of the control of phthisis, and was an active member of the National Association for the Prevention of Consumption. He was a member, and for a time chairman, of the Leicester and Rutlandshire Branch of the British Medical Association, and contributed some interesting notes to this JOURNAL. One of these was a report of a case of complete inversion of the uterus (JOURNAL, vol. i, 1887, p. 508). He took an active part in the controversy about the antiseptic after-treatment of vaccination published in the first volume of the JOURNAL for 1890. Dr. Sessions Barrett left a widow, two daughters, and a son—a Lieutenant in the 26th South Staffordshire Regiment. The funeral took place at Hinckley parish church on November 9th, and was very largely attended, as Dr. Sessions Barrett was deeply respected, so that his death occasioned profound feelings of regret throughout the district.

Medical News.

AT a meeting of the Royal Society of Medicine on Monday, December 20th, at 5 p.m., Sir Ronald Ross, K.C.B., F.R.S., who has recently returned from the Mediterranean, will give an address on the treatment of dysentery, which will be followed by a discussion.

DR. J. A. TURNER, Executive Health Officer, Bombay, who has held that appointment for fifteen years, has been reappointed for a further term of five years, and given permission to hold the appointment of Professor of Public Health to the School of Tropical Medicine which the Government is establishing in Bombay.

THREE months' courses of lectures and demonstrations for the diploma in public health will be given at the North-Western Hospital, Hampstead, by Dr. J. MacCombie, beginning on January 4th, and at Grove Hospital, Tooting, by Dr. J. E. Beggs, beginning on January 6th. Inquiries should be addressed to the Clerk to the Metropolitan Asylums Board, Embankment, E.C.

IT is announced that Dr. F. M. Sandwith has been appointed to be a consulting physician with the Mediterranean Force, and will be stationed in Egypt. He was formerly professor of medicine in the Cairo Medical School, and has been for a good many years an active member of the staff of the London School of Tropical Medicine, as well as Gresham Professor of Medicine.

A MEMORIAL tablet to the late Lieutenant W. T. McCurry, R.A.M.C., has been unveiled and dedicated in St. Mary Magdalene Parish Church, Belfast, by the Bishop of the diocese. Dr. McCurry was killed on March 15th at Ypres while attending to the wounded in one of the first-aid stations near the firing line. His name had been mentioned in dispatches for gallantry in the field.

AT a quarterly meeting of the Central Committee of the Medical Benevolent Fund Society of Ireland on December 1st, when Sir Joseph Redmond, F.R.C.P., was in the chair, Dr. J. Agar Matson was thanked for a donation of 10 guineas and elected a life member of the society. Four urgent applications for assistance were considered, and grants amounting to £58 were made; bills amounting to £56 4s. 2d. were passed for payment.

THE New York *Medical Record* of October 30th states that among the nine German naval officers on the *Prinz Eitel Friedrich* and the *Kronprinz Wilhelm*, interned at Norfolk, who broke their parole, there were two medical men, Drs. Koch and Kronecker. Our contemporary, in

expressing regret for this, said it had hoped that the medical profession at least would have come out of this war without dishonour.

THE death is announced of Dr. James H. Pollock, lecturer on physical and metallurgical chemistry in the Royal College of Science, Ireland. He had given much attention to the investigation of x rays, and had contracted dermatitis in the course of his investigations. On the outbreak of war he organized the Royal College of Science Voluntary Aid Detachment, which, under his command, performed valuable services on the occasions when wounded soldiers have been landed in Dublin.

THE Royal Commission on Sewage Disposal was appointed in 1898. Between 1901 and 1915 it published ten reports in thirty-three volumes, containing some 7686 pages, with maps, pictures, diagrams, and plans. Mr. Kerstlaw has done a useful piece of work in compiling a *guide to this labyrinth of reports, evidence, and appendices*. He has furnished a synopsis of the contents of the volumes and indexes of the names, places, and subjects dealt with. It is published by P. S. King and Son (1915), price 5s. net.

MAJOR W. C. CROLY, R.A.M.C., son of the late Mr. H. G. Croly, the well-known Dublin surgeon, has been awarded the Royal Humane Society's silver medal. During the Nazirich fighting in the Persian Gulf, when the temperature was 113° in the shade, the heat very trying, and many casualties were occurring from heat-stroke, a British soldier jumped overboard from a launch on the Sbat-el-Arab. Major Croly jumped in, and though the water was infested with sharks, attempted to save him, but in vain; being hampered by his clothing Major Croly was nearly drowned himself.

AT the fifty-third annual meeting of the Royal Surgical Aid Society, held at the Mansion House, London, under the presidency of the Lord Mayor, a summary of the work of the society was given by Mr. G. A. Touche, M.P., who said that for the year ending with September 25,741 patients had been relieved, and the number of appliances supplied 39,290. Upwards of 4,000 trusses had been supplied, nearly 4,000 special boots, and 2,000 abdominal belts. A vast number of these appliances had been given absolutely free of charge. The society had also directly helped recruiting by providing artificial teeth for many men who otherwise could not have been accepted for the army. After commendatory speeches by Sir Horace Marshall, Sir William Grey-Wilson, the Rev. G. C. Wilton, and others, a resolution confirming the appointment of Sir Rickman J. Godlee as honorary consulting surgeon in succession to Sir Frederick Treves, and expressing the thanks of the society to its surgical staff, was moved by Sir Dyce Duckworth, seconded by Sir Thomas Crosby, and carried. The vote of thanks to the surgeons was acknowledged by Mr. Muirhead Little.

ON December 2nd a bronze tablet to the memory of Dr. F. M. Bingham was unveiled in front of the Royal Lancaster Infirmary, Lancaster. As noted in the JOURNAL of June 12th, Dr. Bingham, who was captain in the 5th (Territorial) Battalion of the King's Own Royal Lancaster Regiment, was killed in Flanders on May 22nd. His men were engaged during the night making new trenches, and just before dawn one was huried by a bursting shell. Captain Bingham helped in extricating the man, but in the morning light was shot by a sniper through the lungs. The tablet contains a medallion portrait, and bears the following inscription: "Frank Miller Bingham, M.R.C.S., L.R.C.P., captain the 5th Battalion the King's Own Royal Lancaster Regiment, killed in action in Flanders, May 22nd, 1915. In recognition of his life amongst them, and of his gallant death, this tablet was erected by the medical profession of Lancaster and district. He gave his life for his country." Dr. Bingham had been in practice at Lancaster in partnership with Drs. Parker and Dean for fifteen years, and the duty of unveiling the memorial was committed to Dr. G. R. Parker, the senior practitioner of the district. It was, he said, designed to do honour to the memory of a gallant soldier of the King and an honoured member of the medical profession, who lived in Preston for many years, and endeared himself by his bright and cheery manner, and endeared himself by his professional skill, and his blameless life. By his death he has not only added lustre to his profession, but to the town and neighbourhood where he spent so many happy hours. The president of the hospital, in accepting the memorial, said that the appreciation expressed in it by the medical profession was endorsed by the whole of the town and district.

Letters, Notes, and Answers.

AUTHORS desiring reprints of their articles published in the BRITISH MEDICAL JOURNAL are requested to communicate with the Office, 429, Strand, W.C., on receipt of proof.

THE telegraphic addresses of the BRITISH MEDICAL ASSOCIATION and JOURNAL are: (1) EDITOR, the BRITISH MEDICAL ASSOCIATION, *Attingham, Westrand, London*; telephone, 2931. GERRARD. (2) FINANCIAL SECRETARY AND BUSINESS MANAGER (advertisements, etc.), *Articulate, Westrand, London*; telephone, 2630. GERRARD. (3) MEDICAL SECRETARY, *Westrand, London*; telephone, 2634. GERRARD. The address of the Irish office of the British Medical Association is 16, South Frederick Street, Dublin.

Queries, answers, and communications relating to subjects to which special departments of the BRITISH MEDICAL JOURNAL are devoted will be found under their respective headings.

QUERIES.

DR. MEREDITH YOUNG, County Medical Officer (43, Foregate, Chester) is anxious to find a home within a moderate distance of Chester for a man aged 53, suffering from paralysis of both legs, who could only afford a small contribution towards the cost of his maintenance.

ANSWERS.

MR. H. G. JOHNSTON, F.R.C.S.E. (Adelphi P.O., Jamaica, West Indies) writes to recommend for the treatment of chilblains passive hyperaemia, induced by elastic bandages (the 2 in. crepe Velpeau do very well) on the wrists or higher up on the forearms (the site of application of the bandage should be varied from day to day). A little practice soon shows the amount of tension to put on the bandages to give the best results, the itching and pain is often relieved in a few minutes after applying the bandages, and a couple of hours' wear morning and evening may suffice.

THE DESTRUCTION OF RATS.

S. V. suggests that rats may be destroyed by placing a mixture of equal proportions of flour and plaster-of-paris in a bowl, with a bowl of water near by. The theory is that the rats use the bowls alternately, with disastrous results to themselves.

LETTERS, NOTES, ETC.

SCUTELLARIA IN EPILEPSY.

DR. WILLIAM BRAMWELL (Liverpool) writes: In view of the correspondence on bromides in epilepsy it would, perhaps, be worth while to introduce to the notice of the profession the simple herb scutellap, or *Scutellaria latiflora*, in the treatment of this disease. In many cases a simple infusion or extract in correspondingly suitable doses will lessen the severity of the fits and reduce their number equally with bromides and without any of the disadvantages of the latter. Its efficacy appears to be partly due to its stimulating the kidneys to increased activity not only in increasing the flow of water but also the output of urea and uric acid as shown by the increased specific gravity of the urine, the retention of such toxins as a cause of many cases of epilepsy being too frequently overlooked. The medicinal qualities of this simple remedy are even more marked in chorea than in epilepsy, and it is to be hoped that a similar investigation and a similar therapeutic distinction awaits scutellap as happened in the case of comfrey, the invaluable qualities of which were limited to the use of the herbalist and consequently despised by the profession until Dr. C. J. Macalister, wisely setting aside prejudice, determined to investigate it, and having discovered its cell proliferating properties proved it beyond question one of the most valuable of remedies.

TREATMENT OF FROST-BITE.

DR. J. M. JOHNSTON of Toronto sends a note on the treatment of true frost-bite, in which he recommends the application of very hot water. He once tried it on his own ears, with the result that it at once produced a feeling of comfort, the ears did not swell or peel, and were not tender, as he feels sure you will have been the case had he followed the custom of rubbing with snow.

SCALE OF CHARGES FOR ADVERTISEMENTS IN THE BRITISH MEDICAL JOURNAL.

All remittances to Post Office orders must be made payable to the British Medical Association at the General Post Office, London. No responsibility will be accepted for any such remittance not so safeguarded.

Advertisements should be delivered, addressed to the Manager, 429, Strand, London, not later than the first post on Wednesday morning preceding publication, and, if not paid for at the time, should be accompanied by a reference.

Note.—It is usual for the rules of the Post Office to receive *poste restante* letters addressed either in initials or numbers.

A CLASSIFICATION OF MENINGOCOCCI BASED ON GROUP AGGLUTINATION OBTAINED WITH MONOVALENT IMMUNE RABBIT SERUMS.

By ARTHUR W. M. ELLIS, CAPTAIN C.A.M.C.,

No. 5 (CANADIAN) MOBILE LABORATORY, BRITISH EXPEDITIONARY
FORCE, FRANCE.

That all strains of meningococci are not affected equally by an immune serum prepared against any one strain has long been known. This has led to the conception that there are within the meningococcus group types of organisms which are more or less immunologically independent. This conception, borne out by the practical results in the treatment of human cases, has led to the universal adoption of a polyvalent serum in the treatment of cerebro-spinal fever. Though this conception of variant types of meningococcus has long existed, the number of types which occur and the degree of specificity which exists within these types has never been determined. It is for this reason that, in the preparation of the therapeutic serums, as many strains as possible have been used and the strains obtained from widely varying geographical sources. In this way it was hoped to include representatives of all existing types.

The purpose of this communication is to show that, by means of a specific immune reaction, two types of organism causing cerebro-spinal fever can be demonstrated, and that of forty-six organisms studied all belonged to one or other of these types. It will be shown, moreover, that both types are widely distributed, representatives of each type having been found in six different epidemic foci; that they occur in some epidemics with nearly equal frequency; and that the differentiation obtained is such as to suggest the probable complete immunological independence of the two types.

The earliest attempts made to differentiate types of meningococci were mainly directed towards establishing points of difference between the organism isolated in cases of epidemic meningitis and those from the sporadic cases of this disease, the so-called posterior basic meningitis. These attempts were unsuccessful.

In 1909 Elser and Hüntoon¹ described an organism indistinguishable from the meningococcus except by means of agglutinin absorption tests. To this organism they gave the name "pseudomeningococcus." In their article the source from which these organisms were obtained is not very clearly stated, but apparently they were all isolated from the naso-pharynx. They speak of the pseudomeningococcus as "only rarely encountered in the throats of normal and diseased subjects," and do not consider that it interferes with the practical identification of the meningococcus or of meningococcus carriers. They do not seem to look upon the pseudomeningococcus as a causative agent of cerebro spinal fever.

In the same year Dopfer² studied and described a similar organism, also obtained from the upper air passages, to which he gave the name "parameningococcus." This organism, probably identical with the pseudomeningococcus of Elser and Hüntoon, has since been found by Dopfer and other French workers to invade the blood and meninges, and is looked upon by them as one of the causative agents in epidemic meningitis. An anti-serum against this organism has been prepared by Dopfer and successfully used in the treatment of human patients.

Recently Wollstein³ has made a careful comparative study of the immune reactions of the meningococcus and the parameningococcus of Dopfer. From her investigations she came to the conclusion that "the parameningococci of Dopfer are culturally indistinguishable from true or normal meningococci, but serologically they exhibit differences as regards agglutination, opsonization, and complement fixation. Because of the variations and irregularities of serum reactions existing amongst otherwise normal strains of meningococcus it does not seem either possible or desirable to separate the parameningococci into a strictly definite class. It appears desirable to

consider them as constituting a special class among meningococci, not, however, wholly consistent in itself." It will be seen, therefore, that, though there is apparently some variation in the reaction to immune serums of certain organisms isolated from cases of cerebro-spinal fever, no sharp-cut differentiation of meningococci has as yet been made and no record of the frequency with which these aberrant or parameningococci strains occur is available.

In reviewing the literature of meningococcus agglutination two facts immediately impress themselves—first, the wide variation in agglutinability of different strains of meningococci, and, second, the susceptibility of certain strains to agglutination by any serum, normal or immune, that is, susceptibility to non-specific agglutination. Thus Arkwight,⁴ and also Elser and Hüntoon,⁵ have shown that gonococcus-immune serum will agglutinate certain strains of meningococcus in as high dilutions as will meningococcus-immune serum. Elser and Hüntoon, however, noticed that in such cases, while the final result with gonococcus and meningococcus serum was the same, the rate at which the reaction occurred in the two instances varied widely, the reaction being much more rapid with meningococcus serum.

In all previous work upon the agglutination of the meningococcus the agglutinations have been studied with increasing dilution of serum, and the highest dilution in which agglutination has occurred at the end of twenty-four hours has been taken as the standard of agglutination. In the light of the above results, it seemed possible that when a period of twenty-four hours was allowed to elapse before readings were made, a more slowly occurring non-specific agglutination might frequently mask all specific results. It seemed advisable, therefore, to see if, by allowing a powerful serum to act over a short period of time, specific differences could be demonstrated which were missed when the ordinary method of diluted serum acting for twenty-four hours was used. Undiluted serum was therefore employed and the agglutinations which immediately ensued noted. It was at once determined that with this method marked differences between strains of meningococci could be demonstrated.

Method.

Monovalent serums were prepared by immunizing rabbits against single strains of meningococcus. The rabbits were immunized by intravenous injections given at weekly intervals, the dose consisting usually of half a slant culture of twenty-four to seventy-two hours' growth. The first two or three injections were made with organisms killed by heating at 60° C. for thirty minutes; subsequent injections were of living organisms. Five injections usually produced a satisfactory agglutinating serum.

Agglutinations were all done macroscopically, equal quantities of undiluted serum and of rather thin bacterial emulsions being drawn into a capillary pipette, thoroughly mixed on a glass slide and the mixture again drawn into the pipette, the tip of which was then sealed in the flame. In the case of a prompt reaction, agglutination takes place before the mixing is completed, all the organisms becoming almost instantaneously tightly clumped, leaving a clear supernatant fluid. The tubes were read immediately and then left at room temperature, readings being again made at the end of an hour and on the following morning. In recording the results of agglutinations the following designations were employed: C, complete clumping of the organisms, leaving a clear or faintly opalescent fluid; 1, majority of organisms clumped, the supernatant fluid remaining opalescent; L, slight clumping; and 0, no clumping, though in the course of twenty-four hours slight sedimentation may occur.

Experimental.

Rabbits were immunized against eight different strains of meningococci. Unfortunately four of these eight strains were lost before their agglutination reactions could be tested, so that cross agglutinations between the whole eight strains and their corresponding serums could not be carried out. They were, however, done with the four remaining strains. The results are shown in Table I. It is to be understood that these results were not all obtained on one day, but represent the combined protocols of three separate experiments.

TABLE I.—Agglutination of Meningococcus Strains by Homologous and Heterologous Monovalent Immune Rabbit Serums.

SERUMS.	MENINGOCOCCUS STRAINS.											
	M. 4.			M. 7.			M. 9.			M. 13.

Rabbit 69, M. 13...	I	0	0	C	C	C	0	0	I	C	C	C

C = Complete agglutination. I = Incomplete agglutination. L = Least degree of agglutination. 0 = Negative result.

It will be seen that the three strains M. 4, M. 7, and M. 13 were agglutinated by five of the eight serums employed (M. 3, M. 4, M. 5, M. 7, M. 13), though in the case of three of these (serums M. 3, M. 5, M. 7) the agglutination was feeble. Three serums (M. 6, M. 9, M. 11) failed entirely to agglutinate these organisms. The reactions with strain M. 9 were, on the other hand, exactly opposite, the five serums (M. 3, M. 4, M. 5, M. 7, M. 13) failing to agglutinate this strain, while prompt agglutination occurred with the three (M. 6, M. 9, M. 11) which failed to agglutinate the other three organisms. That the feeble agglutination in the case of the serums M. 3, M. 5, and M. 7 was due to a simple lack of potency of these serums, and not to difference in the organisms, seems probable, since in the only case where it could be tested (M. 7) agglutination was equally feeble with the homologous organism.

On the basis of these results it would seem that two types of meningococci can be differentiated according to their reaction to monovalent immune rabbit serums. These we shall designate Types I and II. To Type I belong M. 4, M. 7, M. 13, and since serums prepared by immunizing rabbits to strains M. 3 and M. 5 agglutinate these organisms, it is evident that they also are of this type. Similarly M. 6, M. 9, and M. 11 are evidently another type, which we shall designate Type II. A second point which is brought out in Table I is, perhaps, worthy of mention. This is the well known variation in the agglutinability of different strains of meningococci. It will be seen that M. 7 and M. 13 show almost identical reactions, while with M. 4, though qualitatively the same, they are quantitatively weaker, the three weak serums failing to give any immediate reaction, and showing, only at the end of an hour, agglutinations comparable to the immediate reactions obtained with the more agglutinable strains.

A preliminary classification into two types having been thus obtained, it was necessary to determine whether such results would hold when applied to a large number of strains of meningococci. All available strains were therefore tested with strongly agglutinating serums of both types. The results are shown in Table II. The Type II serum which was at first employed was not as powerful as one which was afterwards produced, so that the reactions of this group were not at first quite as sharp as those later obtained. In Table II strain M. 33 marks the beginning in the use of more powerful Type II serum.

Table II shows clearly the sharp differentiation of two types of meningococci, all the strains tested with three exceptions (M. 18, M. 39, M. 49) belonging clearly to one or other type. These three inagglutinable strains will be considered later. Excepting them we see that in no case did immediate agglutination fail to occur with the proper type serum. Cross agglutination between types was never seen immediately, but did occur three times at the end of an hour (M. 28, M. 32, M. 56). In two of these three instances, however (M. 32, M. 56), the strains showed agglutination of equal extent with normal serum. Only one example of true cross agglutination therefore occurred (M. 28), and here the reaction was so slight that it could not possibly interfere in the differentiation of the type to which this strain belonged. As will be seen by Table II, three strains could not be classified (M. 18, M. 39, M. 49), failing to agglutinate with serums of either type. Further investigation showed that the inagglutinability of these

three strains was only a relative affair, and that when more potent Type II serum—for example, rabbit 66, M. 12, obtained by more prolonged immunization of rabbits—was used, some degree of agglutination of even these resistant strains occurred (Table III). It was noticed, moreover, that the agglutinability of these strains varied from day to day, an organism which had failed to agglutinate one day showing typical prompt agglutination the next. In order to prove definitely the relationship of these exceptional strains monovalent serums were prepared against all three, and cross agglutinations were then carried out between these serums, their homologous organisms, and known representatives of Types I and II. The results are shown in Table III.

It will be seen that all three strains are certainly representatives of Type II, since their antisera give typical agglutination of a known Type II organism (M. 37) and fail to show any reaction with an organism of Type I (M. 20). It will be noticed that the three show a graded variation in their degree of inagglutinability—M. 18 the most inagglutinable, M. 39 next, and finally M. 49, which, with a powerful Type II serum, shows immediate agglutination. It is clearly shown that the failure of these organisms to react is due to their inherent inagglutinability and not to any difference in type, since in every case their antisera agglutinate an agglutinable Type II organism more strongly than they do their homologous organism. Moreover, within the group the reactions take place according to the evident potency of the serums and agglutinability of the organisms, and not according to whether homologous or heterologous serum is employed. Thus rabbit 21, M. 39, fails entirely to agglutinate its homologous organism, while it agglutinates strongly the agglutinable Type II organism (M. 37) and weakly the relatively inagglutinable strain, M. 49. The same phenomenon is seen with the serum of rabbit 4, M. 18.

In Table II the results of exposing a number of strains of meningococcus to Type I and Type II serum were shown. By way of confirming these results the effects of exposing organisms of Types I and II to the action of serums prepared against a number of the strains tabulated in Table II have been studied. These results are shown in Table IV.

It will be seen that these results are in every case confirmatory, the antisera prepared against the two organisms of Type I alone agglutinating the Type I strain,

while the Type II organism is agglutinated only by antisera of organisms previously determined as of Type II.

TABLE IV.

Agglutination of meningococcus strains Type I (M. 4) and Type II (M. 12) by monovalent rabbit serums produced by immunizing with various meningococcus strains M. 4 and M. 49, Type I, the remainder Type II. Normal rabbit serum control.

Distribution and Relationships.

It has thus been shown that without exception all strains of meningococci, so far met with in this investigation, can be placed in one or other of two types. There remains to be considered the distribution of these types and their relations to the parameningococcus of Dopter.

The strains of meningococcus which have been studied were isolated from patients in six different epidemic foci. For those from the Tidworth, Reading, Woolwich and London epidemics I am indebted to Dr. J. A. Arkwright of the Lister Institute, and for some of the strains isolated in France to Captain J. W. McNee, No. 3 Mobile Laboratory. In Table V is shown the epidemic foci from which individual strains were obtained, and the number of each type found in the strains from these various sources.

Organisms of both types were found in all six epidemic foci. Type I was more common than Type II, but in the

case of the British army in France the difference was negligible. It is perhaps of some significance that this group in which the proportion is more nearly equal, embraces the largest number of organisms, the widest distribution in area, and the most nearly constant conditions of isolation and subsequent growth of the organisms. It will readily be seen that in a heterogeneous collection, such as these forty-six strains represent, a slight variation in ease of isolation or in subsequent viability of one type as compared with the other might completely upset all calculations. In contradistinction to the greater frequency of Type I in these strains isolated from the spinal fluid, we have found in five strains of meningococci isolated from the naso-pharynx of healthy carriers Type II four times and Type I once. The exact frequency with which the two types of meningococci occur can, then, only be determined by a study of the infecting organism in every case of a large series. It will probably be found to vary in different places and in different years. It seems obvious, however, that both types are widely distributed, and must be held equally responsible as causative agents of cerebro-spinal fever.

The relation of the parameningococcus of Dopter to the types above described has been determined for one strain of parameningococcus. This strain, known as "parameningococcus St. Quay," was obtained through the kindness of Dr. Armand Netter of Paris, and was isolated by Dr. Matthias Pierre Weil. Its reactions are shown in Tables VI and VII; they are identical with an organism of Type II.

TABLE VI.—Agglutination Reactions of Parameningococcus.

Monovalent rabbit serums of Types I (Rabbit 76, M. 4) and II (Rabbit 66, M. 12) vs. parameningococcus (P. M. St. Quay). Monovalent rabbit anti-parameningococcus serum (Rabbit 42, P. M. St. Quay) vs. organisms Type I (M. 20) and Type II (M. 37). Normal rabbit serum control.

Another strain of parameningococcus, obtained from the Pasteur Institute, has also been studied. Unfortunately, this organism possessed such a high degree of non-specific agglutinability and such low antigenic properties that its exact relations could not be determined. It, too, however, appeared to be a member of Type II.

It would seem probable, therefore, that our Type II meningococcus and the parameningococcus of Dopter are identical. In view of the apparent frequency with which this organism causes cerebro-spinal fever, the identical character of the disease caused by the two types, and, if we except immune reactions, the exact similarity of the two organisms, it would seem desirable to call both types

of organism the meningococcus, and to drop the use of such terms as "parameningococcus" and "pseudomeningococcus," which are only complicating and misleading. In this connexion it may be interesting to point out that the occurrence of types of meningococci differing only in their immune reactions has an exact parallel in the types of pneumococci demonstrated by Dochez and Gillespie,⁶ by whom four types of pneumococci causing lobar pneumonia have been established.

The Bearing of these Observations.

The occurrence of two types of meningococci and the fact that all organisms so far tested will react to a monovalent immune serum of one or other type suggests at once the possibility of the treatment of human cases of cerebro-spinal fever with such monovalent serums. It is probable that in this way more powerful antiserums could be prepared than by the haphazard choice of strains for the immunization of horses such as at present obtains. In the preparation of monovalent type serums the most powerful antigenic strain of each type would, of course, be used. For the first treatment of the patient a mixture of the two serums could be used, to be followed as soon as the type of the infecting organism is determined by the appropriate monovalent serum. Such a scheme would seem to put the serum treatment of cerebro-spinal fever on a much sounder basis and would prevent the occurrence of situations, such as were common in England last winter, where patients were treated with serums which, even *in vitro*, showed no effect on the organism causing the disease. Here we may again point to the parallelism with pneumonia, where the use of a similar method⁷ has led to a much clearer understanding of the difficulties and possibilities of serum-therapy.

SUMMARY.

1. The causative agent of cerebro-spinal fever, the meningococcus, is of at least two types.
2. These two types are, as regards the one immune reaction tested, agglutination, absolutely independent.
3. In a study of forty-six strains of meningococci, obtained from various sources, all were of one or other of these two types.
4. Both types are widely distributed, having been found in each of six epidemic foci. They may occur with equal frequency.
5. Both types have been found in the naso-pharynx of healthy carriers.
6. We have designated these two types, Types I and II.
7. In so far as evidence is available, Type I has been more frequently the cause of the disease in the recent epidemics than has Type II. In view of the wide distribution of the two types, both must, however, be held equally responsible as causative agents of cerebro-spinal fever.
8. The organism herein described as Type II is probably identical with the parameningococcus of Dopter.
9. It is suggested that in the treatment of cerebro-spinal fever better results might be obtained, and more exact knowledge of the adequacy of serum treatment gained, if monovalent horse serum of appropriate type, and therefore known to be active against the infecting organism, were employed in place of the polyvalent serums at present in use.

THE Paris Municipal Council has voted a sum of £2,400 in aid of the scheme of sanitary stations created by the Minister of the Interior for the temporary accommodation of tuberculous soldiers.

THE first National Medical Congress of the Republic of Uruguay will be held at Montevideo in April, 1916 (9th to 16th), under the presidency of Professor José Brito Foresti. Among the members of the honorary committee are the President of the Republic, the Ministers of the Interior and Public Instruction, the Rector of the University, the Dean and Professors of the Medical Faculty, and the officers of the leading medical and scientific societies of Uruguay. Among the subjects proposed for discussion are syphilis, alcoholism, the means of checking the prevalence of abortion, cancer in Uruguay, and the hospital question in that country.

GROUPING OF THE STRAINS OF MENINGOCOCCUS

ISOLATED DURING THE EPIDEMIC OF CEREBRO-SPINAL MENINGITIS IN 1915.

By JOSEPH A. ARKWRIGHT, M.D.,

FROM THE LISTER INSTITUTE OF PREVENTIVE MEDICINE.

The following account refers only to strains of meningococcus which were isolated from the cerebro-spinal fluid or meninges of cases of meningitis. All the strains conformed to the usual morphological and staining characters of the meningococcus. Culturally they did not make growth at the temperature of the laboratory and they fermented glucose but not cane sugar.

The formation of a uniform permanent emulsion in physiological salt solution was a constant characteristic of all the strains, except three, which sometimes showed agglutination in salt solution (NaCl 0.85 per cent.).

Several of the cultures gave a distinctly yoke-yellow growth on glucose agar; this was especially noticeable in the case of two strains, M. 13 and 4410, on some occasions. Many strains made a very mucilaginous growth on moist glucose agar. The culture medium found most convenient for applying the sugar tests was Hiss's serum water. After mixing serum one part with distilled water three parts, the mixture can be autoclaved at about 118° for twenty minutes without causing precipitation of the protein; 1 per cent. carbohydrate and litmus can then be added and the tubes steamed three times. Stock cultures were kept on 1 per cent. glucose agar at 37° in closed tin boxes.

Thirty-five strains were examined, which came from the following sources:

Nine from cases occurring in the first Canadian contingent on Salisbury Plain, found February, 1915.

Four other cases occurring in the first Canadian contingent on Salisbury Plain, found March, 1915.

Eight cases occurring in the Herbert Hospital, Woolwich, received through the kindness of Mr. K. Goadby.

Nine cases occurring among soldiers, kindly supplied to me by Major Gordon and Captain Hine, R.A.M.C.

Two cases occurring in France, received from Major S. Rowland, R.A.M.C.

Two cases occurring at Reading, received from Dr. Donaldson.

One case occurring at Watford.

Agglutination tests have been performed with two main objects: (1) With polyvalent rabbit serum, with the object of obtaining a criterion for the diagnosis of the meningococci. (2) With serum prepared from rabbits with single strains, in order to determine whether these strains of meningococcus, isolated during the epidemic, fell into groups.

At the same time agglutination tests were made with antimeningococcus and antiparameningococcus serums obtained from the Pasteur Institute, through the kindness of Professor Roux.

Preparation of Serums.

In order to obtain agglutinating serums, rabbits were inoculated intravenously with unheated emulsion. Suitable serums, with a sufficiently high titre, were not obtained till the animal had received seven to ten injections; the maximum dose given was two glucose agar slopes. For the tests detailed below three rabbit serums were used:

A. prepared from a single strain—Plank.

B. prepared from a single strain—M. 13.

C. prepared from six strains—Carter, Crisp, Plank, Palmer, M. 1, M. 13.

Agglutination Technique.

Cultures of one day's growth on glucose agar were emulsified in distilled water containing 0.5 per cent. phenol. The serum was diluted with salt solution (0.85 per cent. NaCl). The density of emulsion used was judged by eye, and was of about the consistence obtained by adding 10 c.c.m. of water to one glucose agar slope. Several strains were tested on the same day, and two or four serums were used on each occasion; the results, therefore, to some extent controlled each other. A control

tube with salt solution was always included for each strain, and each strain was tested with normal horse or rabbit serum.

Agglutination was not obtained with $\frac{1}{2}$ normal serum with any strain unless agglutination also occurred in salt solution. It was found that rather higher specific agglutination was obtained when the tubes contained salt solution of half or one quarter the usual strength, than when both the emulsion and the serum dilutions were made up with physiological salt solution (NaCl 0.85 per cent.).

The agglutination tests were carried out macroscopically in small tubes which were put in the incubator at 37° C. for eighteen to twenty hours, and then kept on the bench at the temperature of the laboratory. When complete agglutination (C) occurred there was complete clearing of the supernatant fluid and marked deposit.

The least degree of agglutination (L) noted was shown by the absence of the small round collection of sedimented cocci, rather larger than a pin's head, seen in the control tubes, and by an irregular granular deposit scattered over the concave bottom of the tube.

The results obtained with the multivalent serum C. are shown in Table I. Of 32 strains tested, 30 showed agglutination complete or almost complete in a dilution of 1 in 100. One strain (Llandindod) agglutinated completely, 1 in 800; another strain (Carter) reached 1 in 400, and ten strains were completely agglutinated by a dilution of 1 in 200. Of the remaining two strains, one (Kennedy) only gave incomplete agglutination (I) in 1 in 100, and the other (McPhail) agglutinated slightly in salt solution, and only incompletely 1 in 100. Tests with serum C. of strain of *Diplococcus flavus*, which did not agglutinate in the salt solution control, were negative.

The table also shows the agglutination results obtained with the two univalent rabbit serums A. and B., and also with antimeningococcus and antiparameningococcus serum from the Pasteur Institute.

By means of the two serums A. and B. it was possible to place 27 out of the 35 strains in one or other of two groups:

17 in Group A. were agglutinated best by Serum A. prepared with strain "M. 13."

10 in Group B. were best agglutinated by Serum B. prepared with strain "M. 13."

By means of the two Pasteur Institute serums 27 out of the 35 strains could be divided into two groups:

15 into Group M. agglutinated best by antimeningococcus serum, and

12 in Group P. agglutinated by antiparameningococcus serum.

Whenever the strains could be grouped definitely by both pairs of serums—that is, A. and B. and M. and P. respectively—a strain falling into Group A. also fell into Group M., and those agglutinated by B. serum were also agglutinated by antiparameningococcus serum, except in the case of two strains.

It seems, therefore, justifiable to speak of two main groups, A. M. and B. P., corresponding to the meningococcus and parameningococcus groups of Doetzer. Whenever a strain fell into the B. P. group it appeared to do so quite definitely; the A. M. strains varied more in their agglutinability, and were more influenced by the B. P. serums than the B. P. strain were affected by the A. M. serums.

By means of these four serums it was possible to definitely group 30 strains—18 in the A. M. group, and 12 in the B. P. group. One strain could not be classified. One strain (Chandler) agglutinated not very strongly, but equally with A. and B. serums. One strain (McPhail) agglutinated in salt solution. Two strains (Chase and Berkhamstead) fell in different groups on two occasions. Chase was agglutinated best by P. serum on June 25th, and by M. serum on August 18th. Berkhamstead was agglutinated by P. serum on July 20th, but not on August 30th, on which later date it reacted better with A. serum than with B. serum. One strain (Littledale) gave no reaction with the Pasteur Institute serums, but agglutinated completely with serum C.

Some inquiries were made into the sources of the strains to find out (1) whether the different localities yielded more of one group of meningococcus than the other; (2) whether the clinical symptoms were different or more severe in cases infected with one group than with the other. No decisive answer could be given to either

L = Least degree of agglutination.

0 = Negative result.

question, and neither inquiry supported the view that these two groups of meningococcus are permanently different stocks causing different types of disease, or were confined to different epidemiological outbreaks.

Table II (p. 837) shows the sources of the strains and their grouping by agglutinating serums.

The strains from Woolwich and those from Major Gordon and Captain Hine no doubt came from patients of various origin, but the Canadian strains were all isolated in January and February, 1915, and the four other strains from Salisbury Plain also came from cases in the same area in February and March. Of these thirteen strains from Salisbury Plain, seven fell in the A. and M. group and four in the B. and P. group. D. III and D. V, both coming from Reading in the spring of 1915, fell in different groups.

On analysis of nine cases occurring in the First Canadian Contingent, from which strains of meningococcus were isolated and tested, five cases were infected with meningococci of the A. and M. group; of these one recovered, the remainder died within four days of the onset of the disease. Two yielded cultures of the P. and B. group; one lived five months but eventually died, the other died within two days. The two strains from France—M. 7 and M. 13.—were both B. and P. strain, and both cases were fatal.

This small series shows that severe and fatal cases of the disease may be associated with either group of the two strains of meningococcus found in this epidemic.

Three strains of meningococcus isolated from the throats of persons in contact with cases of cerebro-spinal meningitis have been so far examined with the same

serums. Two of these strains fall definitely into the B. and P. group; the third was feebly agglutinated by both M. and P. serums, but more by M. serum.

REMARKS.

In the first twenty years after the discovery of the meningococcus by Weichselbaum (1887) the tendency to accentuate the variability of this organism was carried by Jaeger (1895) to the point of claiming for it an ability to change into a Gram-positive diplococcus, which grew readily at 20° C., and was very resistant to drying. The observations of Councilman, Mallory and Wright (1898), Albrecht and Ghon (1903), and others confirmed the description of Weichselbaum, and von Lingselsheim (1906) claimed a very high degree of uniformity for the strains isolated by him during the Silesian epidemic, and stated that all these strains of meningococcus agglutinated with a univalent serum obtained by injecting a rabbit with one strain.

Many other writers have reported on the value of agglutinating serum for identifying the meningococcus. Several workers, however, especially Eberle (1908), Elser and Hüntoon (1909), Traubmann and Fromme (1908), Arkwright (1909), described undoubted strains of meningococcus which were inagglutinable with antimeningococcus serum, and pointed out the irregularity with which univalent serums affected strains which had not been used in their preparation. Eberle, and Elser and Hüntoon, moreover, showed that the serum made with one strain might have a far higher agglutination titre for some strains than they had for others, even if the homologous strain remained relatively inagglutinable. Most of these writers, especially Eberle, and Elser and Hüntoon, attributed the irregularities observed to the varied agglutinability of different strains and to their different value as antigen (agglutinogen). Houston and Rankin (1907) claimed to be able to differentiate strains of meningococcus obtained from cases of infantile posterior basic meningitis from strains derived from epidemic cases.

In 1909 and 1912 I was able to divide the sporadic and epidemic strains of meningococcus with which I was working into groups which did not inter-react, by agglutination and complement fixation tests. The groups appeared to overlap somewhat. By absorption of agglutinins the groups could be further subdivided. My results led me to the conclusion that epidemic and sporadic strains were both divisible into an uncertain number of groups which were not closely related serologically, but which were connected by intermediate strains.

Dopter (1909) described a strain which he called parameningococcus. It was isolated from the naso-pharynx, and resembled the meningococcus except in serum reaction. Antimeningococcus serum did not agglutinate the parameningococcus. Subsequently (1911) he recorded the isolation of the parameningococcus from the cerebro-spinal fluid of severe cases of sporadic meningitis, all of which were fatal. He considered that cerebro-spinal meningitis might be caused by either the meningococcus or the parameningococcus. He also began preparing therapeutic serum from horses for the two classes of cases. In 1914 Dopfer described three groups of parameningococci differentiated by absorbing agglutinin from antimeningococcus and from antiparameningococcus horse serums, and also by univalent rabbit serums. He stated that antimeningococcus serum sometimes agglutinates parameningococcus strains as well as the meningococcus, but that parameningococcus serum usually agglutinates both varieties.

The large majority of the strains examined in the present paper appear to fall into two main groups which are identical with or closely allied to the meningococcus and parameningococcus main groups described by Dopfer. This has been shown by using Pasteur Institute therapeutic M. and P. serum for agglutination tests. These serums, however, are no doubt made by the inoculation of several strains, since Dopfer (1914) stated that three parameningococcus strains were used for the horse.

Of the five strains which I have been unable to classify, two (Chase and Berkhamstead) appear to occupy an intermediate position between the two groups, and perhaps contain individual cocci which react with different serums. One (Littledale) was not agglutinated with the serums used. One (Chandler) was feebly and equally agglutinated by serum for both groups, and therefore perhaps belongs to the M. rather than to the P. group.

The strains belonging to the B. and P. parameningococcus group appeared to give sharper differentiating reaction than those of the A. and M. group. This corresponds with Dopfer's observation that parameningococcus serum usually agglutinates meningococci, but that meningococcus serum as a rule has no action on the member of the other group.

Effect of Therapeutic Serums.

The fact that meningococci are not all alike serologically, but fall into different groups, provides a reason why the therapeutic serums used during the 1914-15 epidemic in this country appeared to have so little value. It is probable that the horses from which the serum was derived had not received the same groups or subgroups as occurred in this epidemic. However, the strains isolated in 1915 appear to fall for the most part into the same main groups as Dopfer's meningococci and parameningococci which have been present in France for some years.

A. Netter (1915) had very successful results in France with the Pasteur Institute serum. His cases showed a mortality of only 22 per cent. without excluding fulminant cases and deaths from other causes.

It has been demonstrated by Elser and Hüntoon and other workers that the antigenic properties of different strains of meningococcus are very different in value. It is therefore very probable that where large numbers of strains of meningococcus have not been available for immunizing the horses, those strains which offered the best antigen have not been used.

CONCLUSIONS.

1. Thirty out of thirty-two strains of meningococci tested agglutinated with a polyvalent rabbit serum prepared with six strains isolated in the same epidemic.
2. Thirty strains isolated during the present epidemic fall into two main groups according to agglutination tests. Five other strains presented difficulties in their classification.
3. These two main groups correspond to Dopfer's classification into meningococci and parameningococci.
4. The numbers falling into the two groups—meningococci and parameningococci—were 18 and 12 respectively—that is, 3 to 2.
5. There is some evidence that two of the five unclassified strains were intermediate in character between the two main groups.

6. Neither group was more frequently found among cases from one district than from another.

7. Rapidly fatal cases of meningitis occurred with infection with either type of meningococci.

I must express my thanks to those who have kindly given me cultures, and especially to Captain A. W. M. Ellis, C.A.M.C., who isolated many Canadian strains, and to Major Gordon and Captain Ilinc, R.A.M.C. To these and other workers I am indebted for cultures and for help. I look forward with great interest to the publication of the results obtained from their work during the present year.

Remarks

OS

SOME OF THE EFFECTS OF EXPOSURE TO WET COLD AND THEIR PREVENTION.

(PREVENTION OF "FROST-BITE," "TRENCH-FOOT," "WATER-BITE.")

BY

S. DELÉPINE, M.B. EDIN., M.Sc. MANCH.,

DIRECTOR OF THE PUBLIC HEALTH LABORATORY, UNIVERSITY OF MANCHESTER.

I. FRIGORISM.

In a recent communication¹ I recorded some experiments showing that when the temperature of the skin is reduced by exposure to an external cold medium sensory disturbances, cramps, and anaesthesia are produced when the temperature of the skin is still several degrees above 0° C.

In experiments of this kind it is difficult to ascertain the cutaneous temperature absolutely because the recording instrument cannot be completely protected against the influence of the external medium without causing part of the skin to escape the same influence, but in comparative experiments it is possible to show that a reduction from 30° C. to below 10° C. in the indicated skin temperature is gradually and successively followed by sensations indicating irritation of the cutaneous sense organs, reflex contraction of the vessels, cramps, to which may be added after a variable time more or less complete anaesthesia and motor paralysis. These phenomena are not associated with permanent lesions when the exposure is not prolonged. They are produced in a few minutes when one of the extremities is plunged into salt water at 1° or 2° below 0° C.

They occur more slowly when the temperature of the water is a few degrees above 0° C., but when the water is unlimited in amount and circulating freely, very severe symptoms may be produced even when the temperature of the fluid is as high as 7° C. or even 10° C., more especially when the individual is ill nourished, the general or local circulation is bad, and the exposed part attenuated or protected by an insufficient amount of subcutaneous fat. The latter condition, which is the least important, is not negligible, as is shown by a well-known experiment. A

block of ice being applied to the external, and a thermometer to the internal, surface of one cheek, the thermometer may after one hour indicate a fall of 8° C. in a thin subject, while in a stout person the fall may be 3° C. only.

All these phenomena occur independently of any freezing of the parts. They undoubtedly indicate that cold has a powerful action upon the peripheral nerves and end organs, the vasomotor mechanism, the voluntary muscles, etc. These effects are, however, quite different from the more permanent lesions caused by freezing, and occurring in the blood, blood and lymph vessels, nerves, muscles, etc., which have been described by Pouchet, Tillaux and Grancher, Jamain and Terrier, Cohnheim, and others, in connexion with frost-bite.

Repeated or prolonged cooling of the skin to a temperature a few degrees only above 0° C. is, however, also liable to produce permanent effects, and in the course of my investigations I have observed in a foot which had been cooled several times evidences of permanent increase of irritability of some cutaneous nerves, probably indicating some slight localized peripheral neuritis, and a tendency to disturbances of circulation predisposing to excessive liability to coldness of the extremity.

These effects are not properly covered by the names "frost-bite," "trench-foot," "water-bite," but correspond to a state which is better defined by the term "froidure," used by some French writers, or its English equivalent "frigorism," suggested by me.

This state is produced when the cooling of the body or any part of it is progressive—that is, when it cannot be compensated by the production in the tissues, and the distribution by the circulating blood, of a sufficient amount of heat. Frigorism may be general or local.

When the cooling of a part reaches a certain point, the functions of the tissues are interfered with to an extent determined by the nature of the tissue, the temperature and the duration of the exposure. When the freezing-point is reached certain mechanical complications connected with the change of state are superadded to the effects of lowering of temperature.

When a body is surrounded by a medium at a lower temperature than itself, heat passes from the body into the medium until the temperature of both is the same.

The rapidity of this exchange is determined by many well-known factors. The loss of heat from any part of the body of an animal is governed mostly by the following conditions:

1. The temperature, the thermo-conductivity, the volume, and the movements of the external medium.
2. The duration of the exposure.
3. The bulk, movements, and superficial area of the part exposed.
4. The thermo-conductivity of the tissues and more particularly of the integuments.
5. The amount and velocity of the flow of blood through the part.
6. The state of nutrition, activity and soundness of the tissues locally and generally (the kind and amount of food available being included under nutrition).

The importance of all these factors is a matter of general experience and is capable of experimental proof. Some experiments bearing upon this aspect of the question have been related in my previous communication.

With regard to the share taken by the nature of the external media, it is sufficient to refer to some well-known facts. Exposure to dry air at 0° C. does not materially affect a healthy, active, well-clothed person. Arctic explorers have been able to bear very much lower temperatures without serious consequences on account of the dryness of the air in the polar regions. Exposure to damp air at 0° C. or several degrees higher produces a very marked sensation of cold which is distinctly uncomfortable.

Immersion in water at 0° C. is immediately followed by a sensation of intense cold, and within a few minutes loss of sensation and paralysis occur.

Complete contact of the skin with bars of metal at 0° is immediately painful, and if the temperature of the metal is a few degrees below 0°, the tissues in contact with it are rapidly frozen.

With the object of determining to what extent the low

conductivity of air could be utilized for the purpose of preventing the effects of exposure to cold, I made some experiments which have been described in previous communications^{1,2} (Fig. 1). Within the range of temperature and the period of time covered by these experiments, the effects of exposure of the extremities of a healthy elderly adult to external media colder than the skin were found to be widely different according to circumstances.

1. The lowering of temperature caused by exposure to cold dry air was slight and not progressive. The loss of heat was obviously compensated by the heat yielded by the tissues and the circulating blood.

2. The lowering of temperature caused by immersion in a limited amount of water was rapid and considerable but not permanent. When the bulk of the water did not exceed twice that of the part immersed, enough heat was yielded by the tissues and circulating blood to warm the water to a temperature which was not detrimental to the part (Fig. 2).

3. The lowering of temperature caused by immersion in (a) a large amount of water at a temperature 25° to 30° C. below that of the skin, or (b) water (in limited or unlimited quantity) containing ice, was very rapid, considerable, and progressive. A pathological state, local frigidism, was invariably the result. This state was characterized by contraction of small arteries, more or less complete arrest of flow of blood, various degrees of anæmia or passive hyperæmia (cyanosis of part), irritation of terminal nerves followed by nervous and muscular paralysis (Fig. 3, C, F).

4. Motion of the external fluid medium prevented the formation of a comparatively warm layer of fluid near the surface of the skin and accelerated the loss of heat. The presence of a thick woollen covering retarded the loss of heat, even when the covered part was plunged into water, owing to the warming of the comparatively still layer of water retained within the meshes of the woollen fabric.

5. A thin layer of moderately dry air between the skin and a cold external medium, such as water or ice, was sufficient to reduce the loss of heat to such an extent that the amount of heat brought to the part by the circulating blood was sufficient to compensate for the loss after the temperature of the skin had been reduced by a few degrees (Fig. 3, A, B, C, and Fig. 4).

6. A very thin waterproof covering, used in combination with a woollen covering, was found sufficient to secure an efficient air covering for the skin. The composition of the

covering had no material importance so long as it was completely waterproof.

7. The presence of some moisture under it reduced the efficiency of the waterproof covering, but did not render it useless (Fig. 3, D, E, and Fig. 4).

8. The complete replacement of air by water in the space between the waterproof covering and the skin rendered the covering practically useless (Fig. 3 A₁ to A₂).

II. PROTECTION AGAINST FROST-BITE AND OTHER EFFECTS OF EXPOSURE OF THE EXTREMITIES TO WET COLD (LOCAL FRIGIDISM).

Adequate feeding, perfect circulation, moderate muscular exercise, good general health, warm clothing, all tend to give to the body its maximum power of resistance to cold. It is obvious that anything that tends to im-

pair the nutrition and activity of the tissues, and to interfere with the freedom of circulation, is favourable to the occurrence of frigidism. Tightness of the clothing of the extremities—for example, tight boots, socks, leggings, puttees, etc.—is particularly detrimental. Heavy clothing and other equipment, by increasing fatigue, has also a predisposing influence.

Warm clothing does not mean heavy and thick garments, but clothes capable of keeping imprisoned near the surface of the body a fairly thick layer of air. It is generally recognized that several layers of light woollen or other fabrics form a particularly efficient protection against cold air when the air is not in a state of rapid

FIG. 1.

I. Apparatus used for determining approximately the rate of cooling of 50 c.c. of water contained in an oil-silk cylinder, variously protected, immersed in 1,000 c.c. of melting ice.

A. Cavity of the inner oil-silk cylinder containing the warm water.

B. Annular space between the inner and the outer oil-silk cylinders. This space was occupied during the various experiments by a loose woollen fabric with dry air, or moist air, or water (see III in same diagram).

C. Cavity of the glass jar containing ice and water. *a*. Cork used to close the upper end of the inner oil-silk cylinder. *b*. Lower end of cylinder, closed by means of a cork. *c*. Upper end of outer cylinder. *d*. Lower end of outer cylinder, closed by means of a cork. *e*. Part of the recording thermometer indicating the temperature of the water in the inner cylinder. *f*. Part of the recording thermometer indicating the temperature of the water in the outer cylinder. *g* and *h*. Controlling mercurial thermometers.

II. Transverse section of a apparatus shown in vertical section in I.

III. Diagrammatic representation of the arrangement of experiments the results of which are shown in the curves.

Curves.

A. Shows the rate of cooling from 30° C. to 0° C. of the bulb of the recording thermometers used in these experiments.

B. Rate of cooling of water contained in the inner oil-silk bag without any protective covering.

C. Rate of cooling when the inner oil-silk bag is covered only with a uniform layer of hard 13 mm thick.

D. In the following experiments the annular space between the inner and outer oil-silk cylinders was occupied by a loose woollen fabric of uniform thickness:

E. In addition to the woollen fabric the space was filled with water.

F. In addition to the woollen fabric the space was filled with comparatively dry air.

From the shape of the curves it seems probable that there were some slight errors of observation or defects in the instruments. No attempt has been made to correct these probable errors.

motion. Common experience has also shown that a layer, however thin, of some material impervious to wind, worn outside ordinary clothing, is the most efficient protection against cold draughts and winds. Paper, mackintosh, skins, closely woven fabrics worn outside ordinary clothes, have all been extensively used for this purpose.

With regard to protection against cold water, it is necessary that the external covering should be impervious to and not affected by water. India-rubber stockings, waders, and boots have been used extensively by anglers and men working in water and mud, not only as a protection against wet but also against cold. For the same reason sailors and others have had resort to oilskin.

When at the beginning of the winter of 1914-15 a number of soldiers were invalidated owing to the effects of exposure to cold, there must have been some reason why advantage had not been taken of these well-known methods

of protection. On consideration it appeared to me that the main reasons were that the articles on the market at the time were too heavy, too cumbersome, too expensive, too perishable, and generally incapable of being adapted to the present requirements of the soldier.

The india-rubber boots and the waders available at the time were heavy and clumsy, and would have seriously interfered with that freedom of movement which is so essential to the soldier. Fishing socks or waders, when sufficiently light and well made, are expensive. They are fairly thick and occupy much room; they also require frequent repairs. The india-rubber used in their manufacture is liable to become hard and fissured under the influence of cold, or even when simply stored for any length of time. India-rubber is also easily softened by fatty substances, vaseline, etc.

In addition to the oil of resins, neutral fats, paraffin wax, etc., with the result that lined oil boiled with a lead salt gave satisfactory results when the oil-silk was of moderate thickness.

The methods finally used by me in the laboratory, though comparatively simple, required strict attention to several details, such as the selection of the fabric, the size and uniformity of the meshes, the composition of the "boiled" lined oil, the duration of exposure to various temperatures, the shapes permitting of sound apposition seams being made, the thickness of the oil coating, etc.

I had some difficulty in convincing practical men of the possibility of manufacturing oil-silk bags at a moderate cost, until I met Mr. H. Storey of Lancaster, who took a great interest in the matter. Some modifications which appeared to be convenient for manufacturing in bulk

FIG. 2.

Cooling of the skin of the hand and wrist caused by immersion in ice water and concomitant warming of the water.

A. Indicated temperature of the hand immersed in ice water.

B. Indicated temperature of the limited amount of ice water in which the hand is immersed.

C. Indicated temperature of the same amount of ice water exposed in the same vessel to the air of the room at the same temperature. The curve should be even. The slight irregularities observed probably indicate the extent of the errors introduced by the recording apparatus. The much greater irregularities in Curve A are probably due to movements of the hand and to vasomotor phenomena.

D. Indicated temperature of the air of the room (dotted line).

By this method the number of calories lost by a part of the body immersed in cold water can be estimated approximately.

It occurred to me that a suitable article might be made of a thin fabric rendered waterproof by means of oxidized linseed oil. After several weeks' trial I succeeded at the beginning of last January in manufacturing by simple means thin and soft oil-silk which could be made into absolutely waterproof bags by means of apposition seams.² These bags were used successfully in a number of experimental tests (Fig. 4).

The same material and method can also be employed for manufacturing very light waterproof coverings for various parts of the body, a matter of some importance, since the protection of the body as a whole against losses of heat is of great value in increasing the resistance of any part of the body against local frigorisim.]

Many experiments were made to test the permeability of oil-silk of various thicknesses to water, and the effects

FIG. 3.

Summarizing the results of some of the chief experiments bearing upon the cooling of the hand or foot immersed in ice water, and upon the effects of protecting the hand or foot by means of oil-silk bags.

A. Hand protected by dry sock and oil-silk bag.

A1. Water at 35°C, poured into the oil-silk bag so as to wet thoroughly the sock. Very slight rise of temperature, followed by very rapid fall A2. (Compare with F and G.)

B. Warm foot protected by dry sock and oil-silk bag.

C. Cold foot protected by dry sock and oil-silk bag.

D. Warm foot protected by damp and partly wet sock and oil-silk bag.

E. Cold foot protected by damp and partly wet sock and oil-silk bag.

F. Foot covered only with woolen sock and plunged into refrigerating mixture.

G. Hand unprotected plunged into double its bulk of water at 0°C. (For comparison with F and A1 to A2.)

proved disappointing, and led to serious loss of time, for when rather late in the year the opportunity of trying the bags on a large scale occurred, certain defects were discovered from which the bags manufactured in the laboratory early in the year were free. It has been found necessary, therefore, to return to my original methods.

Bags prepared in this way can be immersed in boiling or in ice cold water without any appreciable damage to the material or to the seams.

Properly prepared oil-silk offers considerable resistance to alcohol, ether, chloroform, acetone, benzol, petroleum, solid or liquid neutral fats, 1 or 2 per cent. watery solution of nitric, sulphuric, and hydrochloric acids, mercuric chloride, iodine, phenol, chlorinated lime, iodo, etc.; it is attacked by 2 per cent. watery solutions of the alkalis, and also, but more slowly, by soap. Oil-silk bags can be kept for many months without undergoing any material change.

* Sewing renders the waterproof material useless, so that sewn seams cannot be used.

² This passage is reproduced almost verbatim from the paper already quoted.

Although the material is wetted by water, its permeability is very slight, and water can be kept inside an oil-silk bag for weeks without any apparent wetting of the external surface. Artificial wetting of the external surface of a bag containing water under pressure is not followed by any appreciable oozing, the wetted surface dries rapidly.

The addition of paraffin wax or of a neutral fat to the linseed oil prevents wetting of the material by water, but does not appear to increase as much as could be expected the impermeability of the fabric to water.

This oil-silk bag, after being creased and submitted to friction for some time, usually show evidence of some superficial damage. This is made evident, when the bag is filled with water, by a slight oozing of the fluid through the damaged parts. This defect can be completely remedied by painting the surface of the bag with a layer of quick-drying linseed oil; after exposure to a current of

FIG. 4.

Photographs (reduced) of two thermographs taken simultaneously to show the effects of the immersion of the two feet (each foot was protected by an inner sock, oil-silk bag, outer sock, and heavy boot) in a refrigerating mixture at a temperature of about -15°C . In the case of one foot (A) the inner sock was dry (Curve A); the sock over the other foot (B) was damp (Curve B). Total duration of experiment: 24 hours.

Cause A.

1. Thermometer fixed to the skin by plaster and bandage; inner sock, oil-silk bag, outer sock and boot put on rapidly.
2. Foot A plunged into refrigerating mixture.
3. Foot taken out of the refrigerating mixture; boot removed rapidly. Thermometer disturbed.
4. Oil-silk bag removed; thermometer refix d.
5. Foot covered with inner sock only, left exposed to -15°C .
6. Foot, with inner sock only, plunged into refrigerating mixture, which is thoroughly stirred. The slight kink in the curve between 8 and 9 is the result of renewed stirring of the refrigerating mixture. Cramps followed by loss of sensation and partial motor paralysis.
7. Foot A removed from mixture; sock removed and foot dried.
8. Thermometer separated from the foot and plunged into the refrigerating mixture.
9. About $\frac{1}{2}$ of the thermometer bulb drawn out of the mixture for three minutes.
10. Bulb pushed back into the mixture and completely immered.
11. Bulb removed from the mixture, dried, and exposed to the air of the room.

In this graph the indicated temperature is a little more than 1°C . lower than that indicated by the mercurial thermometer.

Cause B.

1. Sand 4 as in A. 5 indicates the moment when Foot A was removed from the mixture.
2. Foot B removed from mixture. Boot, oil-silk bag, and socks removed. Foot B dried and exposed to air at 20°C .
3. Bulb separated from foot and plunged into refrigerating mixture.

air for a few hours the waterproofness of the bag is restored. A solution of nitro-cellulose in a mixture of acetone and acetate of amyl adheres firmly to the oil-silk when dry. A tear in the oil-silk can be easily mended by fixing over it a piece of silk by means of this cement. Slight erosions may also be repaired by painting a thin coat of the same material over them.

The bags I used for the purpose of the practical tests conducted during the early months of this year extended up to the knee, and could be worn for twelve or fifteen hours at a time without discomfort and without

undue condensation of perspiration. When, in later experiments, bags reaching up to the hip were used, it was found that, especially after a march, abundant condensation of water from perspiration took place on the inner surface of the bag, and that this water of condensation gradually gravitated into the foot portion. This accumulation of water round the foot reduced to a considerable extent the protection afforded by the bag.

It is obvious that if the use of long bags is essential, those bags should not be worn during long marches, or if they must be worn, their length should be reduced by suitable method of folding during the march. They may also be lined with some absorbent material preventing the water of condensation running down. The use of an absorbent lining should, however, be resorted to only if other methods are insufficient, for one of the advantages of the oil-silk bag is the ease with which it can be thoroughly cleaned both inside and out. I do not think, however, that waders of any kind are suitable for wear during long marches. What is important is that the men wearing them in the trenches should be able to leave the trenches and march or run without the waders interfering with the freedom of their movements. One of the essential conditions for success is that the foot and leg should be left entirely free from pressure causing any sensation of constriction or tightness or any interference with the freedom of circulation. The foot should be dry and warm when the wader is put on.

Large boots and large socks are indispensable; the inner woollen sock should be thick, the outer sock should be large enough to draw easily over the oil-silk bag. It should not be made of a material liable to shrink when wet. In the first tests I conducted both the inner and the outer socks were woollen.

III. MODE OF WEAR AND CARE OF THE ANTIFRIGOR BAGS.

When the bag is put on the long straight seam should be on the inner side of the leg (the tapes being at the upper end of the outer seam). Before a bag is used the hand should be inserted into it and any parts which may have stuck should be separated gently. When the bags are dusted with French chalk (finely powdered talc), as directed, no sticking should take place.

To put the Bags on.

A dry woollen sock or stocking, as thick as possible and not fitting tightly, should be drawn evenly over the foot and leg, all creases being carefully avoided. The skin of the foot and leg should be quite dry and warm. The sock and skin may be put with advantage so powdered with French chalk. The foot so covered should then be introduced into the antifrigor bag gently, so as not to stretch the bag unnecessarily.

When the big toe is within an inch of the toe end of the bag the pointed end of the bag should be turned under the big toe. A second sock, which need not be thick but must be large, in good condition, and not liable to marked shrinkage, should then be pulled over the antifrigor bag, the folds of which should be flattened and equalized by the hands.

Boots two sizes larger than the size usually worn may then be put on and laced carefully. The inside of the boot should be free from nails.

When the bag is to be used for wading through fairly deep water it is pulled over the trousers and fixed by means of the tapes to the braces. When the bags are put on before a march it is preferable to pull the lower part of the bag up to the knee, then to turn it down and up again so that it covers the leg only up to the knee. It can be fixed above the calf by loosely tying the tapes round the leg. To reduce the bulk of the bag it may be twisted gently round the leg. The bags are intended for use in the trenches; they do not interfere with marching or running, but are not made to stand long marches.

Removal and Care of the Bags.

When the bags are removed care should be taken not to pull them off violently. The folds may sometimes

* A better indication of the fitness of the boot is that when it is put on after the foot has been covered with the two socks and bag, there should be no sensation of uncomfortable tightness. Tight puttees are detrimental to the bags as well as to the men. Loose, soft, lined leggings may be used instead, provided they are not tight.

stick together, and should be opened gently. After the bags have been used, the outside should be washed, dried with a duster and in the air, and powdered with French chalk. They should then be turned inside out and washed again, after which they should be dried with a cloth and in the air. The outer surface of each bag should then be painted with a thin layer of the preparation provided for the purpose.

Bags hung in a well-ventilated place should be ready for use again in about twelve hours. In a well-ventilated, dry, warm place the drying may be completed in four hours. The bags should be then thoroughly powdered with French chalk both inside and out. By this process the waterproofness of the bags—which is reduced by wear, especially after marches—is restored.

Mending of Holes.—The bags should be thoroughly clean and dry, and the parts surrounding the tear or hole should be painted with a thin, even layer of the preparation provided for the purpose. A piece of the repairing silk sufficiently large to cover the place, and allow a margin of at least half an inch all round, should then be well pressed upon the part which has just been painted, after a few minutes the patch should be painted again, allowed to dry for about one hour, and finally powdered with French chalk.

Storage.—Before the bags are put away they should be thoroughly cleaned, repaired, and dried. They should then be dusted with French chalk, both inside and out, and folded (altering, as far as possible, the position of the long creases), or rolled, beginning at the toes to facilitate the escape of air. They should preferably be kept in a dry place.

Bags carefully used and not handled roughly should last several weeks. To make them more lasting would add to their cost and weight. Each man should be provided with two pairs, one being repaired while the other is in use. If the inside of the soles of the boots is rough, a felt, linoleum, cork, or even plaited straw sole placed inside the boot would protect both the bag and the foot against injury during marching.

Testing.—The bag, quire, is turned inside out. Water is then poured into the bag to a height of 18 in. without wetting the outside. Serious defects in the foot part are at once indicated by dripping of water. Slight faults are shown by a wetting of the outer surface at defective places which can be marked with a copying pencil. The mouth of the bag is closed by clenching it tightly in the hand. The bag is then turned upside down before it is emptied; defects in the upper part are thus made evident. The defective parts which have been marked can be repaired when the bag is dry. Defective seams are very difficult to repair, but this defect should be quite exceptional.

CONCLUSION.

The use of a waterproof covering that can be worn inside the boot is recommended in this communication not because it is the only or even the best possible method. A waterproof top boot so devised as to leave a fairly wide air space between the boot and the greater part of the foot, ankle, and lower part of the leg would be more efficient and probably more convenient, provided the material used was light and did not interfere with movements. To obtain this result a new type of boots would be required.

The object of this paper is to show that it is possible to secure a sufficient amount of protection against the effects of wet cold without discarding the boots at present supplied to the army, provided the size of these boots is adequate.

THE CARRIER PROBLEM AT HOME IN TIME OF WAR.

By EDWARD C. HORT, F.R.C.P. EDIN.

WITH the consent of the Director-General of the Army Medical Service I have prepared the following sketch of the efforts that have been made in the past year to deal with the carrier problem at home in the Addington Park War Hospital, in so far as the enteric group of diseases is concerned.

The original idea in starting this hospital was the provision of suitable accommodation in the country near London for soldiers suffering from acute infective disorders, such as enteric fever, dysentery, and septicaemia; and a vital part of the scheme was the provision of a well-equipped laboratory in which bacteriological examinations could be systematically carried out. In order to give effect to this scheme three essentials had first to be secured by the civilian committee which had been called together for the purpose—the loan of suitable premises, the approval of the Director-General, and the necessary funds.

Subject to certain conditions designed to protect the interests of the legatees, the trustees of the Addington Park property generously placed the house and grounds at the disposal of the Committee for the purpose desired. The Director-General at once gave his cordial approval to the undertaking, and the entire cost of maintenance was guaranteed by the War Office, the cost of equipment of the hospital and laboratory being generously defrayed by private subscribers and by the Red Cross Society, on the recommendation, in the first place, of Sir Frederick Treves. Work was therefore at once set in hand, and the necessary staff appointed.

Before the opening of the hospital, however, in December, 1914, with accommodation for 150 beds, the Committee were asked by the Director-General if, for the time being, they would consent to admit convalescents of the enteric group (enterics, paratyphoids, dysenterics) instead of acute cases, in order that a search for carriers, and the necessary detention, should be systematically carried out. And for this purpose they were further invited to assume responsibility for additional accommodation to the extent of 200 beds in huts, the cost of erection, equipment, and maintenance being borne by the War Office.

The Committee without hesitation undertook the desired responsibility, and the Palace accommodation of 150 beds was at once taken up by convalescents who were submitted to periodical tests for "carriage." In a few weeks the huts were also ready for occupation, and up to the present date a total number of 330 resident convalescents, replaced at intervals by fresh arrivals, have been periodically examined.

In the early days of the war there was no justification for the provision of a much larger establishment than this to cope with possible emergencies. It was important, however, to make the existing accommodation as elastic as possible. Provisional arrangements were therefore made to use Addington as a clearing-house, with external provision for such convalescents as were proved to be innocent of "carriage" after repeated examinations over an average period of from six to eight weeks. This external provision included detention in secondary convalescent homes, where they were detained for a further period of some weeks, during which time the excreta were sent at stated intervals to the Addington laboratory for further examination. If still found to be free, patients were then discharged on furlough. No patients found to be carriers, whether convalescing or convalescent, were sent to these secondary homes. Under an Army Order true chronic carriers are eventually invalidated out of the army and return to their homes. The medical officer of health of the district in which they reside is informed of this effect.

This arrangement of using Addington as a clearing-house, with the secondary convalescent homes as auxiliaries, still under bacteriological supervision, made it possible, not only to examine a considerably larger number of cases than would otherwise have been feasible, but also to increase the total period of supervision. The total number that have been passed through Addington in this way is at present over 2,000; and in more recent

A FASCICULUS of the *Philippine Journal of Science* has been devoted to the pathological anatomy of bubonic plague, for which Dr. Crowell, working in the Department Pathology and Bacteriology of the University of the Philippines and the Biological Laboratory of the Bureau of Science, Manila, P.I., is responsible. He states that the study is based on 75 cases examined *post mortem* in Manila between June, 1912, and June, 1914. The work has been carefully and methodically done, and as the material on which it is based is sufficiently extensive, the facts, though in many instances not new, are worthy of note.

months the work of the bacteriological departments has been considerably increased by the examination of specimens from convalescents who, for one reason or another, have not been through Addington. On the other hand, the work has been greatly assisted by the co-operation of pathologists attached to various hospitals, as regards patients who have been kept under their observation till vacancies occurred at Addington. In all such cases the search for carriers has been systematically carried out, and we have been regularly kept informed of the results.

The arrangement of secondary homes described, which was only made possible in many instances by the generosity of private individuals who, in some cases, assumed the entire financial responsibility, and by the invaluable help given by Lady Dudley, as head of the Convalescent Home Department of the British Red Cross Society, had, however, certain disadvantages, which were accentuated by the increasing demand for beds. In view of this increased demand, which itself necessitated centralization of existing convalescent homes in the public interest, the Director-General again invited, and obtained, the consent of the Committee to assume the responsibility for fresh extension in Addington Park. The proposal involved fresh hut accommodation for 350 more beds, in addition to the existing 350, of which, by an arrangement with the Australian Commonwealth, 150 were set aside for the reception of Australian convalescents, the Government of Australia paying for maintenance. In addition, the Director-General proposed that a military dépôt should be established in Addington Park to admit 1,000 patients, in order to replace the auxiliary convalescent homes hitherto relied on to clear the beds at Addington.

Arrangements, therefore, are now being made on these lines, with the result that in a short time the increased accommodation available, capable of yet further extension, will allow for the reception and detention of approximately 1,700 potential carriers, who will be replaced as fast as the exigencies of the war demand, compatible with safety to the general population.

Instructions based on these considerations and with particular regard to continuance of bacteriological supervision for as long a period as is practicable, have recently been issued by the Director-General.

The following is an abstract of these instructions:

Acute cases from overseas to be sent direct to the Royal Victoria Hospital, Netley, or to the Military Hospital, Devonport.

Convalescents are to be transferred to Addington Park War Hospital, if accommodation is available. If accommodation is not available they must be sent to suitable auxiliary hospitals (Class B)—formerly known as "Convalescent Homes"—for four weeks. If found to be free at the end of this time they will be granted furlough, and notifications will be issued to the proper authorities.

Acute cases occurring at home to be treated in isolation hospitals. Convalescents to be sent to Addington. If accommodation be not available there, they may be sent to one of the auxiliary hospitals attached to the hospital, provided they are proved at the time to be free. If carriers, they are to be sent to Addington as soon as fit to travel.

In no case must convalescents be pronounced as temporarily free until three negative examinations have been recorded at intervals of a week.

In all cases of transference to an auxiliary hospital, or of discharge to furlough, the Commandant at Addington must be at once informed, and a nominal roll of all cases, giving the date and address to which they have been dispatched, forwarded at the same time. A copy must also be sent to the War Office. Until the military dépôt in Addington Park for the reception of 1,000 additional convalescents is ready for occupation, convalescents to the number of 1,200 will be located in Woldingham Camp, and the excreta of these 1,200 will be periodically examined in the Addington Laboratory.

The personnel of the medical and bacteriological staffs is as follows:

MEDICAL STAFF.

Colonel H. J. W. Barrow, A.M.S., Commandant.
Sir John Broadbent, Bt., M.D., Honorary Physician.
Edward C. Hort, F.R.C.P. (Edin.), Honorary Physician.
W. J. J. Stewart, M.D., Medical Superintendent.
O. Folhill Turner, M.D., House-Physician.

BACTERIOLOGICAL STAFF.

Edward C. Hort, F.R.C.P. (Edin.), Director.
C. E. Lakin, M.D., Assistant Director.
T. H. C. Benians, F.R.C.S., Assistant Bacteriologist.
W. Collingwood, Esq., Assistant Bacteriologist.
Miss Delyell, M.D., Assistant Bacteriologist.
Trained lay lady assistants.

The medical and bacteriological staffs have lost through resignation the services of Dr. Williams and of Dr. Elizabeth Lepper.

It should perhaps here be added that in the interests of the patients themselves, as well as of the local population, every reasonable precaution has been taken since the opening of the hospital to prevent the spread of infection through carriers, whether detected or not, by systematic bactericidal treatment of the excreta and linen. These precautions were adopted after consultation with the Principal Medical Officer of the Local Government Board and the local medical officers of health. In all cases the faecal matter has been incinerated in a special form of destructor, the working of which has given excellent results. And the urine has been disinfected in special receptacles containing bactericidal fluid of proved efficiency in the dilutions employed relative to the time limit of exposure. In the case of linen suitable arrangements have been made for its disinfection. In future, owing to the larger numbers of cases requiring bacteriological supervision, the urine will be treated by the application of heat for sufficient periods to ensure destruction of non-spore-bearing organisms. In the hospital and in the huts the men are also instructed in such special methods of personal hygiene as are necessitated by the grouping together in one place of large numbers of convalescents from diseases of the enteric group.

ROUTINE EMPLOYED AT ADDINGTON IN THE SEARCH FOR CARRIERS OF THE ENTERIC GROUP OF ORGANISMS.

The following scheme of identification of these organisms is one that I drew up a year ago for general use at Addington, with one or two alterations since added. It is collated from several sources, particularly from Ledingham and Arkwright's classical handbook on the carrier problem in disease, to which, as well as to Semple and Greig's well-known memoirs on the subject, I am also indebted for much valuable information on other aspects of this problem. For the additions to the scheme referred to I am indebted to Dr. Henderson Smith's admirable paper and chart published in the BRITISH MEDICAL JOURNAL of July 3rd, 1915, p. 3. In no case has any convalescent examined at Addington been labelled as a carrier unless the incriminated organism has fulfilled in all essential respects the details given in this table under its respective name.

Identification Table of Members of the Enteric Group.

<i>B. typhosus</i> (Motile)	Paratyphoid Group (Motile)	Dysentery Group (Non-motile)
— ...	<i>B. paratyphosus</i> A ...	<i>B. Shiga-Kruse</i> .
— ...	<i>B. paratyphosus</i> B ...	<i>B. Flezner</i> .
— ...	(<i>B. enteritidis</i> Gaertner) ...	<i>B. Strong</i> .
— ...	(<i>B. enteritidis</i> Aertryck) ...	<i>B. Y of Hiss</i> .
— ...	(<i>B. Morgan</i> l).	

Group Characteristics (common also to *B. pestis*, the Pasteurellae group, *B. pseudo-tuberculosis*, and to the Gram-negative cocci—*M. melleusis*, gonococcus, *M. catarrhalis*, and the meningococci of Weichselbaum).

- (1) Pleomorphic.
- (2) Gram-negative.
- (3) No liquefaction of gelatin.
- (4) No production of indol.
- (5) No clotting of milk.
- (6) No action on lactose, saccharose (inulin, salicin, amygdalin).

Individual Characteristics:

- (7) Produce alkalinity in milk, except *B. typhosus*, *B. paratyphosus* A and B, *Strong*, which produce acidity in milk.
- (8) Ferment glucose, mannite, dulcitol, sorbitol, maltose, galactose, inulin, as follows:
B. typhosus and *B. Strong* ... Acid in all.
Paratyphoid group, except *Acid* and gas in all.
B. Morgan l.
B. Morgan 1 ... Acid and gas in glucose, galactose and inulin only.
B. Shiga-Kruse ... Acid in glucose, galactose and inulin only.
B. Flezner ... Acid in all but dulcitol and sorbitol.
B. Y of Hiss ... Acid in all but dulcitol, sorbitol and maltose.

- (9) Agglutination tests (absorption when necessary): Use serum Y for *B. Y* and *B. Flezner*.

Exceptions to Group Characteristics:

- (1) The gonococcus and the *M. catarrhalis* are not known to be pleomorphic.
- (2) Indol is produced by *B. Morgan* 1, *B. Flexner*, *D. Y of Hiss*, and *B. Strong*.
- (3) *B. Strong* clots milk late.
- (4) *B. Strong* produces acid in saccharose.

Note.—Dulcitol, sorbitol, galactose, haeculose have been unavailable in bulk owing to the war. Dulcitol is now being tested as a substitute for dulcitol.

To the list of organisms here given, for which systematic search is made, should be added the *M. melleitensis*. The search for evidence of amoebic dysentery has not yet been made part of the routine.

In the case of strains of organisms from which from cultural and biochemical reactions a positive serum reaction might reasonably be anticipated, but in which, nevertheless, only negative results have been met with, such strains are not at once rejected. On the contrary, whenever practicable, repeated subcultures are made, if necessary, for a period from seven to fourteen days, and serum tests are again applied before final rejection is recommended. The necessity for this, especially with urinary strains, appears to be generally admitted.

On the other hand, numerous aberrant strains have been met with, which one is not really justified always in rejecting as of no pathogenic importance, but which, under the stress of a strenuous routine, it has not been possible further to examine. Some such strains have been reserved for further study in the hope of the advent of less laborious days.

Routine for Faecal Examinations.

Once a week, if possible, each patient provides a specimen after purgation. Notwithstanding this precaution, the number of solid specimens is surprising. An emulsion is made of the fresh specimen in 5 c.cm. of sterile broth, inoculated with two large loopfuls of material. It is then allowed to stand for one hour at room temperature, and a 5-in. MacConkey plate is inoculated with a large loopful of the supernatant fluid. From this plate a second is inoculated without recharging, and both plates are then incubated at 37° C. for about eighteen hours. Whenever possible, the plates are warmed before inoculation in order to diminish the amount of condensation water, and to obtain larger colonies than can be obtained in the colonies. It is absolutely essential that the surface of the medium when inoculated should be free of condensation water. This we ensure by pouring the medium into warm plates, which, when the medium is set, are dried at 37° C. for some hours.

If possible, in each case presenting colourless or orange-tinted colonies, three colonies are picked off and individually emulsified in lactose litmus peptone water. If after incubation for one night growth has occurred and there is no change of colour, milk, peptone water and the available sugars are inoculated from each lactose tube. If growth has not occurred and if no change is noted in the lactose tubes, further incubation is allowed. The complete set of sugars is examined after a suitable period of incubation in order to determine the presence of late lactose fermenters and to reject them. The final examination is made in seven to eight days, and subcultures are then made from likely cultures in order to apply the necessary serum tests in the following day.

Our experience with the actinic rays, recommended by Dreyer on account of their reputed selective inhibition of *B. coli*, has been disappointing, and their use has therefore been abandoned by us, as by other observers. It appears, in fact, to have been unsafe to assume that a laboratory culture will necessarily react in the same way as a culture direct from the faeces, though in the hands of one of us even the former did not yield the results expected. Our experience with endo-fuchsian, and with malachite green, has so far not justified us in using either of these media as a routine optimum medium in preference to MacConkey's medium for faecal examination, though we preserve an open mind as to the possible superiority of brilliant green and other synthetic media not yet fully tested. In the mean while MacConkey's medium is the routine medium for faecal work.

Before leaving the subject of faecal examinations, it may be well to observe that we have deliberately chosen to make serum tests the end point of identification methods, in order to carry out in each case the fullest investigation possible with a view to the study of strains that might prove to differ biochemically from type. In the investigation of acute cases such deliberation is impossible owing to the necessity for early diagnosis. Time in our work, however, is not the primary consideration.

Moreover, a negative serum test early applied rather favours rejection of a strain that repeated subculture, the necessity for which has been indicated by biochemical orthodoxy, may eventually show, when a late serum test is applied, to have been only temporarily inagglutinable.

Routine for Urine Examination.

I have elsewhere shown that in the bacteriological examination of urine the time at which the urine is collected is of some importance. And this applies to haemic infections of the urine in convalescing cases as well as to tract infections in convalescent cases. If, for example, urine be examined which has only recently traversed the renal filter, as in specimens passed during the day after a short interval, the number of pathogenic organisms present per cubic centimetre may be insufficient to allow of their survival when transferred to a solid laboratory medium. On the other hand, if the first specimen after a night's rest be examined, the number of pathogenic organisms present per cubic centimetre is often sufficiently great to survive transference to a laboratory medium.

In the former case, incubation in the bladder has been cut short, and in the latter case incubation in the bladder has been prolonged. Hence the difference in the results obtained.

In other words, the urine in many cases of pathogenic infection is an excellent medium for growth of the organisms causing the infection, and I showed by a large number of observations, published in 1914, that by the simple device of incubating the urine in the laboratory for a night before inoculation of the laboratory medium selected as an index of infection, far better results can often be obtained than if this precaution be omitted. We repeated these observations at Addington a year ago with a small number of urines suspected of containing members of the enteric group, and we found that, examined in this way, the percentage of ordinary carriers in a mixed population of inoculated and uninoculated typhoid convalescents was considerably higher than is commonly believed. This only applied, however, to the convalescing carrier within six weeks or so of his discharge from an enteric hospital, presumably because the degree of haemic infection was slight, requiring incubation for its intensification. In the case of the convalescent or true chronic carrier with a tract infection, incubation in the laboratory appears to be unnecessary if incubation in the bladder be first allowed, presumably because the degree of tract infection—allowing of free discharge of pathogenic organisms—is considerable. As a routine method, therefore, all the specimens of urine at Addington are incubated, usually for forty-eight hours, in the laboratory before inoculation of the medium selected for picking off colonies. In all other respects, except selection of medium, the procedure of urinary examination and identification is the same as for faecal examination.

As regards the optimum solid medium for isolation of urinary organisms, we are not yet satisfied. MacConkey's medium in the commonest form of urinary carrier, the convalescing carrier, is certainly too severe a medium, however suitable it may be for isolation from the convalescent or tract carrier. And the fact that the convalescing carrier is commoner than the convalescent carrier makes this class potentially more dangerous, especially as by the ordinary routine method of examination, without preliminary incubation of his urine, he is more liable to be missed. Even, however, in the case of the incubated urine a MacConkey plate will often show no colourless colonies, or even no growth at all, whereas some of the nasagar plates inoculated in parallel will show colonies of non-lactose fermenting Gram-negative bacilli. For example, forty plates of MacConkey were inoculated from twenty samples of incubated urine, and the same number of nasagar plates were inoculated from the same urine at the same time in parallel. No less than 30 per cent. of the MacConkey plates showed no growth at all, even after prolonged incubation, whilst 5 per cent. of the nasagar plates gave colonies which subsequently proved to be non-lactose fermenters, and all showed growth after one night's incubation. The last fact would suggest that a medium such as nasagar favours the growth of extraneous organisms to such an extent as to make it useless as an isolation medium of pathogenic organisms from the urine. In practice this is not the case, since colonies of organisms of the coli-typhoid group are soon detected with a little experience. And, fortunately, lactose-fermenting coliform organisms are relatively rare in males convalescing from diseases of the enteric group. The expense involved is no doubt a serious item. Experiments with agar plates and with cascin agar plates have not yet proved satisfactory, and, to repeat, the question of

the optimum isolation medium for urinary examination for our convalescents is still *sub judice*, as is also the question of the advisability of currying the urine with albumin prior to incubation.

Scrological Tests.

The routine method employed is macroscopical only. We have recently adopted Dreyer's suggestions of always incubating at 55° C., using his standard emulsions for all Widal reactions, and of using considerable volumes of diluted serum, bacterial emulsion and normal saline. The results so far obtained have been excellent. We do not find the drop method to be of sufficient accuracy for routine use on a large scale. In carrying out a reaction with *H. typhosus* we test the serum in triplicate against this organism, *paratyphosus A* and *paratyphosus B*, and we propose to employ Dreyer's method of curve-recording by multiple examinations at stated intervals. This procedure, of course, is not in our case so much for purposes of diagnosis as, by a systematic investigation of large numbers of convalescents in terms of Widal's reaction, of obtaining some light on several interesting problems that have emerged from our work. One of these is the question of the effect of inoculation on carriage, which, in the light of data we have already collected, appears to be favourable. Much further study, however, will be required before any definite statement can be made as to this. As regards Bordet-Durham reactions with strains of organisms isolated from convalescing and convalescent patients, we have used twenty-four hour emulsions heated at 58° C. for one hour. In all other respects the procedure is the same as in the case of Widal reactions. We do not find it necessary to check our macroscopical results by microscopy, because we are not aware that the latter procedure does more than intensify a well-marked end result already obtained by microscopy alone.

This, roughly, is an outline of the attempts being made at Addington to deal with the carrier problem, and it is only designed to indicate here in a general way what is being done. Unfortunately, the experiences of the moment do not permit of a more elaborate statement, which must be reserved for our official report.

A PRELIMINARY NOTE ON CHRONIC POISONING BY EMETINE.

By H. H. DALE, M.D., F.R.S.

(From the Department of Biochemistry and Pharmacology, Medical Research Committee, the Lister Institute.)

A FEW weeks ago my opinion was asked as to the possibility of producing symptoms of poisoning by the long-continued administration of emetine in individually harmless doses. Those who have had experience of the treatment of amoebic dysentery with emetine have evidently been alive to the possibility of such a cumulative action. Dr. Low, for example, in a recent article in this JOURNAL (November 13th, p. 715), mentions diarrhoea, secondarily arising during treatment with emetine, as possibly caused by the alkaloid, and suggests that an unduly continued use of the latter in too high a dosage may eventually produce symptoms of intoxication. But there seems to be no certainty on the point, and little hope of attaining such by clinical observation alone, owing to the difficulty of deciding whether local effects on the alimentary canal, or more general effects of toxæmia, are to be attributed to emetine, or to the condition which has led to its being administered. On the other hand, I failed to discover any record of direct uncomplicated experiment on the point. It was evidently desirable, therefore, that the matter should be put to the test of experiment on healthy animals. The investigation is still in its initial stage, but the indications that a cumulative action can be produced are already so positive, that it seems desirable to make mention of the results even at this early period, in view of the practical importance of their implications.

At present I have made experiments only on a small number of cats and rabbits. The question as to what doses, in either of these species, can be regarded as physiologically equivalent to the doses normally employed in human therapeutics, can only be answered by further experiment. Up to the present I have used a dosage which, in proportion to the weight of the subject, would be

regarded as rather high for continued administration to man. If we take 65 kg. as the weight of an average man, a dose of 1 grain for such a patient is about 1 mg. per kilogram. So that 5 mg. for a cat weighing 3 kg. corresponds to rather more than 1½ grains for the average man. This is the order of dosage with which I have experimented up to the present—individual hypodermic injections of 5, or occasionally 10 mg., for animals of 2.5 to 3.5 kg. Such a dose, given once only, has no perceptible action of any kind on the animal, and it may be repeated daily, up to a point, without obvious effect. There is considerable individual variation in respect of the number of such daily injections which can be tolerated with full maintenance of health. It has been as few as three in one case, and as many as ten in another. But in all the experiments which hitherto have been carried on as long as a fortnight, symptoms of intoxication have sooner or later appeared, have become rapidly intensified with persistence in the daily injections, and have terminated fatally. In rabbits a profuse diarrhoea, attended with rapid emaciation, has been the most prominent effect. In cats this symptom has been seen, but is apparently of secondary importance, and may be absent altogether; the most prominent effect in this species is pronounced lethargy and somnolence, deepening to a terminal coma. The pathological examination of the material, in which I am fortunate in having the co-operation of Dr. P. P. Laidlaw, has barely been begun. It is only possible to mention, therefore, with all reserve, that there is evidence of damage to the liver and kidneys, in addition to the expected signs of intestinal irritation.

I am aware that the dosage above indicated is somewhat, though not greatly, in excess of that which is habitually employed in human treatment. I deliberately so chose it in order to obtain evidence with a minimum delay on the important question, whether a repetition of individually subtoxic doses of emetine can produce a cumulative poisoning of serious importance. The answer is already very definitely affirmative. I am fully conscious, also, of the care needed in applying results, obtained with experiments on different species, to human therapeutics. But, with all allowance for differences in dosage and conditions, I cannot believe that these results are without significance in indicating a serious danger in pushing the administration of emetine beyond a certain point. My object is not to suggest any modification in the accepted dosage and rate of administration, but rather to reinforce, with the aid of direct evidence, the warning, which has already been sounded from other quarters, against the indiscriminate and unguarded use of emetine beyond the limits which expert observation has laid down for its employment with safety and benefit.

Memoranda: MEDICAL, SURGICAL, OBSTETRICAL.

METHOD FOR QUICK DETECTION OF *S. PALLIDA*.

WITH reference to the method of detecting *Spirorchætes* described by Dr. Alfred C. Coles in the BRITISH MEDICAL JOURNAL of November 27th, p. 777, the following is a simple method of demonstrating *S. pallida* which may be of interest. It is well known, but I am unable to say whose original method it is.

Take a smear of blood and serum from the sore, the exudate being obtained after cleaning and rubbing or scraping the sore, or making a small incision in its margin. The sore should not previously have been treated with antiseptics, or, if it has, should be dressed for several days with a simple saline dressing.

1. Fix in 1 per cent. glacial acetic acid and 8 per cent. formalin. Rough dry the slide.
2. Wash in alcohol and flame off.
3. Gently heat in a 5 per cent. solution of tannic acid.
4. Wash in water and stain with slightly warmed ammoniated silver nitrate solution. (To a 5 per cent. solution of silver nitrate add ammonia solution until the precipitate first formed is just dissolved; add a few more drops of silver nitrate solution until the precipitate just reappears.)
5. Wash in distilled water and dry.

The films should be chestnut coloured. If they have

only become yellow the staining from the tannic acid onwards should be repeated at once.

The slides must not be mounted in balsam, but examined in neutral cedar-wood oil in the ordinary way. The spirochaetes are very clearly demonstrated by this method.

W. H. S. STALKART, M.D., F.R.C.S.E.,

Devonport.

Fleet Surgeon, R.N.

FALLOPIAN TUBE AND OVARY IN INFANTILE HERNIA.

In a female child aged 5 months, breast fed, a swelling was noticed on the right side six weeks before admission. It came down several times, but had returned. On September 17th the swelling came down and did not return. When admitted (September 19th) the child, which was well nourished, presented a right inguinal hernia and an umbilical hernia. On the operating table the bowel was returned and the sac exposed. On opening it, it was found to contain the right tube and ovary; the uterus lay just at the neck of the sac, and could be pulled into it. The tube and ovary were firmly adherent to the sac. The ovary was slightly cystic. The adhesion was ligatured and cut, and the operation concluded in the usual way.

H. H. TAYLOR, F.R.C.S.,

Surgeon to the Royal Alexandra Hospital for Children, Brighton.

Reviews.

OSLER AND McCRAE'S SYSTEM OF MEDICINE.

THE first edition of this excellent encyclopaedia of general medicine came out in seven volumes between the years 1907 and 1909. We now are able to welcome the issue of the second edition in five volumes which have all appeared at one time. By a general condensation, an increase in the size of the page, and by augmenting the number of pages in each volume, the editors have succeeded in reducing the number of volumes from seven to five—a heroic performance worthy of the most widespread imitation, for who is not familiar with the tendency to expansion that proves irresistible to most authors as years advance and editions increase in number? Yet only a few of the articles in the first edition have been excluded, and these deal with subjects such as "Inheritance and disease," and "Life Insurance," that have required no radical overhauling during the few years that have elapsed since their publication. They can still be referred to in the first edition of the *System*. The editors have further made notable changes in the general arrangement of the articles in their five volumes—always a matter of options and arbitrary decision—with every appearance of success. The first two volumes deal with all the various bacterial and parasitic infections, and with diseases of metabolism and of the respiratory tract. The third volume is devoted to diseases of the digestive and urinary systems. The fourth volume is occupied with disorders of the heart, vessels, blood, and ductless glands; the fifth with diseases of the nervous and locomotor systems. In every system of medicine a place has to be found for the rarities and miscellaneous debris of disease that do not fit in elsewhere. The editors have very cleverly managed this in the last volume, an arrangement that does as little violence to the nature of such obscure disorders as achondroplasia, microcephaly, and facial hemiatrophy as any classification we have yet seen.

The individual articles composing the second edition of this *System* are characterized by the same virtues as those in the first, to which reference was made in the reviews published in the *BRITISH MEDICAL JOURNAL* as the several volumes made their successive appearances. While all are excellent, it is not unfair to say that some are better than others, as, indeed, is only to be expected. Discriminative mention, always an odious task, is inevitable in the review of so important a work as this *System*, although it can hardly avoid injustice. Among the most sound and satisfying articles are those by the editors dealing with dis-

orders of the heart and vessels, the kidney, the group arthritis deformans, and syphilis. Dr. Fletcher's accounts of gout and diabetes are first-rate pieces of work, and so are Dr. Poynton's "Rheumatic Fever," Dr. L. Brown's "Tuberculosis," Dr. Garrad's article on renal disorders, Dr. Cushing's articles on the brain, and Dr. Opie's "Diseases of the Pancreas." For full-dress expositions, those on "Diseases of the Peritoneum" and "Congenital Cardiac Disease," by Dr. Rolleston and Dr. Maude Abbott, are models of what writers on medical subjects should aim at producing, and could hardly be bettered. Many of the illustrations in the five volumes of the *System* are good; the paper and printing leave nothing to be desired, the indexes are full, and there are not so many misprints as appeared in the first edition. The *System*, as a whole, contains all that the practitioner of medicine requires, with the exception that it excludes the consideration of mental disorders. It is well arranged, clearly written, full of advice on the many points of diagnosis and treatment that most require elucidation. The editors are to be congratulated upon the skill and care they have lavished upon its production; there is good reason to hope that the second edition of the *System* will enjoy, as it deserves, the great measure of success attained by the first.

PHTHISIS AND DUST.

IN the Milroy Lectures this year Dr. COLLIS gave a most interesting account of the industrial pneumoconioses met with in those who work at dusty trades, and produced a mass of evidence to show that the inhalation of siliceous dust promotes the development of pulmonary tuberculosis in a marked degree. The dangers of the prolonged or repeated inhalation of dust have long been known, possibly Hippocrates refers to them, certainly the elder Pliny describes the use of respirators to protect the lungs of workers in lead. Industrial pneumoconiosis has even made its way into literature, for it seems reasonable to suppose that it was the cause of the hero's death in Hardy's novel, *Jude the Obscure*. Dr. Collis goes fully into the medical literature of the subject from a historical point of view, and has no difficulty in showing that siliceous and granite dusts work havoc on the lungs when inhaled. They are particularly associated in the mortality tables with what is called "dust phthisis"; it is interesting to note his conclusion that some dusts, such as coal, not only appear to have no power of producing pneumoconiosis, but even may possess some inhibitory influence on phthisis. Certain other dusts, such as limestone and plaster-of-Paris, are said to be negative in their action, but most dusts undoubtedly have an injurious influence on the lungs should they be inhaled in large quantities. Among the pulmonary disorders to which occupational dusts give rise are bronchial asthma, pleural adhesions, bronchitis, pneumonia, and, as has been mentioned already, phthisis. Dr. Collis goes fully into the questions raised by these observations, and illustrates the pulmonary changes produced by these conioses with a number of excellent skiagrams and photomicrographs. There is good reason to hope that the pneumoconioses, like other occupational diseases, will in the future be suppressed by the activity of H.M. Home Office until they become as extinct as the dodo. A vast amount of good work in this direction has been done by this office during the past few decades, as, indeed, is shown by not a few of the statistics quoted by Dr. Collis. His lectures should be read by all medical men who have to treat the workers in dusty industries, in factories, mines, quarries, stone-yards, and the like.

A DOCTOR IN HIS LIBRARY.

DR. STUART M. CHISHOLM has collected into a volume bearing the title *Recreations of a Physician* a number of papers read before various societies, some of which have been published in the *Journal of the American Medical Association* and in the *Albany Medical Annals*. Of the

¹ *A System of Medicine by Eminent Authorities in Great Britain, the United States, and the Continent*. Edited by Sir W. Osler, Bt., M.D., F.R.S., assisted by T. McCrae, M.D., F.R.C.P. Lond. In five volumes. Oxford Medical Publications. Second edition, thoroughly revised. London: H. Frowde; Hodder and Stoughton. 1915. (Roy. 8vo, pp. 5,541, 92 plates; 248 figs. in the 5 vols. 35s. net per vol.; £7 15s. net per set of 5 vols.)

² *Industrial Pneumoconioses With Special Reference to Dust-Phthisis*. By E. L. Collis, M.B. Oxon., H.M. Medical Inspector of Factories, Milroy Lectures (1915). Reprinted from *Public Health*, the official organ of the Society of Medical Officers of Health. 1915. (Imp. 8vo, pp. 42; 2 figures.)

³ *Recreations of a Physician*. By A. Stuart M. Chisholm. New York and London: G. F. Putnam's Sons. 1914. (Demy 8vo, pp. 379. 12s. 6d. net.)

variety of its contents an idea may be formed from the titles of the chapters—Specialization; Physicians as Men of Letters; Banquo; The Symbolism of Names; Royal Authors; The Inherent Spirit of Medicine; Translations of Horace; The Science of Medicine in the Seventeenth Century; The Picaro in Fiction; and the Prevention of Disease. On all these subjects the author has something interesting and instructive to say, and he says it in a style that makes his book pleasant reading. We fear it is impossible to deny Dr. Chisholm's assertion that of the doctors who have more or less successfully wooed the Muse few have won distinction in their own profession. As instances he quotes John Keats, Tobias Smollett, Oliver Goldsmith, Mark Akenside, Friedrich Schiller, and George Crabbe, who tried doctoring as a means of livelihood with indifferent success when they did not fail dismally. This would seem to show that there is some incompatibility between medicine and literature. There are, of course, exceptions to the rule. Rabelais, Sir Thomas Browne, John Arbuthnot, and Oliver Wendell Holmes were eminent in medicine as well as in literature. It is curious that Dr. Chisholm, while recognizing that Rabelais was honoured by his contemporaries as a physician, makes no mention of the fact that he was one of the pioneers in the establishment of anatomy as a science. The late Professor Lodouin, in his *Rabelais anatomiste et physiologiste* (Paris, 1899), showed that the creator of Pantagruel gave a public course of anatomy at the great hospital of Lyons between 1532 and 1538. He was one of the first who gave demonstrations on the dead body. In passing, attention may be called to one or two inaccuracies into which Dr. Chisholm has fallen. John Arbuthnot did not take the M.D. degree at Aberdeen but at St. Andrews, as is proved by the records of that university for September, 1696, quoted by George A. Aitken in his life of that famous physician. Nor is it altogether correct to say that Marat was "made an M.D. of St. Andrews University, Edinburgh." The author may, perhaps, deem it worth while to correct these slips of the pen in a future edition. The other essays that make up his volume are all interesting in their various ways, and they are all marked by sound scholarship and a true sense of literary values. His knowledge of Spanish literature is particularly wide, and he has a happy faculty of throwing sidelights from different sources on any subject that he handles. We can heartily commend his book to all readers who wish to distract their minds from the unwholesome excitement of "final war editions" of newspapers.

ANAESTHESIA FOR DOMESTIC ANIMALS.

MR. HOBDAJ has condensed in a small book, entitled *Anaesthesia and Narcosis of Animals and Birds*,⁴ the results of his very wide experience in anaesthetizing animals of various species. The conclusions at which he arrives are founded upon the results of many cases which are carefully tabulated; details of a number of individual cases are included. It may be said, generally speaking, that for one well versed in the use of anaesthetics for human beings there is little that is new in the case of animals. What is, perhaps, surprising to the uninitiated is the amount of knowledge and care that is now brought to bear upon the matter in the case of the animal world, and it is here that Mr. Hobday and others of his school deserve so much praise and support. The anaesthetic agents employed for animals are the same as in the case of human beings, both in the case of general and local anaesthesia, and so are the principles upon which they are employed. One important difference in practice is to be found in the case of dogs in whom narcosis by morphia gives such excellent results that this narcotic may be used with the most satisfactory effect, even for major operations, in so large a proportion as three-fourths of the cases. One grain is the usual dose, though for the largest dogs the author employs as much as two. It has been demonstrated that nitrous oxide is as efficient as in the case of human beings; but, as may be readily understood, inconveniences from the point of view of apparatus and expense prevent any wide use of this anaesthetic. Chloroform is the agent chiefly employed; $\frac{1}{2}$ oz. given gradually until the full effect

is obtained and then withdrawn produces an available anaesthesia of about fifteen minutes in the average hunter. The most useful antidote if respiration fails is Scheel's hydrocyanic acid, which is given on the tongue or hypodermically. The best form of mask allows the tongue to be held forward throughout the administration, which is conducted through the nostrils. The horse is particularly amenable to chloral hydrochlorate in the same way as the dog is to morphia. Interesting details are given as to the management of particularly restive and difficult animals, and the book is one that should be of the greatest value to all practical veterinary surgeons.

NOTES ON BOOKS.

CHURCHILL'S MEDICAL DIRECTORY, 1916.

THE *Medical Directory*'s makes its seventy-second annual appearance in the issue for 1916. As every medical man knows, it is a volume that is not only useful, but even indispensable. Last year, in an effort towards economy that was laudable in itself but not wholly fortunate in its effects, the list of registered practitioners with British qualifications resident abroad was cut down from the customary two hundred pages to a mere dozen. This year we are glad to say the omission has been made good, and the full list reappears; in particular we welcome the reinclusion therein of the British practitioners resident in the overseas dominions. It appears from the numerical summary of the medical profession that the total number of British practitioners in the United Kingdom, abroad, and the Services stands at 42,570 this year, as compared with 42,572 a year ago; the figure in 1910 was 40,469. It has proved impossible to give any estimate of the number of medical men employed in war work; the Services this year are set down as employing 3,274 medical men, as compared with 3,366 last year. No doubt the discrepancy would be made up by an increase in the ordinary list, for the war has taken its toll; but in the *Medical Directory* for 1916, as in that for 1915, the ordinary list has been omitted. The total is, however, very far short of the actual fact, for it would seem that medical officers who hold temporary commissions in the R.A.M.C., as well as officers of the R.A.M.C. Territorial Force, are not included in the "Services" list. This, was, no doubt, the best course to adopt—in fact, the only course open to the editors of the *Directory*; but unless this omission is noted, an erroneous impression may be produced. For the rest, the issue for 1916 seems to contain all the customary serviceable articles on legal medicine, and all the lists of medical boards, officers, sanatoriums, health resorts, and the like that add so greatly to the utility of this invaluable annual.

DIARIES AND ALMANACS.

The centenary of Letts's diaries is being celebrated in the issue of this year, for John Letts, who, it is said, was the first diary publisher, began the business in 1816. The paper used in the diaries, which are now called "Quikref," is of a special quality, designed to secure an absorbent, non-glazed, yet smooth writing surface, and care has been taken in a matter in which many diaries fail, namely, that the binding shall stand constant usage. The publishers, Cassell and Co., issue a great many forms of ordinary diaries, and we have also seen specimens of Letts's medical diaries, which have a high reputation, and a nurse's report book and diary, which is likely to be found useful in private work.

Messrs. T. J. and J. Smith, of 26, Charterhouse Square, London, E.C., have prepared for 1916 the very numerous varieties of diaries and pocket-books which they are accustomed to issue; they vary in size from a foilscape volume showing a day on a page to a waistcoat pocket diary showing a week on a page. A useful desk diary, in quarto form, is the Half-hourly Appointment Diary, which may be had with or without blank interleaved pages or with interleaved blotting paper for 2s. 6d. Another quarto diary, interleaved with blotting paper and ruled for cash or memorandum, but bound in cardboard, costs 1s. 6d. They also issue Wall Tablet diaries to enter recurring or special engagements, and a number of private diaries. In all the samples we have seen the paper is good and the binding strong.

The Ulster Volunteer Force Hospital has issued a Christmas Book and Almanac giving an account of the formation of

⁴ *Anaesthesia and Narcosis of Animals and Birds*. By F. T. J. Hobday, F.R.C.V.S., F.R.S.E. London: Baillière, Tindall, and Cox. 1915. (Demy, 6vo, pp. 94, 24 figures. 5s. net.)

⁵ *The Medical Directory, 1916*. Seventy-second annual issue. London: J. and A. Churchill. 1916. (Roy. 8vo, pp. 1941. 15s. net.)

the hospital and of the manner in which it is conducted, together with a list of the medical and surgical staff, all of whom give their services free. It originally consisted of 114 beds in two buildings, lent by the Belfast Corporation, with 50 beds in a convalescent home. In May a new wing for 100 beds was erected and was provided with a verandah large enough to shelter 50 patients to whom open-air treatment might prove beneficial. Mr. J. C. White has provided a furnished house for use as a sisters' home, and the Queen's University has lent its grounds, and also given full use of its pathological and bacteriological laboratories and x-ray apparatus. The book is copiously illustrated by portraits and photographs of the hospital and of men in training.

Messrs. Abdulla, cigarette makers, have issued an almanac in thirteen sheets, copiously illustrated by eminent artists, and have presented 20,000 copies to the British Red Cross Society. It is hoped that in this way at least £1,000 will be realized for the society. Many of the sketches, all of which have reference to war, are in colours and are very admirably reproduced.

MEDICAL AND SURGICAL APPLIANCES.

A New Inhaler for the Open Method.

Dr. J. H. SUTCLIFFE (Honorary Anaesthetist to the York City Hospital) describes an open method for the administration of ether, chloroform, etc., by the use of a hollow metal mask with large capacity for concentrating the anaesthetic vapour, surmounting on upright detachable standards a graduated glass container of 2-oz. capacity, the anaesthetic being liberated by means of a needle valve on to a diaphragm of lint or other absorbent porous material, allowing a concentration of the anaesthetic vapour inside the cavity of the mask, with an uninterrupted supply of air through the fabric of the diaphragm which can be augmented by a further supply of air through the air valve fitted to one extremity of the mask. The porous diaphragm also acts as an indicator of the character and frequency of respiration by rising and falling, and is constantly under the direct observation of the anaesthetist. The container can be refilled very quickly. The anaesthetic can be administered with the patient's head in almost any position, as the curved adjustable dropper and backward and forward movement of the container permits the anaesthetic to drop on to the diaphragm at

any desired spot. The advantages claimed are that the manipulation is easy, that the risk of respiratory complications is diminished, and that patients rapidly recover and rarely suffer from nausea and vomiting. It is also claimed that the apparatus is clean, and that a new diaphragm can be provided for each patient at an insignificant cost. The apparatus is manufactured by Messrs. Reynolds and Branson, Ltd., Leeds.

A COMPACT little volume with the lengthy title *Rules for Employees of the Bureau of Preventable Diseases, including those for All Employees* is issued by the Department of Health for the City of New York. Apparently every employee of the Department of Health is required to be familiar with these rules, ignorance of which "will not be accepted as an excuse for failure to observe them." Though these rules are many and varied, a provident Board of Health has added to this volume several blank leaves, in which the employee is expected to record additional rules. Some of the rules are suggestive of a dame school. The rule that "all employees must be courteous to the public and to each other" might surely have been taken for granted. The volume, however, contains a quantity of excellent practical advice, and the section on the duties of a district nurse in relation to infectious diseases is admirably concise. Detailed instructions are also given for "Health Squad regarding Dog Complaints." Under this heading is given: "Should the dog be at large in a room, cellar, or stable, the patrolman will not shoot at the animal until he has obtained a snare from the Borough Office, by means of which the animal can be held firmly on ground and shot."

ROYAL MEDICAL BENEVOLENT FUND.

(Continued from p. 561.)

At the November meeting of the Committee 39 cases were considered. One applicant was elected to an annuity of £20 and £273 granted to 23 cases, and the others were either postponed for further inquiries or found unsuitable. The following is a summary of the cases relieved:

Widow, aged 52, of M.D.Edin. who practised at Newcastle-on-Tyne. At husband's death left unprovided for. Has one daughter now, aged 26, who is married, and only able to help her mother slightly. Applicant recently fractured her leg and unable to do anything. Relieved once, £12. Voted £12 in twelve instalments.

Widow, aged 58, of L.R.C.P. and S.Edin. who practised at Cardiff. Only income two small pensions from other charities. Has two sons, both married, and now in the army and unable to help. Applicant's health bad. Relieved ten times, £87. Voted £6 in twelve instalments.

Daughters, aged 51 and 63, of M.R.C.S.Eng. who practised at Bexley Heath. Joint income from needlework and friends less than £30 per year. Both have very bad health. Relieved eleven times, £174. Voted £20 in twelve instalments.

Daughter, aged 56, of M.R.C.S.Eng. who died in 1893 and practised at Liverpool. Lives with brother and sister, both of whom, like the applicant, are through ill health only able to earn very little. An uncle pays the rent of the house. Relieved six times, £68. Voted £12 in twelve instalments.

Widow, aged 57, of M.D.Edin. who practised at Ross, in Herefordshire, and died in 1908. Applicant's income from all sources £35. Tries to supplement this by taking an occasional boarder, but too old to do much in this way. Relieved five times, £36. Voted £12 in twelve instalments.

Widow, aged 78, of M.D.Lond. who practised in London and died in 1895. Applicant's only income £40 per annum from two charities, suffered severely from rheumatism and unable to do anything. Relieved eight times, £45. Voted £10 in two instalments.

Daughter, aged 64, of F.R.C.S.Eng. who practised at Chester and died in 1884. Has been able to earn a living as housekeeper until about three years ago. Since, owing to age, she has not been successful in obtaining a post, and is in great financial distress. Relieved three times, £22. Voted £10 in two instalments.

Daughters, aged 56 and 64, of M.R.C.S.Eng. who practised in Cornwall. Applicants endeavour to make a living by taking in paying guests, but have not been successful, and they both have very indifferently health. Live in own house but unable to make ends meet. Relieved six times, £100. Voted £18 in twelve instalments.

Widow, aged 57, of L.R.C.S.Edin. who practised at Langley and died in 1909. Applicant lives in own house, but it is heavily mortgaged. Endeavours to earn a living by taking in paying guests, but has not had sufficient of late to pay her way. Relieved five times, £50. Voted £10 in two instalments.

Daughter, aged 82, of M.R.C.S.Eng. who practised at Newton Abbot, and died in 1839. Only income a small Post Office annuity provided by friends. Has recently lost a source of income which has left her in great difficulties. Voted £20 in four instalments.

Daughter, aged 61, of L.S.A. who practised in Staffordshire, and died in 1856. Applicant suffers from spinal curvature and very bad sight, and quite unable to do anything. Only income £25 per annum from relatives. Relieved fifteen times, £170. Voted £18 in twelve instalments.

Widow, aged 48, of F.R.C.S.Eng. who practised in London, and died in 1901. Applicant left with three young children. The eldest has now joined the army, the second son is a clerk, and the youngest a pupil teacher without salary. Applicant managed fairly well by taking in boarders at an Essex seaside place, but since the war has scarcely had any. Relief once, £59, some years ago. Voted £12 in twelve instalments.

Widow, aged 77, of M.R.C.S.Eng. who practised at Halderness, and died in 1896. Only certain income £30 per annum. Six children, four of whom are married and unable to help, and the two single children only able to help very little. Relieved five times, £92. Voted £12 in twelve instalments.

Widow, aged 67, of L.R.C.P. and S.Glasg. who practised in Essex, and died in 1896. Applicant was left quite unprovided for. Only income a pension of £30 from another charity. Only son married with five children, and unable to help. Relieved four times, £30. Voted £12 in twelve instalments.

The claims on the fund are steadily increasing, largely in consequence of the war, and although the ordinary subscriptions remain at much the same level, there is a constantly increasing adverse balance. To meet this the Committee has had to draw heavily upon its limited reserves, and unless increased support be rapidly forthcoming the work of the fund will have to be very seriously curtailed. Subscriptions may be sent to the honorary treasurer, Dr. Samuel West, 11, Chaudes Street, Cavendish Square, London, W.

The Royal Medical Benevolent Fund Guild appeals for gifts of secondhand clothing, boots, and shoes in good condition, also household linen. The gifts should be sent to the Secretary, Royal Medical Benevolent Fund Guild, 43, Belsaver Street, W.

British Medical Journal.

SATURDAY, DECEMBER 18TH, 1915.

THE MENINGOCOCCUS AND ANTIMENINGOCOCCUS SERUM.

THE meningococcus has always had a hard struggle to maintain its independent existence. Within a few years of its first discovery it was described as an organism with characters so manifold as to deprive it of most of its individuality. Even quite recently there has been assigned to it a pleomorphism so radical that almost any bacterial growth not otherwise identified would have to be looked on with suspicion as a potential meningococcus. It is gradually, however, freeing itself from the chaos due to insufficient characterization, and there is little reason to doubt that it is a real entity with properties of its own sufficient to identify it amongst the crowd of similar organisms. It is, however, a variable organism, with characters no more fixed than those of some other well-known bacteria—for example, Flexner's dysentery bacillus. But bacterial variation does not occur in the haphazard indiscriminate fashion that many appear to think, and with the increase of careful work the common variations will be worked out and the differential characters clearly established. The papers by Ellis and Arkwright, which we publish this week, are a valuable contribution to this end. These two observers, working independently, find that the strains of meningococci isolated recently from cases of cerebro-spinal meningitis are divisible into two main types, distinguishable by agglutination, that both types occur in the same epidemics and the same localities, and occur with much the same frequency. Both types may produce the severest form of the disease, and there is no reason to believe that one is more benign than the other. Both have been met with in the naso-pharynx of individuals not suffering from the disease. Applying another test, the absorption test, Gordon and Murray¹ have recently divided the strains they examined into four groups, over 80 per cent. of the strains falling into two groups. There seems good ground for hoping that order will shortly be brought into the confusion that has so long prevailed in the meningococci group. The progress recalls the steps in the now far advanced disentanglement of the enteric organisms; the separation of typhoid from the rest by cultural characters, the later subdivision of the others by agglutination into the two paratyphoid and Gaertner's bacilli, and then the absorption distinction of *B. paratyphosus* B from the food-poisoning *B. suiptifer*.

The subject is one of immediate clinical importance. Antimeningococcus serum is one of the few therapeutic serums which can claim to be of real value. Yet it often fails, and failed last winter in the epidemic in this country. The failure can reasonably be attributed to the fact that the horses yielding the serum were not immunized with the strains occurring in the epidemic. We can only expect to prepare in advance satisfactory serums if the strains used in immunization are representative of all the types of the organism, and are selected from among those

types as possessing good immunizing powers. It is to be hoped that we shall soon be in possession of serums representative of all the types, and that these will prove of greater efficiency should the occasion unfortunately arise for their extended use.

THE FINANCE OF THE INSURANCE ACT.

A CONSIDERABLE number of questions pressed recently on Mr. C. Roberts in the House of Commons deal more or less directly with the financial soundness of the Insurance Act and the possibility of much greater economy in administration. Until the proper valuation of approved societies has been made it will, of course, be too early to form any precise opinion as to their general position, but from provisional estimates, and according to statements in the blue books quoted in the House on December 1st by Mr. Currie, it appears to be fairly certain that, dividing insured persons into three classes—men, single women, and married women—the actual sickness among men in the older friendly societies has been well below the expectation, and among single women rather below than above; little fear, therefore, need be entertained as to the financial soundness with respect to these two great classes. With regard to the class of married women, however, it appears that the actual sickness experience of many societies has been vastly in excess of what was provided for, and drastic revision of the finance of the Acts relating to this class will certainly be called for. But this is by far the smallest class of insured persons, and though each class ought to be taken separately, the assurance given by Mr. Roberts that there is no foundation for the alarmist reports as to the general financial soundness of the insurance scheme may, on the evidence at present available, be accepted with some confidence.

But when the question of economy in administration is considered, it is easy to point to numerous directions in which enough is known to justify a very close inquiry as to whether there is not a great waste of insurance funds going on. Opinion seems to be divided on the question whether a large saving might not be effected by having one, or perhaps two, bodies of Commissioners instead of four as at present. On the one hand, certain approved societies that have business in all the four countries—England, Wales, Scotland, and Ireland—may quite naturally prefer one Commission, with uniform regulations as far as possible, for all their branches. On the other hand, many Insurance Committees, especially in Scotland, are very strongly of opinion that the separate Commission for Scotland should be maintained, holding that its continuance is necessary to deal properly with the special conditions in Scotland. It might appear *prima facie* that a reduction of the number of commissioners would lead to a considerable annual saving; but if, as is probable, it is impossible to enforce uniformity in administration in the four countries, it is highly probable that any saving in salaries due to amalgamation of the several Commissions might lead to lessened efficiency. The data for deciding this are hardly available to the public.

But one thing is practically certain—that under all four Commissions there has been an almost reckless waste of money in issuing, altering, rescinding, and explaining almost innumerable regulations, orders, and circulars. Mr. Roberts refused in Parliament to state the number of these documents on the ground that it would serve no particular purpose, but he has described in words as strong, perhaps, as can be expected from

¹ *Journ. Roy. Army Med. Corps*, May, 1915.

a responsible Minister who has to consider the susceptibilities of his predecessors, his consternation when confronted with the huge quantity of literature that had fallen upon the committees. He compared it alternately to a snowstorm and a rainstorm. Officially he had admitted that committees have suffered under the complexities of the present system, and has expressed a hope that something would shortly be done to reduce within manageable compass the documents which have to be issued. It is in truth not merely the expenditure of money on the printing and issuing of so many documents to which objection is taken, but also, and mainly, to the wasted labour also inflicted on Insurance Committees, approved societies, Panel and Pharmaceutical Committees, and on other bodies when they make arrangements to carry out orders which are only in force for a short time and are then replaced by other orders needing altogether fresh arrangements.

But apart from such expenses rendered obligatory by the ever-changing orders and regulations, the ordinary working expenses of approved societies and Insurance Committees call for full inquiry. There is ground for believing that the administration expenses of many Insurance Committees are quite unnecessarily high. Some committees are almost as lavish in their printing and postage accounts as the Commissioners, and from time to time instances of reckless waste come to light which would be ludicrous if they were not signs of a carelessness leading to serious extravagance. Under sanatorium benefit there is little doubt that in some areas persons in advanced stages of phthisis have been sent to expensive sanatoriums simply to satisfy a popular fancy, without the least chance of cure and when much cheaper forms of treatment might have been used with equal benefit.

It may not be easy or even possible to calculate how far the complexities that have been uselessly woven round the Act are responsible for waste of money in administration, but it is quite certain that the working of the Act could be made infinitely simpler, and that the result would be an enormous saving in administration expenses.

Mr. Roberts made out a good case against the appointment of a roving commission of inquiry at the present time, a proposal of which the British Medical Association formally expressed its strong disapproval in the letter addressed to Mr. Roberts and the Prime Minister which was published in the SUPPLEMENT last week (p. 215). No committee of inquiry would be satisfactory unless it had the fullest assistance from all the committees and officials concerned, and, owing to the depletion of the staffs due to the war, it is difficult to see how such assistance could be given. Moreover, as was pointed out in the letter mentioned above, for the proper conduct of such an investigation it would be necessary to secure suitable medical representatives to serve on the committee of inquiry, the attendance of medical witnesses from various parts of the country, and the collection of a great deal of evidence. For none of this work has the medical profession now adequate leisure or opportunity. Many of its members directly affected are on military service with the navy or army abroad or at home, and those that are left are hard pressed in many areas to give the requisite attendance on the civilian population. It must also be recollected that the conditions of war times are altogether exceptional, and methods which might be suggested to meet present circumstances would probably be quite unsuited to times of peace. It is practically certain that any inquiry would be followed by some demands for fresh grants from the Government; but at

present it has its hands full of demands for war purposes which, whatever happens, must be met. Thus, while it is easy to point out directions in which greater economy in administration of the Insurance Act might well be practised at the present time, it would seem that Mr. Roberts gave good reasons for deciding that the appointment of a roving commission is at least inopportune.

MEDICAL LESSONS OF THE WAR.

THE Army Medical Service was in the fortunate position at the outbreak of war that its house had been put in order some years earlier, and that army medical administration was in the hands of army medical experts, subject, of course, to the medical department receiving the support of the Minister, which, as is well known, it has had in full measure. The results have fully justified the policy. The relative freedom from disease in France and Flanders is a record of which the whole medical profession may well be proud, and if the results in the Dardanelles have not been so good, it has to be recognized that the conditions which have led to the invaliding of large numbers of men with dysentery and enteric fever were such as no foresight could entirely have obviated.

The enormous increase in the numbers of the British army during the last fifteen months made necessary a corresponding increase in the number of medical officers. From information given in the House of Commons recently by Mr. Tennant, it appears that the total number of army medical officers now employed is about ten thousand, and he stated last Monday that approximately three-fifths of these held temporary commissions. This has involved a very large draft on the civilian profession. It has responded in the most admirable manner, giving of its best. The men who volunteered were wise enough to know that they had much or everything to learn about military medical administration; they also, as it turned out, had a great deal to learn and to unlearn about clinical surgery and applied pathology and bacteriology. This was, perhaps, something of a surprise to many, but the lessons have been readily and quickly applied, to the great advantage of their patients at home and abroad. But, in addition, those medical officers who a little time ago were civilian practitioners have now learnt a good deal about military hospital administration, and their views as to ways in which it may be conducted with greater economy, especially in personnel, and with no diminution but even with an increase in efficiency, must be deserving on every ground of careful consideration. Economy of personnel is a matter which very nearly concerns the members of the medical profession, both those who have joined the military medical services and those who have hitherto remained at home. On the one hand is the insistent demand of the army for medical officers, and on the other, private interests, the demands of civilian patients, and the alarms of the Insurance Commissioners which find some expression in the letter addressed by the Central Medical War Committee, after consultation with them, to the honorary secretaries of local War Committees (SUPPLEMENT, p. 221).

Suggestions from those lately civilian practitioners who have been gathering experience within the areas of military operations would, we feel sure, be welcomed by the responsible heads of army medical services, but we have not heard that any machinery has been devised for ascertaining the nature of this accumulated

experience so that it may be utilized for the benefit of the army and for economy of energy and public expenditure. We are bound to admit the existence of a good deal of disappointment among those who for the last year or more have been serving with temporary commissions or as Territorial medical officers abroad, and it would be well to find means to relieve it. It is not, as a rule, due to personal considerations; men have made sacrifices, often very serious, and are willing to abide by the consequences. The causes of the state of mind to which we refer are rather national and professional. It is due to an uneasy feeling that the best use is not being made of the medical personnel. It is considered that the British army hospitals in France have been habitually over-staffed; many medical officers accustomed to the strenuous life of a civilian hospital have felt that they had not enough to occupy them, that much of the small amount they had to do could be equally well done by men of less experience, and even by senior students, as it is in civil hospitals, and that the kind of work for which a man has been specially trained by his civilian experience as surgeon, pathologist or bacteriologist, has not always fallen to his lot.

There is, and can be, nothing but admiration among the public and the profession for the manner in which the regular R.A.M.C. tackled the immense task it was called upon to undertake sixteen months ago, but professional opinion is exercised by a doubt whether the lessons of the last year have been sufficiently applied. There have been questions in Parliament about the Army Medical Advisory Board, which, it appears, has not met since the war began. On looking at the list of members of that board given in the monthly *Army List* for June, the last issue published, it will be seen that the majority are engaged either at home or abroad in the active service of the army, and Mr. Tennant said in the House of Commons on November 25th that it was not the policy of the War Office to hold formal meetings for no particular purpose, since medical advice was more effective if given in consultation and not collectively by the Board. We can well believe that this policy is correct, for advisory committees often merely lead to loss of valuable time and the division of responsibility; at the same time we are inclined to think that more use might be made of the experience which has been gained, in the various directions indicated, by Territorial medical officers and by those medical officers now holding temporary commissions. The Army Medical Service has had the pick of the young talent of the profession, and a large proportion of those now employed at military hospitals abroad have had experience of hospital work at home. While military hospital administration must differ in many important details from civil hospital administration, the aim of the two is fundamentally the same—to get the patients cured with the greatest economy in time to them and of material and personnel to the country.

At present there seems to be no section of the Medical Department at the War Office to which medical officers of the Territorial Force or holding temporary commissions feel authorized to take their suggestions. So far as we are aware, the Medical Department at the War Office does not contain any one who has himself passed through the mill which converts the civilian surgeon or physician or pathologist into a temporary medical officer, yet the regular Army Medical Service now probably constitutes not much more than a tenth of the total Army Medical Service of the Crown, and this proportion must tend to diminish.

MEDICAL CLERKS.

CLINICAL clerks we know, and clerks in ho'y orders, but who are these medical clerks? They are a new sect of our many-sided profession, bred of that all-devouring monster bureaucracy. With each new Act of Parliament which ordains an extension of the public health service of the country, whether the direction of the new effort be preventive or curative medicine, there is one certain sequel, not truly that striven for in the Act of Parliament, for from past experience we know that the effect of an Act is not always that hoped for. The certain sequel is the establishment of a new public office, new desks, new clerks, little and big; new forms, many and various; and, alas! some more members of our profession enslaved by these forms, clerks, desks, and the whole paraphernalia of an office. All this is done, no doubt, with good intentions; but the road paved with good intentions does not always lead upwards. The latest of these new forms which we have seen is one issued under the Mental Deficiency Act of 1913 at the instigation of the Board of Control. The form takes the shape of a quarto card. It has two faces, but both are distressing in the insignificance of their features and the total lack of proportion these features bear to one another. The one face gives spaces for data on the civil state of the "Defective" and for his or her family history, for data on the person having charge of the Defective, on the conditions under which the Defective was found to be living, for details of past certificates, the character of the control desired, and finally how the case was dealt with. The other face is headed "Medical Particulars"; it is plotted out into no less than eighty-seven spaces, and since the allowance for the several items is much the same, it gives a fair indication of the lack of proportion with which these items are regarded by the compiler of this precious form. For example, "Height (inches)" gets a line $\frac{1}{8}$ in. long, whilst "General Health" is to be summed up in $\frac{1}{4}$ in. The "Skin" has space for five entries and a joint measure of $7\frac{1}{4}$ in. in line, but the "Nervous System," with seven spaces, gets only 13 in. The last space is headed "Deformities, etc.," that little addendum "etcetera" is perhaps a sign of grace that the compiler felt there might be some things he had overlooked, but for the whole "Deformities, etc.," he gets only 3 in. The greater part of the page is devoted to spaces for Mental State and Parentage. "Mental State on Admission" gets a modicum of room, but that for the "Etiological Factors" is a mere trifle, and even so it has to be filled in according to *sons schedule* undefined. "Details of Parentage, etc.," is underlined by the instruction: "Any present and former mental disease or neurosis (including intemperance) in the parents, grandparents, or brothers and sisters should be recorded, together with any facts of importance in the present physical health of the parents and brothers and sisters. *Every space should be dealt with, a line will mean no stigmata, and N.K. no information.*" The N.K. in the italicized clause suggests the flippant diagnosis of the hospital resident who, stumped for lack of a reasonable conclusion, entered "G.O.K." But that the careful compiler should explain the initials by "no information" is a portent. In the spaces for the parents the dates of birth and marriage and occupation got mere room than "Any mental disease or neurosis" and "Physical health." One would think that the eighty-seven spaces on this face of the card would have exhausted the ingenuity of the compiler. But no! There are footnotes absorbing all the letters of the alphabet from a to t! What useful medical purpose can such a form serve? We cannot tell. However conscientiously filled it would never give a clinical picture of a Defective. Plainly no research worthy of the name could be founded on such scrappy data as the spaces admit. But we had forgotten, this is not a medical document, it is the dossier of a bureau; it will serve a purpose of a sort—it will furnish pabulum for the piling up of figures wherewith to pad a

blue book. For one brief moment vast tables of figures will bewilder the unwary into a belief in a laborious and assiduous public service, and thenceforward they will lumber the good timber of many shelves, until the hungry bookworm riddles them into the dust of forgetfulness. Meantime the initiative, the insight, and the critical faculty of the doctor who has to furnish them are suppressed, and the possible birth of a discovery is ruthlessly overlaid in a smother which steals away the free air in which alone it can live. And all this is done in the name of progress—but which way, up or down? Such an exhibition of the work of bureaucracy would be passing funny if it were not so sad. The narrow-visaged Philistine is consumed with a deep-seated fear of the medical man and all his works. The pioneer of medical progress impresses his public, an enlightened public demands a reform, and the Philistine masks his hate with a smile as he stifles the new endeavour, and rejoices to see the prime mover in the attempt turned into a mere docketing clerk, a slave of a soul-destroying routine. Well may the lover of our profession echo the cry of St. Paul, "Who shall deliver me from the body of this death?"

MEDICAL CERTIFICATES FOR RECRUITS.

The recruiting campaign now in progress in this country has its influence on the medical profession in more ways than one. One effect appears in the increasing necessity for medical men to take service with the new armies; with that we have dealt. The point we wish to deal with now is of another order; it is one with which our professional brethren in other countries are familiar, but it is new to most of us in these islands. The appeal for every fit man to enter the service of his country in a military capacity and the heart-searchings that must follow these appeals to the conscience of men of military age have caused some to realize for the first time the doubtfulness of their physical fitness for military service, just as some of us have learnt for the first time that others do not think our appearance marks youthfulness, as we had cheerfully fancied. Those men go to their accustomed medical attendant and ask for a certificate of their physical condition for use when they present themselves at the recruiting office. There are other men who desire these same certificates with a different end in view; they feel the moral pressure of the call, they propose to present themselves for attestation, but they wish to do this so well armed that they will be sure of a speedy dismissal from the office in possession of a form which states they are rejected as unfit for military service. The armour these men seek is a medical certificate. A third type of man is of those who are still tied to their mother's apron-strings, and the appeal for the certificate comes from her. We do not wonder at her fears, and we can guess that the claim of unfitness is keenly contested in her heart with her pride in the fruit of her body. What is the private medical man to do in the face of these demands for certificates of physical condition? His position is really quite simple. It is within his province to state the facts of the case, but it is not his province to pronounce on the fitness or otherwise of any one for army service; that rests with his professional brother, the recruiting doctor. As the family doctor he may have valuable knowledge on the life history of a man, he can then and there examine him, and it is quite open to him to write down the facts of which he had knowledge. Such a written statement will be of the greatest value to the recruiting doctor, who, in the pressure of his work, will value it in proportion to the terseness with which the facts are set down. But the duty of determining the relation of these facts to the fitness of the man for military service must rest with the recruiting doctor, who may be a commissioned officer of the R.A.M.C. or a general practitioner doing temporary duty, but in either case he acts for the military authority, and

knows the current standards for enlistment. The private practitioner does not necessarily know these standards, they vary from time to time, they vary for the several branches of the service. Even in the same regiment there is room for variation, for not every man wields a weapon; some have to abide by the stuffs of the fighters and prepare their food for them. It is, of course, open to the private doctor to give expression to his opinion of the man's fitness, basing this on the facts that he cites, but so soon as he essays this task his difficulties will begin, both with his client and with the recruiting doctor. His guarded expression of opinion may be altogether unsatisfactory in the view of the man or his friends and yet go too far in the eyes of the recruiting doctor, so in the end his opinion meets the approval of no one. If the private doctor will confine himself to the statement of the facts of the case, pointing out to the man that the determination of his fitness or otherwise must rest with the army doctor, he defines his own position clearly, there can be no room for difficulty with his patient, and he does not prejudice his statement of fact in the eyes of the recruiting doctor by treachery on his work. One word as to the form of these certificates. Some identification of the paper with the bearer is desirable. Invite the man to sign his name at the top of the paper. Beneath this signature the doctor will write in some such fashion as this: "I have this day examined A..... B....., who has signed his name above; I find that he suffers from etc." Or, "A..... B....., who has signed his name above, has been under my care since He has suffered from etc." The certificate should, of course, be dated, and it should give the address of the doctor and the doctor's qualifications. The certificate should not be addressed to anyone, but handed directly to the man; it is an open document given to the man himself for such purposes as may please him.

"TRENCH-FOOT."

THE Académie de Médecine has resolved to draw up some leaflets for distribution among soldiers, describing in simple terms the prophylaxis of some preventable diseases. A committee appointed for this purpose on November 2nd made a report on November 16th, in which it presented leaflets on venereal disease and on the prevention of local lesions due to cold. The former led to a long debate, but the latter was adopted almost without discussion. After pointing out that such lesions occurred particularly in the feet, owing to standing in water, liquid mud, or melted snow, to wearing damp boots, to contraction of the leather and consequent constriction of the foot interfering with the circulation and producing swelling of the foot and the lower part of the leg, the leaflet proceeds to make certain recommendations. It advises that the men should make every effort to render the bottom of the trenches as dry as possible by means of drains and catch-pits, and laying down shingle or hurdles; that men should not remain standing or sitting longer than is necessary; that they should wear large boots; and that it is worth while to wrap the feet with strips of paper under the sock and to keep two pairs of boots and socks, so that those not in use can be dried. The most important point, however, is to take the boots off at least once a day, and to rub the feet and lower parts of the legs thoroughly for ten minutes, while at the same times the toes and ankles are moved energetically. Afterwards a dry pair of socks should be put on. The soldiers are counselled to use the opportunity of being in camp or billets to give particular care to their feet and boots, washing the feet and rubbing them at least once a day. The boots should be cleaned of all mud, dried without hardening them by bringing them too near the fire, and greased. Further, if he has reason to fear that his feet are beginning

to suffer from cold, the soldier is advised to take off his boots, rub the feet gently, put on sabots filled with straw, and see the medical officer at once. The interesting paper by Professor Sheridan Delépine, published at p. 183, discusses the prevention of what appears now to be commonly known as "trench-foot" from a scientific point of view and describes a waterproof silk bag for the foot and leg, to be worn inside the boot. He considers that a waterproof top boot so devised as to leave a fairly wide air space between the foot and ankle and lower part of the leg would be more efficient and probably more convenient, provided the material used was light and did not interfere with movements, and Mr. Tennant told the House of Commons that a large number of rubber thigh boots have been issued. That the matter has already become one of considerable importance is shown by his further statement that 770 cases of trench-foot occurred during the week ending November 27th. Such discussion as did take place at the Académie arose in connexion with a recommendation to grease the foot and the stocking carefully, using for this purpose by preference tallow either alone or mixed with ox-foot oil. This was referred back to the committee.

MILITARY RECORD CARDS FOR HEALTH RESORTS.

The Advisory Committee of the Royal Society of Medicine (Section of Balneology and Climatology) has now issued a second set of case record cards for recording the treatment of wounded and invalid soldiers at the British health resorts. It is the aim of the committee to obtain a permanent record of the many military cases that are now being treated by waters, baths, and climates in this country. A card was therefore prepared in consultation with the Medical Research Committee, which will eventually form a part of the records for the Medical History of the War. A doubt has been expressed whether these cards ought to be used at the hospitals at health resorts (and there are many) where baths and other physical treatments are not chiefly and primarily employed. Such hospitals are already, to some extent, reserved for cases appropriate to the health resort, which offers facilities for special treatment not elsewhere obtainable, and they will, no doubt, be more and more set apart for cases suitable for the health resort as time goes on. In the meantime it is considered well that the cards should be used as freely as possible, in order to obtain something like a complete record of the results of all cases sent to the British spas and climatic stations. In the second edition, which consists of ten thousand, the cards have been modified as experience has shown to be convenient. The back of the card is now devoted to a tabular entry of the particular physical applications employed. The committee is anxious that all medical men in charge of soldiers at the health resorts should avail themselves of this means of making their observations of permanent value. From the point of view of the health resorts themselves it should be unnecessary to emphasize the value of the present opportunity for accumulating a mass of evidence showing the results achieved by means of the various treatments which they have to offer. Fresh supplies of cards can be obtained on application to the printers, Messrs. Adlard, 76, Newgate Street, E.C.

HYGIENE FOR THE MEN IN THE RANKS.

The Ligue Sanitaire Française was established at the French Ministry of the Interior, with Professor R. Blanchard as President, in February, 1914. Its aim was to disseminate the knowledge of elementary hygiene among the French people, French colonies, and countries in sympathy with the French and speaking their language. The organization of the Ligue was only partially complete when the war broke out, but it at once turned its attention to the distribution of information to the soldiers. It has issued a series of pamphlets giving good advice and stating reasons for each recommendation.

The first pamphlet, of which 25,000 copies were printed, contained instructions as to general hygiene and disinfection in war. The second dealt with the plague of lice. The third, of which we gave some account on October 23rd (p. 612), described means for dealing with the plague of flies; and the fourth discussed in particular the safeguarding of food in the trenches and camps. At a meeting of the Académie de Médecine on November 30th Professor Blanchard was able to produce evidence that these pamphlets had been highly appreciated by the responsible military officers, and he went on to describe briefly what was being done in the same directions in other countries. In particular he referred to the articles on Insects and War, published in the BRITISH MEDICAL JOURNAL by Dr. Shipley, some of which were republished in a small volume entitled *The Minor Horrors of War*. The book, Professor Blanchard said, would remain a pattern for its genial combination of humour and science. We are sure he will be able to express the same opinion of the second volume containing the remaining articles published in the JOURNAL, which the Master of Christ's is, we understand, preparing. Professor Blanchard also said that Italian medical officers had prepared leaflets giving brief instructions without explanations, which the distinguished professor of parasitology in Paris considered to be a mistake unless accompanied by much fuller statements, addressed to officers and non-commissioned officers, explaining the motive of the recommendations, after the manner of the French pamphlets and Dr. Shipley's book.

The offices of the General Medical Council have been removed to its new house at 44, Hallam Street, Portland Place, London, W. In future the business will be transacted at this address, to which all communications should be forwarded. The telegraphic address is "Genmedicins, Eusroad, London."

Medical Notes in Parliament.

War Taxation: The Finance No. 3 Act.

We have dealt in previous issues with the progress of the third Finance Act of the War, which is now on the point of becoming operative, and we propose here to consider briefly some of the alterations made in the bill during its later stages.

The Import Duties naturally came in for a good deal of criticism on the question of principle involved, but little change was made in the actual incidence of the taxes. Professional users of imported motor cars are still denied the exemption granted to commercial users, but veterinary surgeons will be allowed the rebate on the motor spirit duty which medical men have always received.

The questions discussed and the amendments carried in connexion with the income tax proposals dealt for the most part with matters of administration; authority was given to exempt the interest on future war loans from tax so far as it may be paid to persons not domiciled or resident in this country. Banks are, in certain circumstances, to receive an allowance in respect of war loan interest, and a new method of assessment was set up, devised to obtain income tax from foreign concerns artificially reducing or eliminating their profits so far as they arise from operations in this country.

The question of the income tax charged on officers was the subject of an interesting discussion. Mr. Pebo (U., Devizes) moved an amendment providing that officers should be relieved from the additional war taxation unless they were possessed of a private income amounting to £1,000 per annum, and Lord Beresford (U., Portsmouth) and others strongly urged the Chancellor to make the desired concession, but in replying he explained that his view was that if the pay of an officer was brought unduly low by the payment of income tax the proper remedy was to increase the pay rather than to make a special allowance from the tax. Asked whether he would be prepared to find the money if a bill to increase the pay were intro-

duced, Mr. McKenna replied that he would have to see what the War Office proposals were. Ultimately he agreed to move an amendment on the report stage providing that the pre-war rates of tax should be applied to officers whose total incomes from all sources did not exceed £300. Speaking on the amendment, Mr. Peto urged that the concession should be extended to cases where the private income did not exceed £450, but finally withdrew his amendment, intimating that the question would be raised again on the next Finance Bill. In the bill as it originally stood it appeared that all "employed persons" would come under the new quarterly system of collection. As a result of discussion with the General Commissioners of Income Tax and others, it has now been made clear that this system will apply only to "weekly wage earners employed by way of manual labour."

We have before pointed out that the Excess Profits Tax breaks new ground and on that account is open to useful criticism to a far greater extent than a tax which, like the Income Tax, has by constant amendment of an original and still operative Act gradually become so complicated that none but experts can readily grasp the effect of fresh legislative proposals. That this is so is shown by the large number of alterations made in this portion of the Act during its passage through the Commons. The functions of the Board of Referees have been so far extended that the Chancellor suggested that they would probably have to act in panels. The right which the bill proposed to give to revenue officers to inspect books of account has been withdrawn, the tax has been extended to mineral royalties, and many other changes have been made which need not be discussed here. One alteration in principle the Chancellor throughout refused to make—namely, to extend the tax to professional incomes. On the other hand, Mr. Montagu introduced on his behalf, during the report stage, a declaratory amendment exempting "barristers . . . doctors . . . and any profession unconnected with the purchase and sale of property or commodities of any description." He explained that a satisfactory datum line for the pre-war standard of professional profits was regarded as unattainable and also that the yield of such a tax would be "insignificant." In deference to the wishes of the House, Mr. McKenna withdrew his amendment, but the existing clauses of the Act already make it sufficiently clear that medical men are exempt, and in their case at least the abortive amendment was not necessary.

It is now nearly three months since the bill was first introduced, and a considerable amount of parliamentary time has been expended upon it. Embodying as it does novel principles and heavy taxation, the application of the measure will be fraught with difficulties both to the taxpayer and to the administration. The great importance in this country of success in fiscal matters should be sufficiently obvious to render all concerned genuinely anxious to make the Act a means of equitable and yet fruitful taxation. If its practical working is carried out in that spirit the result should not be in doubt.

War.

"Frost-bite."—Sir G. Scott Robertson on December 8th asked whether "frost bite" so-called threatened to be as bad among British troops at the front this year as last; whether it was more or less common amongst our men than amongst French and Belgian soldiers; whether French and Belgian soldiers wore puttees; whether rubber thigh boots were provided in sufficient numbers for actual duty in the trenches, and, if so, whether they were worn with puttees or with long woollen stockings. Mr. Tennant said that during the week ended November 27th approximately 770 cases of trench-foot were reported from France. It was hoped that the measures adopted would cause a great reduction in the incidence of the ailment. Rubber thigh boots had been provided in large quantities for the use of men actually on duty in the trenches and further quantities were being sent. So far as was known puttees were being worn with them. He was unable to say whether frost-bite had been more or less common among our soldiers than amongst French or Belgian soldiers.

"Marching Boots."—Mr. Tennant, in answering a question by Mr. Bryce, said that the importance of a soldier's footwear was universally known and appreciated. While unable to accept, without consultation with military

authorities, the classification of feet into the normal, the arched, and the rather flat, he could say that he had received no reports indicating that suffering had been caused by boots to suit these three characters of foot not having been provided. Experts with regard both to boots and feet had been consulted before the present boot was introduced, and this practice would be continued when any question arose requiring skilled advice.

"Eyesight Defects."—Sir J. Rolleston asked whether anything could be done to allay the uncertainty due to recruits not being thoroughly medically examined for eyesight and other defects upon attestation, and whether a recruit or his employer could be entitled to demand a final medical examination at once. Mr. Tennant said that when the present recruiting campaign was over it would be possible to examine recruits properly, and due notice would be given with regard to the arrangements proposed to be made.

"American Medical Men."—In reply to Mr. Pringle, who inquired whether American medical men had been recruited for medical service with the British Army, Mr. Tennant said that he understood that several of the American universities had combined, under the auspices of the Red Cross Society, to send medical men and nurses to form the staff of two general hospitals. These medical men and nurses were engaged in their civilian capacity. Individual American medical men were not being employed in a military capacity. He did not think it was true that they were being employed by the British War Office and placed in uniform, but promised to inquire.

"Dentists."—In reply to questions by Sir C. Kinloch-Cooke, on December 8th, Mr. Tennant said that a considerable number of full-time dental officers had been appointed over and above such as might have been appointed to go with the Canadian contingent and the Australian and New Zealand forces, and any voluntary hospitals. There was no evidence of any increased number of soldiers being invalidated for defective teeth in proportion to the number of men in the field. Whether it was true that eight Red Cross hospitals in France were without dentists he could not say, but all demands for dental surgeons made by the authorities overseas had been met. Another point raised was whether, owing to insufficient dental arrangements at various hospitals in London and elsewhere, men invalidated homo on account of their teeth had to remain in this country a much longer time than would have been necessary had the arrangements been adequate. Mr. Tennant said that men were not kept in hospital for dental treatment, the bulk of the work being done while they were doing their duties. In each command full-time commissioned dental officers had been appointed, and their number was increased when required. General officers commanding were also empowered to employ as many civilian dentists as were needed. The importance of proper dental treatment of officers and soldiers was fully realized.

"Invalided Soldiers."—In reply to Mr. Needham, the Financial Secretary said that the War Office had not lost sight of the question of finding temporary work for soldiers without discharge from the Army.

"Picric Acid and Nitrous Fumes."—In reply to Mr. W. Thorne, on December 8th, the Under Secretary of State for the Home Department said that eczematous ulceration of the skin and poisoning by nitrous fumes were both scheduled under the Workmen's Compensation Act.

"Medical Service of the Army."—Mr. Pringle, on December 14th, asked what was the proportion of regular officers of the Royal Army Medical Corps to officers formerly in civilian practice who have enlisted since the beginning of the war. Mr. Tennant said: The strength of regular officers is 1,034, and that of temporary officers 5,894. This is exclusive of the Special Reserve and Territorial Force.

"Sterilized Tuberculous Meat."—On December 9th Mr. Field asked a question as to the sale at low prices in Continental countries of slightly tuberculous meat which had been sterilized, and whether, in view of the existing conditions in this country, the advisability of avoiding wasteful destruction of food would be considered and this economical method, practised with safety in other places, adopted. The President of the Local Government Board said he was aware of the Continental practice, but did not consider its adoption in this country at the present time expedient.

THE WAR.

A MILITARY MEDICAL SOCIETY.

At one of the British hospital areas in France the class of cases treated is very varied and much of the practice is of a nature in which the experience of peace gives little guidance. Beyond the confines of his own mess the medical officer had comparatively little opportunity of meeting his fellows, of discussing with them matters pertaining to his work, or of interchanging the fruits of experience. It was felt that a pooling of the knowledge gained by individuals in the area would be helpful to all. So a few enthusiastic spirits gathered together, and, under the trees by the banks of a river where Napoleon sat to plan his invasion of England, they evolved a District Medical Society. Each hospital nominated a representative to be responsible for its contributions, and these members in turn elected the office-bearers as follows:

President: Colonel H. Carr, C.B., A.D.M.S.
Vice-Presidents: Lieutenant-Colonel K. Cameron (Canadian General Hospital), Major T. J. Horder, Major M. Dunlop.
Honorary Secretary: Captain Archibald Leitch.
Executive Committee: Dr. Francis E. Fraser, Captain H. Pritchard, Captain F. L. A. Greaves.

The difficulty of a meeting place was solved by the kindness of Sir James Clark, commanding the splendidly equipped hospital of the St. John Ambulance Brigade, who placed the recreation hall at the disposal of the new society. The meetings have been very well attended, far beyond the hopes of the founders. For half an hour before the business proper of the meeting starts the members meet socially over a cup of tea and make new acquaintances or revive old friendships. The consequence has been the welding of the hospitals into one unit and the production of a very lively *esprit de corps*, for which the medical officers have to thank the organizing power and good fellowship of the A.D.M.S.

The first meeting of the society was held on September 1st. Colonel H. Carr, C.B., the A.D.M.S. of the district and the president of the society, being in the chair. Over 150 medical officers attended, and the following were among the papers read and discussed.

Partial Section of the Spinal Cord.

Lieutenant C. H. Treadgold exhibited a *post-mortem* specimen of partial section of the spinal cord produced by a rifle bullet which entered the left side of the neck and after a zigzag course embedded itself in the liver, fracturing parts of the first and second dorsal vertebrae in its course. The cord and membranes were completely divided save for a thin strand of dura and subjacent nervous tissue posteriorly. Superficial sensation had been lost up to the level of the clavicles, but deep sensation was at no time impaired. There was no loss of sensation in the arms and no hyperaesthesia.

Optic Neuritis in Gunshot Wounds of the Skull.

Captain M. W. P. Oliver said that during the previous eleven months he had examined the eyes of 68 patients who had had gunshot wounds of the head. In every one of these cases there was a fracture of the skull, which was shown either by x rays or by subsequent operation. In all the cases there was a fracture of the vault and in a few the base was also involved. Of the 68 cases, 31 had optic neuritis. In the remaining 37 the discs were normal. These cases of optic neuritis might be divided into two very distinct classes:

(1) By far the larger, in which there is merely fullness of the veins, blurring of the disc with very little swelling.

(2) In which there is marked swelling of the disc, associated sometimes, though he thought not very commonly, with retinal haemorrhages. The appearance of the disc in these cases is very similar to the condition found in brain tumours,

Of these 31 cases, 6 were of the second class, with swelling varying from 4 D. to 6 D. In the first class there were 25 cases with not more than 2 dioptres of swelling. Of the 6 cases with marked optic neuritis, all showed some signs of cerebral compression. Two of these, when

operated on, were found to have a cerebral abscess; both of these died. Two had very extensive laceration and destruction of the brain; both of these died. Two were still alive in hospital; one of these, a German prisoner, was found to have a cerebral abscess; the other had very extensive laceration of the brain, but no abscess. In the 25 slight cases the optic neuritis disappeared entirely after any form of local treatment, whether an extensive decompression was performed or merely a local clearing up of the wound. He had even seen it disappear without any form of treatment. In 4 of 6 severe cases that died he was unable to notice any diminution after the operation, as the interval between operation and death was too short. In the slight cases the vision was never affected; in the severe cases it might or might not; consequently, unless a routine examination of the eye was made in these cases, the optic neuritis might very easily be overlooked. The cause of the optic neuritis was undoubtedly increased intracranial pressure, the cause of which was not definitely known. It was probably due to oedema of the brain caused by trauma. He did not think it was septic in origin, as he had frequently seen it in cases in which the dura had not been opened, and in one case found it in a fracture involving the inner table of the skull only, which obviously put out of court any sepsis. The importance of optic neuritis might, in his opinion, thus be stated:

The fact that of the 68 cases examined the disc was found to be normal in 37, showing that in these cases there was no increased intracranial pressure.

In 25 of the cases there was only slight optic neuritis—therefore, presumably, only slight intracranial pressure, and this disappeared entirely under either no treatment or purely local treatment, without any extensive decompression.

Thus, in only 6 of the 68 cases was there any great rise of intracranial pressure.

These facts were of importance in deciding the best method of treating these cases, but this subject hardly came within the scope of the eye specialist.

Dr. Greenwood, in commenting on this paper, emphasized the importance of a routine examination of the eyes of every case of head injury. He would add a third class to those mentioned by the speaker, namely, true optic neuritis following meningitis. There were several cases, he thought, of increased intracranial pressure without increase of blood pressure.

The Gas Bacillus in a Brain Injury.

Dr. Hixon gave the particulars of a case of shrapnel wound of the brain. A *post-mortem* examination was performed within an hour after death, and cultures were made at once from pockets of pus in the brain tissue. The *B. aerogenes capsulatus* was isolated in pure culture from these. He asked whether any officers of longer experience had ever found meningitis due to the gas bacillus.

Lieutenant Morrison pointed out that it was easy to find the *B. aerogenes capsulatus* in the blood *post mortem*; therefore the times given by Dr. Hixon were important. This organism was very often present in wounds, but he doubted whether it was a pathogenic organism to be reckoned with. Probably it did not play an active part in the case reported. It was sometimes found alone in rapidly spreading gangrene without pus formation, but it was unusual to get it in head injuries. It occurred generally in wounds of the lower limbs and hands, seldom in the trunk.

Another speaker maintained that the causal agent of very rapid oedema was not the *B. aerogenes capsulatus*, but another quite distinct anaerobe the characters of which he had not fully worked out, as it easily died in culture.

Lieutenant-Colonel Gordon Watson said that the *B. aerogenes capsulatus* ought to have no terrors for the surgeon, as it was not of itself a pathogenic organism. In cases of gas gangrene he had always found a mixed infection. Quick opening and good drainage of these cases was the most hopeful treatment.

Medical Aspects of Gunshot Wounds of the Chest.

Lieutenant-Colonel N. Raw read a paper on the medical aspects of gunshot wounds of the chest. He had had to

deal with 24 cases of perforating wounds of the thorax, in all of which pneumothorax existed. After the initial severe shock of wounding the condition was comparatively favourable. Pain was usually slight, whereas dyspnoea on exertion was very common, and was due to effused blood that required removal. In some cases rise of temperature of remittent type appeared eight to ten days after the injury, but this was not due to sepsis. He considered that the blood came from the intercostal vessels and not from the lung tissue. The effusion was pure blood at first, but was afterwards followed by serous effusion from the injured pleura. In all cases the effusion was sterile. He had not observed any permanent collapse of the lung after removal of the fluid. He advocated aspiration of the fluid at one sitting as far as safety allowed. He had not introduced gas into the pleural cavity.

Captain Branson was of opinion that these cases did extremely well without tapping. In his experience of some 50 cases there was only one in which the amount of effused fluid was sufficiently large to make it worth while to aspirate. He was much against early aspiration, because the effusion might recur if interfered with; left alone it was usually rapidly absorbed, and even if it were not, the lung would not fail to expand if the fluid were sterile.

Lieutenant-Colonel Gordon Watson was averse to tapping, as it subsequently increased the hæmorrhage. Major Horler doubted if these were true cases of pneumothorax. He thought that usually there was a pure serous effusion due to wounding of the pleura, and was against routine tapping.

Colonel Carr said that these cases should not be evacuated to England within a month at least of their admission into the military hospitals.

At the second meeting of the society, held on September 17th, the President, Colonel H. Carr, C.B., was in the chair, and over 150 medical officers were again present.

Localization of Foreign Bodies.

Captain A. H. Pirie read a paper on localization of foreign bodies in special regions, especially in the upper parts of the limbs, the eye, and the pleural and pericardial sacs. He pointed out the importance of placing the patient in the same position in the operating theatre as he was in the x-ray room, in order that the measurements taken in the latter might be useful. He advocated the Mackenzie Davidson method of localization. In some cases in which there would be a difficulty in keeping to the same position in the operating-room he was accustomed to pass a needle through the tissues till it touched the foreign body, observing the while under the fluoroscope; this needle was left *in situ* as a guide to the surgeon. He used the Snook apparatus for the localization of foreign bodies in the eye, and found that he could localize to within 1 millimetre. When the foreign body lay in a cavity such as the pleural or pericardial sac or in an abscess considerable changes in its position might take place in quite a short time.

Major Maynard Smith thought that the usually adopted methods of localization were wrong, because of the changing position of the foreign body in some cases and the altering relations due to changes of position of the part of the body under consideration. He had therefore made it his practice to operate in the x-ray room, viewing the foreign body and the surgical instruments used from time to time in the fluorescent screen enclosed in a sterile aluminium box.

Sir George Makins considered that the methods advocated by the speaker were extremely useful in the majority of cases, but that the x rays were of very little utility when the foreign bodies were in the abdomen.

Malaria Contracted in the Trenches.

Captain H. MacCormac related the case of a private in a Highland regiment who had lived all his life in Aberdeenshire until September 26th, 1914, when he joined the army. He came to France in May, 1915, having been stationed at Bedford in the interval. The first attack of fever occurred in July after he had been two months in the trenches, where his battalion had relieved Indians; further, they had occupied billets previously inhabited by Indian troops. He had been severely bitten about the legs by flies. The first attack, diagnosed as trench fever, quickly subsided,

quinine being given, but a second occurred about three weeks after the first. On August 23rd he was admitted to a general hospital under Mr. Yellowcotes. A typical attack of tertian ague commenced on August 31st. Mr. Lyn Dimond examined the blood films and reported the presence of tertian benign parasites in the early stage of schizogony; ring forms of trophozoites were also noted. Captain MacCormac considered that it was justifiable to assume that the disease was contracted in the trenches or in billets, the parasite being conveyed by a mosquito.

Lieutenant-Colonel Finley said that he had had a similar case under his care, the patient being an Irishman. He knew of some seven or eight cases of malaria contracted at the front. The *Anopheles* had been found.

Amputations for Emphysematous Gangrene.

Captain H. Burrows raised the question of methods of treatment of cases of emphysematous gangrene requiring amputation. He had not yet found the necessity of having recourse to flapless operations. The process of healing after flapless operations was slow, the protrusion of bone sometimes beyond the soft tissues prevented healing, and subsequent operations had to be done to obtain a useful stump at a higher level. He thought this subsequent operation could be obviated if flaps were taken through apparently healthy tissues, holes cut in them, and the flaps left ununited to secure drainage. After the septic process had subsided he secured the flaps together, and in all his cases, some half-dozen, there was a good result, and no subsequent severe operation was required.

Lieutenant-Colonel Gordon Watson, as the surgeon who was instrumental in starting the procedure in question, disowned the name "flapless operation." It was not a set operation; he preferred to call it a means of saving the patient's life. He recalled the conditions under which patients arrived from the front at a hospital in the earlier days of the war, borne from sodden soiled trenches for perhaps many days in improvised ambulances. The only treatment was then to lop off the damaged tissues without regard to immediate pretty results. They had first to save the man's life, and afterwards consider the cosmetic result. He had avoided exposing the medulla of the bones to the streptococcal and anaerobic organisms in the fleshy part, for absorption by the medulla was fatal. He therefore often left the end of the bone protruding several inches beyond the level of the sound tissues. He had given open-air treatment to such wounds. The shock was minimized in these so-called flapless operations by the intravenous injection of ether to produce the necessary surgical anaesthesia. He was not ashamed of the results of these measures, though the changing conditions of trench life and the improved methods of conveyance of wounded had, he was glad to say, obviated much of the necessity for flapless amputations.

Sir George Makins agreed with the last speaker absolutely. The class of cases had now changed. He was afraid that the necessity of very free drainage was not sufficiently appreciated, and he did not think that flaps with holes could have saved the situation in the earlier days. Short flaps gave no better results than no flaps at all.

GERMAN EXPERIENCES OF TETANUS.

DR. B. O. PEBERAM,¹ in discussing the German experiences of tetanus since the outbreak of the war, states that in the military hospitals of the 15th Army Corps 27,577 wounded were treated between August 1st and October 31st, 1914, and the 1,744 cases of tetanus observed in this period represented an incidence of 0.66 per cent. After a comprehensive survey of the subject and a detailed account of many illustrative cases, the author came to the following conclusions:

Prognosis.

Owing to the apparently capricious nature of the disease it was impossible to estimate the value of different methods of treatment by the mortality statistics, unless careful notes were made on every case. The site of the muscular spasms was a valuable guide to prognosis, which, in the absence of pulmonary and cardiac complications, was relatively good in cases of trismus, opisthotonos, and spasms of the peripheral muscles. The prognosis was

¹ *Berl. Klin. Woch.*, August 16th, 23rd, and 30th.

bad when the diaphragm and larynx were affected, even though every other muscle might have escaped. Unfortunately, no method hitherto employed could check the spasms in these two groups of muscles. A sure and early symptom of incipient diaphragmatic spasm was epigastric pain traceable to increased tone of the muscles of the diaphragm. The old observation that the shortness of the incubation period was directly proportional to the virulence of the infection was not altogether to be trusted. The true incubation period must be reckoned from the time that the infecting organisms produced toxins; but this did not necessarily synchronize with the introduction of the organisms into the tissues.

Differential Diagnosis and Causes of Death.

The localization of the muscular contractions was independent of the site of the wound and of the intensity of the infection. However well developed the facies tetanica might be, increased mechanical irritability of the facial nerve was never demonstrable. The absence of this sign, of a strained position of the hand, and of isolated, adductor spasms were of use in distinguishing tetanus from tetany, two cases of which occurred among the many cases of tetanus. The most frequent complication was lobular pneumonia, which was also the most frequent cause of death after suffocation in diaphragmatic and laryngeal tetanus. Pirbright therefore suggested that greater attention should be paid to the treatment of the lungs.

Status Lymphaticus among the Subjects of Tetanus.

Among the patients dying of diaphragmatic tetanus, it was usual to find subpleural hæmorrhages. Hæmorrhages into the heart, liver, kidneys and diaphragm, and congestion of the liver and kidneys were also often found in these cases. The abdominal organs of patients who had not died of diaphragmatic tetanus contained the usual quantity of blood or less. Obvious signs of status lymphaticus were observed in many of the patients, and in practically every patient dying of tetanus. This condition, therefore, probably played a part in predisposing to infection and also in aggravating the course of the disease. In one case a septic embolus induced a relapse of the tetanus.

Treatment.

The best treatment consisted of the radical excision of all necrotic tissues and of the neighbouring freely bleeding tissues. Antiseptics and the cautery were less satisfactory. The decision for or against amputation should depend rather on anatomical than on bacteriological indications. In fact, the nature of the infection was not by itself any indication for amputation. In some cases the patient recovered in spite of severe phlegmon, while death resulted in others in which the wound was slight. In some cases fatal tetanus did not develop till an amputation had been performed. The view that the development of tetanus depended on the severity of the wound was incorrect; and in one of the author's cases the only demonstrable lesions were excoriations between the toes due to perspiration. To confine prophylactic injections of antitetanic serum to cases of shell wounds was, therefore, indefensible. With regard to general anaesthesia, only pure chloroform should be used, as ether was apt to cause pneumonia and laryngeal spasm. Antitetanic serum was often strikingly beneficial, provided large doses were given. Pirbright gave 200 to 300 units every day, and advocated also an additional intradural injection of 400 to 500 units on the first day of the disease, the patient's trunk being in a dependent position during the injection. The spasms of the peripheral muscles could be successfully relieved by the administration of chloral hydrate (up to 10 grams a day) by the subcutaneous injection of magnesium sulphate (20 c.cm. of a 25 per cent. solution five to six times a day)—and by the hypodermic injection of a 20 per cent. solution of luminal sodium. (The sodium salt of phenyl-ethyl-barbituric acid, a modification of veronal.) The combined use of these drugs, he says, was most satisfactory, but all failed when the diaphragm and larynx were affected. The usual doses of morphine were of little value; but given in large doses—up to 0.3 gram a day—they were useful. Failure of respiration, due to the large quantities of morphine given, was not to be feared, provided everything was in readiness for artificial respiration. Artificial respiration with oxygen also proved very effective.

CASUALTIES IN THE MEDICAL SERVICES.

Killed in Action.

LIEUTENANT JAMES RYTON GARDNER GABBETT, R.A.M.C., was reported as killed in Flanders in the casualty list published on December 9th. He was educated at Aberdeen University, where he graduated M.B. and Ch.B. in 1911; afterwards he filled the post of house-surgeon at the General Infirmary, Macclesfield. He took a commission as temporary Lieutenant in the R.A.M.C. on December 7th, 1914, and was attached to the 8th Battalion of the King's Own Scottish Borderers when killed.

Wounded.

Captain J. W. Wood, R.A.M.C. (temporary), France.
Captain J. V. L. Grant, R.A.M.C. (Special Reserve), France.
Captain H. W. White, R.A.M.C. (temporary), France.
Lieutenant L. J. Legris, R.A.M.C. (temporary), France.
Lieutenant E. G. D. Milson, R.A.M.C. (temporary), Mediterranean.
Lieutenant H. Scott, R.A.M.C. (temporary), France.

DEATHS AMONG SONS OF MEDICAL MEN.

Christison, Frederick John, Lieutenant 10th Battalion Argyll and Sutherland Highlanders, younger son of Surgeon-General Sir Alexander Christison, Bt., 1.M.S. (retired), of 40, Moray Place, Edinburgh, killed in Flanders on December 2nd, aged 21. He was educated at Edinburgh Academy, where he was in the eleven and was captain of the Rugby fifteen in 1912-13, and at University College, Oxford, where he was studying forestry with a view to entering the Indian Forest Service. An accident at Oxford cut short his football career and deprived him of the opportunity of gaining a Blue at Rugby football. He got a commission as Second Lieutenant in August, 1914, when the war broke out, was promoted to Lieutenant in February, 1915, passed through the battle of Loos unhurt, and was acting as adjutant of his battalion when killed.
Dunn, George, Private, the Buffs, East Kent Regiment, son of the late Dr. Dunn of Wolverhampton, died of wounds in No. 3 General Hospital, Le Treport, on December 6th.

NOTES.

Honours.

THE *London Gazette* of December 10th announces that the Territorial Decoration has been conferred upon a number of officers of the Territorial Force, including the following medical officers:

Lieutenant-Colonel W. P. Peake, North Midland Casualty Clearing Station.
Lieutenant-Colonel F. H. Westmacott, F.R.C.S., 2nd Western General Hospital.
Major D. J. Penney, M.B., 4th Highland (Mountain) Brigade, R.G.A.
Major J. Taylor, M.D., attached 6th Gordon Highlanders.
Major J. Robinson, attached 3rd London Regiment.
Major J. A. Clark, M.B., attached 6th Scottish Provisional Battalion.

F.M.S. HOSPITAL.

A hospital for sick and wounded soldiers has been established at Blackmore End, Kimpton, Here's, generously lent for the purpose by the owner, Mrs. Vincent, of Blackmore End, and 35, Portman Square. The funds to cover the cost of the equipment and maintenance of the hospital (to be known as the F.M.S. Hospital) have been provided by the public of the Federated Malay States, all classes of the community—Malay, Chinese, and Indian, as well as European, having contributed liberally. The hospital contains eighty beds, and is under the charge of Captain G. D. Freer, R.A.M.C.(T.), formerly Senior Medical Officer, Selangor, F.M.S. Mr. C. S. Atkin, M.R.C.S., L.R.C.P. Lond., is resident medical officer, and Miss E. M. Willis, of the Royal Free Hospital, Gray's Inn Road, E.C., is matron. The first forty-eight patients arrived at the hospital from France on December 3rd.

MEDICAL OFFICERS WANTED.

Wessex Field Ambulance.

Medical officers wanted. Apply to A.D.M.S., Wessex Division, Exeter.

21st East Lancashire Field Ambulance.

Vacancies for medical officers to replace men who have gone to the front with drafts. Apply Officer Commanding, 21st East Lancashire Field Ambulance, Linden Gardens, Tunbridge Wells.

The Welsh General Hospital.

The personnel of this hospital is to be found for the War Office by Walca. Besides the ordinary medical officers, there will be

officers in charge of medical and surgical divisions who must be consultants in their branches, a registrar, ophthalmologist, ear and throat specialist, pathologist, and radiographer. A dental surgeon with a medical qualification would be accepted. The hospital is for overseas service, and will be commanded by Lieutenant-Colonel A. W. Shoen, R.A.M.C. (T.F.). Particulars and forms of application for posts can be obtained from the Honorary Secretaries, Welsh Hospitals, 47, Principality Buildings, Cardiff.

Ireland.

MEASLES NOTIFICATION IN DUBLIN.

SIR CHARLES CAMERON, M.O.H. for Dublin, has written a letter to the corporation, pointing out that measles is prevalent in parts of South Dublin, and stating that his attention has been drawn to the recent order of the English Local Government Board. Sir Charles does not say whether it has been recommended that the English example should be followed, nor does he himself express any view. It is within the power of the corporation to make notification compulsory. For some years measles was one of the notifiable diseases, but in 1904 it ceased to be so, and about a year and a half ago the Public Health Committee was asked to report on the advisability of renewing the order. The answer was that notification had been given up because the results were not satisfactory and the expense considerable. The matter has again been referred to the committee. At the last meeting of the Public Health Committee Sir Charles Cameron reported that twenty deaths due to measles had been registered during the fortnight as against six in the previous two weeks. The great majority occurred on the south side of Dublin, but the disease was spreading rapidly, and would, he had no doubt, penetrate to all parts of the city. He had recommended the closing of infant schools on the south side, and he now considered it advisable to recommend the closing of all the schools in the city until after Christmas. The committee approved of the suggestion.

ALCOHOLIC POISONING IN A CHILD.

A case of fatal alcoholic poisoning occurred last week at Tullyallen, some five miles from Drogheda. A number of schoolboys, when passing through Tullyallen graveyard, discovered a bottle of whisky, which they shared among themselves. One boy, aged ten, took such an overdose of the whisky that he died next day, comatose death being attributed to acute alcoholic poisoning.

DUBLIN CASTLE RED CROSS HOSPITAL.

At the last meeting of the Committee of the Dublin Castle Red Cross Hospital it was reported that owing to the large increase in the price of all foodstuffs, the daily cost for each patient was 5s. 4d. during November, as against the 3s. allowed by the War Office. There are at present 91 patients in the hospital, and 1,052 have been received since the opening of the institution in the early spring.

Scotland.

REQUESTS TO DUNDEE INSTITUTIONS.

LORD ARMISTEAD, who represented Dundee in Parliament for ten years, bequeathed £10,000 to the Dundee Royal Infirmary, £5,000 to University College, Dundee, £1,000 each to the Sidlaw Sanatorium and the Dundee Convalescent Home, and £500 to the Dundee Sick Poor Nursing Society, in addition to other charitable bequests. The residue of the estate, which will probably amount to over £40,000, will ultimately become available for various institutions and charities in Dundee.

FOG DEATHS.

Dr. A. K. Chalmers (M.O.H. Glasgow) reported to the Health Committee, on December 8th, that during the week ending November 20th the mean air temperature was 28.5 degrees, and there was almost continuous fog from the Monday onwards. The effect on the death-rate was shown rapidly and proved to be cumulative. It rose to 20.5 in that week, and in the following week to 26.2, although before November 27th the frost had relaxed and the mean temperature had risen to 33.8. The age distribution of the deaths, and the cause of an appreciable

portion of them, repeated the experience of former years when similar climatic conditions prevailed. For the three weeks ending November 27th the deaths under one year numbered respectively 76, 82, and 74, and over sixty years 93, 114, and 195; while the total number of deaths at all ages rose from 335 to 389, and then to 509. There was an appreciable increase in deaths from phthisis and pneumonia, while deaths from bronchitis and other diseases of the lungs rose from 39 in the week ending November 13th to 51 in the following week, and 132 in the week ending November 27th. The local distribution of the deaths repeated the experience that such climatic variations told with greatest intensity on the sections of the population whose resistance to fatal disease was at all times low. They were highest in those wards where the annual death-rates from all causes were highest.

MILK SUPPLY OF EDINBURGH.

Deputations from the Public Health Committee of Edinburgh and the Edinburgh and Lothian Dairymen's Association have had an interview with the Board of Agriculture for Scotland and representatives of the Local Government Board with reference to the milk supply. The spokesman of the Public Health Committee said that there had been a large decrease in the number of dairy cows in Edinburgh and its immediate neighbourhood, with an estimated diminution of 1,750 gallons a day in the supply of milk. The president of the Dairymen's Association said that the main cause of the diminution in the number of cows kept was the difficulty of obtaining workers. He suggested that steps should be taken to replace the remaining men on the reserved list. The possibility of employing women and children had been fully considered, but they could only replace men to a limited extent. Sir Robert Wright, chairman of the Board of Agriculture, said, in reply, that several of the classes of agricultural workers in the list of reserved occupations might be regarded as including dairymen employed in Edinburgh, and that if such men enlisted under the group system application should be made to the recruiting tribunal for exemption or postponement to a later group. He suggested that female workers might be obtained from the Highlands and Islands, and that more use might be made of milking machines. He concluded by stating that the Board of Agriculture would be glad to take any steps within its power to assist the dairy industry to maintain the supply of milk.

Wales.

ROYAL COMMISSION ON THE WELSH UNIVERSITY AND NATIONAL MEDICAL SCHOOL.

At the sixth meeting of the Welsh University Education Conference it was reported that the University of Wales and its constituent colleges had accepted the proposal for the immediate appointment of a Royal Commission on the terms proposed by the Treasury, and had agreed to do all in their power to assist the Commission in its inquiries. It was reported also that the board of management of King Edward VII Hospital, Cardiff, had agreed to the conditions laid down, and had expressed its readiness to accept the decision which the Government might base on the findings of the proposed Royal Commission, but, in view of the present necessity for proceeding forthwith with the matter of the National Medical School, had expressed the hope that it would be possible to expedite the proceedings of the Commission. The conference adopted resolutions urging upon the Treasury the desirability of forthwith granting permission for the buildings of the medical school to be proceeded with to completion without prejudice to any decision which might be arrived at as to the scheme for the constitution of the Welsh National Medical School at Cardiff, whether as the result of the report of the Royal Commission or otherwise. An undertaking was given that building operations would be so conducted as not to afford employment to men who might otherwise be employed in rendering war service to the State. It was also resolved to represent to the Treasury that the noble benefaction of Sir William James Thomas for the completion of the buildings of the National Medical School was dependent upon the donor's life and his goodwill, and that he was not willing to agree to any delay. The conference appointed a consultative

committee to consider matters arising in connexion with the Royal Commission. The committee consists of representatives of the colleges, of the University of Wales, and of King Edward VII Hospital, Cardiff, those of the last institution being Colonel E. M. Bruce Vaughan (Chairman of the Board of Management), and Dr. Herbert Vachell (consulting physician).

Correspondence.

THE SOLDIER'S HEART.

SIR, It has interested me to find that the effect produced in the soldier's heart by active service resembles that seen in the heart of the young man of about the same age engaged in hard muscular exercise much more closely than might have been expected in view of the fact that the conditions of life of the two classes differ in many other points.

The chief resemblance appears to me to lie in their plain divisibility into two classes. In one class the effect is that due to overwork in a hitherto healthy muscle. In the other the effect is seen in men who give a history of, for example, influenza, typhoid, "cold" accompanied by severe diarrhoea, trench fever, tonsillitis, septic wounds, and so on.

This second class is, I believe, by far the larger of the two, and is responsible for much of the wastage of men in the army due to "heart disease." The men of this class should be separated from those in the first class and treated as convalescents from the disease which caused the weakness of the heart. In a large number of cases this separation can be made easily when a careful history has been obtained.

It seems to me to be a mistake to tell these men that they have anything wrong with the heart, because they do not believe that a heart disorder can possibly be temporary, and they almost always cease to be of any use as soldiers.—I am, etc.,

ROBERT MICHELL,
British Expeditionary Force, France.

December 8th.

THE TOXIC BODIES OF THE BACILLUS OF MALIGNANT OEDEMA.

SIR,—Drs. Barger and Dale have shown in their article in the *BRITISH MEDICAL JOURNAL* (December 4th, p. 808) that the toxic effects which followed injection of guinea-pigs with cultures of the bacillus of malignant oedema were due to the absorption of certain end products of protein metabolism, in particular of ammonium salts of fatty acids, these bodies being produced by the action of the bacterial ferments, or enzymes, on the artificial substrate. This form of protein destruction is apparently similar to that resulting from the action of trypsin, which, in an alkaline medium, carries the destruction of the protein molecule to a very advanced stage, producing the aromatic bodies, amino-acids, and ammonia; peptic fermentation, on the other hand, takes place in an acid medium, and does not get to the length of producing these simple end bodies. I do not know if Drs. Barger and Dale believe that these ammonium salts of fatty acids are produced *in vivo* during natural infection by the bacillus of malignant oedema. Assuming, however, that these toxic bodies are produced in the natural substrate provided by the infected tissues, I should like to offer the suggestion that it might be possible, by modifying the tissue substrate, to alter the form or degree, and thus the results of the process of fermentation.

Among the aromatic bodies resulting from the action of ferments on protein, the production of indol by bacteria has been closely studied, principally in peptone-water cultures, and it has been found that the presence in the culture medium of glucose, glycerine, and other substances prevents its formation. These latter bodies, in most cases at any rate, are fermented by other bacterial ferments, and the proteolytic ferments have then to act in an acid medium. Whether it is this acidity that modifies the action of the proteolytic ferment I do not know, but certainly its action is modified, with the result that cultures which in the ordinary way are very foul, when grown in a solution containing sugar remain quite sweet. Doubtless the ferments of some bacteria would be much more vigorous and less readily held in check than in the case of

others. In applying this principle to the treatment of cases of bromidrosis I was able to show that the foul smell from the decomposition of sweat might be entirely prevented, and the condition completely cured, by the external application of glycerine.¹ It seems that it would be worth while trying to see whether gangrenous infections could not be treated on similar lines.

It would first have to be established experimentally that the presence of a fermentable sugar—for preference glucose or possibly inositol—could modify the action of the ferments of the bacillus of malignant oedema; it would further have to be shown that these modified products of protein digestion, to say nothing of the alternative substance introduced, are less poisonous than are the unmodified products of fermentation. It would then be the work of the surgeon to apply the alternative material to the substrate in the infected area, either locally through incisions, or by infiltration of the tissues coupled with very free drainage. I attempted last winter to carry out an experiment with the organism under discussion, to ascertain whether the prevention of indol formation, by the presence of glucose and other sugars in the culture medium, was consistent with diminished pathogenicity of the culture; but owing to the fact that my strain of the organism proved to be both non-indol forming, and in broth culture non-pathogenic to guinea-pigs, no results were obtained. I noted that on mannite the foul smell of the culture was much less pronounced, and of a different character from that of the peptone-water culture. On the other sugars there was very little alteration to be observed so far as smell was concerned; one per cent. sugars in peptone water were used. Owing to other work the experiment was not followed up.—I am, etc.,

T. H. C. BENIANS, F.R.C.S.,

Pathological Department, Prince of Wales's Hospital,
Tottenham, N., December 14th.

BROMIDES IN EPILEPSY.

SIR,—The difference of opinion upon the action of the bromides in the treatment of epilepsy, revealed in the interesting correspondence appearing in the *JOURNAL*, shows how great is the difficulty in arriving at the real value of those remedies in this disorder.

Some years ago I collected facts bearing upon this subject from the out-patient records of the Queen Square Hospital, where epileptics attend for treatment over many years. The inquiry brought out the fact that in about 25 per cent. of all cases the continuous administration of the bromide salts led to an arrest or great amelioration of the fits within a short period of commencing treatment. These cases were mainly of a mild type, characterized by an absence of mental symptoms and with fits recurring at long intervals. In a second 25 per cent. the bromides induced a lessening in the severity or in the frequency of the fits. In the remaining 50 per cent. the bromides exerted no influence upon the seizures. These last were cases of a severe or confirmed type, with fits usually of the combined major and minor variety associated with some degree of mental enfeeblement. It is obvious from this that a large percentage of epileptics derive no benefit from the bromides, and this is the experience of those through whose hands large numbers of epileptics pass.

As Dr. Mercier points out, diminution in the frequency of the fits is not the only thing to be considered. There are cases of epilepsy which are doomed to incurability whether treated or not. They are recognized by the co-existence of epileptic attacks and the severer grades of mental enfeeblement.

A further point of practical interest shown by the statistical inquiry was that arrest of the fits following the use of the bromides took place within the first year or two of continuous treatment. I have found in practice that this fact is a good guide to estimate the value of bromide treatment or to form a prognosis upon the likelihood of cure.—I am, etc.,

London, W., Dec. 13th.

W. ALDREN TURNER.

SIR,—Fifteen years' close contact with some twenty epileptics at the Exeter Poor Law Institution has diminished my faith in the specificity of the bromides or even in their general utility. They do not cure epilepsy; they diminish the number of fits, but I have reason to suspect they increase their individual severity.

We have no settled pathology in respect of epilepsy. My own view, based on careful records of the exact moment of the occurrence of the fit and its relation to the prevailing atmospheric pressure, is that changes in barometric pressure cause changes in the blood pressure which suffice in people of unstable nervous organization to precipitate a convulsion. Fits almost invariably coincide with a falling barometer. Epileptic fits cease in pyrexial conditions; epileptics with an average of three or four fits a day will go through an attack of influenza or pneumonia without a single fit. It seems that as long as the arterial tone is relaxed by the pyrexia no fits can occur.

There are atmospheric conditions which bring about groups of diseases, the salient feature of which is free hæmorrhage. When one encounters cases of cerebral hæmorrhage, epistaxis, hæmoptysis, bleeding from hæmorrhoidal veins, and even hæmatemesis, occurring in abnormal numbers within the same period of marked atmospheric disturbance, one must look outside the individual and his personal errors, dietetic or hygienic, for a cause. It is a common experience at the Poor Law Institution to have two or three weeks free of fits and then to have two or three patients struck down together. On the hypothesis that it is hypertonicity of the cerebral blood vessels that causes the fit, I have exhibited vaso-dilators as a prophylactic, giving a mixture of sodium nitrite with the potassium nitrate and bicarbonate. This combination reduces the number of the fits and preserves the mentality of the patient. Unfortunately the human is sometimes more sensitive than the mercurial barometer, and the patient drops first. This mixture has incidentally another advantage. It does away entirely with the bromide rash. My experience with arsenic has been very disappointing.—I am, etc.,

Exeter, Dec. 7th.

J. A. W. PEREIRA.

THE MEMBERS OF THE ROYAL COLLEGE OF SURGEONS.

Sir,—The astonishing explanation vouchsafed by Sir Watson (Cheyne at the annual meeting of Fellows and Members to Dr. Jones and others when asking the views of his Council respecting the representation of Members in the Council of the College, can only be in keeping with all those Conservative and time-honoured bodies which eventually bring about their own undoing by the avowed belief in their own perfection.

The only question, says Sir Watson, in which they were concerned "was that of the interest of the College"—truly a bald statement. He must have only the Fellows in his mind, for as far as the Members are concerned, if I may judge from experience, they are nonentities in every sense of the word. Excepting as being fully licensed to practise, which I admit is a great concession, there is no function or work in connexion with the College in which a Member may take part or voice his views. Sir Watson infers that the Members do not bear in mind any improvement in their educational and scientific position. Perfectly absurd, I say, for Members of the College up and down the country at home and abroad, are found on boards of education, scientific institutions, sanitary authorities, county councils, magisterial benches, working out the salvation of the State. I go further and say that the extraordinary and highly trained technical skill and knowledge of the Fellows, magistrates as they are, in no way render them more skilful in managing our College of Surgeons than the rank and file of Members and general practitioners. "It would be a mistake," Sir Watson says, "to convert the College from a scientific and academic institution into a political one." By this any one would think that the Members had no notion of science or art, or were not even trained medical men.

This is no time for internecine quarrels; our very existence depends upon whether the Kaiser's military despotism shall prevail or not. Still one sees and feels that an injustice has to be righted, and that what seemed good in 1843 has a very different complexion in 1915. Let me ask, Why is it that there is such reluctance on the part of the Fellows to extend the franchise to the whole College? All honour to the late Dr. Joseph Smith, who vainly devoted so much toil to this cause. Lieutenant-Colonel Josiah Oldfield in his letter is courteous and convincing. Unless more weighty arguments than the shelving and ambiguous reasons hitherto proffered against

the franchise for all, one can foresee loss of sympathy and a feeling adverse to the Royal College of Surgeons looming high as a danger in the near future.—I am, etc.,

Jos. W. GILL, M.R.C.S.

Ella-Mill, Cornwall, Dec. 6th.

THE URGENT NEED OF DOCTORS FOR THE ARMY.

Sir,—My colleague and I cover an extensive district with our two practices. My colleague has been forced to take up a commission by the pressure exercised by the Emergency Committee, and I have had to undertake the responsibility of the two practices. Since June we have had charge of the troops stationed here. Now, when my colleague has gone, the military authorities send a whole-time R.A.M.C. man to take over the troops, and so do an infinitesimal part of the work my colleague would have done if he had remained at home.—I am, etc.,

December 11th.

SENEX.

Sir,—I should like to make a few suggestions *re* the present dearth of medical officers in the army. I think that, where a brigade is stationed in a town, or in places adjacent to one another, one R.A.M.C. officer could be put in charge of the brigade, himself taking one battalion, and a civil medical practitioner be appointed (as part-time man) to attend to each of the other battalions under his supervision, instead of having a R.A.M.C. medical officer to each as at present. This I am sure would greatly increase the number of men available for other appointments. If, on the other hand, the brigade was leaving for overseas and required a R.A.M.C. medical officer for each battalion, these could be extracted from the third line, who are draft-finding units, at least in the Territorials.

Again, in the field ambulances the commanding officer of each unit and one junior officer could quite well carry out the work.—I am, etc.,

December 13th.

R.A.M.C.(T.).

Obituary.

GEORGE WALTER STEEVES, B.A., M.R.C.S., M.D.
It is with deep regret that we have to announce the death of Dr. Steeves.

He was born at St. John, New Brunswick, Canada, and was the only surviving son of the Hon. William H. Steeves, Senator and a Father of Confederation. He was educated at the University of New Brunswick, taking there a degree in arts. Coming to England at the age of 21 he married Agnes, the daughter of the late Mr. G. T. Soley of Liverpool, and shortly after commenced to study medicine at St. Thomas's Hospital in the days of Murchison and Bristow. After taking the diplomas of M.R.C.S. Eng. and L.R.C.P. and L.M. Edin. he set up a practice in Liverpool. Dr. Steeves possessed all the qualities requisite for a successful practitioner; not only was he skilled in all branches of his profession, but he possessed a generous disposition, a charming personality, and a love of children, which, combined with his professional ability, won the confidence and affection of his patients. It is not surprising, therefore, that for many years he had a large practice amongst the wealthier classes in Liverpool, and a wide circle of friends. A highly-cultured gentleman with literary tastes and ability, he made many personal friends among the professors at the university. He loved the works of the great masters of English literature and devoted a great deal of his spare time to the acquisition of rare first editions, of which he possessed a fine collection. Especially had he a great regard for Bacon, whose works he had studied and knew well; in 1910 he published a most interesting book entitled, *Francis Bacon: His Life, Works, and Literary Friends*. This work was very favourably reviewed, and its high merit may best be judged by the testimony of Sir Sidney Lee who wrote: "It is undoubtedly the best contribution to Baconian bibliography that has been yet vouchsafed to us." In 1913 Dr. Steeves published a collection of essays entitled *Some Main Issues*. He was the author of several poems, which were greatly appreciated by Canadians, who were justly proud of his attainments.

It must not, however, be thought that Dr. Steeves neglected the work of his profession. He was specially interested in sanitary science, of which he had an extensive practical knowledge and on which he wrote several useful papers, one of which was published in the *Nineteenth Century*. For many years he was M.O.H. for Toxteth, Liverpool; physician to the Urban District Hospital; and U.S.A. sanitary inspector for the Port of Liverpool. He was a vice-president of the Liverpool Medical Institution, and when, some years ago, he left Liverpool to reside in London, the appreciation in which he was held by his professional brethren and many friends was shown by a handsome testimonial. Since the war began his experience in sanitary science and attainments as a physician led to his being given a command in the National Guard of the City of London. Dr. Steeves was, until a few weeks before his death, actively engaged in examining recruits in addition to his practice and other duties. After a week's acute illness it was found necessary to perform an operation.

In his younger days Dr. Steeves was an athlete, and continued to be a fine amateur billiard player and good golfer. In fact, anything he took in hand he did well. He will be greatly missed by all who had the privilege of knowing him, for his gentle, attractive, sympathetic personality endeared him to all.

He leaves a widow, but no family.

COLONEL RODERICK MACRAE, C.I.E., Bengal Medical Service (retired), died in Edinburgh on December 5th, aged 64. He was born on May 25th, 1851, educated at Edinburgh University, where he graduated as M.B. and C.M. in 1873, and entered the I.M.S. as surgeon on March 31st, 1875, becoming surgeon-major on March 31st, 1887, and surgeon-lieutenant-colonel on March 31st, 1895. He was placed on the selected list for promotion from April 1st, 1901, was promoted to full colonel on February 12th, 1905, and retired, on completion of five years' service in the administrative rank, from March 1st, 1910. His first five years of service were spent in military duty, during which he was present in the second Afghan war from 1878 to 1880, was served in actions against the Ghilzais at and near Jazdalak, accompanied Sir Charles Gough's column to Sherpur, and took part in operations in the Kohistan, Logar, and Maidan valleys, receiving the Afghan medal with a clasp. He then entered civil employment in the province of Bengal, and during the next twenty years held many important civil surgeoncies in succession, among them those of Jalpaiguri, Sarun, Champaran, Gaya, and Dacca, at the last being also superintendent of the vernacular medical school in that city. As an administrative medical officer he held the post of inspector-general of civil hospitals in the Central Provinces, in Burma, and in Bengal successively, being the first and last Bengal officer to hold that post in Burma. A good service pension was conferred upon him from December 3rd, 1909, and after his retirement, on June 24th, 1910, he was decorated with the C.I.E. Since his retirement he had resided in Edinburgh. He contributed two articles to the *Indian Medical Gazette* in 1894, the one on cholera and preventive inoculation in Gaya gaol, and the other on flies and cholera diffusion. He was a Fellow of Calcutta University, and administrative medical officer E.B.S. Railway. He is survived by a widow and family.

It is with great regret that we announce the death, at the age of 54, of Dr. BRYANS of Mount Pottinger, Belfast. He had suffered from a serious illness about eighteen months ago, but had recovered and resumed his practice. On the morning of November 21st he was suddenly seized with apoplexy, and died in a few hours. He received his medical education in Dublin and Edinburgh, and, after taking the triple qualification in Scotland, he practised for six years in West Hartlepool. He then settled in Belfast, where he has carried on a large and laborious practice for twenty-four years; he was for many years a member of the board of Poor Law guardians, and for two their chairman. He was a greatly liked and trusted by his patients, and respected by all with whom he came into contact. Much sympathy is felt for his widow and family. His eldest son is in the reserve of the R.A.M.C., and is preparing for the final medical examination; his second son is a Lieutenant in the Royal Irish Fusiliers, 8th Battalion.

VERY deep regret will be felt by a large circle of patients and friends on hearing of the death on December 5th of Dr. JOHN J. ANSTIN of Clifton Street, Belfast. He had been in his usual health when he was attacked by pneumonia, which ended fatally about the fifth day. He was 57 years of age. He had a distinguished career in Queen's College, Belfast, and graduated M.D. in 1882. After practising for a few years in Larne he settled in Belfast, and rapidly gained one of the largest practices. The deep and implicit trust of his patients was well deserved. He was most painstaking, careful, and skilful. His success in obstetrics in private practice was great. He left nothing to chance, and no detail was too small. He carried the same qualities into all his work. Dr. Anstin was of a retiring disposition. He held no public appointment, but was at one time honorary physician to the Johnston Memorial Orphan Training School, an institution in which he took the warmest interest. His wife predeceased him seven years ago. Much sympathy is felt for his three daughters and only son.

The Services.

INDIAN MEDICAL SERVICE.

APPOINTMENTS DURING THE WAR.

It was recently announced in the press that after the open competitive examination held last July for admission to the Indian Medical Service no similar examination would be held during the continuance of the war, but that such appointments as might be required to meet the absolutely indispensable needs of the service would be made by nomination by the Secretary of State. To assist him in making these appointments, which, as already announced, will be limited in number to the absolutely indispensable needs of the service, Mr. Chamberlain has appointed a Selection Committee, who will summon and interview such applicants as may appear to be *prima facie* suitable, and make recommendations for appointment.

Applications for appointment should be addressed to the Secretary of the Military Department, India Office, Whitehall, S.W., and should contain concise particulars of the applicant's medical degrees and career. Applicants must be over 21 and under 32 years of age at the time of application. Particulars regarding pay, promotion, etc., in the service can be obtained from the Secretary, Military Department.

EXCHANGE DESIRED.

LIEUTENANT R. N. MOFFAT, R.A.M.C.(I.F.), attached 14th Queen's Own (Royal West Kent Regiment), Jubbulpore, India, wishes to find substitute (Lieutenant or Captain), so as to enable him to transfer to a unit at home. Details can be obtained from the Secretary (No. 5997), British Medical Association.

Universities and Colleges.

UNIVERSITY OF EDINBURGH.

The following candidates have been approved at the examinations indicated:

FINAL EXAMINATION (Forensic Medicine).—Fakir Chand, E. Chapelle, Bhaskar B. Gadgil, J. A. C. Guy, Balkrishna H. Handoo, N. K. Henderson, J. R. S. Mackay, P. D. M'Laren, M.A., C. P. Kenberthy, J. C. Preston, Satyendra N. Seal, J. M. Smellie, D. G. Stout, Daya R. Thapar, J. M. Watt.
FINAL EXAMINATION (Public Health).—Johannes J. Ackermann, Fakir Chand, E. Chapelle, Demetrius Colomhos, T. F. Corbhill, W. J. Craig, W. H. Ferguson, Bhaskar B. Gadgil, J. A. C. Guy, Balkrishna H. Handoo, C. Harris, N. K. Henderson, Margaret M. McGarrity, Marjorie I. S. McGregor, J. R. S. Mackay, P. D. M'Laren, J. O. Marais, Isabella Morrison, G. A. Paris, C. P. Kenberthy, J. C. Preston, Satyendra N. Seal, J. M. Smellie, D. G. Stout, Daya R. Thapar, J. M. Watt.
FINAL EXAMINATION (M.B., Ch.B.).—W. Brownlie, T. F. Corbhill, H. F. Ferguson, G. W. M. Findlay, Pratul Kumar Ghosh, R. L. Impey, H. B. Kirk, A. J. M'Intosh, Premal Trambakari Majumdar, Kamal Sanjar Ray, A. J. D. Rowan, C. I. Stockley, G. M. Torrance, R. A. Warters, J. A. C. Williams, W. Williams, Tin Po Woo, Margaret Kirk Jolly Wright, P. H. Young.

* With distinction.

UNIVERSITY OF GLASGOW.

UNIVERSITY COURT.

At the meeting on November 23rd the Principal (Sir Donald MacAlister) called attention to the communication issued by the War Office to the effect that students who at or before the close of the present winter session will be qualified for entry to one of the examinations for third-year students in medicine and dentistry at the examination will not be attacked until after its conclusion, and, if they are successful, will be included in the class of fourth-year medical students under Lord Derby's scheme, who are to continue their professional studies with a view to graduation in medicine. The Court determined that in March, 1916, qualified candidates who had completed eight terms of medical study should be admitted to the third

professional examination, the subjects of which might be taken singly or together.

At a meeting of the Court on December 9th the Principal intimated the election of Professor Noel Paton to be an assessor to represent the Senate for the next four years, in place of Professor Muir, of whose services the Principal expressed high appreciation.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.

An ordinary Council was held on December 9th, when Sir W. Watson Cheyne, President, was in the chair.

Issue of Diplomas.

Diplomas of Fellowship were granted to seven candidates found qualified at the recent examination for which twenty-three candidates presented themselves. The successful candidates were as follows:

Devil John Harries, M.D., B.S. Lond., L.R.C.P., M.R.C.S., University College, Cardiff, and University College Hospital, London.
Aspirator Evans, M.A., B.C. Cantab., L.R.C.P., M.R.C.S., Cambridge University and Middlesex Hospital.

Arthur Hughes Southam, M.Ch., M.B., M.A. Oxon., L.P.C.P., M.R.C.S., Oxford University, St. Bartholomew's Hospital, and Manchester University.

Arthur Chane, M.D. Dub., F.R.C.S.I., L.R.C.P., M.R.C.S., Dublin University and St. Bartholomew's Hospital.

William Hugh Cowie Rousses, B.A. Cantab., L.R.C.P., M.R.C.S., Cambridge University and St. Thomas's Hospital.

Reginald Harold Bridge, M.B., Ch.B. Sydney, Sydney University and St. Bartholomew's Hospital.

Michael George O'Malley, M.B., B.Ch., B.A.O., National University Ireland, University College Dublin, St. Bartholomew's and Middlesex Hospitals.

Diplomas were issued to thirty-one candidates found qualified for the licence in Dental Surgery.

The Dalhousie and other Universities.

The Dalhousie University, Nova Scotia, the University of Toronto, and Queen's University, Kingston, Ontario, were added to the list of universities whose graduates in Medicine and Surgery may present themselves for examination for the Fellowship without first becoming members of the College, under the conditions of paragraph 2, section 4, of the regulations for the Fellowship.

Medical News.

The library and offices of the British Medical Association, including the editorial office of the BRITISH MEDICAL JOURNAL, will be closed on Christmas Day, and on Monday, December 27th. The library and offices of the Royal Society of Medicine will be closed from December 24th to December 28th, both days inclusive.

The annual general meeting of the London Cremation Company Limited will be held at 324, Regent Street, W., on Monday next at 3 p.m.

We regret to have to announce that Dr. George Allan Horon, consulting physician to the City of London Hospital for Diseases of the Chest, died on December 10th, aged 71.

The Royal Institution, following an example set by many theatres in London, has arranged that for the present the discourses usually given on Friday evening shall be delivered at 5.30 p.m. The first will be given on January 21st by Sir James Dewar, on problems in capillarity; the second, by Dr. Leonard Hill on January 28th, on the science of clothing and the prevention of trench feet; and the third, by Professor William Bateson on February 4th, on fifteen years of Mendelism.

The *Queen's Gift Book* is a most attractive volume containing the work of many authors and artists of distinction; it has been published to aid Queen Mary's Convalescent Auxiliary Hospitals, institutions for the relief of soldiers and sailors who have lost their limbs in the war. The need is great; already between two and three thousand names appear on the registers of Dover House and Rochampton House, the convalescent hospitals where the artificial limbs required are fitted to these patients, and more than a thousand cases are ready or nearly ready to be admitted. Workshops and fitting rooms have been installed, and it is hoped that over seventy limbs a week will presently be supplied. The purchaser of the *Queen's Gift Book* not only makes a contribution to this work, but will buy stories or poems from the pens of all the most popular British writers living, and illustrations in line or colour by the most skilful artists and illustrators of the present day. The book is, in fact, one that everybody should buy and enjoy; we cannot imagine that half a crown could be expended to any better purpose. It is published in London, New York, and Toronto, by Hodder and Stoughton.

Letters, Notes, and Answers.

ATTORNS desiring reprints of their articles published in the BRITISH MEDICAL JOURNAL are requested to communicate with the Office, 429, Strand, W.C., on receipt of proof.

THE telegraphic addresses of the BRITISH MEDICAL ASSOCIATION and JOURNAL are: (1) EDITOR of the BRITISH MEDICAL JOURNAL, *Attingham, Westrand, London*; telephone, 2531, Gerrard. (2) FINANCIAL SECRETARY and BUSINESS MANAGER (Advertisements, etc.), *Articulate, Westrand, London*; telephone, 2530, Gerrard. (3) MEDICAL SECRETARY, *Medicera, Westrand, London*; telephone, 2531, Gerrard. The address of the Irish office of the British Medical Association is 16, South Frederick Street, Dublin.

Queries, answers, and communications relating to subjects to which special departments of the BRITISH MEDICAL JOURNAL are devoted will be found under their respective headings.

QUERIES.

INCOME TAX.

ENQUIRER I asks whether the gratuity payable to medical officers leaving the navy is liable to income tax.

There are several forms of gratuity, but we presume that our correspondent refers either to a gratuity for wounds or injuries or a gratuity to a retiring officer not entitled to superannuation. Such payments appear to be regarded as of a capital nature and not subject to income tax; a pension being an annual payment would of course be on a different footing entirely.

LETTERS, NOTES, ETC.

IRISH UNION HOSPITALS.

DR. THOMAS LAFAN (Cashel) writes: I have exception to that paragraph in your Irish correspondent's letter, in which he writes of the exclusive power of Irish union hospital physicians to send on grave cases to Dublin. Now if we are deprived of the power of keeping these cases in our hospitals and only sending on those which, from their rarity, can only be dealt with by hospital men whose patients are recruited from all Ireland, a deadly blow will have been struck at a great provincial hospital system. It is not red tape which is at stake, but the efficiency of a network of hospitals which has been growing yearly in popularity and efficiency.

What our Irish correspondent protested against was the red tape of the Local Government Board's regulations, which do not permit Poor Law medical officers, whether they are dispensary or workhouse doctors, to send Poor Law patients requiring immediate operations or other treatment which cannot, in some instances, be performed at their homes or at the workhouse hospitals, to Dublin and other hospitals without first sending such patients to the workhouse, where they must wait perhaps one or two weeks for a meeting of the board of guardians to give the medical officer the necessary permission to send them away. It is evident that Poor Law patients whose only chance of recovery depends on as early an operation as possible, may be sacrificed to meaningless departmental red tape which has no better justification than to prevent the possibility of the occasional abuse of Poor Law medical officers sending for treatment to city and other hospitals patients who are not entitled to free treatment at the expense of the ratepayers.

SEA-SICKNESS AND ACIDOSIS.

A. W. S. writes: Among the theories concerning the etiology of sea-sickness, has an acidosis ever been considered? Sodium bromide has sometimes proved effectual, in which cases the soda as well as the bromide has to be considered, and the combination of chlorotone with the three bromides is still more alkaline. Perhaps some ship surgeon might think it worth while to investigate this question.

SCALE OF CHARGES FOR ADVERTISEMENTS IN THE BRITISH MEDICAL JOURNAL.

	£	s.	d.
Seven lines and under	0	5	0
Each additional line	0	0	8
A whole column	0	3	0
A page	10	0	0

An average line contains six words.

All remittances by Post Office Orders must be made payable to the British Medical Association at the General Post Office, London. No responsibility will be accepted for any such remittance not so safeguarded.

Advertisements should be delivered, addressed to the Manager, 429, Strand, London, not later than the first post on Wednesday morning preceding publication, and, if not paid for at the time, should be accompanied by a reference.

NOTE.—It is against the rules of the Post Office to receive postage letters addressed either in initials or numbers.

The Bradshaw Lecture

ON

WOUNDS IN WAR.

[WITH SPECIAL PLATE.]

BY

SURGEON-GENERAL SIR ANTHONY BOWLBY,

K.C.M.G., A.M.S.,

SCURGEON IN ORDINARY TO H.M. THE KING; CONSULTING
SURGEON TO THE BRITISH EXPEDITIONARY FORCE IN
FRANCE; SURGEON TO ST. BARTHELOMEW'S
HOSPITAL.

It is a striking testimony to the advances made in our knowledge of the healing of wounds that one of the most important points for prescut consideration in connexion with the wounds of war is the geographical situation of the battlefield. In all old treatises on gunshot wounds we find that the authors devoted their attention mainly to the nature of the projectile and its direct effects on the tissues of the body; but, important as are still these considerations at the present day, they must now be studied in conjunction with the terrain of the war.

It is for this reason that I would preface what I have to say to you to-day with the statement that my own experiences are limited to two wars, the one in South Africa in 1899-1900, and the other the present war in Northern France and Belgium. So widely different have I found the conditions of the wounds in these two campaigns that I realize it would be unwise to speak too dogmatically of wounds in those many other fields of the war now being waged in different parts of the world. I propose, therefore, to speak only of the wounds I have seen during the past fifteen months, for it was in September, 1914, that I went to France, at a time when the battle of the Aisne was in progress. From that time until the second week in October I was chiefly occupied at the hospitals at Rouen, although I also visited Paris and its neighbourhood.

Early in October, however, I was directed to join the General Head Quarters in the North of France, and ever since that time I have visited daily the various casualty clearing stations at the front, and have also seen from time to time the work done in the field ambulances. My experiences, therefore, are on the whole concerned with recently wounded men, but many of these latter have been kept under observation for several weeks, either in the clearing station or in the large stationary hospital where Mr. W. Dickie is in chief surgical charge.

COLLECTION OF WOUNDED: GENERAL CONDITIONS.

In the first place I wish to point out how radically different are the fields of war in South Africa and in France. In the former we had to fight in a very thinly inhabited country which supported very few domestic animals, and which for the most part was quite uncultivated.

The soil was dry and sandy, and in many places the rocks projected in the form of the well remembered "kopjes." The ground was uncontaminated by manure and was to a great extent "virgin soil." Rainfall was slight, cloudy days were few, and a hot sun with fresh breezes or strong winds desiccated the soil and prevented the growth of any luxuriant vegetation. The consequence of all these conditions was that, in the absence of decaying vegetable and animal matter, the soil was almost entirely free from all pyogenic organisms, and bacteriological examination proved that all forms of pathogenic bacteria were absent from the soil of the veld except in the neighbourhood of the dwellings of man.

At the present seat of war we find all these conditions reversed. The country is thickly populated with human beings and supports many cattle and pigs; the soil is a rich loam, and rocks nowhere project through it; it is more heavily manured with the excrements of men and animals than almost any other land, and is covered by luxuriant crops. Rainfall is copious, cloudy days are numerous, and in many months sunshine is almost absent for long periods. One result of these conditions is that every form of micro-organism flourishes, and even in soil

taken from a considerable depth below the surface the spore-bearing pathogenic organisms abound.

The behaviour of the wounds in the two wars presents an unfortunately grave difference, which corresponds to some extent with the conditions I have just enumerated. But, in addition to the differences in the soil and surroundings, the wounds of the South African war also differed in almost every way from the injuries of the present campaign. The "ogival" bullet of that day produced much less smashing and rending than does the pointed bullet now in use; and, while in this war the majority of the wounds are inflicted at close range by a missile travelling at the height of its velocity, in South Africa they were more often due to bullets fired at a distance of half a mile or more, and which, travelling at a much lower speed, had infinitely less power for harm.

In addition to this, shell wounds amongst the British troops were extremely rare in the African campaign, while in this war they are, perhaps, quite as numerous as those caused by bullets. In general terms it may be said that the injuries seen in the Boer war were infinitely less severe, and the complications due to them far fewer and less serious than those of the past year in France, so that it very soon was evident that we had to unlearn most of our South African experiences. I will give but one example to illustrate this. In January, 1900, two Australian troopers were sent into the Portland Hospital in South Africa, in each of whom the femur was fractured and comminuted in its upper third by a bullet wound. The injuries were three days old, and the only treatment had been the application of a small first field dressing and the bandaging of the limb to a rifle with puttees thick with dust. The blood-stained breeches had not been removed and the first dressing and the puttees had not been changed. Yet the men were in excellent condition, and their wounds never gave the slightest trouble. But similar injuries with similar treatment in the present war would almost certainly have resulted in the death of the patients from gangrene, or at least in prolonged suppuration and probable loss of the limb, and many surgeons who are familiar only with South African conditions seem unable to realize the completely altered picture of the present war.

I am very well aware of the difficulty of explaining with sufficient clearness the conditions under which our men in France are wounded and treated; nevertheless, before I attempt to describe the general nature and treatment of their wounds, I will endeavour to put before you the circumstances in which these wounds are received.

All are well aware that ever since the battle of the Marne the opposing armies have lived and fought in trenches, but it must be remembered also that in both of the battles of Ypres, as well as at Neuve Chapelle and Loos, and on many other occasions, there has been a great deal of fighting in the open as well. Still, the fact remains that, owing to their partially subterranean life, men are usually covered thickly with either mud or dust at the time when they are wounded, and their comrades who help them are in a similar condition. When a man in one of the advanced trenches is hit and falls he lies in mud or dust, or else in muddy water a foot or more in depth. Close at hand, or else perhaps some hundred yards distant, the regimental medical officer has prepared a larger and deeper excavation commonly known as a "dug-out," and to this the wounded man will walk if he is able. If unable to walk, he must be carried, but he cannot be carried on the usual stretcher, because it is too long to pass along the narrow trench, which is rendered tortuous by the many "traverses." In these circumstances he may be carried sitting on sacking slung from a pole, if he is well enough to help himself, or else he may be taken on a "trench stretcher," which is much shorter than the usual stretcher and is a very simple and ingenious invention which has been of great service. His wound is not infrequently dressed by his muddy and dusty comrades if it is accessible to them, and in any case it is dressed in the dug-out, if not before. From here the patient has now to be transferred to the first-aid post, which is established by a section of a field ambulance at some place which is as much sheltered from fire as may be, half a mile or more in the rear. Access to this is generally obtained by passing along a "communication trench," which may be 6 ft.

or 8 ft. deep and more or less muddy or wet. The first-aid post is usually above ground, but may be in a "dug-out" or in a cellar. The patient is not detained here longer than absolutely necessary, but is transferred by a horse drawn vehicle or on a wheeled stretcher to the main field ambulance a mile or two further back. Here are either tents or buildings which have been adapted for use, and here fresh dressings and food and much-needed rest on stretchers are all provided. The wounded man is now in comparative safety, and if his injury is slight and there is no crowd of wounded he may remain here for some hours. If, however, his wound is serious or dangerous, or if a battle is in progress, he is taken in a motor ambulance to the "casualty clearing station," a very few miles further back, and usually placed so as to be just out of the range of ordinary shell fire.

These clearing stations were the invention of a date subsequent to the Boer war, and were for the first time put to a practical trial in the present war. Their personnel and equipment were provided for the treatment of 200 wounded, and they were originally intended merely to enable the field ambulances to "clear" themselves and then to pass the wounded on to the stationary hospitals or to the base. The circumstances of this war, however, soon showed that they could be made infinitely more useful than this, and before the end of the year 1914 they had been transformed into well-equipped hospitals capable of dealing with all urgent operations and of retaining and nursing those patients whom it was not advisable to send on by rail. It is into such hospitals as these that the wounded come from the field ambulances, and at which they often arrive within a very few hours of being injured.

It must next be realized that in the early days of trench warfare the long "communication trenches" of the present day did not exist, for they may take months to complete, and, as a consequence, men had usually to be retained in the advanced or support trenches till night afforded some protection from the enemy's fire, and in this way much delay necessarily ensued in getting the patient out of his muddy surroundings and to a place where he could be adequately treated. There are some trenches in which similar conditions still prevail and from which the wounded can only be evacuated after dark.

On many other occasions, after a fight in the open, badly wounded men have been left lying between the opposing trenches, because any attempt to rescue them at once drew the fire of the enemy, and might easily have resulted in the death of the patient as well as of his would-be rescuers. In such circumstances, after night-fall men will crawl in even with badly smashed limbs, and in other cases they are brought in by stretcher-bearers at very great risk. Others of them, however, cannot be brought in, and, especially after an unsuccessful attempt to capture an enemy position, they sometimes lie out for even days and nights. No doubt many such have died, and in others who have been ultimately rescued the condition of the wounds has been very bad. It was, of course, the men who were the worst wounded who had the most difficulty in getting into our lines, for those who had badly fractured legs or thighs or were shot through the head, the lungs, or the abdomen were quite unable to save themselves, and had to wait till the enemy was driven back or till darkness allowed their comrades to try and help them, in spite of the light given by the frequent "star shells" and the subsequent fire from the German lines.

One man lay out in a coppie last January for ten days with only a little pond water to drink, and lost both his feet from gangrene but escaped with his life. Another man lay for eight days in a German "dug-out" with a completely smashed leg and in constant expectation of being discovered and killed, yet he also survived after amputation of the leg.

THE MISSILES.

It is now time to turn attention to the nature of the missiles which cause the wounds we are considering, and they are certainly more varied and numerous than in any previous war. It is not yet possible to say with any accuracy what proportion rifle bullet wounds bear to the whole, and it must be remembered that the quick-firing machine gun, which has borne so prominent a part in the German armament, fires the ordinary rifle bullet, as does

also our own quick-firer. The rifle bullet of British, German, and French alike differs from all the bullets of the Boer war period. The point of the older bullet was rounded or ogival, and the whole bullet was of the same diameter in nearly its whole length. The point of the present bullet is like that of a sharpened lead pencil, and the consequence is that the balance of the bullet is altered, so that its posterior half or base is much the heavier, and its centre of gravity further back. The importance of this to the patient and the surgeon is that the bullet is very easily caused to turn completely over on its long axis and so to enter the body sideways or base first. This is all the more likely to occur because in trench warfare bullets often pass through the earth of the parapet or strike a sandbag, but it is also true that when the speed of one of these pointed bullets is much diminished towards the end of the flight it will readily turn over within the body after entering with its point first.

The German and the British bullets are much alike. Each of them consists of a soft core of lead or other metal contained in a sheath or "mantle" of hardened steel, and, though the German bullet has a higher muzzle velocity, I do not think there is much difference in the effects it produces in the human body, and I have seen a considerable number of Germans who have been wounded by our bullets. As is well known, the impact of the mantle-coated bullet on a rock or stone may break the mantle and allow the core to extrude, so that when it strikes a resisting structure, such as a large bone, it spreads and breaks up, and causes much more extensive damage to the tissues as a result. It is seldom in my experience that the bullet is broken up by mere impact on a bone, though no doubt this does occur.

The French bullet is made of a copper compound, and is solid and homogeneous throughout, so that it has neither core nor mantle. It is longer and heavier than either of the other bullets, but, as I have not seen very many patients wounded by it, I do not propose to allude to it further beyond saying that I think there is very little difference in the effects it produces on the human body.

In addition to bullets, an immense number of other forms of missiles have been employed, so that wounds have presented the utmost variety. It is not possible or necessary to describe in detail all the forms of shell, but in order to understand the nature of wounds it must be realized that shells differ immensely in their structure and in the way in which they produce injury.

1. Shrapnel.

Shrapnel shells of all kinds and sizes are characterized by the fact that they contain some 250 to 400 round bullets of lead which is in some shells soft but in others is hardened by various agents. These bullets vary in size—in proportion to the size of the shell, but are never more than about $\frac{1}{2}$ in. in diameter. The shell is usually timed by a fuse to burst in the air over the object aimed at, and the shell case being blown open by the explosion, the bullets are propelled in a cone-shaped stream whose velocity is dependent on the velocity of the shell, and is not due to the force of the explosion which bursts the shell. The violence of their impact is great in proportion as the shell is still travelling at high speed and is not too far from the ground where it bursts, and the direction of the blow is generally downwards. Wounds may also be caused by the metal case, which is a foot or more long and weighs several pounds at least, but such wounds do not differ from those caused by the solid variety of shell. The velocity of the bullets is never as great as the muzzle velocity of a rifle bullet, and, as they very quickly lose force and power of penetration, their effective range is not a long one.

2. High Explosive Shells.

These shells vary in weight from a few pounds to about a ton, and they consist of a thick iron case containing in a central cavity a violent explosive charge. The latter is, in the case of German shells, trinitrotoluene, and as much as 200 pounds weight of the latter may be present. Such shells are usually burst on percussion by a detonator which acts by the impact of the shell on the ground or on some other object. These shells do not contain bullets, and the injury they do is caused in chief part by the jagged fragments into which they are split by the explosion, and also to some extent by the impact of portions of buildings,

such as stones or bricks, which are scattered with immense force by the violence of the explosion. The fragments of the shell are always very rough and ragged, and of every variety of size and shape. For example, the base of a 17-in. shell may weigh 150 pounds, and if it struck the body of a man would completely destroy it. Other fragments may weigh a few pounds and may tear off a limb or crush it to pulp, while in the smaller shells there may be scores of fragments about the size of the end of a finger, or much smaller.

It must also be kept in mind that the mere explosive force of the gases of a large shell exercises great powers of destruction. The expansion of the gases is alone sufficient to kill, and in the only case in my experience in which an autopsy has been made, the brain was the seat of very numerous petechial hæmorrhages.

3. Bombs, Hand Grenades, Rifle Grenades, Shells from Trench Mortars, etc.

All these are characterized by a shell case of iron or other metal containing a relatively large charge of a high explosive. In the German projectiles this is always trinitrotoluene. The bomb case varies immensely. In some it is composed of iron about half an inch thick, often partially cut up into segments about half an inch square. In others, chiefly German, it is composed of quite thin steel

Wounds caused by shrapnel bullets are not so extensive as the worst of those caused by the pointed rifle bullet, for although the former may make a large hole of entry they do not exercise the same divisive or explosive force as the latter; they are, however, often multiple, and on account of the fact that this form of shell bursts in the air, the bullets very often wound the skull and brain.

The wounds caused by shell high-explosive fragments and by bombs and grenades are so infinitely various that it is not possible to describe a characteristic shell wound as a type. It may be noted, however, that all shell fragments being rough and jagged, tear away parts of the clothing and carry the latter into the extreme depths of the wound. The large fragments tear away from the limbs or trunk huge masses of skin and muscle, so that the whole of the calf or the front of the thigh, or the gluteal or deltoid regions may be destroyed and the tissues from which these have been avulsed are themselves so crushed and lacerated that all the vessels are pulped and extensive areas die. In the neighbouring tissues there is, of course, widespread contusion and extravasation of blood, and, as a result of these injuries, the exposed muscle often loses all its natural characteristic appearance and looks exactly like a mass of mud, for it becomes a homogeneous mass of dark brown or slate-coloured matter without any appearance of striation or vitality, and, as it is quite dead, it may

Fig. 4.—Pole and racking for sitting cases.

Fig. 5.—Major Rogers's trench stretcher in use.

Fig. 6.—Orderly carrying Major Rogers's trench stretcher.

or other metal. When a bomb or grenade bursts, the case is commonly broken up into very numerous fragments of every size, from a pin's head to a lump of metal weighing as much as an ounce. Some of these may be quite pointed, and with an edge like a knife; others are often quadrilateral. Some of the German bombs contain also irregular jagged pieces of loose metal, and others are loaded with rough iron boot nails about half an inch long and pyramidal in shape.

All forms of shell and bombs also scatter stones, earth, or sand from the parapets, and these all become projectiles, and are specially liable to injure the face, neck, and shoulders of men standing in the trenches.

THE WOUNDS.

Such, then, are the various projectiles by which the wounds of the present war are caused, and it will be readily appreciated that the wounds are as various as the projectiles themselves.

The so-called "normal" bullet wound, such as was common in the South African war, and was characterized by a tiny aperture which might have been made by a gimlet or a trocar, is in this war quite rare, and even if the entry is of this nature the exit is almost always ragged and large. In many of the cases bullets tear the soft tissues to rags and blow out the muscles and fascia through great rents in the skin, and when no bone is struck such injuries as these are always due to the discharge of the rifle at close quarters, and generally within fifty yards. When a large bone is struck the damage is yet greater, and the part looks as if it must have been struck by a large fragment of shell. This is due to the fact that the bullet, travelling at the height of its velocity, not only smashes the bone, but also imparts its momentum to the shattered fragments and drives them in every direction, so that the injury to the soft tissues is inflicted in great part by the fragments of bone themselves.

to be cut away without causing either bleeding or pain. The condition is one which I have never seen in even the worst machinery accidents in civil life. In other cases fragments of big shells may tear away the abdominal wall and expose the viscera, or may carry away portions of the face or neck, while the bones of the limbs may be fractured or the limb itself may be completely shot away.

Nothing is more striking than the immense amount of destruction wrought by even quite small pieces of a shell burst by a large charge of a high explosive, for the wound in the tissues may be ten times as large as the missile. Thus I have seen a man in whom a piece of shell not so big as the end of the little finger tore a large wound in the liver and then rent completely away the whole of the hepatic flexure of the colon, while in the limbs I have seen wounds as large as a clenched fist caused by quite small fragments which evidently mainly owed their power of destruction to the extraordinary velocity with which they travelled as well as to their jagged edges.

The various forms of bombs and grenades are specially liable to cause multiple wounds, for they generally wound by bursting close to the patient; they break up into very numerous fragments, some of which are large and heavy and some of which are quite minute. At very close quarters quite small, sharp-edged strips of metal may penetrate very deeply, and even be driven into the intestine or lungs through tiny apertures, while many other men who are hit at some little distance by similarly small pieces of these bombs suffer little violence, for, as the fragments quickly lose their great initial velocity, such wounds as these are often slight. It has thus happened during the last months of the war that a very large number of men have had small wounds from which they quickly recovered, although, on the other hand, it is often noticeable that many of these grenade and bomb wounds are on the face, and that one or both eyes are often blinded by small pointed fragments or by gravel or

stones. These wounds are also specially liable to be badly infected, and for the reason that, as the bomb usually falls to the ground before bursting, it scatters showers of mud in every direction and plasters it into the wounds.

It will thus be seen that the wounds in this war are often quite unlike those of previous wars because they have been caused by new and different missiles, and it is further to be noted that the proportion of wounds by rifle bullets compared to wounds caused by shells or bombs is certainly much less than in previous wars. It is well known that never before has such extensive use been made of artillery and bombs, nor have armies ever previously faced each other over fronts of hundreds of miles at a distance of a few yards. It is this proximity and shortness of range which has caused bullet wounds to be so severe, and it is by the same proximity that the injuries by bombs have been made possible and frequent.

GENERAL CHARACTERS OF GUNSHOT WOUNDS.

The very various wounds I have thus briefly described are for the most part quite different from injuries met with in civil life, and all surgeons in past years who have had war experience have recognized that gunshot injuries form a class apart. It is of course true that a very large number of slight and superficial wounds and some cases of fracture present no striking features, but where missiles have penetrated the body at high velocity the differences between such injuries and those of civilian life are radical.

The essential nature of all accidents such as are caused by machinery in motion, by vehicles of all kinds, or by kicks or blows is a crushing and mangling of the limbs or trunk by force applied from without inwards, so that the parts involved are crushed by a comparatively slowly moving object. On the other hand, in all penetrating wounds by bullets of all kinds, and by shell fragments moving at immense speed, the main injury is done by a force of a divisive or expanding nature, so that the tissues are torn asunder

from within instead of being crushed slowly from without. It is this rending asunder which is the special characteristic of all typical "gunshot" wounds, and it has been shown that the injury caused by a bullet is largely due to the wave of compressed air which the bullet drives in front of it, and which expands within the tissues. In all wounds which completely traverse the tissues this divisive or explosive force is present to a greater or lesser extent, and the effect produced is heightened by the resistance offered to the explosive power. The result is that the injury, instead of being limited to the tissues on each side of the bullet track—as it would be if the wound were not made by a bullet but by a trocar—is diffused in every direction, and radiates through all the surrounding structures. It is of course well known that in the case of the brain enclosed in the skull, or in the liver enclosed in its capsule, explosive effects are typical, and this is attributed to the enclosure in a strong capsule of tissues which are largely composed of water. But it is not sufficiently appreciated that these same effects are produced in every other part of the body and limbs also, and are directly proportionate both to the speed of the whirling projectile and to the resistance offered it by the structures which it encounters. The truth of this may be demonstrated on any limb shattered by a bullet or a fragment of a high velocity shell perforating it, for it will be found on examination that the missile has not only shattered the tissues in the line of its flight, but that the divisive force has separated the fascia from the skin and split the muscles from each other along their intermuscular planes.

The effect of the injury may, indeed, spread up and down

a great part of the length of the limb, and vessels may be burst and extravasation of blood may be found far from the obvious track of the missile.

But, although the effects of a bullet or piece of high-velocity shell are so evident and extensive, it will be found by microscopical examination that they are even more extensive than appears to the naked eye, for muscles whose sheath is yet intact, which appear perfectly normal, and are at some distance from the wound, are so examined there will be found fractures of the muscle bundles, extravasation of blood, and necrotic changes in the surrounding fibres.

This microscopical evidence of widespread injury is found not only in the limbs but also in the viscera, so that the liver and the kidney may show extensive interstitial hæmorrhage and a very remarkable disintegration of the cells at a considerable distance from the site of the obvious injury. I am much indebted to Lieutenants Adrian Stokes and McNee for the following reports on various specimens they have examined, and on which, amongst others, the above statements are based.

KIDNEY.

CASE 1.—Sergt. C. died about twelve hours after shrapnel wounds of the chest and the abdomen, and the right kidney presented a perforation in its lower pole. A piece of kidney was taken from what was apparently a healthy portion of the upper pole, for microscopical examination. It was hardly recognizable as kidney. There was present only a fibrous stroma of the tissue without any of the specific kidney cells, and only one or two glomeruli were recognizable. The tubules had apparently desquamated all their lining epithelium, and in a few of the collecting tubules there was present some granular material perhaps representing the destroyed cells. The whole section was full of small hæmorrhages, and in places there was a slight infiltration with polymorphonuclear cells.

LIVER.

CASE 11.—Pte. C. C. S., wound by bullet of anterior margin of liver, 2.30 p.m., October 6th, 1915; died 8.20 p.m., October 7th.

Condition of Liver.—The bullet had penetrated the organ close to the anterior margin, just internal to the line of the gall bladder. The laceration extended for a depth of $\frac{1}{2}$ in. into the liver substance. On cutting the liver into two parts so as to include the line of the laceration an irregular area was observed, different in colour from the other parts of the organ, and situated almost 3 in. from the tear. No direct track could be found leading from the site of the injury to this yellowish area.

Microscopic sections from this yellowish zone showed the following appearances:

"The cells of the lobules are in many places very well preserved, the only abnormal feature being the great vascular engorgement of all the capillaries. Scattered throughout the sections, however, are numerous hæmorrhages, some of them exceeding in size two liver lobules. Round the margins of the areas of hæmorrhage the liver cells are definitely necrotic, nuclear staining being lost, and the protoplasm granular and faintly staining. In most places the ring of necrosis is narrow, but in others a wider area is involved in the process. In some sections areas of necrosis alone seem present, but these are evidently in relation to hæmorrhages not included in the same section. No leucocytic infiltration or other evidence of sepsis is present anywhere."

MUSCLE.

CASE 111.—Corp. (S.F.), wounded by shell, 9 a.m., on October 11th, 1915. Superficial injuries to foot, hand, and scap. Three deep wounds on front of right upper arm, just below insertion of pectoral muscles. The patient collapsed from hæmorrhage on admission. Amputation was performed at the shoulder-joint on October 15th, and tissue was taken for examination from the belly of the biceps muscle, 2 in. below the lower margin of the wound, at a place where the muscle appeared to be quite normal.

Condition of Muscle Examined.—The most interesting finding is the presence of a definite transverse rent, tearing across several bundles of muscle fibres, as seen in longitudinal section. (See Fig. 3.) The ends of the muscle fibres torn across show necrosis, and the rent itself is filled up entirely by a mass of red cells and polymorphs, showing an intense

DESCRIPTION OF SPECIAL PLATE.

[From drawings by Mr. J. R. Ford.]

Fig. 1.—From the upper pole of the kidney of a soldier who died about twelve hours after shrapnel wounds of the chest and abdomen, the kidney having been passed through its lower pole. The epithelium of the tubuli is desquamated, and most of the tubuli contain red blood cells; on the lower left-hand side there is shown part of a hæmorrhagic extravasation, in which there is an excess of polymorphs.

Fig. 2.—From the liver of a soldier who died thirty hours after being wounded. The bullet perforated the anterior margin of the liver; the section is made at a distance of about 3 in. from the laceration. It shows extensive hæmorrhage, and areas of necrotic tissue in which the hepatic cells are no longer recognizable. An undamaged area is shown at the lower left-hand corner of the drawing.

Fig. 3.—From the biceps humeri, taken from the belly of the muscle, 2 in. below the lower margin of the wound, at a spot where the muscle appeared to be normal. The section shows one of several microscopic ruptures, the fissures between the retracted fibres of which are filled with blood. (In some fields the injured muscle fibres were necrosed.)

FIG. 1.

FIG. 2.

FIG. 3.

inflammation to be present. Everything points to this small tear having occurred at the time of the original injury higher up the arm.

"In other parts of the sections bundles of muscle fibres are widely separated, the interval between the bundles being filled entirely with polymorphs and red cells. One such bundle, separated from its neighbours on either side by a gap containing inflammatory cells, shows absence of all striation of the fibres, and is evidently approaching a condition of necrosis."

CASE IV.—Pte. F. (D.C.L.I.), gunshot wound of left leg above the ankle, causing compound fracture of both bones. Wounded October 11th. Amputation 24 hours after the wound was received.

Muscle tissue taken for examination from the tibialis anticus several inches above the seat of the wound.

Condition of Muscle Examined.—"The most striking feature in the sections is the wide separation of bundles of muscle cells from one another. A condition of very acute inflammation is present, all the spaces between the bundles being full of polymorphs. A distinct transverse tear is seen going half-way across one bundle. The muscle fibres involved in the tear are quite without striation and obviously necrotic. The gap between the torn ends (see Fig. 3) is filled in by polymorphs and red corpuscles, indicating, along with the necrosis of the muscle fibres, that the rupture occurred *ante mortem*, and not during the preparation of the sections."

It is very easy to demonstrate the far-reaching effect of bullets when the bones are involved, and I will quote the two following cases as striking examples.

In the first case a man was shot across the face and through the nasal cavities, the entrance wound being below the zygoma on one side and the exit through the zygoma on the other side. His symptoms were those of a man shot through the brain, and he died on the fourth day. The autopsy by Mr. Adrian Stokes showed that, although the track of the bullet was an inch or more below the level of the base of the skull, yet the latter was fractured right across, and although the dura mater was unharmed, one frontal lobe and one temporo-sphenoidal lobe were more or less pulped.

In the second case a young officer was shot across the back of the neck and became completely hemiplegic, although the wound was apparently superficial. He died in two days, and an autopsy by Mr. Stokes showed that the bullet had only broken off the tip of the sixth cervical spine. The laminae were not fractured and the dura mater was intact, yet the cord had been contused and its grey matter was broken up by haemorrhage. But it is possible also for the spinal cord to be injured by a bullet which does not even touch the vertebral column, and one patient died with haemorrhage into the spinal cord in whom the bullet had merely passed through the muscles at the side of the neck and had caused no hurt to any of the vertebrae.

Other very striking examples may be cited in which the intestines have been torn open by bullets without the peritoneal cavity being opened. In one case a bullet passed across the pelvis at the level of the trochanters, causing immediate collapse, from which the patient never rallied. He died in about ten hours, and at the autopsy it was found that the bullet had passed in front of the sacrum and had not entered the peritoneum. Yet, when the peritoneum was opened anteriorly it was found that a coil of the ileum 6 in. from the caecum had been completely torn across. In a second case of the same kind a bullet entered the upper gluteal region and emerged in the inguinal region, cutting the spermatic cord, but not opening the peritoneum. Nevertheless, the patient died from rupture of the intestines.

It will thus be seen that, whatever tissue is examined, or whatever part of the body is involved, all the evidence goes to show that in gunshot wounds the passage of the missile results in injuries to tissues which appear to be quite remote from its track, and it must be concluded that the vibrations set up by the projectile in the fluids of the body result in very widespread disintegration of both the small blood vessels and of the cells of the parenchyma themselves.

As will be seen on further consideration, these changes are of great interest in considering the resistance of the body to microbic infection.

CONDITION OF THE WOUNDED MAN.

The next matter which demands consideration is the condition of the wounded men themselves. This necessarily depends on other circumstances besides the nature and extent of the wound, for it is influenced by the time

that elapses before assistance arrives, by the amount of blood lost, by exposure to cold and wet, by want of food and drink, and by exhaustion due to want of sleep; and it is seldom that, even in the case of slight wounds, none of these factors complicate the injury.

I think that the thing that would strike most forcibly any observant person who was brought into a room filled by large numbers of recently wounded men from a big fight would be the fact that nearly all of them were asleep, in spite of wounds which one might well suppose would effectually banish sleep. There they lie on their stretchers with muddy or wet clothes, with bandaged limbs or head, quite content with the transition from the turmoil of battle to the comparative peace of a crowded room which in itself offers little comfort. Some of them ask for food, but with many this is a secondary consideration, for when a man is worn out by long periods of watchfulness and laborious work in the trenches, and when the intense excitement of fighting for life and killing other men in the midst of the crash of shells and the clatter of rifles and machine guns has passed, then there comes the reaction and exhaustion of a tired-out man and an overwrought nervous system. It is only a few of these men who are excited and talkative, and still fewer who wish to talk of their recent experiences, and these who only see wounded men in the base hospitals have little idea of the silence of a crowded room in a clearing station when heavy fighting has been in progress for a day or more.

But as the surgeons work their way from man to man it soon becomes evident that some of those who are asleep are also suffering from profound collapse, so that there are many in whom the hands and feet are cold, the lips pallid, and the pulse either very small and rapid or quite imperceptible at the wrist. The wound of such a patient may, for its own sake, demand prompt treatment, but all who have had experience know that there are hundreds of men whose best chance of life is to be kept warm and left absolutely quiet, and persuaded to take hot soup, or cocoa, or perhaps alcohol, before again going to sleep. It is at first surprising to find how many quite pulseless men will slowly pull round if they are only given time and kept thoroughly warm, and there are no more striking cases of this than men with bad compound fractures of the lower extremity, or with multiple injuries. They are indeed often so nearly dead that it may be several hours before any attempt can be made to dress their wounds, and, even with every care, there are not a few who die. The common causes of this collapse I have enumerated above, but it is often true that various causes all combine to bring about the condition. It thus happens that when a man has had a bad smash of a limb by a bullet or shell, the shock caused by such an injury is alone sufficient to cause much collapse. Yet in many cases this is followed by the anxiety of prolonged exposure to further wounds and often by hours of wet and cold spent in the open, with no food, and with an undressed wound which hourly becomes more painful. And after all this there is the unavoidable pain of moving him from the battle-field to the hospital.

It is also a very noticeable fact that in many of these cases the patients are quite unable at first to retain any food, and that, even if no food is taken, retching and vomiting are very common for many hours. This is a complication of shock of which I have had no similar experience in civil practice, but it is, unfortunately, not only common, but often serious in gunshot wounds, as men who are much in need of food are unable to retain it.

In many of these cases of vomiting, and also in all cases of severe collapse, numerous lives have been saved by the subcutaneous or intravenous injection of normal saline solution to the extent of several pints, and enemas of hot water and brandy have been similarly useful. As far as drugs are concerned, nothing has been more helpful than pituitary extract. There are also very many men who have sustained multiple injuries from bombs or shells and some of whom have had two or even three compound fractures, and no class of case suffers more from shock than this. In others of these cases of multiple injuries the whole chest or back, or the surface of both thighs or legs, is covered with numerous wounds which are caused either by fragments of the bomb or else by gravel and mud from the parapets, and, although the wounds may be quite superficial, the patients are very frequently severely collapsed. I have been in the habit of comparing

these cases of multiple surface wounds with those of extensive superficial burns where there is also much shock, and I think the two classes have much in common, for not only do they suffer from shock, but the sepsis following a burn is more than paralleled by the severe infection with anaerobes due to the multiple infection carried in by the mud and bomb fragments. As in the case of burns, also, picric acid is at once an excellent analgesic and antiseptic.

SECONDARY COMPLICATIONS OF WOUNDS.

The primary complications of haemorrhage and collapse are accompanied or followed by the secondary complications of bacterial infection, and it is practically true that every gunshot wound of this war in France and Belgium is more or less infected at the moment of its infliction. I have already described the condition of the men and their clothing, and how mud and dirt pervades everything, and bacteriological investigations of the soil, of the clothing, and of the skin, demonstrate the presence of the most dangerous pathogenic organisms in all three.

No more interesting work on this matter has been recorded than that done by Mr. Alexander Fleming,¹ in Colonel Sir Almoth Wright's laboratory, and his whole paper is well worth study. I will here only quote some of his conclusions, and, in the first place, the results of his examination of the clothing of wounded men. He says: "From this it will be seen that of the twelve samples of clothing examined *B. aerogenes capsulatus* was found in 10, *B. tetani* in 4, *Streptococcus* in 5, and *Staphylococcus* in 2, besides other organisms." It is therefore evident that the patient and all his surroundings when he is wounded are grossly infected, and all missiles which pass through the contaminated skin as well as through the clothing are liable to carry bacteria into the depths of the wound. And it must also be kept in mind that, even when no large piece of clothing is found in the wound, in practically all cases of injuries by shells or shrapnel bullets minute shreds of coat, shirt, or jersey, will be found by a careful search.

Mr. Fleming gives the following table, showing the microbial infection of 127 patients at different stages.

Time after Infection.	Total No. of Cases.		B. tetani.		Putrefac-tive Bacilli.			Streptococci.		Coliforms.		Staphylo-cocci.		Wisp bacilli.		Diphtheria bacilli.		Larger Bacilli.	
	B.	Streptococci.	B.	T.	B.	X.	Y.	S.	S.	S.	S.	S.	S.	S.	S.	S.	S.	S.	S.
	(1)	(2)	(3)	(4)	(5)	(6)	(7)	(8)	(9)	(10)									
STAGE I: 1 to 7 days ...	127	103	22	14	5	102	37	40	9	0	2								
STAGE II: 8 to 20 days ...	56	19	5	4	1	51	18	16	17	4	4								
STAGE III: Over 20 days ...	27	5	0	0	0	24	19	19	16	0	6								

He adds: "The spore-bearing anaerobes . . . progressively diminish in relative frequency as the age of the wound increases. . . . In the early stages these spore-bearers are present in much greater numbers than anything else, whereas later . . . their numbers are relatively few." He considers also that all the first eight of the group of organisms tabulated above are of faecal origin, including the streptococcus which is so common an infection.

The work of pathologists at the front (Major Rowland and Lieutenant Stokes and McNece) has also demonstrated the presence of anaerobic and other organisms in quite recent wounds, and the conclusions arrived at in the British army are all supported by the surgeons in the armies of our allies.

Such, then, are the main facts as to the nature of the infection of the wounded parts, and it is the result of this infection that is the all-important question which has so deeply interested not only the medical profession, but also the public in general.

TREATMENT OF SEPTIC INFECTION.

I think it may truly be said that nothing has more impressed the public mind than the septic nature of many wounds and the prolonged sufferings caused thereby. It may also be said that this sepsis came as a surprise to

most surgeons, and as a disappointment to those who had believed that in antiseptic surgery we had forged a weapon to combat all such conditions. Many, indeed, have not hesitated to blame the surgeons in France for the conditions of the wounds, while others have devised and advocated many new remedies to deal with the unexpected condition.

It becomes, therefore, a matter of much interest to try and analyse the different bearings of this septic infection and to suggest how it may best be combated.

Gas Gangrene.

In the first place we must realize that, in the gas-forming anaerobes at least, we have to deal with an infective agent which is to all intents a new experience, and not only are these bacteria found in almost every wound, but they also attack the tissues more rapidly and violently than any other organism. They are practically unknown in civil practice in Great Britain as a regular wound infection, for they are so rarely encountered that prior to this war most of the younger British surgeons had never seen a case of gas gangrene.

I will not here interpose a long description of this condition, but will merely state that these anaerobes cause an inflammation characterized by great swelling and a copious sanious discharge full of bubbles of gas. This may only result in a cellulitis, or may involve the whole of the tissues of a limb, and has a special tendency to extend in muscles. It may cause discoloration and death of the skin alone, or else the whole limb may swell enormously and be rapidly converted into a gangrenous mass of putrefying material emitting the odour of a newly manured field. The patient in the worst cases presents all the appearances associated with severe shock or collapse, is often very sick, rapidly becomes pulseless, his hands and feet become damp and cold, the tongue dry and furred, and death follows the onset of the disease within about forty-eight hours. There is often very severe pain in the early stages, and most of this is due to the extreme swelling and tension, but, as the tissues die, all sensation is lost, and the end is usually quite painless. In the vast majority of wounds, however, although the same anaerobes are present, they are comparatively powerless to do much harm, their action is localized to the wounded area, and they produce merely a local sepsis and inflammation. The question naturally arises why such very various results should ensue from the same infection, and it is a noteworthy pathological fact that the action of the gas-producing organisms is greatly assisted by the presence of staphylococci or other bacteria.

In considering the explanation of these phenomena we are at once struck by the fact that these anaerobes attack a recent wound with the most alarming rapidity, and they produce their characteristic local and constitutional effects more rapidly after being inoculated than do any other organisms. I have, indeed, seen well-marked infection with the formation of gas within five hours of the receipt of a wound, and I have seen a whole limb gangrenous in ten hours, and the patient dead from haemic infection sixteen hours from the time he was injured. It was evident, therefore, that in such cases the organisms meet with no resistance from the tissues, and the question to decide is why do not the tissues resist in some cases when in very many other wounds the anaerobes have evidently but little power for harm?

A good deal of light is thrown upon this matter by the behaviour of the anaerobes in question when a limb dies from injury to its main vessels. I have seen many cases of gangrene due to injury to the iliac, femoral, or popliteal vessels, and some due to injury of the axillary artery, and in every case but one as soon as ever the limb has died from loss of its circulation it has at once been invaded by the gas-forming anaerobes, and, if it has not been removed, typical gas gangrene has extended and killed the patient. In other patients where wounds have been infected to only a slight degree before death, as soon as death has occurred typical gas gangrene has so rapidly spread that within three or four hours the limb has become a putrefying mass.

The important facts to keep in mind, then, are, first, the extreme rapidity with which recent wounds become infected, and, secondly, the fact that these anaerobes develop most characteristically on dead or dying tissues. Keeping these in mind, we can appreciate why certain

wounds are affected more than others, for, other things being equal, it may be briefly said that "the more severe and extensive the injury, and the more the tissues are lacerated and devitalized, the more is the wound likely to be badly infected."

I have already described how the tissues are pulped by bad shell smashes and by bullet wounds with explosive effects, and I have mentioned that the muscles which have been crushed out of all resemblance to muscle may be cut away without causing pain or bleeding because they are dead. The fact is that the tissues left behind when a piece of shell has torn away a great mass of skin, cellular tissue, and muscle are either dead or partly devitalized over a very large area, and I have described how microscopic examination shows that the injury is really very much more extensive even than it appears to be. It is in the widely extravasated blood and in these dead and dying tissues that the anaerobic bacilli in particular find an unresisting prey, and it is a matter of daily experience that in the very large shell wounds of the shoulders and pelvic region, where amputation cannot be performed, gangrene almost inevitably supervenes. In simple flesh wounds it is quite rare, and the peritonium is practically immune even when the abdominal wall is fatally infected.

Streptococcal Infection.

Much of what I have said of the anaerobic bacilli is true also of the streptococcus, which is found in such large numbers by Mr. Fleming, for Sir Almoth Wright has specially pointed out that this organism, like the anaerobic bacilli, also grows with extreme rapidity. It is therefore evident that in the wounds in France there are at least two organisms with which in civil practice in England we are not familiar, and the whole group of faecal bacilli has been hitherto comparatively unknown in modern surgery. It must, of course, be evident that the common pyogenic streptococci and staphylococci are also liable to infect wounds in France as well as in England.

Effect of Exposure on Wound Infection.

But, important as are the nature of the wounds and of the microbic infection, if we are to realize to the full the conditions that favour the growth of organisms we must turn from the conditions of the wounds to the conditions of the patients, for the wounds that undoubtedly do the worst, apart from the severity of the injury, are those in which the patient could not be rescued for some time, and has been left lying out and got thoroughly chilled, or has had severe bleeding, and these two conditions are often combined.

As I see it, the whole picture is much as follows: The man is wounded, and simultaneously inoculated with organisms which immediately fasten upon any dead tissue. The safety of the patient depends for the time on his own inherent ability to resist, and if he is collapsed from loss of much blood, and is wet, cold, and starving, his leucocyte defence is enfeebled or absent; the bacteria grow unopposed, and either destroy the unresisting dead or partially devitalized tissues locally, or else, in addition, poison him by their toxins. The condition of the man himself to a great extent determines the reaction of the injured part, and must be taken into consideration, together with all the local complications, if the infections of wounds are to be really understood.

It is very natural, therefore, that suggestions should have been made for the application of an antiseptic agent by the wounded man himself or his comrades as soon as he is wounded. But, although such treatment sounds plausible, it is really perfectly useless, for not only would very large quantities of any agent be required for the numerous large wounds, but it would be obviously useless to employ antiseptics unless they could penetrate to all injured tissues and unless the wound could at once be protected from further contamination. If the man lies in the open he cannot generally get at his own wound at all, either because of its situation or because he cannot remove his clothes, while he is also tolerably certain to be shot if his movements show that he is yet alive. Or if one pictures to oneself the wounded man lying in a deep and narrow trench, still covered by his muddy clothes, possibly in the dark, and perhaps with a broken limb, his own hands and those of his comrades grimed with mud, and no one know-

ing till clothing is removed where the wounds are situated or how numerous they are, it becomes evident that to apply antiseptics under these conditions is worse than useless, and no one familiar with these conditions would ever think of advising such treatment. It is indeed clear that the very best thing is to get the patient away as soon as is possible to some place where he can be thoroughly treated and kept in safety for a sufficient time, and in the British army that place is in some cases the field ambulance, and in all the worst cases the casualty clearing station.

Antiseptics.

It is at this stage that we find there are two different schools of thought amongst those who are not at the front as to what is best to be done in the treatment of the wound. One school, which draws its experience mainly from the surgery of civil life, would persuade us that all our wounds, if properly treated, should be completely sterilized—at a single dressing if seen early enough—by the application of this or that antiseptic agent, and can only see in any subsequently septic wound evidence that the surgeon's work has not been done as well as it ought. The other school, which draws its limited experience from this present war, asserts that antiseptics are useless as such, and considers that they should not be used at all.

I am myself very decidedly of the opinion that neither school is right, and that, on the one hand, the badly infected wounds in badly injured men can seldom be completely sterilized at a single dressing, and, on the other hand, I am quite certain that antiseptics are useful and necessary for the proper treatment of all the wounds of war, and that they have been of the utmost service.

For many years I have been on the staff of St. Bartholomew's Hospital, and I have seen both the end of the pre-antiseptic days of surgery, and the whole of the antiseptic period since Lister's views became generally accepted. I have seen many changes in methods and practices, and I know full well that in each succeeding decade the results obtained by surgery have been better and better. Consider for a few minutes what is the practice which is commonly accepted as correct for a bad compound fracture of the leg caused by the wheel of a heavy vehicle. My own house-surgeon would proceed much as follows: The patient would be deprived of his dirty clothes and washed, and would then be taken into an operating theatre where every one would wear sterilized gloves and gowns. His skin would be shaved and washed with acetone or ether, and then painted with a 2 per cent. solution of iodine in spirit. The wound would be enlarged if necessary; the dirty ragged skin edges and bits of torn muscle would be cut away; sufficient drainage would be provided; loose bone fragments would be removed; the whole wound would be thoroughly washed again and again with a solution of mercury bichloride (which I prefer to perchloride because it does not coagulate albumin), sterilized or cyanide gauze would be applied, and splints would be fitted to the limb.

And what would be the result? In my experience, in nine cases out of ten the fracture would heal as well as if there had been no wound, and the wound itself would heal either by first intention, if not too lacerated, or else by granulation with the minimum of suppuration if it was extensive and if some of the skin had been destroyed. What has the treatment effected? I should reply that it has at least mechanically cleansed the wound without adding to its previous contamination any microbes on the hands of the surgeon or on his instruments, and that further, it has rendered harmless any bacteria in the skin of the patient, and has both mechanically removed organisms already in the wound and has temporarily inhibited the growth of those remaining, so that the healthy tissues could quickly destroy them.

And if I am told that the antiseptics I have employed to the skin and to the wound itself have played no part, and that sterilized water would have done as well, I should reply that I know by experience that until we did use antiseptics very thoroughly we did not get these results, and that the wounds which have been treated in the manner described have done consistently better than those of previous years. I should add that practical experience has shown that suitable dilute antiseptics have never done harm, and that consequently there can be no possible objection to their use.

But if, on the other hand, I am taken to task as to why we cannot get as consistently good results in war as in peace, my answer is to be found in what I have said—namely, that, in the first place, neither the conditions of the patients themselves nor the character of their wounds are at all comparable; and, in the second, that the microbial infection is also quite different from that in civil life.

And if the question be asked, Are, then, antiseptics to be used in the case of the recently wounded men, and, if so, what good can be expected from them? I should unhesitatingly answer that, whenever possible all these soiled wounds should be treated just as carefully and thoroughly by antiseptics as any dirty wounds would be in any great British hospital, and that exactly the same amount of good is to be expected in recent gunshot injuries from the cleansing of the skin and of the wounds. The ordinary pyogenic organisms, at least, can be eliminated in sufficiently early and favourable cases, and the patient has in consequence a much better chance in his fight against his new enemies. If we cannot kill all the bacteria there is no reason why we should not kill as many as we can, and as we have in civilian practice already succeeded in sterilizing for all practical purposes by a single dressing very many of the septic wounds which we habitually treat, we naturally do not credit those who assure us, as a result of experimental evidence, that this cannot be done, and we not unreasonably hope that we are already succeeding in finding better methods than we have hitherto possessed for the wounds of war and the anaerobic and faecal infections. I altogether object to the attitude that antiseptics never have and never will overcome early sepsis.

The line of treatment I have indicated above, with minor variations such as more extensive excision of injured tissue, has been carried out in thousands of patients in this war, and I claim that practically all those who have had slight wounds, as well as many who have had serious wounds, have done exceedingly well. We have, indeed, had abundant evidence of this both in the way our patients have recovered, and also in the numbers of wounded men who have returned to the colours, and that it should be a satisfaction to every one to know that except when overcrowded by the rush of battle the conditions for the treatment of the wounded in well-equipped operating theatres are not one whit behind the best that can be found in civil life. No better work has been done during this war in the saving of lives and limbs than the thorough cleansing and dressing of severe wounds, whether complicated by fractures or not, and except for the very great difficulties inherent in warfare which I have already described, there is no more delay in conveying the patient to field ambulances and clearing stations than in getting a patient from an accident into a civilian hospital. I am also quite certain that it is most inadvisable to teach that no wound can ever be sterilized by the proper use of antiseptics, for in the first place the statement is contrary to the experience of surgeons for many years past, and in the second it is liable to discourage well intentioned efforts.

Bad Fractures and Shell Wounds.

But if it be asked whether the treatment I have advised can be relied upon to sterilize completely the large lacerated shell wounds and the bad compound fractures, the answer must be that up to the present time neither this nor any other treatment yet adopted and described in the armies of the enemy or of the Allies can claim to have accomplished this end in this class of injury by any single dressing or cleansing, even when the wound is treated at once. It is, indeed, a notable fact that no surgeon who is familiar with the wounds and conditions at the front has ever made such a claim, and it is only those who know these wounds subsequently who are prepared with antiseptics which have each failed when put to trial. And it is for this reason and with this knowledge that we, who see these men soon after injury, say that such wounds should never be treated as if they had been rendered aseptic, and as if they could be safely closed by suture. There is, of course, no doubt that slight and simple wounds may be so completely excised that all infected tissue is removed, and all the surrounding skin cleansed so thoroughly that primary aseptic union may ensue in a large percentage, but no such result as this has been obtained in the very large lacerated wounds where com-

plete excision is an impossibility as a routine consequence of any method of disinfection at a single dressing. The best we can reckon on is that only after several or many days may the wounds become free from dead tissue and virulent bacteria.

DRAINAGE.

It is especially in these cases of bad compound fractures and in the lacerations by shells that free drainage is so absolutely essential, and my colleague, Surgeon-General Sir George Makins, directed special attention to the need for this very early in the war. Colonel Burghard and Lieutenant-Colonel Sargent were each subsequently insistent, yet in spite of this it was some time before we could get free drainage universally adopted at the front, and for the following reason: It became evident that some of the most recently qualified medical officers had been so much accustomed to deal with clean wounds which could be safely sutured, and had got so accustomed to obtaining union by first intention, that they could not believe that the gunshot wounds they treated had not also been satisfactorily sterilized. The fact is that owing to the very success attending the practice of surgery in recent years there was a certain amount of ignorance of septic wounds—an ignorance which is easily accounted for when one considers how very little suppuration is to be found in the wounds in all civil hospitals of the present day. But when sutures were finally given up and large drainage tubes were used freely all the wounds did better, and the stimulus supplied by the work of Colonel Sir Almoth Wright was of inestimable value in promoting sound practice on these lines. Let us clearly recognize, however, that the provision of efficient drainage is no new thing, and that it is, of course, quite easy to appreciate its benefits in the infections by anaerobes when we remind ourselves of the fact, on which I have already laid stress, that the anaerobes live mainly in dead tissue and are quickly killed by healthy cells. It is not material whether they find dead muscle or dead fluid, and the surgical principle that septic wounds should be drained is an established practice of surgery and was thoroughly understood in all its bearings long before the present war supplied so large a field for its use.

MEANS OF COMBATING ADVANCED SEPSIS.

But while we should strive to cleanse all recent wounds, it must constantly be borne in mind by all military surgeons that the longer the time that elapses between the infliction of the wound and the first thorough dressing the more impossible does it become to obtain a good result. I have already pointed out the many reasons why and how this delay is so fatal, but all of them lead finally to one paramount reason—namely, that the longer the wound is left in its primitive state of blood-stained and crushed tissues, contaminated by a bacteria-laden soil and muddy clothes, the more extensive and far-reaching is the growth of the micro-organisms, and the more impossible does it ultimately become to attack them with any hope of immediate success. The more likely, also, is the patient to be already infected beyond hope of recovery, and I have known men who, before they could be rescued, were already dying of the results of the infection by gas-forming organisms. How, then, are we to treat cases where advanced sepsis is definitely established beyond hope of early sterilization?

Hypertonic Salt Solution.

We have the choice between the hypertonic salt solution of Sir Almoth Wright and the use of antiseptics, and each of these has many supporters. The object of each is the same in reality, for it is recognized by the advocates of both that it is necessary for dead tissue to be disintegrated or cut off as sloughs, and for granulation tissue to grow before healing can take place; and as one watches the blood-stained unhealthy discharge from the dead and dying tissues give place to the formation of pus by healthy granulations, one appreciates more clearly than ever before why the older surgeons spoke of "pus laudabile et bonum." They understood that when the velvety granulations and the creamy fluid appeared destruction had ceased and repair had begun, and we recognize to-day, as they did, that there is such a thing as a relatively "healthy" suppuration.

I think that those who prefer antiseptic to saline treatment have found, as in all sloughing wounds and cellulitis of civil practice, that nothing is so good as prolonged immersion in an antiseptic fluid; but unfortunately most of the wounds are not so situated that this is possible. When this is the case then the next best thing is to employ constant irrigation, and very many wounds have done exceedingly well under this method, whether saline or antiseptic fluids have been used. But, whatever fluid is employed, every surgeon knows by an experience which is far more valuable than any other source of information that good results in complicated wounds can only be obtained if the treatment of the wound is varied according to its conditions. It could only be inexperience of wounds that would limit a surgeon to a single form of lotion, and it is the merest truism to say that in complicated and septic wounds a change of lotion or other application is as necessary as is a variation in the diet of the patient.

It has seemed to me that the period during which the saline hypertonic treatment is useful is strictly limited to the separation of sloughing and unhealthy tissue, and that once a granulating surface is obtained throughout it had better be abandoned, for it is generally painful, and if it is continued the skin becomes irritated, the granulations often become exuberant and flabby, and the healing process is correspondingly slow. The use of such well-tried applications as silver nitrate and zinc sulphate may then well prove more beneficial than that of the most potent solution of antiseptics or salines, for to treat wounds according to the daily report on their microbial infection to the neglect of all else is as foolish as it would be to treat every symptom of an illness rather than to treat the patient who is ill.

Hypochlorous Acid.

Within the past few months the treatment by solutions of hypochlorous acid has been most extensively tried, and the methods of producing it, advocated by Dakin and Carrel and Lorrain Smith respectively, seem to most observers to be equally good. Personally I may add that, as far as I have seen, there is nothing to choose between the two solutions, and I think I may safely say that almost all surgeons are pleased with the results obtained in the early treatment of recent wounds, and many have given up other methods in its favour. Where wounds of the hands and feet have been immersed in the solution, they have cleared up with great rapidity, and where extensive lacerated wounds and bad compound fractures have been treated by irrigation many patients have done extremely well. I think that wounds of this class have done better under treatment by hypochlorous acid than under any other, but I cannot say that they have become sterilized as rapidly as the cases recently described by Carrel, and I do not think that the good results he obtained were in wounds of the class I specially refer to—namely, extensive lacerations by shells and bad compound fractures. It is, however, my very decided opinion that the hypochlorous acid treatment is an important advance, more especially when used in recent wounds and before separation has occurred, and I find that it has to a great extent displaced all other forms of treatment in many of the casualty clearing stations. It is generally believed to have prevented the occurrence of gangrene in many bad lacerated wounds and to have arrested its progress in others; and, although I am well aware that it has not always been successful, I consider that it has already been productive of very much good and to be more useful in this class of wound than any other application we have yet tried. It is also a very remarkable fact that, unlike most antiseptics, it can be used in solutions sufficiently powerful to destroy virulent microbes very quickly without at the same time injuring the tissue cells. It should, however, be only used in solution, for if used as a powder, it, like many other powders, is liable to form hard lumps, which obstruct free drainage and so counteract its good effects.

CONCLUSION.

I have now, Mr. President, completed the task I set myself at the beginning of this lecture, and I have placed before you as well as I am able to do in so brief a space of time the circumstances and conditions of our wounded

soldiers in France and Belgium and the nature and treatment of their wounds.

But there remains yet a duty which I feel I owe both to the army itself and to the medical profession at large, and that duty is to express to you how deeply I feel the whole country is indebted to the medical officers in whose hands are ultimately placed the duties of caring for our sorely tried soldiers.

I do not propose to say one word about the general efficiency of the corps to which I have the honour to belong, for it needs no words of mine. What I do wish to say is that nothing has impressed me so forcibly or so favourably as the qualities of many of the younger surgeons on whom has rested the chief stress of the actual treatment of the wounded. There is not a medical school in Great Britain or Ireland that has not reason to be proud of its pupils, and the work of the surgeons has been equalled and supported by that of their pathological colleagues.

I do not know whether to admire most the energy and keenness which has enabled the staffs to work days and nights without adequate rest, or the technical surgical skill in the complicated and difficult operations on the abdomen and limbs alike, which has been so conspicuous a quality in so many officers. The care, the zeal, and patience displayed in efforts to save limbs and life have been no less praiseworthy than operative dexterity.

The Royal College of Surgeons of England has influenced and guided the teaching of surgery during many years, and all who have shared in this responsibility may feel a legitimate pride in the splendid work now being done by its pupils. "The tree is known by its fruit," and the future of British surgery is in safe keeping, for many of the best brains and hands which guide its course are yet young.

IODINE AND SODIUM HYPOCHLORITE AS WOUND DISINFECTANTS.

BY

HARRY SCHÜTZE, M.D.,

LISTER INSTITUTE OF PREVENTIVE MEDICINE, LONDON.

WHILE the use of iodine and the recently revived hypochlorites as surgical disinfectants is of old standing, very little in the way of laboratory records of their efficacy, particularly with regard to the special difficulties occasioned by the sterilization of wounds, is to be found in the literature, and although the actual lethal effect of a disinfectant on the bacterial flora of a wound to which it is being applied is only one of a number of qualities desired from an antiseptic, it has been thought of interest to carry out a number of comparative tests with phenol, iodine, and Dakin's hypochlorite solution. Noguchi,¹ Turner and Catto,² Kutscher,³ Brünnig,⁴ Réclus,⁵ Firth and Macfadyen,⁶ among others, have investigated the sterilizing power of iodine, but in most cases from the point of view of its application to the skin before operation, in the manner advocated by Grossich.⁷ Based for the most part on the older thread and garnet methods, the results are in marked conflict. Firth and Macfadyen employed both the thread and Riddell and Walker's drop method, and used as test bacteria *B. prodigiosus* and *B. typhosus*; with the latter they determined as well the efficiency of iodine in the presence of a certain amount of urine.

In the experiments which are described below the drop method was followed; the organisms used were *Staphylococcus aureus* and *B. oedematis maligni*, as examples of the sporing and non-sporing groups; and, as a test of the efficiency of the disinfectant in the presence of organic matter, in one series disinfection was carried out on bacteria suspended in distilled water; in another series on bacteria suspended in sheep serum.

In the case of the staphylococcus, an emulsion was prepared in distilled water and in serum from a twenty-four hours agar shape culture. These suspensions were then counted in Thoma-Zeiss slides; the predetermined density was effected, and to 4 c.cm. placed in a sterile test tube were added 4 c.cm. of disinfectant. In this way both emulsion and disinfectant were diluted one half, and it is in this ultimate working strength that the disinfectants

and emulsions are reported in the tables below. Each test tube had its own 1 c.cm. pipette bound in with the cotton-wool plug, the two being removed together when it was required either to open the tube or to take out a measured quantity of its contents.

To determine when sterilization was complete a 0.1 c.cm. sample was taken from time to time by means of the pipette and dropped—when iodine was the disinfectant—into 0.2 c.cm. of a 10 per cent. sodium thiosulphate solution placed in a sterile Petri dish—when phenol was the disinfectant into an empty Petri dish; the plates were then poured with agar. An incubation of one to two days revealed whether the sample taken was sterile or not, sterility being roughly taken as meaning the disinfection of all bacteria present in the disinfectant emulsion mixture.

As a control of a possible inhibitory power of the neutralized iodine or of the surplus sodium thiosulphate in the amounts used in the experiments a series of plates was poured as given in Table I. The figures tend to show—and on other occasions similar results have been obtained—that inhibition of growth does not occur at all, but that, on the contrary, in those samples in which iodine and serum are present a somewhat greater number of colonies is obtained, either owing to a stimulating effect of these substances on the growth of the cocci, or more probably as a result of clumps of cocci being broken up by an alteration in surface tension.

TABLE I.

Number of cocci per c.cm. of a *Staphylococcus aureus* emulsion estimated from an average of four agar plates, poured after the addition of 0.1 c.cm. of the emulsion to a Petri dish containing:

0.1 c.cm. (serum and iodine) neutralized with		
0.2 c.cm. sodium thiosulphate:		
Not mixed before plating	2,412	
Mixed before plating	2,570	
0.2 c.cm. sodium thiosulphate:		
Not mixed before plating	2,155	
Mixed before plating	2,210	
0.2 c.cm. distilled water:		
Not mixed before plating	2,007	
Mixed before plating	2,250	

The serum-iodine mixture was one containing equal parts of sheep serum and 2½ per cent. iodine in 5 per cent. potassium iodide. The sodium thiosulphate solution = 10 per cent.

TABLE II.

Disinfectant.	Environment.	14.5 Million <i>Staphylococci</i> per c.cm. at 22° C.	
		Are not all Killed after	Are all Killed after
0.0015 % iodine	Distilled water	—	2 minutes.
0.125 % iodine	50 % serum	16 minutes	32 minutes.
1.0 % phenol	Distilled water	16 minutes	33 minutes.
1.0 % phenol	50 % serum	32 minutes	—
1.5 % phenol	50 % serum	8 minutes	16 minutes.
1.75 % phenol	50 % serum	4 minutes	8 minutes.

In the experiments with malignant oedema spores, the method of procedure had to be slightly varied. To obtain a finely divided emulsion, a seven to nine days' old broth culture of *B. oedematis maligni*, which generally contains about one fully developed spore to three or four rods, was centrifuged and the deposit resuspended, partly in distilled water and partly in serum. After enumeration in Thoma-Zeiss slides and regulation of the number of spores per cubic centimetre according to one's wishes, 4 c.cm. of emulsion were added to 4 c.cm. of disinfectant. When the disinfectant was iodine or hypochlorite, the sample taken as a test of sterility was 0.2 c.cm. in amount, and was dropped into 0.4 c.cm. of 10 per cent. sodium thiosulphate, contained in a sterile test tube; after neutralization 0.15 c.cm. of this, representing 0.05 c.cm. of the original disinfectant-emulsion mixture, was dropped into a test tube of meat medium, and incubated under anaerobic conditions for five to seven days. The meat medium employed consisted of finely minced fat free meat, preferably heart muscle, autoclaved with a small quantity of water and brought well to the alkaline side of the litmus neutral point; the meat is then ground to a paste in a mortar, and

portioned off into test tubes with sufficient of the liquid extract to cover the fine meat deposit half an inch or so; the tubes receive a final sterilization by steam at atmospheric pressure or by autoclave. The medium has been found by Miss Robertson, working in the institute on the anaerobe group, to be one of the best for the growth of *B. oedematis maligni*.

Where the disinfectant used was phenol, 0.05 c.cm. of the disinfectant-emulsion mixture was dropped directly into the meat tube. The higher concentrations of iodine were obtained by dissolving in a potassium iodide solution double the percentage of the iodine required. The hypochlorite solution was prepared according to Dakin,⁵ and consisted of a mixture of bleaching powder and sodium carbonate solutions neutralized with boric acid. That used in these experiments was very kindly prepared, and its percentage of sodium hypochlorite estimated, by Professor Harden. It will be observed that the amount of sodium hypochlorite in the solution fell from 0.337 per cent. to 0.24 per cent. after an interval of eight days, during which period the solution stood in a corked glass cylinder on a laboratory bench.

TABLE III.

Disinfectant.	Environment.	102 Million Malignant Oedema Spores at 19° C.	
		Are not all Killed after	Are all Killed after
Dakin's solution, diluted one half, containing 0.1685 % NaClO	Distilled water	—	½ hour.
Ditto	50 % serum	5½ hours	—
5 % iodine	Distilled water	1½ hours	2 hours.
5 % iodine	50 % serum	2 hours	3½ hours.
10 % iodine	Distilled water	½ hour	1 hour.
5 % phenol	Distilled water	8 days	—

Table III shows the failure of 5 per cent. phenol to sterilize malignant oedema spores and the difficulty with which iodine does so, whether serum be present or not. Dakin's solution, even in half the strength at which it is usually employed, is, on the other hand, in the absence of serum, most effective, though, as seen in Table IV, even small quantities of serum can interfere with its action; this would lead one to expect no direct lethal effect of the solution on similar resistant spores embedded in the tissues of a wound unless by irrigation the serous fluid surrounding those spores could be replaced to well above 95 per cent. by the hypochlorite solution.

TABLE IV.

Dakin's Solution (full strength, containing 0.24 % NaClO and Sheep Serum).	Serum.	84 Million Malignant Oedema Spores per c.cm. at 15° C.	
		Are not all Killed after	Are all Killed after
80 %	20 %	6 hours	—
90 %	10 %	6 hours	—
95 %	5 %	5½ hours	—
99 %	1 %	10 minutes	20 minutes.
100 %	—	8 minutes	16 minutes.

THE Director of the United States Bureau of Mines recently announced that the cost of radium had been reduced from £24,000 to £7,200 a gram. This reduction is the outcome of the work of the research bureau which has been engaged during the past year in studying the problem of the cheaper production of radium.

THE USE OF QUININE HYDROCHLORIDE SOLUTION AS A DRESSING FOR INFECTED WOUNDS.

By KENNETH TAYLOR, M.A., M.D.,
PATHOLOGIST, AMERICAN AMBULANCE, NEUILLY, PARIS.

It was found in previous experiments in this laboratory that quinine hydrochloride possessed the following qualifications which are desirable in a dressing solution for infected wounds:¹

1. It had high bactericidal properties *in vitro*, especially marked in the case of the *B. aerogenes capsulatus*, against which it was more than ten times as effective as carbolic acid. It reduced the mortality of experimental gaseous gangrene in guinea-pigs from 100 to 41 per cent. It did not inhibit phagocytosis in the animals treated.

2. It had a strong antiferment (antitryptic) action *in vitro*, preventing the digestion of proteins and the consequent production of a medium favourable to bacterial growth.

3. It formed no stable chemical combination with proteins, so that its activity was not greatly reduced by the presence of serum or pus.

4. It was practically non-irritating when applied in effective concentration to exposed tissues, or even when injected hypodermically into muscles.

5. It was non-toxic when used in adequate dosage, producing no systemic reaction except a frequently desirable antipyretic effect.

6. The cost of the materials used was not prohibitive for general application.

7. It presented no difficulties of preparation and did not alter its composition on standing.

On the basis of these observations the treatment of clinical cases of infected wounds has been undertaken.

The majority of the cases have been subjected to wet dressings of a 1 per cent. solution of quinine hydrochloride in cold boiled water. The same solution has been used for instillation. In about 12 cases a continuous drip of $\frac{1}{2}$ per cent. solution of quinine hydrochloride, with the addition of $\frac{1}{2}$ per cent. of hydrochloric acid or of 1 per cent. of alcohol, has been used. In addition to these procedures, a few patients have received hypodermic injections into the tissues about the wounds of the same solution as that used for wet dressings.

About 125 cases of infection have so far been treated in this hospital with one of these solutions. These cases have been for the greater part fairly fresh wounds, having usually been received within forty-eight hours of injury. Most of them (70 per cent.) have been heavily infected with the gas bacillus, and all with staphylococci, streptococci, and the usual flora of putrefactive bacteria. About one-half have had open fractures of long bones of arm or leg.

Clinical Course of the Infections.

Most of the wounds treated with quinine solution have run a very favourable course. There has been a rapid improvement in the appearance of the wound itself, manifested by the speedy disappearance of the sloughs, by the vanishing of the putrefaction odour (frequently within twenty-four or forty-eight hours), by a marked decrease in the discharge, and by the unusually rapid appearance of red vascular granulations.

Nearly all the most serious wounds showing heavy mixed infections, or those showing the presence of the gas bacillus, have been placed upon this treatment immediately, so that control cases have been difficult to obtain. Ten patients, however, on admission to the hospital were treated with dressings other than quinine; the treatment was continued for a number of days and then changed to the quinine solution. All of them showed sudden improvement associated with the change. In three instances there was an almost immediate drop in temperature coincident with a marked improvement in the appearance of the wound.

Bacteriological Findings.

An examination of the discharges from the wounds in a series of 35 cases showing the heaviest infectious bas

been conducted by Dr. Bertram H. Buxton, of this laboratory, with a view to ascertaining the time at which the gas bacillus disappeared from the wounds. The annexed table shows the result of his investigations. It may be noted that the incidence of this bacillus in the wounds decreases rapidly under the treatment. All the 7 cases in which the gas bacillus was obtained in the last culture from the wound showed clinical improvement and a great decrease in the number of bacilli present.

Table of Cases Infected by *B. aerogenes capsulatus*, and Treated by Dressings of Quinine Hydrochloride.

No. of Cases.	Interval between First and Last Cultures.	<i>B. aerogenes capsulatus</i> Present in Last Culture.	<i>B. aerogenes capsulatus</i> Absent in Last Culture.
2	4 days	1 case	1 case
12	10 days	5 cases	7 cases
15	14 days	1 case	14 cases
6	18 days	0 cases	6 cases

In previous examinations of cases infected with the gas bacillus in this hospital it has been found that the organism has usually persisted for three weeks or more in wounds of the same type—for instance, in a group of 19 cases treated with dressings other than quinine hydrochloride the bacillus was found

In 7 cases 10 days after injury.
In 7 cases 30 " "
In 3 cases 60 " "
In 2 cases 100 " "

There appears to be associated with the decrease in the incidence of the *B. aerogenes capsulatus* in the wounds treated with quinine a progressive increase in the occurrence of the *B. pyocyaneus*. It was found in the first series of cultures that while the latter bacillus was reported in only 4 out of 35 cases at the first cultures, it was reported in 14 out of the same 35 cases in the last cultures. This bacillus seemed to occur much earlier in wounds treated with quinine dressings than in those treated with other routine antiseptic solutions. (It was found in previous investigations in this laboratory on the sterilization of pus with quinine that the *B. pyocyaneus* was the most resistant to this alkaloid of the organisms commonly present in pus.)

Special attention has been paid to the leucocytes present in the discharges from the quinine-treated wounds. These cells have shown a healthy appearance associated with the clinical improvement of the wounds, and frequently active phagocytosis of the organisms present, with the exception of the *B. aerogenes capsulatus*, which is rarely ingested by them.

As a result of the observations on the cases treated by these solutions and the bacteriological examination of the wounds, considerable confidence has been placed in the use of quinine as an antiseptic as well as in its specific action upon the gas bacillus. Surgeons at this and other hospitals where the treatment is in use have consistently reported that the wounds treated by wet dressings of 1 per cent. quinine hydrochloride have done unusually well. Several have reported that they are using this dressing exclusively for all types of fresh wounds.

SUMMARY.

1. The clinical experience with quinine hydrochloride has been consistent with the laboratory work previously reported.¹

2. It has been active in ridding heavily contaminated wounds of the gas bacillus.

3. The solution has appeared to act as an antiferment, inhibiting the activity of the putrefactive organisms and reducing the offensive odour associated with them.

4. The solution has not appeared to be precipitated by the serum or discharge from the wounds in the case of the 1 per cent. solution. At this concentration it had been found previously that its bactericidal activity *in vitro* was not very markedly diminished by the presence of serum or pus. The $\frac{1}{2}$ per cent. solution has occasionally shown precipitation when used without the addition of $\frac{1}{2}$ per cent. hydrochloric acid or of 1 per cent. of alcohol. The addition of neither of these drugs has appreciably increased

the bactericidal activity of the quinine solution *in vitro*, but appears to prevent precipitation of the alkaloid caused by the strongly alkaline discharge present in some profusely suppurating wounds.⁵²

5. There has been no report of any injurious effects from the application of any of the methods described above.

6. There has been reported no unfavourable systemic reaction from the absorption of the solution, while a few cases have shown a desirable decline in temperature associated with the substitution of quinine dressings for others.

The cost of the solution should not prevent its fairly general use. The 1 per cent. solution amounts to about 8d. per litre—rather more expensive than some of the other solutions in general use—but as it has seemed considerably to shorten the course of convalescence, it is not regarded as an expensive solution. It is further believed, from observations on *in vitro* experiments, that a solution of $\frac{1}{2}$ per cent. would be effective on the wounds if the acidity of the solution were increased by the addition of $\frac{1}{2}$ per cent. of hydrochloric acid. This latter solution has not been used clinically except on a few cases, each of which has run a satisfactory course.

It is a pleasure to acknowledge the laboratory's financial assistance from Mr. Robert Walton Götzel; the co-operation of Dr. Joseph A. Blake, in whose wards much of the work has been conducted; and the aid of Dr. Bertram H. Buxton, who has made the bacteriological examination of the wounds.

NOTES ON TRAUMATIC AND ARTERIO-VENOUS ANEURYSM.

By CAPTAIN F. L. A. GREAVES, R.A.M.C.

The following notes of one case of traumatic aneurysm and four of arterio-venous aneurysms will afford an opportunity for discussing some of the symptoms and treatment of this condition.

CASE I.—Traumatic Aneurysm of Right Popliteal Artery.

Multiple shrapnel wounds sustained July 25th; admitted three days later. Severe compound comminuted fracture of left tibia and fibula badly infected by *B. perfringens*. There were smaller wounds at the back of both popliteal spaces, which were much cleaner, and no operation was done on them, but the left leg was carefully cleaned up and wide drainage established. Continuous irrigation with isotonic saline was employed and the leg speedily became healthy.

About three weeks after admission a swelling was noticed in the right popliteal space, lying just internal to the biceps tendon. The skin was hotter over it than normal, the swelling was soft and fluctuant, but there was marked expansile pulsation. No thrill was present, palpation elicited slight pain; movement of flexion of the right knee-joint was limited. A definite systolic bruit was heard with the stethoscope over the swelling; this was conducted upwards to the external iliac artery and downwards to the posterior tibial at the ankle and also to the femoral puls. Neither of these vessels was palpable. The foot was quite warm and no swelling or pain was present in the leg.

For two days the swelling increased slightly and was softer and more superficial; after this it became gradually and progressively harder, more defined, and more circumscribed. The skin became cooler and the pulses eventually returned in the posterior tibial and dorsalis pedis arteries. At the time of receipt of injury there was no hæmorrhage from this right popliteal wound. An x-ray plate showed the presence of a bit of metal.

The patient was evacuated for England on September 25th (nine weeks after injury) with a small, firm aneurysm of the right popliteal artery still contracting, a united left tibia and fibula, and all wounds healed.

Treatment of the aneurysm was simple rest, obtained by pillows and sandbags, with the limb in position of slight flexion and elevation.

CASE II.—Arterio-venous Aneurysm of Third Part of Subclavian Vessels.

Single wound from bomb explosion, August 27th, 1915, on the right side of the neck, with severe hæmorrhage, which was arrested by a private soldier compressing the wound with his

⁵² It was reported from one hospital that this solution showed the formation of a precipitate on standing, but it was found that the water used came from a very highly alkaline spring. No difficulty was experienced after the addition of a few drops of hydrochloric acid to the litre.

thumb. Admitted next day, very pale and faint, rapid respiration and feeble pulse; perspiring slightly about forehead and nostrils. There was a wound horizontally placed above the junction of the inner third and outer two-thirds of the right clavicle, and swelling of supraclavicular triangle, and upper pectoral region. Marked pulsation was felt above and below the clavicle and very marked thrill, like the purr of a cat. On auscultation with a stethoscope a loud continuous murmur was heard like the whirr of machinery; the point of maximum intensity of thrill and bruit was just below the mid-point of the clavicle. The bruit was well heard all over the right pectoral region and conducted to the axillary and radial arteries. No radial pulse could be detected, and only a possible brachial puls. The right hand and arm were cold. He had pain in the hand and arm, which was quite paralysed and anæsthetic up to a point 2½ in. above the elbow. Presumably, therefore, a severe injury to the brachial plexus had occurred.

Treatment.—Isotonic solution to the wound, rest and elevation and warmth to hand and arm; he was kept very quiet in semirecumbent posture. The after-history was that of a gradual general improvement; respiration soon became normal, the pulse-rate dropped very slowly, the pain in hand and arm diminished in intensity, but never quite disappeared. No power of motion or improved sensation occurred, and where he picked at the skin of two fingers he developed very indolent little sores. There was never any pulmonary complication. He was evacuated to England on September 1915, in good general condition with the signs of arterio-venous aneurysm much localized, but with a completely useless right arm. X rays showed a bit of metal lying vertically below the mid-clavicle anterior to the upper part of the scapula, below and internal to the coracoid process.

CASE III.—Arterio-venous Aneurysm of Second Part of Right

Clavicle. Single wound on right side of neck from piece of shrapnel from a "whizz-bang," sustained on September 5th, 1915. Not much immediate bleeding. When admitted, three days later, he was pale, with rapid pulse and respiration; he had not coughed up any blood; general appearance that of internal hæmorrhage. Small entrance wound, moderately septic on the right side of the neck close to the inner end of the clavicle. There was a small amount of swelling and ecchymosis over the clavicle and upper pectoral region, and well marked thrill and bruit very like the former case, and conducted in a similar way. The brachial plexus was damaged; he could flex his fingers and use his biceps group. Other muscle groups of arm and hand were paralysed. There were two days' loss of vocal function. A small aneurysm at the right base (? right hæmothorax). The bruit was heard with a stethoscope all over the right chest and conducted to the radial artery at the wrist. The radial pulse was present, but feeble; no swelling of hand or arm.

The general condition improved with treatment similar to that in Case II; circulation in radial pulse also soon improved. The thrill and bruit became more localized to a point internal to the mid clavicular line. He was evacuated to England on October 6th, 1915. The fluid in the chest had cleared up, and his general condition was excellent; there was no improvement in sensation or muscular power in the right arm. X rays showed a bit of metal posterior to the fifth rib 1½ in. from the front of the chest.

In neither of these two cases could the patient hear his own bruit.

CASE IV.—Arterio-venous Aneurysm of Axillary Vessels.

Sustained a circular wound over the upper part of the right deltoid region from a high explosive shell on September 6th, 1915. Some smart hæmorrhage was stopped by dressing. When admitted, two days later, the wound was moderately septic; there was general swelling of right shoulder and slight ecchymosis, and a diffuse swelling extending from the axilla a short distance down the arm on the inner side. Expansile pulsation was seen and felt. A very marked thrill was present. A loud continuous murmur was heard with a stethoscope over the swelling and conducted to the root of the neck and down to the radial at the wrist. The distal circulation was good; the radial artery was easily felt. There was an area of anæsthesia of the hand and forearm corresponding to the ulnar distribution. No loss of motion. In addition to the swelling mentioned, a tumour (? foreign body) could be felt high up on the inner wall of the axilla. No pulmonary complications were present.

The swelling gradually contracted and became harder and more defined; the point of maximum intensity of thrill and bruit also became more localized, the ulnar anæsthesia gradually passed off, and he was evacuated to England on October 12th, 1915. X rays showed a metal fragment on the outer side of the chest wall high up in the axilla, with eight other tiny fragments lying along the track of the larger piece.

CASE V.—Arterio-venous Aneurysm (Femoral).

Struck by shrapnel bullet on outer side of the left thigh on September 6th, 1915; not much hæmorrhage at the time. Admitted two days later with nearly clean entrance wound just in front of the left great trochanter. The general condition was good, but he had pain in the outer side of the left thigh and leg—distribution of long saphenous nerve. A probe introduced into the wound failed to reach the bullet. An x-ray photograph showed a shrapnel bullet in the adductor region. An anæsthetic was given and, the dressing being moved,

Captain Addisell) noticed that there was diffuse pulsation, with a thrill over the base of Scarpa's triangle. No operation was attempted.

When I saw the case, two days after admission, there was slight swelling over the base of Scarpa's triangle, a very marked thrill, and a bruit so loud that it could be heard by approaching the ear to the thigh without touching it. The murmur was conducted to the tibial vessels and upwards to the abdominal aorta. The whole leg was slightly oedematous. Although rest by sandbags and elevation of the limb were used, the leg and thigh became progressively more oedematous, and the pain persisted. After ten days this gradually passed away and the posterior tibial and dorsalis pedis arteries became palpable. The point of maximum intensity of thrill and murmur became more localized to a point just below Poppart's ligament. He was evacuated to England on October 8th, 1915, with his leg normal in size, less pain, and in good general condition.

Having briefly related the symptoms and history of these cases, I should like to compare some points with the description given in Keen's *Surgery* (edition 1914).

1. *Time of Appearance.*—The textbook statement gives from four hours up to many weeks after injury. Three of my cases were noticed on admission—that is, twenty-four hours to three days. The femoral case was not noticed until two days after admission—that is, four days after injury. It is possible that this case was overlooked, but I do not think it likely, as the medical officer in charge had examined it carefully and probed the wound. Possibly the communication between artery and vein took place in consequence of this probing. The popliteal aneurysm I know, from my own observation, had no swelling in the popliteal space until at least a fortnight after admission. That it appeared suddenly was borne out by the fact, for two days after its appearance it became larger and softer and the skin became hot. If one had not been on the look-out for pulsation, it was very like an abscess arising from a foreign body coming up to the surface, and might have been incised with disastrous results.

2. *Primary haemorrhage* is said rarely to be severe, and this was so in all my cases, except possibly in Case 11—the arterio-venous aneurysm of subclavian—where the haemorrhage was stopped by a private soldier.

3. *Local swelling* is stated to be diffuse, at first increasing for a few days and then contracting. This was so in all cases.

4. *Echymosis of skin* is stated to be seen when the vessels are superficial. This was only noticed in one case, and was never a marked symptom.

5. *Thrill*, a very marked and striking symptom, quite absent in ordinary traumatic aneurysm where the vein is not involved. This was well marked in all cases.

6. *Murmur* is described as like the whirr of machinery, or a fly in a paper bag. This describes the condition in all the arterio-venous aneurysms, and is quite different from the blowing systolic bruit heard in the traumatic aneurysm. The pitch of the murmur varies in different cases and also from time to time. In one of the subclavian aneurysms Sir George Makins pointed out the slamming character of the murmur, possibly due to vibration of a tag in the vessel. The murmur is stated to be heard by the patient if in the subclavian or carotid regions. Neither of my subclavian cases could hear his own murmur.

7. *Changes of Pulse.*—The pulse is said to be fuller than normal proximal to the aneurysm, and absent or feeble distal to it. This was so in all cases.

8. *Superficial veins* above or below the aneurysm are said to be (a) dilated—very slight dilatation of veins was seen in one subclavian case, none whatever in the others; or (b) tortuous—not seen in any case; or (c) pulsating with systole—not seen in any case.

9. *Peripheral temperature* is stated to be lowered at first, but soon compensated. Cold extremities were noticed in four out of five of my cases, but it is important to note the coincident damage to important nerves in those of my cases in which this coldness was noticed.

10. *General Effects.*—Faintness and rapid pulse until the system has learnt to tolerate the altered arrangement of the circulation. This is a very difficult thing to say much about. It is quite true that in both subclavian cases it was noted, but the coincident injury was severe. In the case of the femoral arterio-venous aneurysm, which apparently was formed whilst in our hospital, it was absent. As a whole, my cases all had rather rapid pulses, and they were still rapid—about 100 to 110—on evacuation.

I can say nothing about the secondary result of these

lesions, and I much regretted having to part with the cases before I could observe the effect subsequent to their moving about.

The question of after-treatment also does not come into the scope of this very imperfect note.

ARTERIO-VENOUS ANEURYSM: ANASTOMOSIS OF VEIN, AND SUTURE OF ARTERY.

By H. J. GODWIN, F.R.C.S.E.,

SENIOR SURGEON TO THE ROYAL HAMPSHIRE COUNTY HOSPITAL, WINCHESTER.

In the following case arterio-venous aneurysm of the popliteal vessels, caused by gunshot wound, was successfully treated by end-to-end anastomosis of the vein and suture of the artery.

Private H. was wounded on November 2nd, 1914, in France, the bullet passing through the lower third of the right thigh; it was a clean wound and healed up quickly, but an arterio-venous aneurysm developed.

On November 19th he was operated on in France; the surgeon exposed the femoral vessels, did not find the communication, ligatured the anastomotic magna, and closed the wound.

The patient, after being in various hospitals in England, returned to his depot at Winchester for light duty, but, owing to pain and swelling in his leg after exercise, was admitted to the military hospital, and from there transferred, on April 9th, 1915, to the Royal Hampshire County Hospital for operation. He complained of pain in his right leg, especially after exercise, and said that sometimes his right foot would go white and cold and become very swollen. There was some swelling and oedema of the leg, and on palpation a very distinct thrill was perceptible over the whole of the inner side of the right thigh and popliteal space, and a very loud, harsh, roaring bruit was heard all over the femoral and popliteal vessels. The patient was kept at rest for two weeks, but as the pain returned after allowing him up, it was decided to operate.

Fig. 1. A, Artery. B, Vein. C, Communication between artery and vein. D, Hole in artery after dissecting out communication and refreshing edges. E, Dilated portion of the vein ready for end-to-end anastomosis, the dilated portion having been cut away in order to get healthy vein tissues for anastomosis. F, Artery sutured laterally with fine silk suture. G, Vein sutured, end-to-end anastomosis. H, Graft from internal saphenous vein surrounding the sutured artery, and sutured on opposite side to sutured artery at I.

Operation.

An elongated incision was made in the line of the adductor magnus tendon, giving enough room to have control of the lower end of the femoral and popliteal vessels. It was found that the communication between the artery and vein was just below the opening in the adductor magnus tendon, and that there was quite a small sac between the artery and vein (Fig. 1). A careful dissection of the vessels was made, and Cric's clamps applied to the vessels about and below the aneurysm. On removing the small sac it was seen that the hole in the artery was smaller than that in the vein (Fig. 2). After removing the dilated portion of the vein and excising it as far as healthy tissue, it was found possible to do an end-to-end anastomosis of the vein without producing any tension on the vessel. It was not possible to do an end-to-end anastomosis of the artery because the diameter of the artery on the distal side of the hole was a good deal smaller than that on the proximal side, and because it was found that there would have been too much tension. The edges of the hole in the artery were refreshed, and

the artery sutured laterally with fine silk sutures. A graft taken from the (Fig. 3) internal saphenous vein was sutured to the opposite side of the sutured artery (Fig. 4). The operation lasted two hours. On removing the clamps the circulation was perfect, and there was no haemorrhage from the line of suture. The wound was closed without drainage and the stitches were removed on the tenth day.

The patient made an uninterrupted recovery. I examined him five months after the operation; he was then doing light duty, and the circulation in the limb was normal.

THE CHARACTER AND TREATMENT OF FROST-BITE.

By H. E. MUNROE, M.D., C.M.McGILL,
L.R.C.P. and S. EDIN.,

MAJOR C.A.M.C., SURGEON TO SASKATOON CITY HOSPITAL, CANADA,
AND CANADIAN STATIONARY HOSPITAL.

WHILE reading with interest *The Memorandum on the Treatment of Injuries in War*, issued under the authority of the War Office, it occurred to me that, in view of the possibility of another winter campaign and the importance of adopting the proper treatment in "frost-bite," a few remarks on this subject might be of interest to those who, owing to climatic conditions, may not have had an opportunity of treating this injury.

The prophylactic measures, so far as protection of the feet is concerned, may be summed up in three phrases: (1) Loose, water-tight boots should be worn; (2) dry woollen socks changed daily; (3) maintenance of the circulation of the feet by moving them freely.

The toes and heel are the parts most liable to be attacked, and, unless the circulation is re-established by friction or heat, the condition will spread until the whole foot is involved. This extension is painless. Pain is experienced before the part becomes frozen. A few sharp stings following a period of pain is the usual experience. These stings, followed suddenly by cessation of pain, is a sure indication that the limb is being frozen.

I had an opportunity of observing a few cases among the soldiers from Flanders during the winter of 1914-15. They could not be regarded as true "frost-bite," but rather erythema pernio, as the borders of the feet and not the toes were the parts involved.

Three degrees of frost bite were generally recognized: (1) Erythematous, (2) bullous, (3) gangrenous.

1. In the first degree the skin only is affected. The anaemic appearance rapidly disappears with friction or exposure to the higher temperature. The localized anaemia is followed by erythema and occasionally slight oedema, which disappears in a few days.

2. The second degree is characterized by the formation of blebs filled with serum. These blebs, as a rule, appear within eighteen hours of exposure of the part to a higher temperature. The skin is a bluish colour, more oedema is present than in frost-bites of the first degree, which indicates the involvement of the superficial tissues in addition to the skin.

3. The third degree follows the exposure of the part to prolonged intense cold, and involves the skin and superficial and deep tissues. If the part is seen when in a frozen condition it is white, cold, and sensation is absent; on exposure to a higher temperature it assumes a swollen and congested appearance. Within eighteen hours the proximal area of the limb involved assumes the characteristic erythema of the first degree, while lower down the limb we have an area of blebs indicating the second degree of frost-bite. The distal portion of the limb—namely, the heel or toes—becomes cyanotic and later shrunken, and may become definitely gangrenous within forty-eight hours.

The treatment consists in using every available means to prevent an excessive reaction. Left to nature the partially devitalized cells become destroyed by the sudden engorgement of the part. The more severe the frost bite the more oedema is present and the more pain is complained of. If the patient is seen while the part is still frozen, the circulation should be gradually restored by placing the limb in ice-cold water, or by using gentle friction, with snow when available. The part may be covered with gauze or absorbent cotton, which should be

frequently saturated with an evaporating lotion. I use a lotion composed of liq. plumbi subacet. ʒi, spirit. rectif. ʒiij, aquam ad ʒj. When blebs form, they should be punctured. The application of the evaporating lotion is continued for the first twenty-four to thirty-six hours, until the swelling begins to subside or there is an indication of a cyanotic or shrunken appearance in the toes, or fingers if the hand is involved. Hot boracic fomentations should now be employed in order to overcome the reactive vasomotor constriction and consequent anaemia of the parts. This treatment is kept up for twenty-four hours, or until the cyanotic and shrunken appearance disappears or gangrene has definitely formed.

Amputation of a gangrenous area should not be undertaken until the line of demarcation between the dead and healthy tissues is well formed, which indicates the line of operation. While waiting until amputation should be performed, a powder of boracic acid and charcoal may be employed if any moisture or perceptible odour is present.

Memoranda:

MEDICAL, SURGICAL, OBSTETRICAL

APPENDICITIS AND MEDICAL TREATMENT.

I HAVE full notes of 9 typical cases of appendicitis which occurred among the average daily population of 3,000 Indian labourers, consisting chiefly of Tamils and Telugas during a space of eight years. These cases were of all grades of severity, and in at least five of them immediate surgical operation was deemed advisable. But as is well known, the illiterate coelic classes always dread the knife, and owing to the strong opposition raised in every one of these individual cases, the idea of operation had to be abandoned. Blood examination revealed leucocytosis, and there were other unmistakable symptoms of the malady, subjective and objective, present as well. In the last two cases of the series, one a male and the other a female, the life of each was considered to be in imminent danger, as it was thought that infection of the general peritoneum through perforation of the appendix, could occur at any hour. Of these 9 cases, 8 recovered fully under conservative treatment; the one death was in an infant 15 months old. *Post-mortem* examination showed that the appendix was gangrenous and that there was generalized peritonitis; the causative organism of the infection was the pneumococcus; the appendix was widely ruptured, and an orange pip was found adherent to its interior. The adhesions round the affected cul-de-sac were poorly formed and were therefore unable to protect the general peritoneum.

The recovery in the last two cases was really most instructive. A careful consideration of the facts of these cases fully justifies the opinion that even seemingly hopeless cases might at times do well under proper medical care and treatment.

PNEUMOTHORAX FOLLOWING PNEUMONIA.

A BRICKLAYER, aged 40, of healthy appearance, had had a cold for a few days before he sought advice but had been able to continue at work. I saw him about midday on October 6th, diagnosed pneumonia, and ordered the routine treatment.

At 10 p.m. of the same day I was hastily summoned as he was feeling very ill. He had great dyspnoea and marked cyanosis, and pain over the right hypochondriac region, and evidently was suffering from a good deal of shock judging by his small and rapid pulse. Percussion over the right lung and liver areas was markedly tympanic, and with the *bruit d'airain* and a very soft amphoric breathing over the right posterior base gave all the signs of pneumothorax.

The liver on deep pressure could be felt extending to four fingerbreadths below the costal margin, the heart appeared to be little displaced, no fluid could at any time be made out. A few days later the sputum was examined by the thorough bacteriologist, and found to contain numerous pneumococci, a fairly plentiful number of staphylococci, but no tubercle bacilli.

The patient improved rapidly, but the air was slowly

absorbed. I kept him in bed for ten days and then gradually increased the amount of daily exercise. He returned to work on November 4th, a month after the commencement of the illness. Before permitting his return I made him vigorously exercise his arms, and found his pulse very little raised as a result. He appeared and felt quite well.

Treatment consisted in the first place of relieving the pain and shock by a hypodermic injection of morphine followed by small doses of brandy during the night, later by a heart mixture, and a diet carefully chosen to avoid flatulence.

Dr. Arthur Latham informs me that "some few years ago the pneumonia cases at the London general hospitals were analysed for a period of ten years at the Medical Section of the Royal Society of Medicine. As far as I know, in over 7,000 cases there were not more than three complicated by pneumothorax, and two of them proved fatal."

Reports of Societies.

TREATMENT OF DYSENTERY.

At a meeting of the Royal Society of Medicine on December 20th, Sir RONALD ROSS gave a lecture on the treatment of dysentery.

Historical.

In sketching the history of the treatment of dysentery he said that he was a convinced believer in the specific value of ipecacuanha. It was formerly customary to repeat the ipecacuanha at least once a day for about a week or more in spite of vomiting. Later on he used to prefer giving opium every night and the ipecacuanha in a bolus with a single mouthful of milk at about 4 a.m., the patient not being allowed to eat or drink until about 9 a.m. He thought that, with this method, one daily dose sufficed. Later in the case it had been usual to combine 5 to 10 grains of tannic acid with the ipecacuanha, especially in cases of "running" dysentery, but practice was generally opposed to the use of astringents until the disease had first been mastered by ipecacuanha. In those days no distinction had been made between the bacillary and amoebic forms and ipecacuanha was given in both; he was not yet convinced that it was of no value in the bacillary form. Bismuth, calomel, and the sulphates of sodium and magnesium were little used, and many were opposed to enemata, at least in recent cases. In chronic dysentery ipecacuanha was often given daily for some weeks, then omitted for another week or so, then begun again, and so on. Enemata were much more certainly useful than in acute dysentery, and silver nitrate was almost a classical drug for the purpose. The dietary was almost a science in itself.

After speaking of the recognition of the intestinal amoebae as pathogenic organisms, which he ascribed to Kartulis, in Alexandria, and of his own studies on amoebae and on intestinal flagellates, he said that it still seemed to him to be safe teaching that all intestinal amoebae and flagellates should be considered potentially dangerous.

Emetine.

He then referred to the introduction of emetine, first recommended by Bardsley in 1829, and given by the mouth by Tull Walsh in 1891. The elaborate studies of Leonard Rogers had first established its use in 1912. It was accepted everywhere, not perhaps as being essentially superior to ipecacuanha powder, but because the hypodermic injection was much less troublesome to the patient. By this method the drug was brought more directly into conflict with the amoebae at the bottom of the ulcers, whilst ipecacuanha did more to attack amoebae on the surface of the mucous membrane and in the lumen of the intestine, so that he favoured the use of both at the proper stage in the treatment. As an immediately applicable routine treatment the hypodermic injection of emetine had become a great boon to humanity. The use of the sulphates of magnesium and sodium had now become almost universal for bacillary dysentery. According to many, ipecacuanha and emetine were powerless against bacillary dysentery, salines powerless against amoebic dysentery.

Recent Experiences.

Sir Ronald Ross then narrated his experiences of the recent cases of dysentery among soldiers. Both forms had occurred largely among the troops near the Mediterranean and the Red Sea. Apparently bacillary dysentery prevailed in the earlier part of last year, but there was certainly an epidemic of amoebic dysentery in July and August. As Consulting Physician for Tropical Diseases, he had had unusual opportunities for studying the practice of the physicians in all the hospitals in Alexandria. Up to June amoebae had not easily been found in Egypt, but towards the end of July they began to be recovered without difficulty in a large number of cases, and this continued till the end of September or later. After that amoebae began to be more scarce, and the amoebic dysentery was likely to be supplanted by the bacillary form in the winter. Unfortunately, however, amoebic dysentery tended to be so chronic a complaint that its treatment continued to be of interest long after the commencement of epidemics, and it was necessary to guard against not only the chronic form, but hepatic abscesses. As soon as the presence of amoebic dysentery was recognized among the troops, emetine began to be employed by, he thought, every officer in charge of medical wards, and the Principal Director issued orders to use it in every suspicious case. This order proved to be very beneficial, for the sooner that treatment was commenced in dysentery the more likely was it to prevail. Every hour counted at the beginning of the infection, and the delay of a few weeks often meant almost irreparable damage to the colon, even if the patient survived. It was useless to wait for laborious laboratory examinations as to the exact nature of the infection, for emetine was so benign a drug that it might well be administered on the chance that the infection was amoebic. The results were remarkable. After the order had taken full effect the newer cases were not so grave as the earlier ones.

The bulk of the troops came from Britain, Australia, and New Zealand, and were therefore men who had never had amoebic dysentery before. Many of the cases were exceedingly grave, and many men died before reaching the base hospitals; those that survived had frequently acquired the condition of "running" dysentery. Among the Indian troops, on the other hand, severe cases were much less frequent; they did not suffer much from the disease, and such cases as occurred were comparatively slight. From this it appeared that a certain amount of immunity to dysentery was acquired during childhood in localities where it was endemic. Among the European and Australasian troops the acute amoebic dysentery had to be dealt with in its most unmodified and malignant form, a point to be remembered in estimating the results from emetine treatment. Equally rapid results could hardly be expected as those obtained by Rogers among Indian patients, yet all were convinced of its remarkable efficacy. Usually doses of 1 grain a day were prescribed, either as one subcutaneous injection or in two doses, morning and evening. Practice differed considerably as to the number of doses administered. In one hospital the rule was that of three days on and three days off, in another of five days on and five days off, whilst many practitioners preferred to give it daily, even for some weeks without intermission. In one hospital three cases of dysentery died without obvious cause, and some suspicion was aroused that it might have been caused by cumulative action of the drug, but the case against the drug was weak. Nevertheless practice gradually crystallized into the formula that unless there was very strong reason for continuing emetine, it should be remitted, at least for a time, after about ten days, especially if it had ceased to do good. In about 10 or 20 per cent. of the cases emetine failed to cure. Most, but not all, of these were patients who had not received emetine early in the infection, and in whom, therefore, the mucosa was probably largely destroyed before the treatment was begun. Emetine could only destroy the parasites in the ulcers, and could not heal the lesions themselves. It was almost certain that in most cases the original trench work of the amoebae was followed by an extensive bacillary invasion of some kind. Complex infections were exceedingly common. Both forms of dysentery occurred together in a certain

proportion of cases, and in others both forms complicated the typhoids, or were complicated by obstinate diarrhoeas, many of the latter being probably due to flagellates. In such cases it could not be expected that emetine would do more than its own proper work; it destroyed the amoebae, but the patient was afterwards obliged to combat the secondary or complicating maladies. The conditions found at 33 *post-mortem* examinations carried out by Lieutenant G. B. Bartlett forced the conclusion that the amoebic ulceration did not always declare itself during life in the form of a typical dysentery which could be diagnosed by the well-known signs. Much mischief might be caused by amoebae without any signs resulting, and in many cases the disease did not manifest itself until some secondary infection had supervened. Indeed, he was much inclined to recommend that emetine should be given to all hospital patients as a preventive measure.

The cases practically divided themselves into two groups—those in which one week's emetine treatment practically resolved the dysentery, and those in which it failed to do so. The latter generally resulted in "running," or even incontinent, dysentery. *Post mortem* such cases always showed most extensive lesions, amounting to almost complete destruction of the mucosa. Many of the severe cases died; others ended in chronic dysentery.

The Sulphates.

The sulphates of sodium and magnesium had long been recognized as invaluable for the treatment of bacillary dysentery. Their purgative action was due to an increase of the secretion of fluid, and to retardation of its absorption. Recent experiments by Cook and Schlesinger suggested that the drugs were first absorbed from the stomach and then caused a rush of fluid from the mucosa of the large intestine. He inferred that the salts in this disease acted simply by flushing out the large intestine and washing away the parasites, amoebic or bacillary, by a strong current from within. This hypothesis encouraged their use in both forms of dysentery, and the practice of administering the sulphates, together with emetine, in the earliest days of a dysentery was becoming almost universal; the emetine killed the amoebae, and the salts washed them and injurious bacteria out of the follicles. In more advanced cases the value of salts was more problematic in the case of amoebic dysentery, and the risk of exhausting patients by further purging had to be guarded against. Many practitioners, however, gave the salts in almost all cases of whatever duration.

"Running" Dysentery.

The treatment of "running" acute dysentery was a difficult problem. Antidysenteric serum was tried in many such cases; it was beneficial in some; other observers had seen little benefit from it, and still others argued that ordinary horse serum would probably have been just as useful. A heaped teaspoonful of bismuth subnitrate three or four times daily, as recommended by Deeks, was largely employed, and he thought, proved distinctly useful. It was generally administered continuously, beginning a day or two after the initial treatment with emetine had been commenced. He had always favoured tannic acid in conjunction, say, up to 10 grains with each dose. It was a good general rule, however, not to use astringents until the specific remedies had had time to take effect. Afterwards opium, bismuth, tannic acid, catechu, and others often succeeded in terminating the attack very rapidly. Many cases became examples of established running dysentery in spite of all treatment.

Collapse.

Collapse was another difficult condition to combat. Lieutenant-Colonel A. H. Lister often used the subcutaneous infusion of hypertonic saline together with 10 minims of adrenalin solution (1 in 1,000) every four hours, hypodermically, with very good results.

Opium was an invaluable drug at certain stages, though some practitioners appeared to fear it.

Enemata.

The use of enemata was a vexed question. There was no question of their value in chronic dysentery, especially when the ulceration was low down, but some felt that they were contra-indicated in very early cases. He could not understand the *rationale* of using massive lavations,

which depressed the patient, and might rupture the thin walls of the ulcers; the morbid purging and the sulphates continually washed the bowel from within. Some objected to enemata on the ground that they might engender secondary infections from without, others adopted enemata as a standard treatment. Thus Professor Kartulis was most confident that tannic acid was most beneficial from the first, Rogers often recommended quinine lavations, and Colonel Lister was an advocate of 3 or 4 oz. of olive oil containing a drachm of ichthyol, preceded by a morphine suppository half an hour before the injection. Silver nitrate had always been employed in chronic dysentery, but nowadays was replaced by protargol or similar salts, which were employed with fairly good results in many of the fresh cases. If lavations were employed at all he preferred warm water without salts, or warm and weak permanganate solution, or warm and weak solution of quinine, but he did not favour this form of medication in very acute dysentery. He did not speak with much favour of appendicostomy, but said that irrigation with oil through the appendix appeared more promising than that with other fluids.

Subsidiary Treatment.

Among subsidiary items of treatment he mentioned the general use of cholera belts or warm applications to the abdomen. Very hot hip baths gave great relief, often lasting for several hours, and could be repeated several times a day if the patient were not too weak. He favoured the use of oils administered by the mouth. A dessertspoonful of olive oil with a pinch of salt might be given several times a day, but the patient soon sickened of it. It might then be replaced by non-purgative medicinal paraffin, or this might be given from the first. He was sceptical whether any particular form of diet presented any real advantage. Cases not given the advantages of perfected hospital diets often suffered least. Large bulks of fluid diet were injurious in very "running" dysenteries and caused sometimes within ten minutes copious evacuations, harmful to the patient. In such cases he preferred a comparatively dry but varied dietary.

Hepatic Abscess.

The most important question of all was the prevention of hepatic abscess. It followed in a large proportion of amoebic infections whether they had presented dysenteric symptoms or not. No history of previous dysentery was obtainable in about a quarter of the cases; in fact, he had often thought that abscess followed the milder cases more frequently than those more severe. The abscesses might appear years after the infection. The only way to avoid this danger was to give courses of emetine or ipecacuanha in convalescent cases every month or so. He suggested emetine in doses of 1 grain for three days every month until the patient was finally returned to duty, whether symptoms of dysentery persisted or not, even in the absence of a positive diagnosis. Acute dysentery was a grievous malady, but it was only the first act of the tragedy; chronic dysentery was the second act, and was still worse; but hepatic abscess was the third act, and was worst of all. Some clinicians thought that ipecacuanha was still useful in the later stages of dysentery, and especially as a prophylactic, and he was inclined to agree with them. Although emetine destroyed the parasites in the mucosa, he doubted whether it had the same effect upon those which were living in the lumen. For these, perhaps, the powder was still useful, and could be administered in smaller doses when emetine had preceded it. For example, 5 grains each of ipecacuanha powder, Dover's powder, tannic acid, and quinine sulphate could be given the last thing at night on an empty stomach without precatory opium, and would not cause vomiting, at any rate after the first few doses. If abscess began to manifest itself, return to full doses of emetine should be enjoined, combined, of course, with suitable diet.

The treatment of chronic dysentery was a very large subject, upon which he had no time to dwell.

Diagnosis.

In conclusion, he referred to two methods of diagnosis. Lieutenant Glasson had worked out a method of diagnosing dysenteric ulceration by means of x rays. A bismuth meal was given and then cleared by means of oil. Some of the bismuth remained in the ulcers and showed in

radiograms. The nuclei of the amoebae could be beautifully and rapidly stained by H. C. Ross's jelly method, but unfortunately permanent specimens were difficult to obtain by this process.

Reviews.

OBSTETRICS AND GYNAECOLOGY.

ANY attempt to divide up the subject of gynaecology into obstetrical and non-obstetrical sections is bound, if pursued far enough, to end in failure. There are certain conditions, it is true, which fall at once into one or the other category, but there are many which cannot either helpfully or scientifically be so classified—conditions which sometimes do and sometimes do not have any etiological connexion with childbirth, or in which the link is too remote to have any important bearing. Disappointment therefore lies in wait for the many who will be arrested by the suggestive title, *The Gynecology of Obstetrics*,¹ assumed by Dr. HADDEN for a volume which purports to be "an exposition of the pathologies bearing directly on parturition." Perusal of the volume shows it to contain a full account of the anatomy of the cervix and of the pelvic diaphragm and floor. The relationship of the anatomical points to the occurrence and repair of cervical and perineal lacerations is well brought out and emphasized. A well illustrated chapter on the pathology of the cervix covers such subjects as primary tuberculosis of the cervix, epithelioma, and adeno-carcinoma. Other chapters deal with ectocele, post operative complications, sterility, bladder infections, and ptosis of the kidney. Dr. Hadden has put much painstaking work into his book, and this deserves every acknowledgment. His views are surgically sound, and much benefit may be derived from a study of the volume. But we must lodge a protest against the title as being misleading in its comprehensive claims. There are several notable subjects omitted that ought to be included if the title is to be justified—for example, the disease of fistulae and of backward displacement of the puerperal uterus, to mention only two of the more obvious. And there are others which have no real place under such a title, such as fibro-sarcoma and primary tuberculosis of the cervix, and ptosis of the kidney. The illustrations are a striking feature of the book. The photomicrographs are excellent, and the coloured photographs of dissections admirably reproduced. It is all the more pity that, as the author himself admits, they are too small to be helpful in elucidating the text. The general appearance of the book is in keeping with the usual high standards of its publishers.

The usefulness and popularity of Professor DE LEE'S *Principles and Practice of Obstetrics*² is evidenced by the appearance of a second edition two years after the first. The author is well known on this side of the Atlantic as the editor of the volume on *Obstetrics* in the Practical Medicine Series, and his work in that capacity must unquestionably have given him an exceptional command of the current literature of the subject. Like most second editions, the present volume is larger than its predecessor; but although it runs to nearly eleven hundred large pages, the actual cubic size and avoirdupois weight of the book have been diminished by the use of a thinner paper. The general get-up of the book is excellent, and the illustrations, many of them specially drawn for this edition, are both lavishly numerous and well designed and executed. It is an eminently practical book; indeed, considering its immense size, it is disappointing to find how abbreviated some of the more theoretical sections are. Some are not up to date either, as, for example, the section on the development of the ovum, in which Peters's original work is closely followed, although in some points his conclusions have been shown to be wrong. While the whole text has been revised, special additions have been made in the sections dealing

with the biological test for pregnancy, "twilight sleep," and extraperitoneal Caesarean section, amongst others. In regard to the first of these subjects Professor DE LEE is wisely non-committal. Such work as has been done upon it in his own clinic indicates that a negative result is strongly against the probability of pregnancy existing. His recommendation that the method should be tested to the fullest extent, in view of the light it may shed on numerous dark problems, will be cordially homologated by all. "Twilight sleep" he uncompromisingly damns. In view of the extremely unbalanced and ignorant advocacy of this discovery in lay magazines and books by writers incompetent to judge its merits or demerits, an authoritative warning of this kind was probably not undesirable, especially in America. We entirely agree with Professor DE LEE that the method is not one to be used indiscriminately in private practice, least of all in general practice, where the physician may often be unable to remain beside his patient all the time. But we cannot help feeling that his own experience of it has been so particularly unfortunate as to have prejudiced his judgement of its value in skilled hands. The section on extraperitoneal Caesarean section offers a very judicious summary of the possible advantages of a method of operating which has been little tried in this country. The author adopts no strong views here, but awaits the result of further trials. In his introduction Professor DE LEE makes a strong plea for the wider recognition of what few would deny to be the fact—that parturition is becoming less and less frequently a strictly physiological act. There may be some difference of opinion as to the percentage of cases in which labour is definitely pathological, but with the general plea there will be unanimous agreement. It cannot be doubted that the fuller recognition of this point would be followed by greater care of the mother in pregnancy as well as in labour and the puerperium, and the benefit which would thus accrue to the race and the State is a subject which in these days merits the most serious consideration.

The editor of the Oxford Medical Publications is to be congratulated upon having secured the services of Dr. COMYNS BERKELEY and Mr. VICTOR BONNEY for the production of *A Guide to Gynaecology in General Practice*.³ Apart from the fact that the wide experience of the authors at once gives it the stamp of authority requisite in a work of the sort, the volume is another example of that very harmonious literary collaboration which they have so successfully established in recent years. There is no patchwork in it; the literary style—easy, fluent, and lucid—is the same from beginning to end; and there is an apparent concord of opinion in regard to the teaching which the authors wish to drive home. The book is more deliberately and successfully designed to meet its specific object than, unfortunately, is often the case. It is arranged for the use of general practitioners and there is no attempt to make it subservient any secondary purpose. Accordingly it is not loaded with any unnecessary information, and everything is put as concisely as perspicuity permits. The limitations of time and opportunity under which the general practitioner has to do his work are always wisely borne in mind, and he is never left in doubt as to which method of treatment is thought most desirable by the writers in cases where there is a choice. The book is divided into several sections, the first of which is devoted to the examination of the patient by abdominal, vaginal, and bimanual methods, and to the diagnostic use of such instruments as the speculum and uterine sound. The second section deals with the significance of symptoms—menorrhoea, haemorrhage and other discharges, pain, and sterility. This is followed by a discussion of the interpretation of physical signs, which forms the longest section of the whole. Then comes a section on treatment; and, lastly, what is more or less a novelty, a section upon the medico-legal aspects of gynaecology. Between the various sections there is an elaborate series of cross-references which is calculated to save the reader much time and unnecessary hunting in the excellent and very complete index.

¹ *The Gynecology of Obstetrics: An Exposition of the Pathologies bearing directly on Parturition.* By D. Hadden, B.S., M.D. New York: The Macmillan Co. 1915. (Roy. 8vo, pp. 213; 63 figures, 14 plates. 7s. net.)

² *The Principles and Practice of Obstetrics.* By J. R. De Lee, A.M., M.D. Second edition, thoroughly revised. Philadelphia and London: W. B. Saunders Co. 1915. (Imp. 8vo, pp. 1087; 917 figures. 35s. net.)

³ *A Guide to Gynaecology in General Practice.* By C. Berkeley, M.A., M.B., M.C.Cantab., F.R.C.P. Lond.; and V. Bonney, M.S., M.D., B.Sc. Lond., F.R.C.S. Eng., M.R.C.P. Lond., Oxford Medical Publications. London: H. Frowde, and Hodder and Stoughton. 1915. (Cr. 8vo, pp. 475; 160 figures. 2s. net.)

In the section on treatment the authors have, very judiciously we think, omitted all details of operative methods. The practitioner who wishes to operate himself, or is by force of circumstances compelled to do so, will in any case require more detailed instructions than could well be given in a book of this kind without enlarging it to a burdensome extent. The medical aspects of treatment, on the other hand, receive full attention, and many useful prescriptions are given, the quantities being stated both in the ordinary and in the decimal scales. Two or three useful pages are devoted to the treatment of a class of cases very familiar and very troublesome, but usually ignored altogether in textbooks—cases of abdomino-pelvic pain in which no physical signs can be detected. Many harassed practitioners will welcome not only the suggestions as to treatment, but even the frank avowal that the existence of such cases is recognized by the most experienced. The discussion of the less common problems, such as sterility, is very satisfactory, and the family practitioner who is called upon to give judgement in regard to sexual union and relationships of his patients will find full and wise guidance. The chapters on medico-legal questions will be of the greatest value. They include sections on the nullity of marriage, rape, a full discussion of that thorny problem—the attitude and responsibility of the physician in cases of criminal abortion, known or suspected—and an alarmingly long list of conditions in which the practitioner or gynaecologist may render himself liable to claims for damages. The volume is profusely and well illustrated through the pencil of Dr. George Dupuy. The only slip we happened to notice is in the legend under Fig. 135, which is called a cyst of the right "labium minora"! The book is well got up and strongly bound. From every point of view it forms a very distinct enrichment of the Oxford series.

*Operative Gynaecology*⁴ is a modern treatise of a type familiar to those who study the finely illustrated textbooks and "systems" issued in the United States. The first ninety-four pages of the treatise are occupied by descriptions of operations for retro-displacements of the uterus, then follow fifty-two on prolapse of the uterus and bladder, three on chronic inversion, and forty-five on pelvic floor relaxation and fistulae. Dr. CROSSEN admits that the treatment of displacements of the pelvic organs is unsatisfactory, and, in reference to methods which have been employed to hold the uterus in anterior position, he judiciously reminds us that "certain factors in uterine support are not yet fully understood in physiological conditions, much less in pathological conditions." The reader cannot but be struck by the multiplicity of operations still in favour, a certain indication that surgery is yet far from a solution of the question. The illustrations, nearly all made by Mr. Ivan Summers, are good and instructive. The application of sutures is indicated much more clearly than in most works of this class. As in all current books on gynaecology, ovariectomy occupies a very small space, compared to what would have been the case had the treatise been issued thirty years ago. Dr. Crossen, like most younger authorities, seems to dread a short incision as much as Spencer Wells and Lawson Tait feared a long one. It is satisfactory to find Dr. Crossen teaching that "a patient who has a small fibroid that is causing no symptoms requires no treatment for the fibroid." He advises that when the fibroid must be removed, supravaginal hysterectomy "is the form of operation preferable in most cases." The physiological and technical advantages of leaving the cervix and keeping the pelvic floor intact are, he considers, beyond question, though he does not deny that malignant disease of the stump has frequently been noted. To amputate the cervix with the uterus in every case would be an easy solution of the problem as far as the operation is concerned, but the mortality and the morbidity would both be higher, and Dr. Crossen holds that the necessary security can be obtained by proper inspection of the cervix before, during, and even after operation; if in the subsequent examination of the specimen any suspicious area be proved to be malignant on microscopical examination, the cervical stump must be promptly removed. Radical procedures for the extirpation

of carcinoma of the cervix are described at full length with a copious supply of instructive illustrations, among the best of which are those which indicate the manoeuvres for keeping the ureters intact and for treating them if wounded. Unfortunately bladder complications of a distressing nature not rarely develop many months after a "successful" operation, even by an experienced operator. As to radium therapy and roentgenization, Dr. Crossen expresses the opinion, which will command general agreement, that until they can show as large a proportion of permanent cures as can be claimed by radical operations they cannot be recommended in removable tumours. Dr. Crossen very properly avoids any suggestion that operations on the pelvic or external organs of relatively small extent are "minor." "The excision of a cyst of the vulvo-vaginal gland is a small operation, but not so simple as might be imagined by the inexperienced. The tendency to haematomata present in all the loose connective tissues of the genital tract, is especially marked here because of the masses of veins (the bulbs of the vestibule)." We regret to find that Dr. Crossen cannot dispense with stem pessaries, though he rejects the vaginal holder, once held to be an essential part of the stem. As far as description can teach the reader, Dr. Crossen's work is an excellent guide.

FORENSIC MEDICINE AND TOXICOLOGY.

THE title-page of Professor BUCHANAN'S *Textbook of Forensic Medicine and Toxicology*⁵ states that it is the "eighth edition, revised and enlarged"; the preface tells us that it is the forensic medicine and toxicology section of the late Dr. Husband's work on these two subjects combined with hygiene. Accepting the latter view, our only objection to Professor Buchanan's editorship is that he has so altered the dimensions of the volume that it will now no longer fit an old coat pocket as a companion; otherwise he is to be sincerely congratulated on the new garb with which he has clothed the old "Husband," for it seems to have been almost entirely rewritten and vastly improved in the process.

A textbook intended for students and young practitioners must necessarily be written in a somewhat dogmatic style, otherwise principles are lost in discussion. Professor Buchanan seems to us to have hit a very happy mean between dogmatism and discussion. Those tables of points, to be noticed in various subdivisions of the subject which admit of no discussion, are full enough for students and for refreshing the minds of practitioners, while the more debatable tables which have to be treated by the touchstone of experience are elucidated by just enough discussion to enable experience to dovetail in with them. Perhaps the happiest illustration of Dr. Buchanan's success is the section dealing with the distinction between the two questions, "Has this child breathed?" and "Was this child born alive?"—a distinction which it is particularly difficult to drive into the student mind; he has said just enough on the subject without confusing the very important distinction between the two positions.

We can very strongly recommend the book to all students, and prophesy that if it be, as it would seem to be, Dr. Buchanan's first edition, it will speedily reach the position which the title-page claims for it.

There is an unfortunate error in the make-up of the book, which we hope will be remedied in the next edition; the pulse tracings taken "after execution by hanging," should be so labelled and inserted between pp. 126 and 127, instead of being left without a title and placed between pp. 120 and 121, to which they have no reference.

HAEMATOLOGY.

DR. GORDON R. WARD'S book on *Bedside Haematology*⁶ is intended to serve as an introduction to the clinical study of the so-called blood diseases; the author holds that the subject has been unduly overshadowed by exclusively pathological investigations. After a short discussion of the blood-forming organs, the marrow, lymphoid tissues,

⁴ *Textbook of Forensic Medicine and Toxicology*. By R. J. M. Buchanan, M.D., F.R.C.P. (Lond., etc.). Eighth edition, revised and enlarged. Edinburgh: J. B. and S. Livingstone, 1915. (Demy 8vo, pp. 427; 46 figures. 7s. 6d. net.)

⁵ *Bedside Haematology: An Introduction to the Clinical Study of the So-called Blood Diseases and of Allied Disorders*. By G. R. Ward, M.D. (Lond.). Philadelphia and London: W. B. Saunders Co., 1914. (Roy. 8vo, pp. 391; 45 figures. 15s. net.)

⁶ *Operative Gynaecology*. By Harry Sturgeon Crossen, M.D., F.A.C.S., Associate in Gynaecology, Washington University Medical School, etc. London: Henry Kimpton, 1915. (Sup. roy. 8vo, pp. 670; 770 illustrations. 31s. 6d. net.)

and the spleen, a description is given, with suitable illustrations, of the blood and its cells, and in a separate chapter a detailed account of the method of making a blood examination. Thereon follows a discussion on generalized affections of blood-forming tissues, and the consideration of this subject is succeeded by an account of localized affections of blood-forming tissues, and by a series of chapters on other conditions in which the blood is affected. The author gives a classification of some forty blood diseases and allied conditions, in which the attempt is made to arrange the disorders in accordance with their pathological causation. The attempt is bold, and certainly appears to break new ground. It is interesting to find Dr. Ward describing chlorosis and haemophilia as "primary affections of the plasma," a view that is worthy of full consideration even if it does not command immediate acceptance. Good clinical descriptions of the various diseases treated are given, while diagnosis and treatment are fully described. Although Addisonian (or pernicious) anaemia is said to be a specific infection of the alimentary tract nothing is said as to its treatment by intestinal disinfectants, a line of therapeutics not infrequently adopted. The book is well worthy of study by medical practitioners who have to treat patients with disorders of the blood.

CERTIFIED INSTITUTIONS FOR IDIOTS, IMBECILES, AND FEEBLE-MINDED.

THE Earlswood and Royal Albert Asylums are now known respectively as the "Royal Earlswood Institution for Mental Defectives" and the "Royal Albert Institution, Lancaster, for the Feeble-minded of the Northern Counties"; and it would seem that, in view of the statutory definition of the term "feeble-minded" connoting one only of the four classes into which mental defectives are divided for the purposes of the Mental Deficiency Act, the designation adopted by the Earlswood Asylum is the more accurate, as both institutions receive cases belonging to each of the four classes. In the report of the acting medical superintendent of the Royal Albert Institution we find an animadversion upon the difficulty some certifying practitioners experience in selecting the appropriate statutory term, and the impression that "feeble-minded" is inclusive of all types may perhaps be fostered by the title of the institution. Further, the fact may not be generally known that Section 3 of the Mental Deficiency Act requires that where the defective is not certified as an "idiot" or "imbecile" the medical certificates must be endorsed by a judicial authority before becoming legally valid.

The report for 1915 of the Royal Earlswood Institution refers to the year ending December 31st, 1914. The board of management, in alluding to the alteration in name, notes that the word "asylum" does not now convey exactly the same idea as it did in 1847, when the pioneer labours of this national institution began. The effect of the war in curtailing subscriptions to permanent home charities is mentioned, as also the increased expenditure entailed by the enhanced cost of provisioning so large an establishment. The new regulations (termed "provisional") made by the Secretary of State under the Mental Deficiency Act are criticized as likely to defeat the intended object of legislation—to retain the feeble-minded under control—by imposing hardships on poor parents as regards cost of certification and unnecessary clerical labour upon officials by requiring a multiplicity of notices and reports not appropriate in the cases of stationary and unimprovable patients. Favourable reports from Visiting Commissioners of the Board of Control are quoted. The financial statement shows amongst receipts over £10,000 in voluntary contributions and £16,000 in payments for patients, in addition to legacies, income from investments, etc.; but a loan of £1,000 from the bankers has been needed to meet payments amounting in the year to £38,079 (including £1,943 invested).

The report of the Resident Physician and Superintendent (Dr. Charles Caldecott) records the fact that fourteen officials, including Dr. Gage (senior assistant medical officer), are serving with the army and navy, their places being kept open till the end of the war and allowances being made to wives of married attendants when needed.

Trenchant criticism is bestowed upon the legislative changes and administrative regulations under the Mental Deficiency Act, which have had the practical effect of bringing once more the old voluntary charitable institutions for mental defectives under provisions similar to those of the Lunacy Acts, owing to the Idiots Act having been repealed, and no compensatory changes having been introduced into the new Act, as had confidently been anticipated. The consequence has been that, while admissions are rendered more difficult, there is considerable risk of certain cases being injudiciously discharged. The number of admissions during 1914 had been 45 (21 males, 24 females); of discharges 41 (26 males, 15 females)—all but 2 "relieved"; of deaths 10 (6 males, 4 females); so that the number of inmates remaining on December 31st, 1914, was 484 (327 males, 157 females) as compared with 490 at the beginning of the year. The average number resident in 1914 was 490 (335 males, 155 females). The percentage death-rate, calculated on this average was 2.04 (1.78 males, 2.57 females), the lowest rate recorded for many years, and remarkable in view of the advanced age of some of the inmates: 30 per cent. of the deaths were due to tuberculosis and 20 per cent. to pneumonia. Nothing had occurred in the way of infectious disease beyond a few cases of chicken-pox. Investigations as to Wassermann reactions have been undertaken by Dr. Stephen, assistant medical officer.

The fifty-first annual report of the Royal Albert Institution includes the period from July 1st, 1914, to June 31st, 1915. A mournful note is added in the reference to the lamented death in August of Dr. Archibald R. Douglas, who had ably filled the post of medical superintendent for upwards of ten years, in addition to an equal period of medical service to the institution under other designations. The report of the Central Committee refers to war services rendered by its chairman (Lord Richard Cavendish) and by two other of its members, and to the fact that twenty-two of the male staff had joined the colours (two of whom had been killed in action). Six ex-patients, improved by institution training, had also been accepted for military service. Notwithstanding the disturbing effect of the war, an all-round increase of about £900 in receipts had taken place during the year. The financial statement showed an income of over £31,000, including £3,760 in voluntary contributions (legacies amounting to £2,750 odd were invested for the sustentation fund) and £17,574 in payments for patients, while £6,840 is derived from interest on sustentation fund investments. The Central Committee have been earnestly considering how best to extend the activities of the institution in view of the responsibilities cast upon public authorities by the Mental Deficiency Act; and with regard to this, they have had the advantage of conferences with Sir George Newman, Chief Medical Officer, Board of Education, and Sir William Byrne, Chairman of the Board of Control. Extracts are quoted from the official report of a two days' visit made by the Inspectors of the latter board.

The report of the Acting Medical Superintendent (Dr. W. H. Coupland) states that during the twelve months ending June 30th, 1915, 51 patients (31 males, 20 females) had been admitted, 50 (30 males, 20 females) discharged, and 25 (11 males, 14 females) had died, so that 705 patients (462 males, 243 females) remained at the end of the period under review, as compared with 729 (472 males, 257 females) at its commencement. The daily average had been 711 (459 males, 252 females), and the percentage death-rate, calculated on this, works out at 3.5. Seven of the deaths are attributed to tuberculosis, 6 to pneumonia, 1 to acute bronchopneumonia, and 7 to influenza. An epidemic of measles affected 73 patients, and influenza in a severe form was prevalent in the winter months. The addition of a balcony for open-air treatment on the southern aspect of the Rodgett Infirmary is recommended, and would, no doubt, prove serviceable.

The report is embellished with numerous artistic illustrations, which afford graphic representations of the occupations of the patients.

THE American College of Surgeons, which held its fourth convocation in Boston recently, has endorsed the request to American universities to create a distinct degree differentiating the surgical and medical branches of the profession.

British Medical Journal.

SATURDAY, DECEMBER 25TH, 1915.

MEDICAL CERTIFICATION OF SICKNESS BENEFITS IN IRELAND.

THE letter, signed on behalf of the Irish Medical Committee, recommending the acceptance by the Irish medical profession of the agreement for the certification of sickness benefits under the Insurance Act, which was published in the SUPPLEMENT to the JOURNAL last week, p. 224, was sent by the Irish Insurance Commission to every member of the profession in Ireland. Before making its final recommendation to the profession the Committee had to be satisfied by the Commissioners that the main principles—especially those of an ethical character—were safeguarded, and, as stated in the letter which appeared on behalf of the Committee, the Commissioners met the deputation in a friendly spirit, and accepted the majority of the proposed amendments, which they undertook to embody in a memorandum to be circulated to the profession at as early a date as possible. The Irish medical profession is to be warmly congratulated on its well-deserved victory; to win it it made very great sacrifices, and made them cheerfully.

For the proper understanding of the prolonged controversy between the Irish Commissioners, the approved societies, and the medical profession it is necessary to recall how it came to pass that Irish doctors had to fight only the question of the certification of sickness benefits under the Insurance Acts.

The Irish profession was eventually prepared to accept the medical benefit clauses of the Insurance Act as intended to apply to Great Britain, and made representations to that effect to Mr. Lloyd George. In July, 1911, however, the Irish Parliamentary Party decided, with the view of making the bill more popular in Ireland by reducing the contributions of employer and employees, that medical benefit should be deleted from the bill in its application to Ireland. The party sought to justify its action on the ground that the vast majority of the insured had free medical treatment at the hands of the Poor Law medical officers under the Medical Charities Acts in Ireland, which it further alleged, for the first time, was not only an efficient but an excellent system. The decision of the Irish Parliamentary Party caused much dissatisfaction amongst Irish doctors, who felt that it was as the result of gross abuse of the Medical Charities Acts that so many wage-earners in Ireland received free treatment and medicine, and that the opportunity presented by the Insurance Bill should be taken to relieve a very underpaid body like the Irish Poor Law medical officers of the obligation of affording free medical treatment to workers of a class similar to that for which the Insurance Act made provision in Great Britain. Notwithstanding all the representations made by the British Medical Association and the Irish Conjoint Committee for the reinstatement of medical benefits in the Insurance Bill in its application to Ireland, the wishes of the Irish Party prevailed, so that the only question of any interest to the Irish medical profession that remained was the certification of sickness benefits.

At a meeting of delegates representative of the entire Irish profession, held in the Mansion House, Dublin, on June 11th, 1912, amongst the resolutions passed dealing with the new situation was one demanding for the certification of sickness benefits under the Insurance Act in Ireland, 3s. per insured person in rural districts; and in the case of urban districts (with a population of over 10,000) 2s. 6d. per certificate. At this meeting another resolution was unanimously passed making it a cardinal principle that all certificates, in the first instance, for sickness benefits under the Insurance Act should be issued by the medical attendant on the insured patient. No special provision was made by Parliament for a grant to defray the cost of medical certification of sickness benefits under the Insurance Act as it applied to Ireland. In Great Britain the capitation fee for each insured person covered treatment and certification. It was only when Parliament made the additional Imperial grant of £1,650,000 for Great Britain that an equivalent grant became available for Ireland, which the then Chancellor of the Exchequer stated could be used for the purpose of paying for the certification of sickness benefits. Medical treatment under the Insurance Act in Great Britain came into effect on January 1st, 1913, while the payment of sickness benefits did not take effect in Great Britain and Ireland until the following April, and as medical benefits were deleted from the Act in its application to Ireland there was no urgent necessity to arrive at a settlement as regards certification until the approach of April, when the payment of sickness benefits would come into force; and it was not until January 1st, 1913, that the Commissioners met the representatives of the Irish medical profession. At this interview the Commissioners were undoubtedly desirous to come to a friendly arrangement with the Irish doctors, and they believed that owing to the Chancellor's additional Imperial grant for the British doctors they would find no difficulty in providing the full equivalent grant for the Irish doctors, which would have been sufficient to meet their demands for certification. When, however, the chairman of the Irish Commission applied to the Treasury for the equivalent grant, which, at the rate of 2s. 6d. per insured person in Ireland, amounted to about £91,000, the application was refused by the Treasury: though the claim was made on the ground of an equivalent grant, it appears not to have secured the support of the Irish Parliamentary Party, which considered that a considerable portion of the grant should be expended for purposes other than medical certification. A grant of £50,000, however, was made by the Chancellor of the Exchequer, with which, as remuneration for the doctors, the Commissioners formulated a scheme to supply medical certificates for sickness benefits to insured persons in Ireland free of cost. This scheme offered to the doctors capitation fees for the certification of insured persons varying from 9d. in urban areas to 1s. 6d. in rural areas. Though each member of the profession in Ireland was invited to accept the Commissioners' terms, yet so few did that in twenty-two counties in Ireland the Commissioners were compelled to abandon the scheme. In the remaining ten counties, which, especially in Ulster, contained the chief industries of the country, the scheme was only a partial success, and even this was due to the impossibility, from the doctor's point of view, of conducting working men's practices without the medical attendant certifying for sickness benefits, rather than to any satisfaction with the Commissioners' terms. In the twenty-two counties in which the Commissioners failed to form panels of

doctors for certification they appointed as many local doctors as were willing to accept service under the name of medical advisers, whose duties were, for the most part, to certify for insured patients attended by the doctors who had declined the Commissioners' terms. Tempting salaries were offered; in many instances it meant doubling their income, but the duties were so objectionable from a professional point of view that for whole counties only two to four doctors could be found to accept such positions, while there were counties that did not even supply one man. The inconveniences to which insured persons were subjected, as the result of the very vexatious and imperfect arrangements made by the Commissioners for medical certification, can easily be imagined; they were frequently under the necessity of making a special double journey of twenty miles to get a certificate from a medical adviser when they could have got it under other arrangements at their homes or at the house of their medical attendant when undergoing treatment. The Irish Insurance Commission even went so far as to permit approved societies to accept certificates from lay persons. This state of affairs lasted from April to August, 1913, when the Chancellor of the Exchequer was made aware, through parliamentary representations, of the very unsatisfactory state of medical certification under the Insurance Act in Ireland, and he stated in the House of Commons that he had satisfied himself that his original grant of £50,000 was inadequate and that he was prepared to increase it to £201,000, which, so far as it was a question of money, would have satisfied the doctors. Owing to the Chancellor's statement, an early settlement was expected, but in the negotiations that followed, in the hope of arriving at an agreement between the profession and the different interests concerned, some representatives of the approved societies refused to accept any system of medical certification at the hands of the medical attendants, even when supported by a further system of medical referees or second opinions. This led to an immediate renewal of hostilities, as the veto was interpreted by the members of the profession in Ireland as a wanton insult, implying that they were unworthy to be trusted with the discharge of a public duty. This was the condition of medical certification in January, 1914, and, notwithstanding the general protests of public bodies in Ireland, and in spite of the fact that even some approved societies had, in the interests of the insured, repudiated the very unsatisfactory certification arrangements made as the result of the irreconcilable attitude of certain officials of approved societies by the Commissioners, so remained until last summer, when, owing to the friendly offices of Dr. C. Addison, M.P., Dr. Macdonald, Chairman of the Council of the British Medical Association, and the Medical Secretary, Dr. Cox, an interview was arranged between Mr. C. Roberts, M.P., who had assumed responsibility in Parliament for the administration of the Insurance Act, and the representatives of the Irish medical profession. Thenceforward the negotiations for a settlement progressed satisfactorily though slowly, with the result that the new arrangements will come into force on January 1st, 1916. The conditions of certification from an ethical and a monetary point of view are on the whole satisfactory, especially when, as the Commissioners guarantee, they have been amended in some respects.

As regards remuneration, the doctors in rural districts have got their full demand of half a crown per insured person, the mixed urban and

rural areas 2s. per insured person, and in urban areas with over 10,000 population, where the doctors demanded 2s. 6d. per certificate, they are to be paid at a capitation rate of 1s. 3d., which may or may not be the equivalent of 2s. 6d. per certificate. The provisions made in the certification scheme for the appointment of whole-time medical referees have been abandoned for the present lest they might interfere with the supply of doctors for military service. The Commissioners have not reached any final decision as regards the distribution of the money beyond admitting the principle that the remuneration must bear a direct ratio to the work done, and undertaking that they will adopt no scheme that shall not be acceptable to the representatives of the profession.

TRENCH FROST-BITE.

THE results of clinical and experimental observations on the pathology of "trench frost-bite" carried out by Professors Lorrain Smith and James Ritchie, and Dr. James Dawson, in the department of pathology of the University, and in the laboratory of the Royal College of Physicians, Edinburgh,¹ are of considerable interest at the present time, when again a large number of cases of trench-foot are occurring among British soldiers serving in France. How far this renewed incidence might have been prevented by an earlier use this autumn of rubber thigh boots we are unable to say, but it appears that there was considerable delay in their issue in sufficient numbers.

The authors justify their retention of the term "frost-bite" on the ground of its convenience, but explain that the effects observed are broadly divisible into two groups—those in which extreme cold directly and immediately causes death of the tissues, and those in which cold originates an impairment of vitality of the tissues with or without subsequent death of the affected cells. The investigations, which were made at the request of the Medical Research Committee, were partly experiments on animals and partly clinical, the cases observed being soldiers invalided from the front suffering from the affection.

From their experimental investigations the authors conclude that the essential change consists in the damage to the blood vessels. There is probably an initial constriction of the vessels; when this passes off it is due to their damaged condition that the swelling of the feet occurs while the circulation is being restored to the normal. The damage is evidenced by the swelling of the endothelial cells in vessels of all kinds, and by the vacuolation of the muscle fibres in the arterial walls. An excessive amount of fluid is poured out into the tissues, and in some cases the vessels rupture and haemorrhage follows. Along with the injury to vessels there is also an interference with the vitality of the cells of the surrounding connective tissues. Evidence of this was found in the readiness with which fibrin formation occurred in the exuded fluid as contrasted with the absence of thrombi in the blood vessels. Further evidence of injury was afforded by the infiltration of the parts with leucocytes and other phagocytic cells whose function is the removal of the products of tissue destruction. These cells were abundant immediately around the blood vessels, and were scattered through the tissue spaces. The fibrous bundles of the connective tissues were separated by the accumulated fluid, and became swollen and disintegrated. It is considered probable that the etiological factors concerned in the damaging of the vessels and tissues are

¹ *Journal of Bact. and Path.*, vol. xx, p. 159.

complex. The condition may be due, on the one hand, to the direct effects of the cold, and on the other to the starvation of the parts resulting from the vascular constriction and the sluggishness of the circulation generally. The necrobiotic changes affected muscle, but the nerves were found, comparatively speaking, resistant, though oedema was noted in the axis cylinders, and was thought to indicate a slight depression of vitality. The exudation must throw a great strain on the lymphatic arrangements of the parts. Not only are the lymph channels dilated with a fluid richer in proteins than natural (as shown by the presence of fibrin), but the germinative capacities of the lymph glands are called into reaction by the necessity for disposing of the dying cells, of the cellular products, and of the fibrinous exudate which are passing through them.

When the experimental results of moderate wet cold for long periods and those of very low temperatures for a short time were compared, it was seen that there was no difference except in degree. When the results in animals were compared with those observed in soldiers a very close similarity was observed. Though the pathological changes in man could not be observed histologically, it seemed clear that a close parallelism existed between them and the artificial lesions in animals. All the clinical observations could be rationally interpreted in the light of the experimental results.

The nature of the changes produced sufficiently explains the slowness of the recovery in man. For this to be complete not only must there be subsidence of the swelling, but there must be a restoration of the vessel walls so that they can bear the strain of the changes in the circulation which take place in walking, for example. There must also be a clearing of exudates from the lymphatic paths. Both processes require time, and it often happens that, even when the swelling has disappeared, pain, tenderness, and disturbance of feeling still persist; the patient is unable to walk about freely, and any application of warmth to the feet tends to bring back the symptoms.

It is necessary to lay stress on the need for care during the stage when, immediately after the exposure to cold, circulation of the limb is returning to normal. As has already been noted in the *JOURNAL*, LARRY came to the opinion, from his experience during the Napoleonic wars, that the application of heat in these circumstances favoured the production of necrosis. The experimental results recorded by Professor Lorrain Smith and his colleagues bear this out. Although the heat applied by them was below the temperature of the animal's body, yet its damaging effect was clearly demonstrated in oedematous swelling and a considerable amount of haemorrhagic infiltration. The warmth had caused congestion in the damaged foot, and the blood vessels were unable to stand the strain. Dry warm air had less effect than warm water, but under field conditions heat is very likely to be applied to limbs which still have their ordinary coverings saturated with wet mud.

With regard to the way in which the condition is brought about special attention is directed to pressure and constriction. The latter, which may often be due primarily to the boots, may be aggravated through the soldier's common habit of wearing two pairs of socks; and it is noted that in all the cases observed the lesions were confined to the feet and were specially apt to occur in the parts where corns and callosities are common—that is to say, on the inner and outer aspects of the toes, over the joints, on the anterior part of the plantar aspect of the foot, and on

the plantar aspect of the heel. Puttees may not only constrict the leg and so obstruct the circulation, but when wet may cause a continuous loss of heat from the limb, for even when the wearer comes out of the mud it is a considerable time before the interstices of the clothing of the limb are refilled with air, the non-conducting qualities of which are so important to the effect of clothing in maintaining warmth.

MEDICAL EXAMINATION OF RECRUITS.

FROM communications received from medical officers of units both at home and abroad it appears that a serious proportion of men are being enlisted into the army who are physically unfit and who, after a longer or shorter trial, have to be returned home and discharged. This causes great and unnecessary expenditure of energy and money. Stories are going round of men with deformities of the upper limbs, and even the lower limbs, due to injuries received years ago, of chronic epileptics, of men suffering from pulmonary tuberculosis in a more or less advanced stage, and of men suffering from chronic bronchitis and rheumatism, who have managed to pass the examination of the medical recruiting officer. Nobody will attempt to excuse such cases, which must have been due either to carelessness, or to the recruiting medical officer allowing himself to be hustled, or his own judgement to be overborne by too ardent recruiting officers, but we are informed that cases of hernia, and varicose veins, and very defective vision, have also been passed in considerable numbers. It appears also that the standard of fitness in the foot is not always sufficiently high; men with flat-foot, hammer-toe, or bunions cannot stand the hard foot-work entailed by marching, by labour in making trenches, and by fatigues. Many of these men have gone to France or other areas where fighting is going on, and have there broken down and have had to be sent home. No doubt the degree of flat-foot or hammer-toe which justifies rejection is a matter of opinion, but in all doubtful cases it would seem right that the recruiting medical officer should reserve the decision and send the man before the travelling medical board, which periodically visits each unit. The primary duty of these travelling boards is to invalid unfit men out of the army, but we believe that they would equally undertake the duty of deciding whether men were physically fit to be enlisted.

THE BRADSHAW LECTURE.

AS was expected, a large audience awaited Surgeon-General Sir Anthony Bowlby when he entered the theatre of the Royal College of Surgeons of England on Monday afternoon to deliver the Bradshaw Lecture. Having gained experience for many years as a hospital surgeon, and having also served in two campaigns, the lecturer has enjoyed unrivalled opportunities of comparing civil with military surgery. The full text of his lecture is published in this issue. He contrasted the conditions under which war was conducted in South Africa with those that have prevailed in Flanders. The Boer campaign was mostly conducted in dry sunny weather in wide wastes never brought under cultivation, and far from human habitations. France and Belgium are lands of copious rainfall, with frequent cloudy days, civilized and cultivated for nearly two thousand years; their population for long has been dense, their rich loamy soil allows of luxurious crops, is freely manured, and supports cattle, swine, and poultry in abundance. In consequence all septic micro-organisms, including one of the worst, practically unknown in civil life, flourish even deep down from the surface of the soil. Wounds are therefore infected from the first and at the same time are very severe owing to mechanical causes.

Mud, dust, and pieces of stone from the soil or the trenches are blown into the wound; the expansion of gas is alone sufficient to kill, as in one case where numerous minute hæmorrhages were detected in the brain; a bullet in its passage through the tissues exerts great force from within outwards, and imparts its momentum to the fragments of bone that it shatters. Muscles and solid organs are widely damaged, as shown in the microscopical drawings reproduced in the special plate with which the lecture is illustrated, and this far-extended microscopic damage must favour septic complications. As might be expected, Sir Anthony Bowly admitted the beneficial results of subcutaneous or intravenous injection of normal saline solution, of enemata of hot water and brandy, and of pituitary extract. Speaking particularly of the gas-forming anaerobes, now almost unknown in civil practice, he said that they are found in almost every wound in this war; they attack the tissues more rapidly and violently than other organisms, and multiply freely in the dying substance in the midst of the muscles and harder structures damaged by the expanding force of the projectile. While admitting that severe wounds caused by modern projectiles can hardly be completely sterilized at a single dressing, he at the same time expressed his conviction that antiseptics are useful and necessary for the proper treatment of wounds. With regard to the organization for the care of the wounded, he said that except during occasional rushes, when extensive fighting was in progress on a narrow front, the conditions of the treatment of the wounded in war are in no way behind the best that can be found in civil life. He illustrated his discourse by aid of the epidiascope.

PROPORTION OF RECOVERIES AMONG WOUNDED.

THE *Times* published on December 20th a paragraph to the effect that the German newspapers had been supplied "with extraordinary figures concerning the low rate of mortality and the high rate of recoveries among German wounded." The figures for the first month of the war are the same as those given in an article on the proportion of recoveries among the wounded in the German and British armies published in the *BRITISH MEDICAL JOURNAL* of September 11th. So far as the German army was concerned, the statistics dealt with the first eight months of the war, and were taken from an article contributed to the journal of the Danish Medical Society (*Ugeskrift for Læger*) by Louis Fraenkel. The paragraph in the *Times* states that "the monthly average for the first year of war was in the German army," for every 100 wounded, 89.5 fit for service, 8.8 discharged or sent on leave, and only 1.7 deaths. It is added that the German comment on the figures is that "no army in the world can show such favourable returns," and our contemporary's comment is that "if the figures are even approximately accurate, they certainly very greatly impair the value of most of the rough calculations of German casualties." The claim that no army in the world can show such favourable returns is a boast which cannot be accepted without fuller information and more detailed examination. When considering the figures published by the Germans for the first eight months of the war we were able to state that the percentage of wounded who had died in British military hospitals in Great Britain and Ireland during the first year of war was 0.86, the percentage permanently unfit 4.14, and the percentage discharged to duty, on furlough, or sent to convalescent homes, 95. In the German returns originally published the percentages now given as "discharged or sent on leave" were returned as "rejected." This either corresponds to or must include the percentage returned from the British military hospitals as "permanently unfit." Such statistics, however, though they possess a certain interest, do not render it possible to draw any conclusions as to the ratio

of men who have died of wounds to those who have recovered more or less completely, much less do they warrant any conclusions as to the number of those who can again take their place in fighting units. With regard to the first point the figures refer to soldiers treated in the military hospitals in Germany and in Great Britain and Ireland respectively, and it cannot be doubted that a large number of men treated in the most advanced medical units, and on the lines of communication, must have died before they reached the hospitals in Germany or the United Kingdom. As to the second point, it is obvious that much depends on the definition of the terms "fit for service" and "discharged to duty." It is certain that a large proportion of the men in both cases, though they return to the army, will only be fit for light duty in the auxiliary services. In connexion with this subject, we note that in a communication to the Academy of Moral Sciences on December 18th, M. Jacques Bertillon, director of medico-surgical statistics of the French Army, stated that the mortality among the French wounded is now 2.5 per cent. as compared with 5.8 per cent., the rate at the beginning of the war.

THE BIRTH-RATE IN WAR TIME.

In a letter published in the *Spectator* of November 13th a correspondent who signs himself "F." quotes some interesting statistics tending to show that in time of war many more males than females are born in belligerent countries. "F." writes from Lucknow in India, and draws his figures from the births recorded in the *Times*. He finds that for one period in 1914 there were 353 male and 352 female births recorded in this daily paper, whereas for a longer period in 1915 the figures were 1,292 male children and 1,091 female. As "F." himself suggests, his figures are so arbitrary, as indeed is inevitable considering the method of their collection, that they cannot serve as a basis for any general conclusions as to the relative proportions of male and female births. But Dr. Peck, writing to the *Spectator* a fortnight later, is able to bring forward some interesting figures relating to the births recorded in the Chesterfield district, of which he is medical officer of health, that possess a distinctly greater value for the determination of the point at issue. At the census of 1911 the district contained over 38,000 male and 34,000 female inhabitants. During the five years 1909 to 1913 there were born 6,010 male and 5,773 female children, giving the male sex an average preponderance of just over 4 per cent. But during the period May to November 20th, 1915, the male births were 10 per cent. more than the female. Naturally these statistical results would require confirmation and great extension before they could be taken as proving that war is a factor in the increase of the proportion of male births.

THE FIRST OPERATION UNDER ETHER IN ENGLAND.

In the *American Journal of Surgery* for July Dr. F. William Calk, of London, gives an interesting account of the first major operation performed in this country under ether. It was done, as is well known, in University College Hospital by Robert Liston, on December 21st, 1846. That great surgeon had not long before received an account of Warren's historic operation in Massachusetts General Hospital and determined to make a trial of what he described to the onlookers in the theatre as "a Yankee dodge for making men insensible." The anaesthetic was administered by William Squire, on whom its effect had been tested the day before by his uncle, Peter Squire. The patient was Frederick Churchill, a butcher aged 36, who was suffering from disease of the tibia caused by a fall. The limb was amputated, the patient feeling no pain; as he was carried out of the theatre Liston turned to the audience so excited that he had some difficulty in saying, "This Yankee dodge, gentlemen, beats mesmerism hollow."

The following is an extract from the official record of the case: "Not the slightest groan was heard from the patient nor was the countenance at all expressive of pain. This is the first capital operation which had been performed in this country under the narcotising influence of ether vapour, and it was perfectly successful. The patient did not know that the limb was removed, and declares distinctly that he has no remembrance of having suffered any pain, either in the theatre or coming away. There was a great sensation of cold and a desire to be covered up expressed as he was being removed back; and this is remembered now one hour after the operation. It was some minutes after being laid in bed before any pain was felt. There is a remembrance of 'something like a wheel going round his leg.'" After the tedious recovery, with offensive suppuration and slow granulation, usual in those days, the patient was discharged cured on February 11th, 1847. In 1911 Dr. Cook had an interview with an old man of 77 who, when a boy of 13, had had his leg amputated by Liston for white swelling of the knee. The operation was done without anaesthesia a week or two before Churchill's leg was removed under ether. The man said he was blindfolded and taken to the theatre, where he was laid on a table and firmly held there. He had been assured by Liston that the operation would not hurt more than having a tooth out, and, as a matter of fact, although, in his own words, he was bowling all the time, it was not painful; but "then," he added, "he only took twenty seconds to take off my thigh." Nowadays we are perhaps apt to exaggerate the horrors of surgery before the advent of anaesthesia. Dr. Cook says it is recorded that a man on whom Liston performed lithotomy declared that the sensation was not worse than that of being shaved with a blunt razor. But the stories of patients hopping off the table and running away, sometimes to the relief of the surgeon, show what dread was caused by the thought of the operating knife. Yet the blessing which the discovery of ether brought to mankind was not recognized even by some among the leaders of the profession whose business is largely the relief of pain. The following passage from the *Edinburgh Medical Journal* of April 1st, 1847, should be a warning against hasty judgement and premature prophecy in regard to innovations in medicine: "At present various members of the profession think of nothing but the inhalation of ether as a means of mitigating pain, and enabling patients to undergo operations. Before twelve months are completed many shall have recovered from this etherising reverie, and the subject will then be considered on its actual merits." *O cecitas hominum mentes!*

SIR HENRY ROSCOE.

SIR HENRY ROSCOE died suddenly on December 18th at his residence near Leatherhead. He was born in London on January 3rd, 1833, and was a grandson of William Roscoe of Liverpool, the biographer of Lorenzo de Medici and Leo X. From an early stage of his career he showed a bent towards chemistry, which he studied first under Thomas Graham and Williamson at University College, London, and afterwards under Bunsen at Heidelberg. When he was awarded the Royal Medal by the Royal Society, it was for his photo-chemical work with Bunsen from 1855 to 1863, and for his work on vanadium after he had gone to Manchester. As professor of chemistry in Owens College he was, from his appointment in 1857 until his resignation in 1887, one of the small band of men who raised that college from an apparently moribund condition to the great place which it now holds. His name is well known to many generations of medical students by his *Lessons in Elementary Chemistry*, a work which only a master of his subject could have written, and one worthy to stand beside Huxley's *Physiology*. It

was, perhaps, after he began to take an interest in public affairs, and especially after his election to Parliament as Liberal representative of South Manchester, that he did his most important work for science. Before this he had said "the spirit of research must be in the air of the laboratory." He was a man of strong character and convictions, but of a genial temperament, which enabled him easily to make friends, so that his influence with the governing classes became very great. Few men did more for scientific education, both directly and indirectly, than Henry Roscoe. He had lived out his life and died full of honours, but the country very much needs men of his type to day to take up his mantle.

THE NATIONAL DOLL LEAGUE.

AN entirely praiseworthy attempt to raise money for the British Red Cross and the Order of St. John of Jerusalem has been set on foot by the recently organized "National Doll League." This league, backed by a list of influential patronesses, has acquired the rights of an invention known as the "Unconscious Doll Exerciser." The name, perhaps, requires a little explanation. The "exerciser" is a child, aged from 4 to 14 years, who employs the doll in the execution of various exercises or drills of Swedish or eurythmic type, speaking broadly. With each doll goes a large diagram, to be pinned up in the nursery, to show how the exercises may best be performed. The "doll" may be regarded as the spoonful of jam with which childhood is traditionally beguiled into doing what is good for it. Any child who acquires so admirable a doll (in the form of a hospital nurse or a boy scout) as that issued by the league is to be congratulated; the jam is good jam. The "unconscious" stands for the powder traditionally concealed in the jam. The child is to believe that it is playing with the doll when in reality it is going in for a course of stereotyped physical exercises which, to quote the league's pamphlet, "prevents spinal curvature, round shoulders and stooping, promotes suppleness, assures a good deportment, and builds up a vigorous constitution." The doll, made entirely by British labour, is solidly constructed of papier-mâché, strongly articulated in defiance of all anatomical precedent, and provided with spiral springs for its arms that are capable of expanding and contracting as the child does its exercises, holding the doll's hands in its own. The price of the doll is a guinea, and all profits resulting from its sale are to go to the two funds already mentioned. The head quarters of the National Doll League are at 64, Regent Street, W., and the dolls may be purchased either there or at any of the great shops where such toys are usually to be found. We wish the league all success in its effort to combine the amusement of the young idea with its physical training, and trust that it will be able, as it deserves, to make solid financial contributions to the war funds it designs to support.

LIVINGSTONE COLLEGE IN WAR TIME.

DURING the last two-and-twenty years nearly four hundred missionaries have received two terms of training in elementary medical and sanitary science at Livingstone College, Leyton, while over a hundred and fifty more have received one term's instruction. The teaching given at this institution is of very great value to men who have chosen the arduous calling of missionaries in Central Africa, China, and other such countries where health, the prime necessity of life, is precarious and apt to be wholly neglected. To illustrate the excellence of the work done by such centres as Livingstone College the following quotation may be made from a speech delivered six months ago by the secretary of the London Missionary Society: "In the first years of the history of our mission in Central Africa eleven of our missionaries died and six were invalided home and, with one exception, were never able to return to their work. In the last twelve years we have not had a single death in the mission, nor a single case

of a man being invalided home. Let me put it another way—take the first ten men who were sent to Central Africa, and we find that their average term of service was well under three years; take the last ten men sent to Central Africa, already their average term of service is over fourteen years." Comment is needless. For the last five months Livingstone College has been converted into a hospital for wounded soldiers and accepted by the War Office, with the principal, Dr. L. E. Wigram, as resident medical officer in an honorary capacity. As a place of instruction for missionaries the college is therefore temporarily closed; the college staff is temporarily scattered. But when the war is over the intention is to fill once more the great need and to start again the courses of elementary medical training that have proved of such striking utility in the past. May that day be soon! Personal hygiene and the sanitation of communities are subjects of daily increasing importance in tropical and backward countries, and missionaries go doubly armed when they carry knowledge of such things with them to heathen countries.

THE HALF-YEARLY INDEXES FOR 1915.

THE usual half-yearly indexes to the JOURNAL, to the EPITOME, and to the SUPPLEMENT have been prepared and will be printed. They will, however, not be issued with all copies of the JOURNAL. Any member or subscriber who desires to have one or all three of the indexes can obtain a copy of what he wants, post free, by sending a post-card notifying his desire to the Financial Secretary and Business Manager, British Medical Association, 429, Strand, W.C. Such copies will be dispatched shortly after the middle of January.

Medical Notes in Parliament.

War.

Soldiers Discharged as Medically Unfit.—In reply to Mr. Stewart, on December 17th, the Financial Secretary to the War Office said that the question of expediting the discharge of soldiers who had no further military value was receiving the close attention of the Army Council. "The duty of the travelling medical board is," he said, "to bring to the notice of the local medical authorities men who, in their opinion, are unfit for further service, in order that these may be invalided and discharged from the service in the usual way." In reply to Mr. Needham, on December 20th, Mr. Forster said that wounded or invalided soldiers physically of no military value and willing to be discharged to return to their civil employment had the right, like other soldiers, to see the medical officer in charge of their unit. If the medical officer considered that the case justified discharge he would take the necessary steps to have it brought before the proper authorities for decision.

Recruits: Minor Physical Defects.—Mr. Boyton asked, on December 20th, whether a number of proposed recruits were rejected for minor physical defects, many of which could be successfully treated in general hospitals, and whether it was desirable to pay those who offered to undergo operations or treatment at army rates with dependant allowances whilst they were detained in hospitals. The Financial Secretary to the War Office replied that the number of men rejected for physical defects of a kind which could be cured by surgical operations was inconsiderable, and the risk and disadvantages of the course suggested were so serious that he feared it could not be adopted.

London Ambulance Column.—In reply to a question by Mr. Evelyn Cecil, Mr. Tennant said that he understood that the London Ambulance Column was a purely voluntary body. If a promise had been made to its members that certificates of indisposability would be granted them, it had been made without the sanction of the War Office.

He did not think that certificates of such a nature would have any influence with local tribunals in view of the fact that the Red Cross Society had arranged with Lord Derby to release every available man possible for military service.

Distists.—Mr. Tennant stated on December 20th, in reply to Sir Arthur Markham, that 43 dentists are employed with the expeditionary forces in France, exclusive of those employed with the Canadian contingent.

Antityphoid Inoculation.—The heckling of Mr. Tennant with regard to the right of soldiers to refuse to submit to preventive inoculation against typhoid has been resumed. On December 20th the Under Secretary for War said that a commanding officer of any unit would be within his rights and powers in preventing any uninoculated officer from proceeding on active service overseas, because such an officer might, if he contracted enteric fever, be a grave source of danger to his brother officers and the men under his command. He denied that men were refused Christmas leave on the ground that they had refused to be inoculated.

Revaccination.—In reply to Mr. W. Thorne, on December 20th, Mr. Tennant said that vaccination or revaccination was a condition of enlistment to the regular army; for the Territorial Force it was not.

Dry Powder Fire Extinguishers.—In reply to Mr. Denniss, the Home Secretary said that the warning to the press against publishing anything likely to promote the sale of dry powder chemical fire extinguishers was issued because the claims put forward by the makers of certain of these devices were likely to mislead the public into believing that such powders could be relied upon in preference to water as a means of extinguishing or controlling incendiary bombs, and the fires caused by them. An investigation made by the Commissioner of Police with the aid of a committee of experts, showed that the powder extinguishers were ineffective as compared with water for dealing with such fires, and that the danger and serious damage caused by such fires would be greatly increased if the public relied on these appliances. There had been no actual prohibition of advertisements, but extravagant advertisements were to be deprecated, especially in cases where a panic might be caused if a bomb were dropped.

German and Austrian Red Cross Employees.—On December 20th Commander Bellairs asked how many German and Austrian doctors and so-called German and Austrian Red Cross employees had been allowed to go through our naval blockade under safe conducts to Europe; how many under instructions from the Foreign Office without safe conducts, and what equivalent was obtained from Germany in the number of British subjects released. Lord Robert Cecil said: The number of such persons given safe conducts is eighty-six, and the number of those who were to be allowed to pass without safe conducts is sixty-nine. I am not aware of the precise number in each category who may have been arrested on the way owing to suspicion of fraud, but the number is not large. With regard to the last part of the question, His Majesty's Government have not so far felt obliged to refuse requests made to them on the ground of the Geneva Convention for the free passage of enemy doctors and Red Cross employees returning to their own country from overseas. In most cases doctors and Red Cross officials captured or detained by the Germans have been also released. But as in some cases they have not done so, His Majesty's Government are considering the advisability of detaining similar German individuals who would otherwise be returned.

Midwives (Scotland) Bill.—The Midwives (Scotland) Bill was read a third time, as amended by the House of Lords, on December 16th. The Lords' amendments were considered and accepted on the same day by the House of Commons. By one amendment the provision empowering the Midwives Board in Scotland to suspend a midwife from practice "for such period as the Board think fit" was altered by the omission of the words within quotation marks. The only other amendment had reference to the selection of an accountant. The clause as amended provides that the financial statement of the Board shall be certified as correct by an accountant practising in Scotland, appointed annually by the Secretary for Scotland.

THE WAR.

A MILITARY MEDICAL SOCIETY.

THE third meeting of the Military Medical Society, the formation of which was mentioned last week, was held on October 13th, Colonel H. Carr, the President, presiding over an audience of about 120.

Splint for Fractures of the Arm.

Major T. C. Lütler Jones gave a demonstration of his splint for fractures of the arm. This simple and ingenious splint is made of iron wire framework moulded to distribute the weight of the arm on to the trunk and chiefly the hip, and allows the patient to walk about or to lie down in bed. It obtains flexion and abduction of the arm, and allows septic wounds of the arm to be dealt with without disturbing the position of the splint. The cost of making should not exceed 1s. It does not press in the axilla and yet it can be adapted for the application of traction to the long bones. Major Lütler Jones did not claim for it that it was absolutely ideal in every case, and he admitted that it did not prevent internal rotation of the lower fragment in cases of fractures of the humerus. The weight of the splint was negligible, and one felt as if one's arm was resting lightly on the arm of a chair. This splint has become very popular at the hospitals.

Traumatic Aneurysm.

After Captain F. L. A. Greaves had read the paper published at p. 924, Surgeon-General Sir George Makins remarked that arterio-venous aneurysm was in comparison with its frequency in the last war proportionately rare. One reason for this probably was that the German bullet causes more serious injury to the blood vessels. Now they were becoming fairly common, and he attributed this to the fact that they were the result of shell wounds. It was a strange fact that the shell fragment caused less damage to the blood vessel than the bullet: the shell incised, the bullet contused. He wished to emphasize the point that though all wounds by shrapnel were infected, yet these wounds of blood vessels did not show signs of infection; he thought this was due entirely to the bactericidal power of the blood. He believed that the aneurysm began at the time when the artery was wounded, though it might not be detected for some time. There might be a considerable hæmatoma at first; sometimes the blood clotted and became hard, and a secondary change took place in the clot, the blood emerging from the wound meeting a cavity in the clot with the production of a false aneurysm; in other words, there might be clotting at the periphery with a large irregular cavity. The latter was a serious condition, for secondary hæmorrhage was a probable sequel. Dealing with arterio-venous varices, Sir George said that generally there was a direct communication between the two vessels without any trace whatever of blood effusion, the two vessels uniting at once and the anastomosis being established within a few moments after the man was struck. The wounded vein might become thrombosed after injury, but when the thrombus softened the double murmur became evident.

Paratyphoid Infections.

At the fourth meeting of the society, held on October 27th, Captain J. M. Fortescue-Brickdale, M.D., M.R.C.P., said that the group of diseases which included typhoid fever, paratyphoid A, and paratyphoid B, was conveniently designated the "enteric group." An individual might be protected against one without necessarily acquiring protection against the other two, and two infections might coexist in the same person, or at least follow each other very closely. The presence of two causal organisms in the blood of one patient had not been demonstrated in the area of the society, but one might be shown to be present in the blood and another in the excreta. In making a diagnosis the clinician and bacteriologist must work together. If a certain one of the organisms was found in the blood, nothing more need be said, but in many cases it might not be possible to demonstrate its presence; the faeces and urine must then be searched, but this was not such a satisfactory proof, as the "carrier" question came in, and additional evidence from agglutination reactions

was required. A well-marked agglutination was no doubt a strong point in diagnosis, but in the absence of direct bacteriological evidence must be considered in relation to the clinical picture. On the other hand, it was often impossible to diagnose a case on purely clinical grounds, but it was possible in a large number of cases to form a fairly accurate opinion when looking back on the case as a whole (epignosis). Certain types of cases would be found to harmonize with the bacteriological findings. Local experience of the group so far showed roughly the following proportions: Paratyphoid B, 81 per cent.; paratyphoid A, 4 per cent.; true typhoid, 10 per cent. About 5 per cent. showed no sufficient evidence, either clinical or bacteriological, to allow of their being placed, and these were diagnosed as belonging to the "enteric group."

Paratyphoid B Infection.—The degree of severity varied extremely. It might be a very severe and even fatal disease, or it might be a moderately severe case. Mild attacks were the most frequent. They were very liable to be overlooked, and labelled influenza or P.U.O.; the characteristic clinical symptoms might be few or absent, and the diagnosis depended mainly on careful bacteriological investigations. The illness might last only three or four days. In one such case, in which the fever only lasted four days, there were six rose spots, the patient was dull and apathetic, the tongue was furred, bronchitis was present, and there was tenderness over the spleen. Paratyphoid B was demonstrated in the blood, faeces, and urine, and the agglutinations to paratyphoid B were positive. In other cases the symptoms were not so typical; the spleen might not be enlarged and no spots might be present, yet the organism might be demonstrated. A very large majority of the cases gave a history of abrupt onset, but occasionally a vague indisposition of a week or two's duration preceded definite onset. In cases in which spots appeared they were generally quite well marked on the tenth day. In mild cases a few might appear on the fourth or fifth day or earlier. They might persist for a long time, coming out in crops for three weeks; the last crop might appear after the temperature had fallen. The rash was marked by pleomorphism, and roughly three sorts might be distinguished: (1) Small, well-defined, dark pink, not much raised; (2) large, light pink, well raised, with ill-defined irregular margins; (3) fairly well-defined, bright pink, surrounded by faint pink or purplish irregular areola. These groups melted into one another and all might be represented on the same patient. Enlargement of the spleen was a very important diagnostic point in diseases of the enteric group. In any case of acute fever where it was present a full bacteriological investigation should be made. Herpes was seen in several cases. Mild conjunctivitis was present in a few at the beginning. Cough was common, but definite bronchitis uncommon; when present there was generally a history of asthma or chronic lung trouble. Headache was almost universal at the onset and was apt to persist. It might continue after the temperature had fallen, especially in older men. Epistaxis was fairly common. The general constitutional disturbance was not so great as would be expected from the temperature and other signs. The temperature was apt to be very intermittent, falling to normal in the morning or remaining normal for several days and then rising again. In other cases it was markedly remittent. In some there was a sharp initial rise, followed by a low type of fever continuing for some weeks. The serious complications of true typhoid might occur in paratyphoid B, but were not very common. The mortality was not high—probably under 2 per cent. The *post-mortem* findings resembled those of typhoid fever, the large intestine and colon, however, being more usually markedly involved. Only a few cases of paratyphoid A had been seen. The temperature chart was much more regular, and more like the typical typhoid chart, and a larger portion of the cases were severe, and no mild cases had been seen. Typhoid inoculation seemed to alter the degree rather than the characteristics of the disease. Severe cases, which occasionally occurred, did not differ from the ordinary type; the very mild cases were of course atypical, but only in the same way as "ambulatory cases" in uninoculated persons.

In the discussion Captain Parsons related his experiences with cases of similar fever in Malaya. In none did

the temperature remain up after the fourteenth day; in none was there a rash afterwards, and the malaise lasted for over three days. Ho had, however, no bacteriological evidence of the identity of the disease.

Captain Wood related what he had seen in sixteen *post-mortem* examinations on patients who had had paratyphoid B. The lesions were varied and peculiar. In nearly every case the large intestine was involved, and usually extensively, being deeply ulcerated. In three cases the large intestine had perforated once at the caecum, once at the splenic flexure, and once at the sigmoid flexure. In two cases the appendix had perforated. The small intestine showed lesions similar to those seen in true typhoid. In other cases he had seen abscess of the liver and spleen. In all cases the *B. paratyphosus B.* was isolated, and it was an interesting point that the lesions of the large intestine were similar to those seen in swine fever, with which was associated an organism, *B. suispestifer*, which the German school did not differentiate from *B. paratyphosus B.* His Indian experience was that paratyphoid A was a milder and shorter fever than paratyphoid B, but he had not seen one case of the latter in India. The paratyphoid A he had seen in France was, on the whole, a more severe disease than that seen in India, but perhaps the milder cases had not reached an isolation hospital.

Captain Pritcheard said he had isolated an organism of the colou-typhoid group from a case with renal symptoms, without, however, attempting further to classify it. This case died in England, and extensive ulceration of the intestines was found *post mortem*.

Captain A. Leitch remarked on the great uncertainty that prevailed as regards the subdivision of the typhoid group of fevers. It was questionable, from the clinical point of view, whether anything was to be gained by the attempted subdivision. The differentiation of the various organisms included in the group on cultural grounds was difficult, and the characters were not constant. Agglutination tests were important, but not specific. He was interested to learn that the *post-mortem* appearances of paratyphoid B and hog cholera were the same, and he agreed that *B. paratyphosus B.* and *B. suispestifer* were practically indistinguishable. The latter organism, however, though frequently, if not invariably, found in hog cholera, was not the causal agent of that disease. A similar position might be reached eventually regarding paratyphoid fever.

Captain Adler recalled Twort's experiments on the mutability of organisms of the coli-typhoid group, and Colonel Carr expressed a doubt whether anything was to be gained by a subdivision of the typhoid infections; unless the practitioner had a bacteriologist at his elbow he would be unable to distinguish the one from the other.

Oxygen and Suppuration.

Captain Clarke read a paper in which he contended that as free oxygen was essential for the growth of pyogenic organisms in culture media, he considered that, in the treatment of septic wounds, precautions ought to be taken to exclude it. In test tube experiments he had found that the streptococci were less inhibited by anaerobic conditions than the staphylococci, but in the wounds with which he had to deal the latter organisms were the chief noxious agents. He condemned the use of hydrogen peroxide in septic wounds. He believed that secondary haemorrhage was favoured by the access of oxygen allowed by drainage tubes. In all cases gauze drains should replace tubes. Major Coupland joined in the condemnation of the use of hydrogen peroxide. Surgeon-General Sir George Makins pointed out that in his experience streptococci were extremely prevalent in the septic wounds, and that the staphylococci were relatively less important. Gauze plugs were often fairly good, but they were very apt to become clogged, and to arrest the drainage of the discharge.

"Trench Shin."

Captain J. G. Brown (C.A.M. Corps) described under this name a group of cases characterized by the syndrome "fever, leucocytosis, and pain in the shin bones." The pain felt in the tibia was of a dull, aching character, always bilateral, increasing when the patient attempted to walk, and diminishing when he lay in bed. It increased at night time, and required analgesics. Tenderness was marked all

over the tibia, in the head of the bone, and also in the malleolus; even light pressure on the crest of the bone caused the patient to wince. There was no pain in the femur. X-ray photographs showed no abnormality. Head-ache and general malaise accompanied the condition. Blood examination showed that the red cells were normal, but the white cells were increased over 9,000; in differential counts there was an increase of lymphocytes. Blood cultures were negative. Most of the cases showed a low-grade fever, lasting from five to ten days, and gradually dropping to the normal. Syphilis was excluded by the results of the Wassermann reaction and the lack of improvement after the administration of iodides. From the enteric group the disease could be differentiated by the negative results of the Widal reaction, blood cultures, and bacteriological examination of the stools. The symptoms of the disease did not correspond with the textbook descriptions of those of dengue. Colonel Carr pointed out that the distribution of pain and tenderness corresponded to the parts covered by puttees and thought that the local bony disturbances might be the result of tight puttees. He agreed that this explanation failed to account for the general condition, but suggested that the other symptoms might be fortuitous. Lieutenant-Colonel Finley said that he had seen cases corresponding to those described by Captain Brown, but they were not so sharply defined, and he had been content to label them as myalgia. The bony pains were not confined to the tibia. In many of these obscure cases he had found that there were leucocytic counts of 14,000 to 25,000.

GERMAN EXPERIENCES OF WAR SURGERY.

TREATMENT OF ABDOMINAL WOUNDS.

THE vexed question as to the treatment of abdominal wounds in war has drawn from Professor Wieting Pasha¹ a memorandum in which he attempted to harmonize conflicting views. He argued that a procedure which was sound under certain conditions, such as the nature of the fighting, of the locality, the roads, or the weather, might be altogether indefensible under other conditions. All surgeons, he said, agreed in advocating early operation for abdominal injuries under favourable conditions in times of peace; and this view could be modified in war time only by the local conditions obtaining at a given time. The choice of treatment accordingly depended on what he called "sanitätstaktische" considerations rather than on purely surgical factors. As for these medico-tactical problems, they were, he said, understood and provided for, and there should, accordingly, be little or no differences of opinion on this score. Apparently this point of view has also been accepted by the authorities; for Professor Wieting Pasha referred to certain orders given to the surgeons of the various army corps. These orders, he said, ranged from the complete prohibition of all operative treatment, to the organization of laparotomy stations, such as were established and soon given up again in the fighting around Port Arthur in the Russo-Japanese war. Though this arrangement seemed unnecessarily arbitrary, in practice considerable latitude was, he said, allowed to the operating surgeon, whose views might not coincide with orders from head quarters.

TREATMENT OF FRACTURES OF THE THIGH.

With an experience of about 180 cases of fracture of the thigh, Dr. M. Alexander² has undertaken to outline the most suitable treatment for such cases. His patients were treated in every stage of fracture, from recent fractures to fractures inflicted eight weeks earlier and treated elsewhere. He was thus enabled to control the results of other surgeons' methods as well as his own. He employed three methods of immobilization—extension, plaster-of-Paris, and splints. He came to the conclusion that each case must be treated on its merits, and that no one method should be adopted to the exclusion of others. But he had also learnt to classify his cases, and to adopt a definite line of treatment for every case belonging to a particular class. In a recent case in which the wound was slight, and the discharge so insignificant that infection was improbable, a plaster-of-Paris splint fulfilled every requirement.

¹Deut. med. Woch., August 12th, 1915.

²Beri. litn. Woch., August 9th, 1915.

On the other hand, wounds which had remained undressed for a considerable time, with extensive shattering of bone or severe suppuration, called for other treatment, including free incisions and drainage, as in the following illustrative case. A reservist was wounded in the right knee by a fragment of shell, and was admitted to hospital two days later with the limb fixed by large splints. The whole of the thigh was much swollen, and there was extensive subcutaneous effusion of blood. On the outer side of the knee was a wound as large as a hand, covered by a gangrenous crust, from under the borders of which pus escaped. The knee-joint was much swollen, and there was abnormal mobility of the bone above the joint. There was, however, no crepitation and little pain. The parts were immobilized by splints and extension aid. The temperature remained normal, the wound healed by granulation, and an uninterrupted recovery followed. In such a case the employment of plaster-of-Paris was indefensible, for under it suppuration was apt to escape notice, and pus could track a considerable distance before its presence was detected. On the other hand, the employment of readily adjustable splints enabled the operator to change the dressings frequently and to control the progress of the wound. The importance of this control, notably in febrile cases, could not be over-estimated. Yet, obvious as these principles might seem, they were not always appreciated, as the following cases showed:

A non-commissioned officer was wounded by a rifle bullet which shattered the middle of the femur. When he reached Dr. Alexander's hospital on the eleventh day, his limb was found to have been put up in a fenestrated plaster-of-Paris splint. There were two large wounds in the outer side of the thigh, and the temperature was very high. When the plaster-of-Paris splint was removed, on the twenty-first day, large abscesses were found. Several drains were inserted, and the limb was immobilized by extension. This change of treatment was rapidly followed by improvement in the local and general condition; the temperature fell to normal, and the limb was saved. In another patient, a volunteer, a rifle bullet had entered a breadbreadth below the great trochanter, had fractured the bone, and had made a large wound of exit on the inner side of the thigh. When the patient was admitted to Dr. Alexander's hospital, on the eighteenth day, the wounds of entry and exit were freely suppurating. Dressings and splints were applied; but on the advice of a consulting surgeon the splints were replaced by a fenestrated plaster-of-Paris cast; three days later the temperature was above 39° C., and as the patient continued to be febrile, the plaster-of-Paris was removed after it had been in use for twelve days. Its removal was followed by the free opening and drainage of the wounds, the limb being put up in ordinary splints, which were replaced some days later by extension apparatus. Under this treatment the temperature fell to normal, and the patient recovered sufficiently to be transferred to another hospital.

Dr. Alexander had learnt to confine the use of plaster-of-Paris in fractures of the femur to temporary immobilization of the limb during transport, to recent cases in which fracture of the femur was uncomplicated by large wounds of entry and exit or by sepsis, and to the immobilization of limbs at a late stage of the wound, when suppuration had ceased and severe injuries were well on the way to recovery.

CASUALTIES IN THE MEDICAL SERVICES.

Killed.

LIEUTENANT ANDREW HEGARTY, R.A.M.C., is reported to have been killed in France on December 16th. He was the fourth son of Dr. A. Hegarty, of Magherafelt, co. Londonderry. He took the diploma of L.A.H.Dubl. only this year and joined the R.A.M.C. as a temporary Lieutenant last July; he was attached to a battery of Royal Field Artillery when killed. Two of his brothers are now on active service, one in the R.A.M.C. and one in the motor transport.

Wounded.

Navy.—Surgeon C. F. Schuller, R.N., Hawke Battalion, Dardanelles.

Army.—Captain H. P. Brownell, 7th Field Ambulance, Australian Army Medical Corps, Dardanelles.

Captain K. K. Mukerji, I.M.S., Persian Gulf.

DEATHS AMONG SONS OF MEDICAL MEN.

Blake, Harry Douglas, 10th Battalion Royal Fusiliers (City of London Regiment), son of the late Dr. E. H. Blake, of Upton, Essex, killed in action recently in France, aged 25.

MEDICAL STUDENTS.

Hogben, Henry Francis Thomas, Lieutenant 10th Battalion Middlesex Regiment, attached 2nd Battalion Norfolk Regiment, killed in the battle of Ctesiphon in Mesopotamia, November 22nd to 24th, aged 25. He was born in 1890, the eldest son of Mr. F. Hogben, of Sunderland, and was educated at Parsonsloan School, Ireland, at Bedford Grammar School, and at Guy's Hospital, which he entered in 1907, gaining the London University Open Scholarship. He was a member of the Bedford School Cadet Corps, 1905-09, and of the Artists' Rifles, 1909-15. He got his first commission in the Middlesex Regiment in July, 1915, was promoted to Lieutenant on August 26th, 1914, went with his battalion to India in October, 1914, and in April, 1915, was selected to take a draft from the 10th Middlesex to the Persian Gulf. He played football for Guy's, and was a skilful boxer and a powerful swimmer, but specially excelled as a shot. He was in the Bedford school shooting eight, twice captained the London University eight, won the open championship of London University Athletic Union Rifle Association, and the All Comers' aggregate at Bilsley in 1915, and was in the King's Hundred in 1915 and 1914.

The Aberdeen University "Roll of Fallen" up to December, 1915, includes the names of seven medical students. Notices of the two following have not previously appeared in our columns.

Mackay, Keith, Corporal 4th Battalion Gordon Highlanders, died in a casualty clearing hospital in France on April 28th, of wounds received on March 20th, aged 20. He was a first year medical student at Aberdeen.

Munro, Gordon Dean, Private 4th Battalion Gordon Highlanders, died of wounds received in action near Ypres on September 25th, aged 20. He also was a first year medical student at Aberdeen.

MEDICAL MEN AND DENTISTS KILLED OR DIED OF WOUNDS WHILST SERVING AS COMBATANTS.

The following is a list, as complete as we have been able to make it, of medical men and dentists holding commissions as combatants who have been killed or died of wounds since the beginning of the war. The list is very possibly incomplete, and we shall be obliged if relatives of any other medical men who have been killed or died of wounds while holding commissions as combatants would communicate with us. We should also be glad to receive particulars of any medical man who may have been killed or died of wounds whilst serving as a combatant but not holding a commission.

The names in the list are arranged in alphabetical order:

MEDICAL PRACTITIONERS.

Bingham, F. M., L.R.C.P., M.R.C.S., Captain 5th King's Own Lancaster Regiment, Flanders, May 22nd, 1915.

Clifford, A. C., L.R.C.P., M.R.C.S., Second Lieutenant 3rd Dragon Guards, Ypres, Flanders, June 1st, 1915.

Crowthor, S. N., L.R.C.P., M.R.C.S., dispatch rider, Flanders, October 13th, 1914.

Huddleston, S. C., M.B.Édin., Second Lieutenant 3rd Black Watch, France, January 25th, 1915.

Hughes, B. M., L.R.C.P., M.R.C.S., Captain 14th Norfolk, Dardanelles, September 15th, 1915.

Hunter, H. G., M.B.Édin., Captain 6th Northumberland Fusiliers, Ypres, Flanders, April 26th, 1915.

Jessop, J. W., L.R.C.P., M.R.C.S., Lieutenant-Colonel 4th Lincoln, France, June, 1915.

Lukis, T. S., M.D.Lond., Lieutenant 13th London Regiment, France, March 15th, 1915.

Maitland, W. E., M.B.Glasg., Lieutenant 3rd Seaforth Highlanders, France, December, 1914.

Wallace, A., M.B.Édin., Captain 14th K.O.S. Borderers, Dardanelles, July 12th, 1915.

DENTISTS.

Dykes, J. J., L.R.C.P. and S.Édin., L.R.F.P.S., L.D.S., Captain 15th K.O.S. Borderers, Dardanelles, July, 1915.

Morham, J., L.R.C.P. and S.Édin., L.R.F.P.S., L.D.S., R.C.S.Édin., Captain 4th Royal Scots (missing), Dardanelles, September, 1915.

Neely, H. B., L.D.S., 2nd Lieutenant 1st Suffolk, Ypres, Flanders, April 25th, 1915.

NOTES.

ARRIVAL OF HOSPITAL SHIP IN DUBLIN.

ON December 16th a hospital ship arrived at Dublin from Havre, bringing 536 wounded and invalid soldiers from

France. The St. John Ambulance Brigade and the Dublin and Kingstown divisions of the British Red Cross Society had made ample arrangements for the disembarkation and transfer of the men. The cases were distributed—120 to Belfast by special train, 100 to Cork, and 50 to the military hospital at the Curragh Camp. The remaining 266 cases were distributed among the Dublin hospitals, 143 being sent to the Castle Red Cross Hospital. There were no very serious cases; a fair number of the men had been wounded; the majority, however, suffered from such diseases as pleurisy, pneumonia, acute rheumatism, and appendicitis. The malady, however, most in evidence was the condition now generally known as "trench-feet." It is to be noted that the cases of this kind are not so severe as those met with last winter; this is probably due partly to the precautions taken to avoid prolonged exposure of the feet to cold and wet, and also to the fact that the condition is recognized at an earlier stage and not allowed to advance too far.

MEDICAL OFFICERS WANTED.

Field Ambulance.

The Officer Commanding a Field Ambulance, who has had ten months' experience at the front in France and Belgium, is fitting out a Territorial London Field Ambulance for service abroad, and has vacancies for five medical officers. Rates of pay, etc., higher than temporary commissions abroad. Gratuity after one year, 296 2s. Address, No. 999, BRITISH MEDICAL JOURNAL OFFICE, 429, Strand, W.C.

2/2nd North Midland Field Ambulance, R.A.M.C.

Wanted immediately, four medical officers. Pay and allowances as in regular army, with bonus at termination of service. Those accepting commissions must sign for foreign service. Applications to Officer Commanding, 2/2nd North Midland Field Ambulance, Harpenden.

2nd South-West Mounted Brigade Field Ambulance.

To King's men and others. Two officers required to complete 2nd South-West Mounted Brigade Field Ambulance (Imperial Service). Apply, Lieutenant Colonel Benson, Officer Commanding, "Fedoram," Lexden Road, Colchester.

2/2nd South Midland Mounted Brigade Field Ambulance.

Medical officers are urgently wanted for the above. Intending candidates must be willing to sign for foreign service, and should apply to Major A. G. Magrath, Officer Commanding, 2/2nd South Midland Mounted Brigade Field Ambulance, London Road, King's Lynn.

Canada.

THE MILITARY HOSPITAL COMMISSION.

THE problem of providing employment and a new start in life for the members of the Canadian Expeditionary Force on their return to Canada has been engaging the attention of the Dominion Government for some time. Steps were taken some months ago by the Department of Militia and Defence to arrange for convalescent homes for those who will require a period of rest in order to recover the health which they have lost. This work was later committed to the charge of the Military Hospital Commission which was appointed by the Government for this purpose by Order in Council. A recent amendment empowers the Commission to deal with the question of employment for members of the Canadian Expeditionary Force on their return to Canada, and to co-operate with provincial governments and others for the purpose of providing employment as may be deemed necessary. At the invitation of Sir Robert Borden, the Premiers of the nine provinces of the Dominion and the representatives of the Commission have met in Ottawa to discuss the problems which arise. The meeting had before it a statement setting out a plan whereby employment could be provided for both disabled and, if necessary, able-bodied men on their return from the front. Particulars of the measures taken in Great Britain and on the Continent of Europe were given in appendices. As representatives of the provincial governments, the Ministers signified the willingness of each province to do the utmost in its power to aid the Commission. The facilities offered in each province will be investigated, and it is probable that a subcommission will be appointed in

each province to act under the control of the Commission, and that the provincial commissions in turn will appoint local committees. In Canada all matters pertaining to education, etc., are in the hands of the provincial governments, and the conditions differ in each province; for instance, in Quebec the technical schools belong to the government, but the universities and agricultural colleges do not; in Ontario the technical schools are not under governmental control, whereas the Guelph Agricultural College is a government institution; in some cases the sanatoriums are maintained by the provincial government, in others by private subscription. The intention is to arrange with a number of sanatoriums for the reception of soldiers suffering from tuberculosis, with schools for the blind for those who have lost their sight, and with universities, technical schools, agricultural colleges, and so on, for the training of such men as are unable to follow their former occupation; whenever feasible the men will be allowed to choose the part of the country to which they wish to go and the calling they wish to pursue. Negotiations will be entered into with the Canadian Manufacturers Association, which will be asked to provide employment for able bodied men who were out of work at the time of enlistment, or partially disabled men who cannot resume their former occupation, and to co-operate with the provincial governments in giving training to men, either in the form of apprenticeships or by placing workshops at the disposal of technical experts or foremen who are willing to give instruction as a service to their country. It is suggested also that land should be placed at the disposal of the Commission so that men who wish to do so may become farmers. Major Doherty has now returned to England; his mission to Canada was one purely of enquiry; all matters connected with the reception of wounded men from the front are in the hands of the Military Hospital Commission.

MUNICIPAL CONTROL OF HOSPITALS.

At the annual meeting of the General and Marine Hospital at Collingwood, Ontario, Dr. David Williams criticized the present system of management; the responsibility so far as financial matters are concerned rests upon a few who are willing to undertake the burden and entails constant appeals to the public. He gave notice that at the next annual meeting he would make the following motion:

That, in the opinion of the meeting, the present system of controlling and conducting the hospitals scattered throughout the province of Ontario has outlived its usefulness, and that the time has now arrived when it is deemed advisable that these institutions should be made part of the municipal system, controlled by a board of governors appointed by the municipal councils and such other bodies as may be deemed advisable, the appointments to rotate and to extend over a term of years, such as may be determined to be in the best interest of these institutions. That this proposal be recommended for the serious consideration of the Ontario Hospital Association and the provincial legislature, with the view of memorializing the legislature of the province of Ontario to enact such legislation as will provide for the taking over of hospitals at present in existence by the municipalities and for the conversion of them into municipal institutions; also for legislation governing these and controlling the establishment of hospitals in the future.

PATRIOTIC MEDICAL BUREAU IN REGINA.

The physicians of Regina have formed a Patriotic Medical Bureau, which, in co-operation with the local branch of the Canadian Patriotic Fund, will give medical assistance to all dependants of those who have gone to the front. Applications for assistance must be made to an attendant, whose duty it is to investigate the case. Patients will be sent either to the outdoor department of the general hospital or to the office of one of the physicians who has joined the bureau. Those who are too ill to go out will be visited by a physician, and in cases of emergency a physician will be called immediately. If the patient cannot be admitted to the hospital, a nurse will be supplied by the Patriotic Fund Committee. If assistance is required in the home of the patient, a woman will be sent by the Patriotic Fund to give the necessary help, and in cases where there are no relative or friends able to look after the home and the patient a housekeeper will be sent, who will be under the supervision of the visiting attendant.

Scotland.

MEDICAL INSPECTION OF SCHOOL CHILDREN.

At the meeting of the Aberdeen County Committee on Secondary Education on December 17th it was reported that the Education Department had been informed that the county scheme of medical inspection had been suspended owing to the medical officers being on military duty, and that it was proposed that the scheme of medical treatment should also be suspended. It was arranged that cases of defective eyesight obviously requiring treatment reported by school boards and head masters should still be referred to the oculist for treatment. At the meeting of the Stirlingshire Committee on December 14th, Dr. Thomas Adams, the chief school medical officer, reported that of 1,457 school children examined between August 17th and October 18th, 57.1 per cent. were found to be medically defective. The Committee resolved to submit to the Education Department a scheme for the education of mentally defective children in the county.

SPHAGNUM MOSS WORKS IN EDINBURGH.

Works have been erected close to the workshops of Messrs. Redpath, Brown, and Co., engineers, Edinburgh, for the preparation of sphagnum moss as a surgical dressing. At the opening ceremony, Mr. Cathcart, who described the merits of this dressing in our columns for July 24th, 1915, p. 137, said that he believed sphagnum moss properly prepared was superior to absorbent cotton-wool as a surgical dressing. Cotton wool absorbed the discharge, but did not spread it, whereas sphagnum moss absorbed like sponge and did not exude until every part of it had taken up the discharge. There were, he said, several tons of prepared moss in hand, including forty-nine sacks from Shetland, the largest single consignment. We understand that in France an order has recently been issued directing that cotton-wool used for surgical dressings shall be collected, disinfected, and used for the manufacture of explosives.

Ireland.

PRESENTATION TO ALDERMAN DR. J. J. O'SULLIVAN, WATERFORD.

THE medical colleagues of Dr. J. J. O'Sullivan in the City of Waterford recently presented him with a piece of plate to mark their appreciation of the services he rendered the profession as their local representative on the Irish Medical Committee. Owing to the position Dr. O'Sullivan occupied in the civic affairs of the City of Waterford, he had frequent opportunities of rendering very important services to the medical profession not only in Waterford but throughout Ireland. He was, on different occasions, the spokesman of medical deputations which, in connexion with matters under the Insurance Act, waited on Mr. Redmond, M.P., Chairman of the Irish Parliamentary Party, and the late Most Reverend Dr. Sheehan, Bishop of Waterford.

IRISH WORKHOUSE AMALGAMATION.

At a conference of delegates of the Poor Law boards of the co. Kilkenny to consider the amalgamation of unions, the Local Government Board inspector said that the county was to be congratulated on being the first to take practical steps towards carrying out a scheme of workhouse amalgamation with a view of benefiting the ratepayers. It the number of unions in the county could be reduced from five to two a very substantial saving would be effected. A resolution was passed agreeing to the principle of amalgamation, so that there might be only two unions in the county. The matter will now be submitted to the Local Government Board, which will hold a sworn inquiry. The two unions of Dublin have received letters from the Local Government Board asking them to consider the question of amalgamation; the South Dublin Union has appointed a day to discuss it, but the North Dublin Union merely marked the letter "noted"; but the Local Government Board has the power itself to effect the amalgamation. Better progress might have been made if the Local Government Board had taken the

initiative in drawing up at least the outlines of a scheme. It was stated at the last meeting of the North Union that the expenditure will, it is feared, by the end of the financial year exceed the estimate by £6,000. The guardians are reported to be engaged in a complete revision of outdoor relief cases, and the guardians of the South Union seem to be undertaking a similar task. A careful investigation by the guardians should result in a number of small savings, which, when taken together, might reach a considerable figure; but this should not blind them to the great advantages and economies to be made by adopting a scheme of amalgamation for the two unions.

Correspondence.

DIFFERENTIATION OF MENINGOCOCCI.

SIR,—The valuable and independent papers of Captains Arkwright and Ellis on this subject published in your last issue are of great general interest, and are particularly welcome to those working in this laboratory, since they corroborate the observations here made on the same subject partly with the same strains, but mostly with others isolated from the cerebro-spinal fluid of military cases in this country during the recent outbreak of cerebro-spinal fever.

As our observations have been published in the *Journal* of the R.A.M.C. for May and October it is unnecessary to describe them in detail. The chief object of the present letter is to refer as briefly as possible to the present stage of this investigation, and to explain the steps taken to obtain antisera.

The agglutination test, valuable though it be, is of course handicapped by the fact that even a univalent serum contains, in addition to specific homologous agglutinin, group agglutinins. Hence the need, when possible, of checking the result by an after-test to see if the specific agglutinin has been absorbed or not. Proceeding by this method, the results obtained in this laboratory up to the present with meningococci isolated from the cerebro-spinal fluid of cases during the present outbreak are as follows:

Number of specimens tested	72
Number classified	63
Number unclassified as yet	9

Relative Frequency of the Four Types among the Sixty-three Classified Meningococci.

Type.	Specimens.	Percentage.
I	31	50
II	20	31.97%
III	10	16
IV	2	3

It is seen that Type I, which includes the strains Plank, Palmer, and Goodyear, given to us by Captain Arkwright (who generously placed his stock at our disposal for the purpose), still keeps its lead, followed by Type II, which includes Captain Ellis's M. 13, also given to us by Captain Arkwright. Between them, these two types account for 81 per cent. of our classified meningococci. It should be mentioned that meningococci belonging to Type III frequently agglutinate with the antiserum of Type I, but they fail to remove the homologous agglutinin therefrom.

Of Type IV so far only two specimens have been obtained. The nine unclassified cocci fail to agglutinate or absorb with any of the univalent serums prepared against the four types. These meningococci are being further investigated. There are certainly three more types among them; probably more.

Dr. Louis Martin of the Pasteur Institute kindly sent us a culture of parameningococcus in order that it might be compared with our strains. This has been done both by putting up this coccus against the four univalent serums, followed by absorption tests, and also by the reverse test. As a result, it has been found that although it agglutinates to some extent with the antisera to Types II and III, the parameningococcus fails to absorb the specific agglutinin of any of these types; and, conversely, specimens of those types fail to absorb the specific agglutinin of Dopter's coccus. In view of this evidence the parameningococcus—using that term—only as applying to the particular culture received by us—would seem to be acquitted of a share in our outbreak so far.

Now, at first sight, this plurality of types of the meningococcus is somewhat perplexing. Practically, however, as regards the epidemic, this is not so, because of the comparative rarity of Types IV and onwards. It has been stated that up to the present no less than 81 per cent. of the classified cocci belong to Types I or II; if Type III is included, 97 per cent. of them are accounted for.

A further point of particular interest is that Type I, which had been getting scarcer during the decline of the epidemic, and was not found in the autumn, has recently reappeared.

As regards the preparation of antisera, specimens of the first four types of meningococcus are in the hands of Dr. MacConkey, of the Lister Institute Serum Department, and also of Dr. O'Brien, of Messrs. Burroughs and Wellcome's Laboratory, Brockwell Hall. Towards the end of September Mr. E. G. Murray kindly took cultures of them over to Paris and presented them to our allies and colleagues at the Pasteur Institute. Dr. Louis Martin and Dr. Dujardin-Beaumez at once took steps to prepare trivalent sera against Types I, II, and III, and it is hoped that these sera, as well as the others, will be available in case of a recrudescence.—I am, etc.,

M. H. GORDON,
Major R.A.M.C.

The Central Laboratory for Cerebro-spinal Fever,

THE AUSCULTATION OF THE HEART.

SIR,—I find that your issue of December 4th (p. 807) contains an attack upon me by Sir James Mackenzie, in which I am held up to scorn as a person who is unaware of the great advances that have been made during the last twenty-five years in our knowledge of affections of the heart.

The ostensible reason for this attack is that I republished in your issue of November 20th extracts from articles written in 1890. I should have thought that it was fairly obvious that I wished to make it clear that certain fundamental facts about the examination of the heart and the significance of murmurs were known at that date—for example:

1. That many fallacies attend the auscultation of the heart.
2. That the mere presence of a murmur is no evidence of valvular disease.
3. That loud murmurs often disappear when the patient lies down.
4. That serious organic disease of the valves, causing, for example, aortic stenosis and regurgitation combined with mitral regurgitation, is quite compatible with life prolonged to over seventy years, during which the patient for fifty-five years carried on a laborious occupation, without a day of illness.

I can assure Sir James Mackenzie that I have read and, if he will allow me to say so, admired his works, and that I have before me now the Register of the Beit Fellowships for Medical Research, in which, amongst more than fifty such entries, I find one which always gives me special satisfaction. It is:

No. 1. Thomas Lewis, D.Sc.(Wales), M.D.(Lond.), etc.

Nature of research authorized: The Mechanism of Irregularities of the Heart.

I am, at any rate, well acquainted with the work of Dr. Thomas Lewis, and also with the depths of my own ignorance, but I do not wish that prospective candidates for the Beit Fellowships should think that they will find me unsympathetic towards those who desire "to advance the science of medicine by research."—I am, etc.,

JAMES K. FOWLER,
Trustee, Member of the Advisory Board,
and Honorary Secretary of the Beit
Memorial Fellowships for Medical
Research.

London, W., Dec. 21st.

THE NEED OF DOCTORS FOR THE ARMY.

SIR,—It was with a feeling of surprise amounting almost to consternation that I noted in the JOURNAL of December 11th a remark to the effect that next year the needs of the army might demand almost half the registered medical practitioners in the country.

The obvious question arising is, How will the general public fare? For such a drastic arrangement will mean that close upon 47 million people will have to depend upon the same number of medical men as an army of 4 million. Is this reasonable? Is it just? Is it in harmony with national interests? That the necessities of the fighting services should be fully met everyone must desire, and the successful prosecution of the war demands this. But the suggestion that such necessities demand the services of half the medical community surely requires some substantiation. It savours of the extravagant; indeed, it is impracticable. Before disturbing thousands of busy practitioners, a thorough investigation of the efficiency and economy of the present Army Medical Service should be made, and inquiries should be instituted to ascertain whether that service is being managed in the best possible manner.
